receptor that recognizes carbohydrate moieties on multiple pathogens and is involved in the clearance of inflammatory molecules in vivo (Gruden-Movsesijan and Milosavljevic Lj 2006), and DC-SIGN (dendritic cell-specific ICAM-3-grabbing non-integrin) that selectively detects viral glycoproteins, such as HIV-1 gp120 glycoprotein (Curtis et al. 1992). The interaction between HIV-1 gp120 and DC-SIGN plays an important role in the CD4-independent association of HIV with human cells (Curtis et al. 1992). Thus, carbohydrates are suitable for storing biological signals in forms that are identifiable by other biological systems.

In the immunological and glycobiological literature, "glyco-epitope" is often used to specify the carbohydrate moiety that is recognized by an antibody or by a GBP. The antibody-binding glyco-epitopes are also classified as B cell epitopes or antigenic determinants. The term "glyco-epitome" was recently introduced to describe the entire repertoire of glyco-epitopes, including the B cell epitopes and those that are recognized by GBPs. Differing from the term "glycome," which covers all the existing carbohydrate molecules in living organisms, glyco-epitome refers to a unique subset of carbohydrates that serves as the sugar signatures for molecular recognition and biosignal transmission. "Glyco-epitomics" is, thus, an area of glycomics research focusing on identifying, characterizing, and understanding the carbohydrate moieties that serve for multiple levels of biocommunication.

It is noteworthy that glyco-epitope characterization requires not only carbohydrate structural analysis but also immunological studies. The structural aspects of glyco-epitomics focus on the elucidation of the glycan structures that display glyco-epitopes. This research area has been substantially enhanced by the development of advanced profiling and structural characterization strategies. Notably, these include high-resolution chromatography methods coupled with exoglycosidase digestions (Campbell et al. 2008; Royle et al. 2008), modern mass spectrometry (Babu et al. 2009; Goldberg et al. 2009; North et al. 2009) and nuclear magnetic resonance spectroscopy analyses (Petrescu et al. 1997; Wormald et al. 2002; Petrescu et al. 2006) of carbohydrates and state-of-the-art methods of glycan structural modeling (Woods and Tessier 2010; Jo et al. 2013).

However, availability of carbohydrate structural information alone is not sufficient in defining a glyco-epitope unless its specific binding by an antibody or a GBP is also demonstrated immunochemically and/or cryptographically. For example, chemical determination of a tetrasaccharide that decorates the spore of *Bacillus anthracis* appears to be an important discovery in microbial glycomics (Daubenspeck et al. 2004). Based on past knowledge of immunogenic carbohydrate moieties, this structural glycomics progress may suggest that this unique sugar moiety may have potential in an immunological application (Saksena et al. 2005, 2007). However, whether such a carbohydrate moiety preserves a B cell epitope or a potent antigenic determinant must be determined immunologically, including at least demonstration of its antibody-binding specificity and capacity in eliciting immune responses in vivo (Wang et al. 2007). It was the integrated structural and immunological investigation of glyco-epitopes (Wang et al. 2007; Lucas et al. 2008) that has revealed anthrose tetrasaccharides as key immunological targets of *B. anthracis*.

2 Classification of Carbohydrate Microarrays

Four research articles about carbohydrate microarrays first appeared in the scientific literature in 2002 (Borman 2002, 2012). These include polysaccharide and glycoconjugate microarrays, reported by Denong Wang's group at Columbia University's Genome Center (now at SRI International, CA, USA) (Kiessling and Cairo 2002; Wang et al. 2002); monosaccharide chips, by Milan Mrksich and coworkers at the University of Chicago (Houseman and Mrksich 2002); arrays of natural and synthetic neoglycolipids, by Ten Feizi's group at Imperial College Faculty of Medicine, Harrow, UK (Fukui et al. 2002); and arrays of synthetic oligosaccharides in microtiter plates, by a Scripps Research Institute group led by Chi-Huey Wong (Bryan et al. 2002). A specialized book, "Carbohydrate microarrays, Methods and Protocols (Humana Press)," recently edited by Dr. Yann Chevolot of Université de Lyon in France (Chevolot 2012), provides a comprehensive summary of the emerging technologies for construction of carbohydrate microarrays.

2.1 Spotting Carbohydrates with Different Structural Characteristics

Given the various structural characteristics of carbohydrates displayed on chips, carbohydrate microarrays are classified as monosaccharide chips (Houseman and Mrksich 2002; Park and Shin 2002), oligosaccharide arrays (Bryan et al. 2002; Fukui et al. 2002; Blixt et al. 2004; Wang et al. 2007), and microarrays of carbohydrate-containing macromolecules (Wang et al. 2002; Willats et al. 2002). The latter includes polysaccharides and various glycoconjugates. These different sugar chips or arrays were developed to accommodate multipurpose applications in carbohydrate research. For example, mono- and disaccharide microarrays are suitable for screening and characterizing novel carbohydrate-binding proteins or carbohydrate-catalyzing enzymes and for identifying novel inhibitors of carbohydrate-protein interactions.

A large class of carbohydrate-binding proteins, called lectins, was initially classified by their binding specificities to monosaccharides and recently by disaccharides. However, there are lectins and many antibodies with anti-carbohydrate reactivities that bind to larger and more complex carbohydrate ligands or antigenic determinants. Mono- and disaccharide sugar chips are not sufficient for investigations involving such molecular targets. Oligosaccharide, polysaccharide, and glycoconjugate microarrays fill this gap by displaying carbohydrates of complex structures or longer sugar chains on the chips.

2.2 Strategies for Carbohydrate Immobilization on a Chip

Based on the technologies that are applied to immobilize carbohydrates on bioarray substrates, the various methods to construct carbohydrate microarrays can be classified as distinct technological platforms. These include technologies that directly utilize underivatized carbohydrates in microarray construction,

technologies that require chemical modification of carbohydrates before microarray fabrication, methods of non-covalent immobilization of carbohydrates, and methods of covalent coupling of saccharides on array substrates.

The use of underivatized saccharides for microarray construction has the advantage of preserving the native structures of the carbohydrate molecules. It requires, however, a ready-to-use microarray surface with appropriate surface chemistry that can be directly used to fabricate comprehensive carbohydrate microarrays with underivatized carbohydrates from a wide range of sources. Methods currently in use include non-covalent binding of underivatized carbohydrate antigens by passive adsorption on a chip, such as nitrocellulose-coated glass slides (Wang et al. 2002) or black polystyrene surfaces (Willats et al. 2002), and methods for covalently immobilizing underivatized carbohydrates on a slide surface by appropriate chemical linking techniques (Angeloni et al. 2005; Lee and Shin 2005; Carroll et al. 2006; Zhou and Zhou 2006; Wang et al. 2007; Zhou et al. 2009, 2012).

Carbohydrate microarrays can also be fabricated by using derivatized carbohydrates. Due to their small molecular size and hydrophilic nature, most oligosaccharides cannot be directly immobilized onto nitrocellulose or black polystyrene surfaces for microarray applications. However, an oligosaccharide probe can be modified with a tag or coupled to a larger carrier molecule for non-covalent immobilization. Methods include non-covalent immobilization of derivatized carbohydrates on microarray chips (Fukui et al. 2002; Palma et al. 2006) or on enzyme-linked immunosorbent assay (ELISA) microtiter plates (Bryan et al. 2002) and covalent immobilization of derivatized carbohydrates on microarray chips. The latter includes, but are not limited to, the popular Consortium for Functional Glycomics (CFG) printed glycan arrays (Blixt et al. 2004; Bochner et al. 2005) and various technologies of notable technical features that were developed independently (Houseman and Mrksich 2002; Park and Shin 2002; Galanina et al. 2003; Kohn et al. 2003; Park et al. 2004; Parthasarathy et al. 2006; Gerland et al. 2012a, b; Morvan et al. 2012; Goudot et al. 2013).

Affinity immobilization is another class of approaches for coupling derivatized carbohydrates to solid surfaces. For example, biotin-derivatized carbohydrates can be immobilized on a streptavidin-coated substrate through the affinity interaction of the streptavidin–biotin pair to create carbohydrate microarrays. Biotin-derivatized carbohydrates include carbohydrate ligands that are biotinylated via a short aliphatic spacer or at the peptide part of glycopeptides (Guo et al. 2004; Bochner et al. 2005; Dyukova et al. 2006). DNA-directed immobilization (DDI) is another practical strategy for immobilization of oligonucleotide glycomimetic conjugates on a chip surface for the preparation of carbohydrate microarrays (Gerland et al. 2012a, b; Morvan et al. 2012; Goudot et al. 2013).

2.3 Common Technical Features of Carbohydrate Microarrays

Despite technical differences among different platforms of carbohydrate microarrays, they are all solid-phase binding assays and share a number of common

characteristics and technical advantages. For instance, they contain the capacity to display a large panel of carbohydrates in a limited chip space, they are high-throughput quantitative assays, they make an effective use of carbohydrate substances that are often difficult or cost-inefficient to synthesize, and, as discussed below, they are highly sensitive in monitoring carbohydrate-anti-carbohydrate interactions in multiplex manners.

In a carbohydrate microarray, each carbohydrate is spotted in an amount that is drastically smaller than that required for a conventional molecular or immunological assay. This technical feature ensures a condition in which the binding of a molecule in solution phase to an immobilized microspot of ligand on the microarray substrate has minimal reduction of the molar concentration of the molecule in solution (Ekins et al. 1990). Thus, microarray-based assays are intrinsically optimized for binding equilibrium to take place, which is the basis for this class of hypersensitive binding assays (Stoll et al. 2002). Carbohydrate microarrays have higher detection sensitivity than most conventional carbohydrate analytical tools, such as carbohydrate-specific ELISA and the glycolipid-based "Eastern blot" assays that were developed in the 1980s by a number of early researchers in this field (Wood and Kabat 1981; Tang et al. 1985). Historically, this situation is very similar to the relationship between conventional blotting methods for nucleic acids or proteins, such as Southern, Northern, and Western blots, and nucleic acid–based or protein/peptide–based microarrays.

2.4 Complementary Platforms of Carbohydrate Microarrays

Carbohydrate microarrays constructed by various methods may differ in their technical characteristics and suitability for a given practical application. Some platforms may be applied complementarily to solve a practical question. For example, the method of nitrocellulose-based immobilization of carbohydrate-containing macromolecules, including polysaccharides, glycoproteins, and glycolipids, is suitable for the high-throughput construction of carbohydrate antigen microarrays (Wang et al. 2002, 2005; Wang and Lu 2004) to support the large-scale immunological characterization of carbohydrate antigens and anti-carbohydrate antibodies. However, the detection specificity of this carbohydrate microarray would be at the level of a carbohydrate antigen, not a glyco-epitope, if the native carbohydrate antigens were spotted. This is owing to the fact that many carbohydrate antigens display multiple antigenic determinants or glyco-epitopes (Cisar et al. 1975; Wang and Kabat 1998; Wang 2004). Examining the finer details of the binding properties would require the use of microarrays of defined oligosaccharide sequences. Oligosaccharide array-based binding assays can be applied, in combination with saccharide competition assays, to decipher precise saccharide components of a specific antigenic determinant or glyco-epitope (Fukui et al. 2002; Blixt et al. 2004; Wang et al. 2007; Zhou et al. 2009). These technical features of carbohydrate microarrays are further discussed in two models, i.e., a carbohydrate antigen microarray platform and a technology of photogenerated oligosaccharide microarrays in subsequent sections.

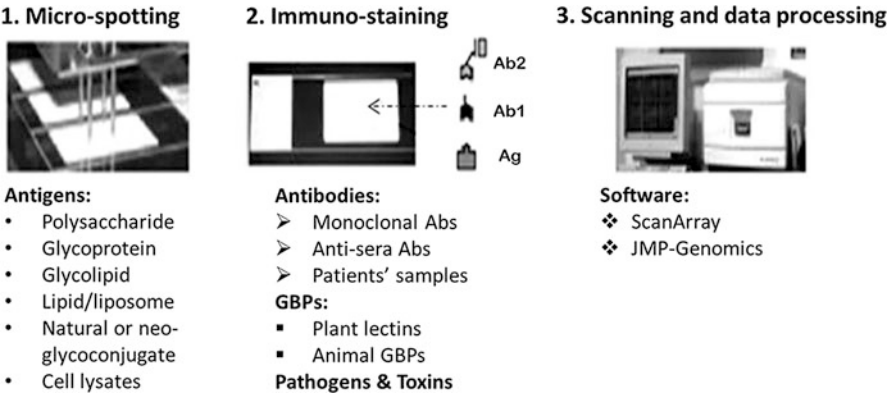

Fig. 1 A high-throughput platform for carbohydrate-based microarrays. A high-precision robot designed to produce cDNA microarrays is utilized to spot carbohydrate antigens of various structural configurations onto a nitrocellulose-coated glass slide. The microspotting capacity of this system is approximately 20,000 spots per chip. The antibody- or GBP-stained slides were then scanned for fluorescent signals with a microarray scanner that was developed for cDNA microarrays. Toxins or viral pathogens can also be applied on this platform of carbohydrate microarrays to probe potential glycan-receptors of viruses or toxins

3 A Versatile Carbohydrate Antigen Microarray Technology

A practical approach for construction of carbohydrate microarrays is to print carbohydrate antigens onto nitrocellulose-coated glass slides. This was the first reported method for high-throughput production of carbohydrate microarrays (Borman 2002; Kiessling and Cairo 2002; Wang et al. 2002). Using this technology, carbohydrate-containing macromolecules of diverse structures, including polysaccharides, natural glycoconjugates, and mono- and oligosaccharides coupled to carrier molecules, can be stably immobilized on a glass chip without chemical modification. This approach was subsequently extended to production of lipids/glycolipid and liposome microarrays (Fukui et al. 2002; Wang et al. 2005, 2014). Recently, this approach has been applied to produce integrated protein, lipid, and carbohydrate microarrays (Wang et al. 2014). Owing to the technical simplicity of this approach, anyone who has access to a standard cDNA microarray facility would be able to explore this technology for his or her own research interests (Fig. 1).

3.1 Preparing Carbohydrate Antigens for Microarray Printing

Soluble antigen preparations are generally applicable for construction of microarrays in this platform. Except certain antigens that require special solutions, proteins and carbohydrates for spotting are dissolved in phosphate-buffered saline (PBS; pH 7.4) and saline (0.9 % NaCl), respectively. Liposomes of various compositions, including *homo*- and *hetero*-liposomes, are suitable for printing on this

substrate (Wang et al. 2014). The former were produced via a single lipid preparation, e.g., phosphatidylcholine (PTC), cerebroside, and sulfatide. The latter contained two different lipid molecules with PTC as the support to display other lipid/glycolipids in desired ratios or epitope densities. For example, the *hetero*-liposome of sulfatide is composed of sulfatide and PTC at a ratio of 1:10 (wt/wt), i.e., 0.2 mg sulfatide and 2.0 mg PTC per ml of liposome suspension in saline. Methods employing sonication and extrusion (mechanical energy) to produce liposomes for microarray production were similarly described by a number of investigators (Wang et al. 2005; Palma et al. 2012).

3.2 Printing Carbohydrate Microarrays Using Conventional Microspotting Devices

Microarray printers that were designed for DNA or protein microarrays, such as PixSys 5500C (Cartesian Technologies, Irvine, CA), are suitable for spotting carbohydrates onto glass slides pre-coated with nitrocellulose polymer (FAST Slides; Schleicher and Schuell, Keene, NH) (Wang 2012). We often spot antigens in triplicate with spot sizes of 150 μm and at 375 μm intervals, center to center. The printed microarrays are air-dried and stored at either room temperature or 4 °C before application.

3.3 Staining and Scanning Microarrays

Immediately before use, the printed microarrays were rinsed with PBS, pH 7.4, with 0.05 % (vol/vol) Tween 20 and then blocked by incubating the slides in 1 % (wt/vol) bovine serum albumin (BSA) in PBS containing 0.05 % (wt/vol) NaN_3 at room temperature (RT) for 30 min. They were then incubated at RT with antibodies at an indicated titration in 1 % (wt/vol) BSA in PBS containing 0.05 % (wt/vol) NaN_3 and 0.05 % (vol/vol) Tween 20. The secondary antibodies or streptavidin conjugates applied for microarray staining are specified in the figure legends. The stained slides were rinsed five times with PBS with 0.05 % (vol/vol) Tween 20, air-dried at room temperature, and then scanned for fluorescent signals using a ScanArray 5000A microarray scanner (PerkinElmer Life Science) following the manufacturer's manual.

3.4 Producing Customized Arrays for Defined Purposes

Large-scale "repertory" microarrays containing thousands of microspots or larger are powerful means for discovering unexpected molecular targets. For example, microarray scanning of autoantibody responses allows one to "fish out" potential autoantigens in the glycome in autoimmune diseases. Customized, smaller scale carbohydrate microarrays containing a few dozen antigens are, however, suitable

for more defined purposes, such as antibody fine-specificity mapping, differential diagnosis among a number of known infectious diseases, measurement of autoantibodies for known targets in autoimmune diseases, etc. Fig. 2 shows a sub-array design where each chemically modified microglass slide contains eight separated sub-arrays. The microarray capacity is ~400 microspots per sub-array. A single slide is, thus, designed to enable eight microarray assays. Similar sub-array designs with various array capacities are commercially available (Schleicher and Schuell, Keene, NH; ArrayIt, Sunnyvale, CA).

- Each microglass slide contains twelve sub-arrays of identical content. There is a chip space for about 400 microspots per sub-array, with spot sizes of approximately 200 μm and at 300-μm intervals, center to center. A single slide is, therefore, designed to enable 12 detections. This design is typically for printing four 96-well plates of antigen preparations ($96 \times 4 = 384$).
- Repeats and dilutions: Our team usually prints carbohydrate antigens at the initial concentration of 0.1–0.5 μg/μl. The absolute amount of antigens printed on the chip substrate is in the range of 0.1–0.25 ng per microspot for the highest concentration. They are further diluted at 1:3, 1:9, and 1:27, or as specified in each experiment. A given concentration of each preparation is repeated at least three times to allow statistical analysis of detection of identical preparations at given antigen concentrations.
- Positive controls and standard curves: Fluorescent conjugates, such as BSA conjugates of FITC, Cy5, Cy3, or other dyes, are routinely applied for microarray printing to provide positive markers for each fluorescent channel. These markers are helpful for scanning calibration, alignment of microarray spots during data-capturing, the subsequent microarray data normalization, and cross-chip scaling of microarray detection. For serological studies, antibodies

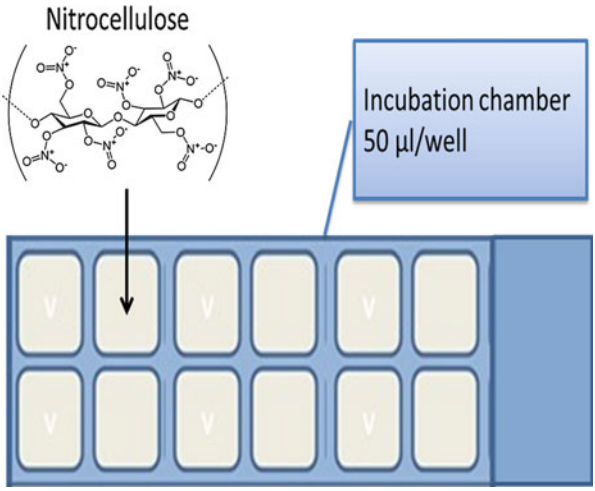

Fig. 2 Illustration of the 12-chamber sub-arrays

of IgG, IgA, and IgM isotypes of corresponding species are spotted to produce standard curves in microarray format. These curves serve as reference standards for quantifying antibody signals of a specific IgH chain isotype that are captured by spotted carbohydrate antigens.

3.5 Technical Notes of Nitrocellulose-Based Bioarray Substrate

A number of nitrocellulose-coated glass slides with different technical characteristics are commercially available. Given the structural diversity of carbohydrate antigens, examining each antigen preparation to determine the efficacy of its immobilization in a given type of substrate and the surface display of the desired glyco-epitopes in a microarray assay is essential. A practical approach is to incubate the printed microarrays with antibodies, receptors, or lectins known to react with the printed substance.

Figure 3 is an example of such analysis where lectin *Galanthus nivalis agglutinin* (GNA) and antibody 2G12 were applied to examine specific glyco-epitopes on the spotted microarrays. Inspection of both microarray images (Fig. 3a) and the quantitative datasets show that the GNA-epitopes were presented by three glycoconjugates (Fig. 3c), i.e., Man9-cluster ($4^{\#}$), M9_2G12-cluster ($3^{\#}$), and Man5-9 RB ($1^{\#}$). In contrast, 2G12-glyco-epitopes were preserved only by one of the three, i.e., M9_2G12-cluster ($3^{\#}$), on this microarray substrate (Fig. 3d). This carbohydrate microarray analysis demonstrates, therefore, an example that the same sugar chain may generate different glyco-epitopes when the sugar moiety is presented in different cluster configurations. In this case, the Man9GlcNAc2Asn moiety was coupled to the protein carriers in either (Man9GlcNAc2Asn) n- or [(Man9GlcNAc2Asn) $_4$] n-configurations (Fig. 3b). The latter but not the former preserves well the 2G12-defined broadly HIV-1 neutralizing epitope.

4 A Photogenerated Glyco-Chip Technology

Carroll and colleagues (2006; Wang et al. 2007; Carroll and Wang 2012) developed a photochemical method to covalently immobilize carbohydrates on chips. As illustrated in Fig. 4, the method employs a self-assembled monolayer to present photoactive phthalimide chromophores at the air-monolayer interface. Upon exposure to UV radiation, the phthalimide end-groups graft to surface-adsorbed carbohydrates to form a covalent bond. The amount of surface-grafted carbohydrate is enhanced when carbohydrate surface interactions are increased by the incorporation of amine-terminated molecules into the monolayer. One of the important applications of this technology is to identify immunogenic sugar moieties of microbial pathogens by screening the corresponding antisera obtained from vaccinated or infected subjects.

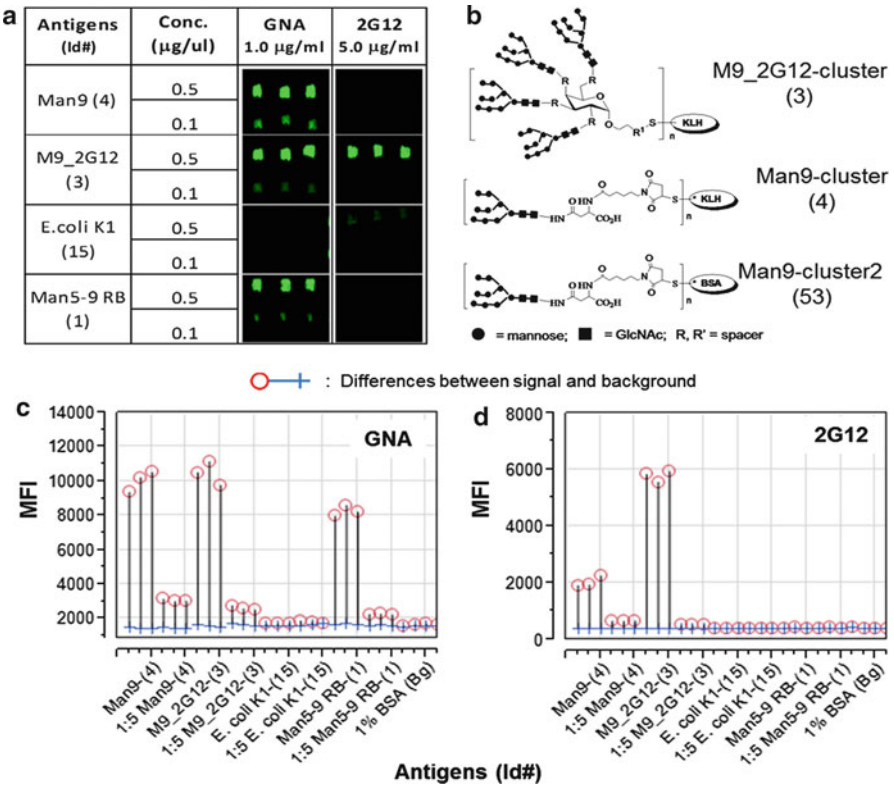

Fig. 3 A carbohydrate microarray analysis of oligomannosyl antigens for expression of the 2G12-like and GNA-like glyco-epitopes. The mannose-cluster-containing microarrays were stained with 2G12 (5 μg/ml) and a biotinylated GNA (1.0 μg/ml), respectively. The former was revealed by Alexa^{647}-tagged Goat anti-human IgG Fc-specific antibodies at 2 μg/ml and then developed with Streptavidin-Cy5 conjugate at 2 μg/ml. (**a**) Shows microarray images stained with either GNA or 2G12. (**b**) Illustrates the cluster configuration of the three Man9-conjugates. Microarray detection signals are shown as the mean fluorescent intensities (MFIs) of each microspot as captured by the ScanArray 5000A for the arrays stained with GNA (**c**) and 2G12 (**d**), respectively. Results were compared using overlay plots of the MFIs of staining signal (*red circles*) versus those of local backgrounds surrounding the antigen microarrays (*blue* +) (**c**, **d**) (Adapted from Wang et al. (2014))

4.1 Synthesis of Photoactive Compounds

The phthalimide chromophore used in the photogenerated glycan-chip was modified with a silane derivative in order to form a stable bond to glass. A 3.3 mmol portion of 11-bromoundecanetrimethoxysilane (Gelest) was added to a solution of an equimolar amount of potassium phthalimide (Aldrich) in 60 mL of anhydrous DMF (Aldrich). The solution was stirred overnight at room temperature (RT) under argon. Chloroform (50 mL) was added. The solution was transferred to a separatory flask containing 50 mL of H_2O. The aqueous layer was separated and then extracted

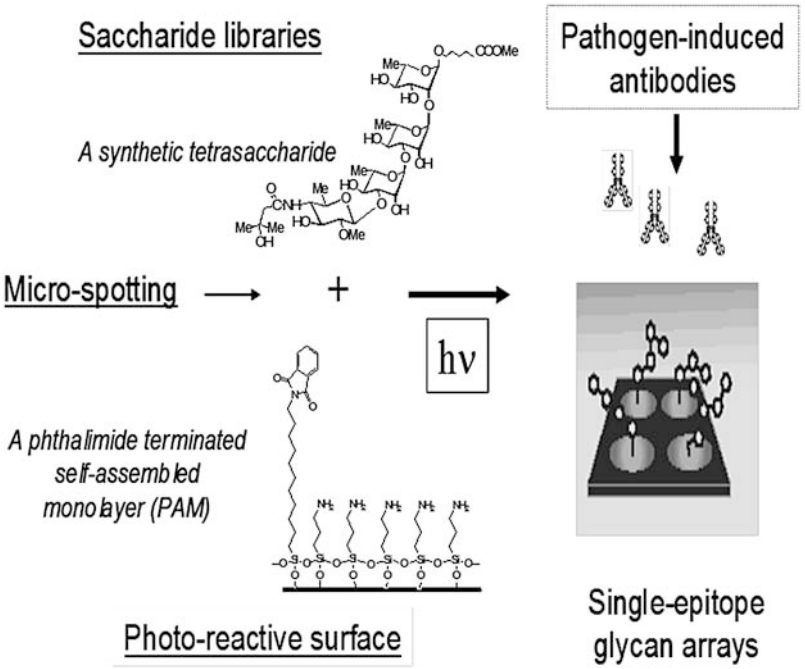

Fig. 4 Photogenerated glycan arrays for rapid identification of pathogen-specific immunogenic sugar moieties. Saccharide preparations were dissolved in saline (0.9 % NaCl) at a given concentration and spotted using a high-precision robot (PixSys 5500C, Cartesian Technologies, Irvine, CA) onto the phthalimide amine (PAM)-coated slides. The printed PAM slides were subjected to UV irradiation (300 nm) for 1 h to activate the photocoupling of carbohydrates to the surface. Pathogen-specific antisera were then applied on the glycan arrays to identify potential immunogenic sugar moieties of given pathogens (Adapted from Wang et al. (2007))

with two 20 mL portions of chloroform. The combined chloroform extract was washed with several 20 mL portions of H_2O. The chloroform was removed by rotoevaporation, and residual DMF was removed on a high vacuum line to give a pale yellow liquid (0.99 g, 72 % yield). The compound was used without further purification. Note that, for self-assembly experiments, residual DMF was not removed. 1H NMR: (CDCl3) *ä* 7.82 (m, 2H), 7.69 (m, 2H), 3.66 (t, *J* 7 Hz, 2H), 3.55 (s, 9H), 1.44–1.15 (m, 18H), 0.71–0.51 (m, 2H). LRMS-FAB+ (*m/z*): (M-H) 420.2 (experimental), 420.2 (calculated); (M-OCH3) 390.1 (experimental), 390.2 (calculated).

After synthesis of the phthalimide-silane, PAM was prepared by immersing a clean glass slide into a toluene solution containing 1 mM of the phthalimide-silane and 5 mM of aminopropyltrimethoxysilane (Gelest). The H_2O contact angle of the resulting surface was 72 ± 1°. Note that the glass slide was cleaned with a 7:3 mixture of H_2SO_4: 30 % H_2O_2. Extreme caution should be used when preparing and using such a solution, which can react violently and explosively if mixed with other chemicals.

4.2 Photocoupling of Carbohydrates onto Chips

Microarray spotting is performed as outlined in the above section. After spotting of carbohydrates, the PAM slides were air-dried and placed in a quartz tube. The sealed tube was subsequently purged with argon or nitrogen before irradiation. UV irradiation was conducted by placing the quartz tube under a desktop lamp containing a 300 nm Rayonet bulb for 1 h. Precaution was made to avoid skin and eye contact with the radiation during the irradiation process.

4.3 Probing Immunogenic Sugar Moieties Using Photogenerated Glyco-Chips

The photogenerated glycan arrays were applied to probe the potential immunogenic sugar moieties of *Bacillus anthracis* spores (Wang et al. 2007). The rationale was that if *B. anthracis* spores expressed immunogenic carbohydrate structures, the spore antigen-immunized or *B. anthracis*-infected animals would be possible to mount antibody responses to these carbohydrates. This assumption was made on the basis of the fact that the host immune system is able to recognize subtle changes in sugar structures, especially those that are exposed on the surfaces of microbial pathogens that are foreign components of the mammalian hosts.

Figure 5 below is an example of photo-chip characterization of the rabbit antisera elicited by *B. anthracis* spores. The photo-chips used were spotted with a large panel of saccharide structures, including synthetic fragments and derivatives of the anthrose-containing tetrasaccharide side chain of the *B. anthracis* exosporium and a number of control carbohydrate antigens. Antibody staining was performed in the presence or absence of saccharide inhibitors. Images (a–f) display a portion of the stained glycan arrays: (a) no saccharide inhibitor; (b) anthrose; (c) D-glucose; (d) α-anthrose trisaccharide; (e) α-anthrose tetrasaccharide; (f) β-anthrose tetrasaccharide. The locations of surface-bound anthrose-containing saccharides that are recognized by the antibody in the absence of inhibitor are highlighted by colored boxes: *White*, β-anthrose-trisaccharide; *Brown*, β-anthrose-tetrasaccharide; *Yellow*, α-anthrose-tetrasaccharide. Microarray data sets are available upon request.

This analysis confirmed that a tetrasaccharide of BclA glycoprotein bears a dominant antigenic determinant, which is composed of a terminal anthrose residue and three adjacent L-rhamnoses. The terminal trisaccharide unit is essential for the constitution of a highly specific antigenic determinant. Given the fact that this carbohydrate moiety is displayed on the outermost surfaces of *B. anthracis* spores and its expression is highly specific for the spore of *B. anthracis*, the anthrose-containing tetrasaccharide can be considered an important immunological target. Its applications may include identification of the presence of *B. anthracis* spores, surveillance and diagnosis of anthrax infection, and development of novel vaccines targeting the *B. anthracis* spore.

Fig. 5 Photogenerated glycan arrays recognize immunogenic sugar moieties of the *B. anthracis* spore. A panel of 35 mono-, oligo-, and polysaccharides were photocoupled to the surface of derivatized glass slides. After incubating the glycan arrays with rabbit anti-*B. anthracis* spore polyclonal IgG antibodies (Abcam, Cambridge, UK) in the absence or presence of saccharide inhibitors, the bound rabbit IgG was revealed by a tagged anti-rabbit IgG antibody (Adapted from Wang et al. (2007))

4.4 Technical Notes for Photogenerated Glyco-Chips

A unique technical advantage of this method is the ability to produce epitope-specific glycan arrays using unmodified mono- and oligosaccharides. The quality of the surfaces obtained depends in part on cleanliness. Ideally, water with a resistivity of 18.2 MΩ-cm and total organic contaminant of less than five parts per billion should be used; however it is still possible to prepare the surfaces after rinsing with water of lower quality. Self-assembly of trimethoxysilanes can be enhanced by adding small amounts of water and acid. Such treatment was not used for the mixed surface described above but may possibly enhance the reaction times or surface coverage obtained. If the surface is allowed to dry upon removal from self-assembly solution, the aminosilane may polymerize, leaving white deposits that are difficult to remove.

5 Carbohydrate Microarray Data Processing and Statistical Analysis

Although specialized bioinformatics tools for carbohydrate microarrays are yet to be developed, some software packages developed for cDNA microarrays are applicable for carbohydrate microarrays. This is owing to the fact that these different microarray assays are commonly based on the laser fluorescence detection systems regardless of the contents of the spotted microarrays. A number of advanced microarray software packages are currently available. These include, but are not limited to, Significance Analysis of Microarrays (SAM, http://www-stat.stanford.edu/~tibs/SAM/), Prediction Analysis for Microarrays (PAM http://www-stat.stanford.edu/~tibs/PAM/index.html), and JMP Genomics (www.jmp.com/genomics).

5.1 Presenting Microarray Raw Datasets and Microarray Images

A straight forward way to present the raw results of a carbohydrate microarray assay is to illustrate the microarray raw datasets and/or images. For example, carbohydrate researchers often present microarray raw datasets with or without background substraction for the carbohydrate-binding profiles of monoclonal antibodies (Palma et al. 2011), lectins (Blixt et al. 2004), or viruses (Childs et al. 2009). Figure 3 above illustrates two examples of binding profile presentations based on microarray raw data.

In this experiment, the mannose-cluster-containing microarrays were stained with mAb 2G12 (5 μg/ml) and a biotinylated GNA (1.0 μg/ml), respectively. Figure 3a shows microarray images and Fig. 3b illustrates the cluster configuration of the three Man9-conjugates. Microarray detections are shown as the mean fluorescent intensities (MFIs) of each microspot as captured by the ScanArray 5000A for the arrays stained with GNA (Fig. 3c) and 2G12 (Fig. 3d), respectively.

Results were compared using overlay plots of the MFIs of the antigen-binding signals (*red circles*) versus those of local background signals surrounding the antigen microarrays (*blue* +) (Fig. 3c, d). Analysis of such microarray raw data in association with visual inspection of the microarray image provides an initial evaluation of reproducibility and variation of this antigen microarray technology.

5.2 Statistical Tests of Carbohydrate Microarray Detection

In order to identify disease-associated biomarkers, such as antigen-specific antibodies with diagnostic and/or prognostic values, we compare microarray detection between a disease group and a normal control group or to more generally between multiple groups. Proper statistical analysis is essential for making generalizable conclusions. Typical steps include quality control, normalization, and statistical model fitting. In our general practice, carbohydrate array datasets are preprocessed and statistically analyzed using JMP Genomics software from SAS Institute.

Antigen-specific antibody reactivities are represented as microarray scores, which are the log2 transformed values normalized by some method. We have explored several different normalization methods, including mean and/or variance centering, loess, and quantile normalization, and found the interquartile range (IQR) method to provide an appropriate degree of standardization (based on distribution and correlation plots) without overly correcting the data. The IQR method sets the 25th and 75th percentiles of the microarray distributions to be equal.

After normalization, we utilize an antigen-by-antigen ANOVA model to obtain statistically significant differences. Data from triplicate spots for each antigen are included in the ANOVA model for that antigen. A cutoff to detect significant differences is determined by applying a multiple testing correction to statistical results from the ANOVA model. These procedures are further discussed below in an example of clinical sample analysis.

5.3 Clinical Sample Analysis Using Customized Carbohydrate Microarrays

Here we present an example to illustrate general statistical approaches to carbohydrate microarray analysis of clinical samples. In this case, customized autoantigen microarrays were applied to characterize the cerebrospinal fluid (CSF) of multiple sclerosis (MS) patients. MS is a complex neurological disorder in which an adaptive autoimmune response is thought to target myelin sheath in the central nervous system. We created a microarray displaying a panel of 32 carbohydrate and lipid antigens to examine MS-associated autoantibody responses.

A technical challenge to this study is the fact that the total Ig concentrations in the CSF of MS patients are higher than those in the CSF of other neurological diseases (OND) subjects, which reflects one of the hallmarks of MS

(Kabat et al. 1948, 1951; Steinman 1996; Genain et al. 1999; Raine et al. 1999; Hueber et al. 2002). However, it causes difficulty in identifying the disease-specific autoantigens and autoantibodies. In our microarray analyses, we reconfirmed this observation. Figure 6a, b show the overlay plots of antibody profiles of the two groups. The colored needles that link the pairs of group mean values provide a global comparison of the antibody profiles between the MS group (*red circles*) and the OND group (*blue crosses*). This comparison reveals global differences in antibody profiles between the two groups. Specifically, the microarray scores of CSF-antibody activities in the MS group are generally higher than those seen in the CSF of OND subjects. These include not only anti-lipid antibodies (*Right*, *26–44*$^{\#}$), as previously reported (Ho et al. 2012), but also anti-carbohydrate antibodies (*Left*, *1–22*$^{\#}$).

We further examined whether there is any selective enrichment of antigen-specific antibodies in the CSF of MS patients. We reasoned that identifying such antibodies might provide clues to pinpoint key autoimmunogenic targets of MS. For this purpose, we introduced an approach to establish RAR scores for microarray signals and then sought targets that capture the antibody signal with higher RAR scores in MS patients. Specifically, we normalized the microarray datasets by setting their IQR to be identical using the JMP Genomics software package. This statistical operation effectively "quenches" the variation seen between subjects that are due to variable antibody concentrations in the CSF. The two groups illustrate similar Ig-RAR profiles for both IgG and IgM antibody activities (Fig. 6c, d). However, a number of probes show higher IgG-RAR scores in the MS group than in the OND controls. These include two Man9-clusters (3$^{\#}$, and 4$^{\#}$), three glucose polysaccharides, dextran N279 (8$^{\#}$), B1299S (9$^{\#}$), B1355S (10$^{\#}$), and a Bacto-Agar (20 °C, extracted) antigen (13$^{\#}$) (Fig. 6c).

In Fig. 7, an antigen-by-antigen analysis of variance (ANOVA) model was applied to obtain statistically significant differences between groups in comparison. Results are graphically presented as a volcano plot (Zink et al. 2013) for a global comparison of all RAR scores between the groups in comparison (Fig. 7a) and as one-way analysis scatterplots for selected targets (Fig. 7b, c). In the volcano plot, each dot represents a statistically weighted and quantified difference between MS and OND groups. The x-axis is the normalized difference (log2 scale) and the y-axis uses –log10 (p-value) for the difference. Spots above the red-dashed line represent signatures that differ significantly between the groups after a multiple testing correction.

For the one-way scatterplots in Fig. 7b, c, each data point represents the mean of triplicate determinations. The means of the points are shown as horizontal green bars and standard deviations as green diamonds around the mean value. The comparison circles for the Student's "t"-test appear to the right of the mean diamonds to illustrate the significance of the differences among the means. These circles allow visual inspection of the statistical significance of the differences. The more the circles intersect, the less significant their difference, and vice versa.

Of the 126 antibody signatures captured in this assay (Fig. 6c, d), two were above the cutoff line [–log10 (p-value) = 2.5] as highly significant

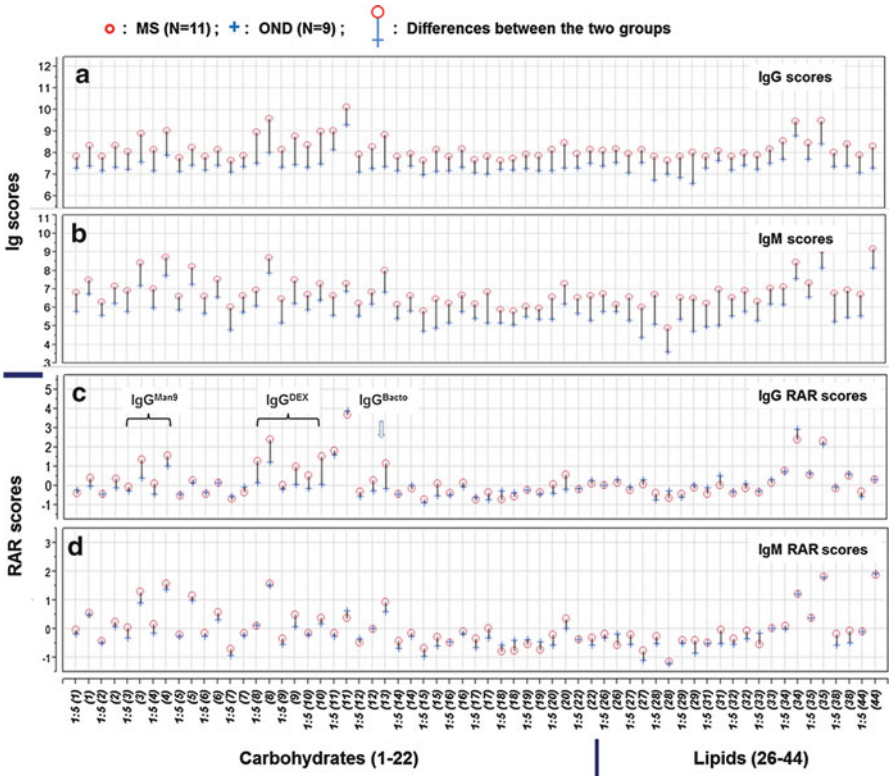

Fig. 6 Integrated lipid/carbohydrate arrays recognize globally elevated antigen-specific antibodies in the CSF of MS patients as compared to those detected in the OND CSF. CSF samples from 11 MS (10 RRMS and 1 SPMS) and 9 OND subjects were characterized using microarrays spotted with 12 lipid and 20 carbohydrate antigens. Each preparation was spotted in triplicate at 2–4 dilutions. As illustrated in the overlay plots (**a**–**d**), this microarray supports detection of 126 unique antibody signatures. These included 63 IgG (**a**, **c**) and 63 IgM (**b**, **d**) signatures. Anti-human IgG or IgM secondary antibodies were used to reveal the antigen-specific antibodies detected by these microarrays. The captured IgG were stained with an anti-human IgG antibody conjugated with Cy3 at 2 μg/ml and the captured IgM in the same array revealed by a biotinylated anti-human IgM secondary antibody at 2 μg/ml and developed with Streptavidin-Cy5 conjugate at 2 μg/ml. Microarray datasets in (**a**) and (**b**) were illustrated as microarray scores. In (**c**) and (**d**) microarray datasets were further processed using JMP Genomics to produce RAR* scores. The results are presented as overlay plots of the mean microarray scores for each group. The colored needles that link the group mean values of each pair of scores provide a global comparison of the antibody profiles of MS (*red circles*) and OND (*blue crosses*) groups (Adapted from Wang et al. (2014)). **RAR Score*: *RAR* **R**elative **A**ntibody **R**eactivity, the value of log2 transformed and IQR-standardized microarray value (mean-background). For each antigen in a given concentration, the mean value of triplicate array detections was calculated

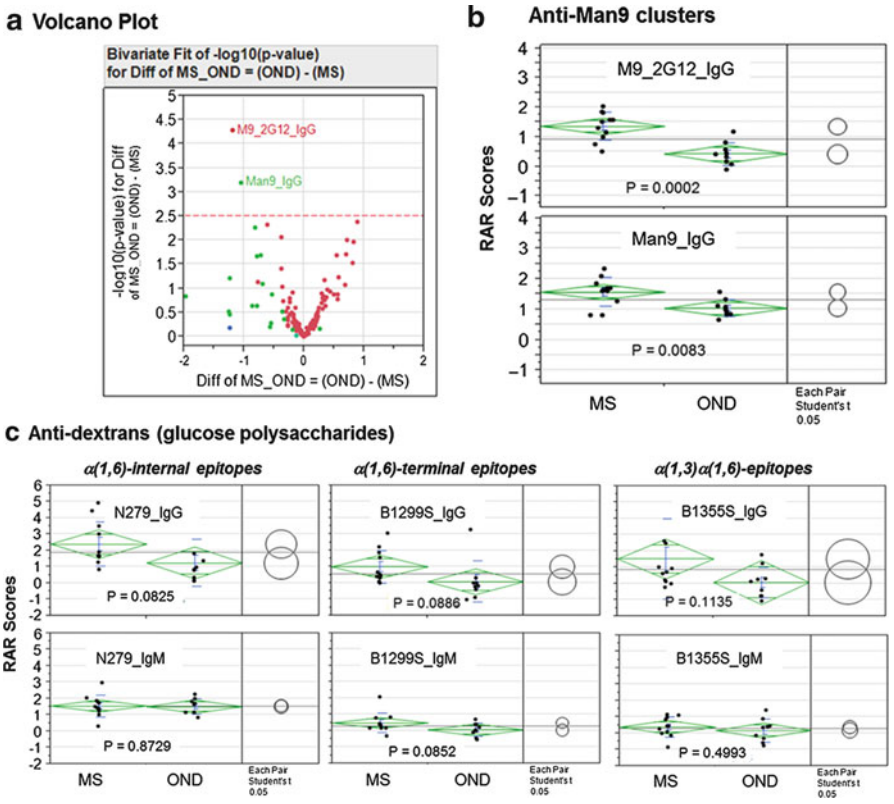

Fig. 7 MS-associated autoantibodies in CSF samples target high-mannose clusters, the cores of N-glycans. (**a**) is a volcano plot analysis of the RAR scores of all antibody signatures. In the volcano plot, each point represents a biologically unique feature captured by the microarray, i.e., a normalized difference for a specific antibody signature (RAR^{MS}-RAR^{OND}). The x-axis is the normalized difference (log2 scale); the y-axis is the –log10 (*p*-value), which weights the levels of significance of a difference. Points above the *red-dashed line* (cutoff level 2) represent signatures that differ significantly between the groups based on the Bonferroni test. Two signatures, M9_2G12_IgG and Man9_IgG, were identified by this critical statistical test as highly significant markers. In (**b**) and (**c**) one-way analysis was performed to compare group means among the selected carbohydrate antigens listed in each panel. Each point in the panels represents the mean value (RAR score) of triplicate array detections of a subject (Adapted from Wang et al. (2014))

differentiators between MS and OND. These were M9_2G12_IgG and Man9_IgG. Results of the one-way ANOVA of the two Man9 clusters are shown in Fig. 7b. All other antibody signatures had –log10 *p*-values below the cutoff line (Fig. 7a), including four signatures that were variably higher in the MS group than in the OND group. These were N279_IgG ($P = 0.0825$), B1299S_IgG ($P = 0.0886$), B1355S_IgG ($P = 0.1135$), and Bacto_Agar_IgG ($P = 0.021$). This microarray analysis identified, therefore, oligomannoses as potential immunological targets

for further investigation. Overall, JMP Genomics is a valuable tool for statistical analysis of carbohydrate microarray data.

6 Conclusion/Prospects

Modern carbohydrate microarrays emerged in 2002 (Borman 2002, 2012; Kiessling and Cairo 2002; Wang and Collins 2013) and introduced new glycomics tools to decipher the biological information content in the glycome. These technologies are especially useful in exploring the repertoire of glyco-epitomes. A number of carbohydrate microarray platforms have now reached or are very close to the technical stage of the current nucleic acid–based or protein-based microarrays that are readily available for practical uses. Technical issues that require further improvement may include, but are not limited to, optimization of existing technologies for array construction, quality control and technical standardization in both microarray production and application, and establishment of specialized bioinformatics tools to handle the massive amount of carbohydrate microarray data and to effectively extract diagnostic or research information from each microarray assay.

Nevertheless, exploring the repertoires of glyco-epitopes represents a long-term goal of glycomics research. It was estimated that the human glycome contains 10,000–20,000 minimal epitopes for glycan-binding proteins (Cummings 2009). In considering the repertoires of the "hybrid" structures that are generated by protein posttranslational modification, including both *N*- and *O*-glycosylation, the repertoires of carbohydrate-related antigenic structures can be much larger. Furthermore, the conformational diversity of carbohydrates and microheterogeneity of carbohydrate chains substantially increases the repertoire of carbohydrate-based antigenic determinants or glyco-epitopes (Wang and Kabat 1996; Wang 2014). Including carbohydrate structures of the microbial world, which are directly relevant to medicine, the sizes and diversity of the repertoires of glyco-epitopes are unpredictable.

Further development of carbohydrate microarrays requires libraries of carbohydrate antigens, including purified natural antigens and synthetic glycoconjugates, as well as anti-glycan mAbs, lectins, and other glycan-binding proteins. Naturally purified carbohydrate antigens have the advantage of preserving the native antigenic structures and often offer highly sensitive detection of antigen-specific antibodies. Availability of synthetic oligosaccharides and glycoconjugates is, however, critical for epitope determination and fine-specificity studies of carbohydrate-anti-carbohydrate interactions.

Anti-glycan mAbs and GBPs of known carbohydrate-binding specificities are required to characterize glyco-epitopes that are presented by carbohydrate microarrays. Thus, collaborative efforts by both academic and industrial sectors are required to facilitate the establishment of large collections of glycan-targeting probes. This situation is similar to established flow cytometry technology and services. Availability of specific antibody probes for CD antigens, in combination with the state-of-the-art technologies of flow cytometry (high-dimensional

fluorescence-activated cell sorting, or Hi-D FACS) (Tung et al. 2004), has revolutionized research in cellular biology and immunology and medical applications of CD antigens, especially in the clinical diagnosis of leukemia and other human diseases. Exploring the repertoires of carbohydrate-based biomarkers and targeting agents, with the aid of carbohydrate microarray technologies and other high-throughput omics tools, may represent one of the highly active areas of postgenomics research and technology development in future years.

Abstract

Starch as a biopolymer directly extracted from nature has received much attention in recent years due to its strong advantages such as low cost, wide availability, renewability, and total compostability without toxic residues. Starch-based materials always display properties that are less satisfactory than those of traditional polymer materials, which can be ascribed to the inherent characteristics of starch. To make such materials to be truly competitive and to widen its applications, the development of starch-based nano-biocomposites could be a promising solution. This chapter provides the fundamental knowledge related to starch-based nano-biocomposites as well as the most recent developments in this area. Various types of nanofillers that have been used with plasticized starch are discussed such as montmorillonite, cellulose nanowhiskers, and starch nanoparticles. The preparation strategies for starch-based nano-biocomposites with these types of nanofillers and the corresponding dispersion state and related properties are also largely discussed.

Keywords

Starch • Nanocomposites • Biopolymers • Biodegradable polymers • Bioplastics • Nanoclays • Cellulose nanowhiskers • Starch nanoparticles • Carbon nanotubes

Abbreviations

AFM	Atomic force microscopy
BCNW	Bacterial cellulose nanowhisker
CB	Carbon black

1 Introduction

The increasing environmental concerns, the strong decrease of the availability on the market of some conventional refinery fractions which are more or less refined (e.g., isoprene, butadiene, bitumen, etc.), the expected shortage of fossil resources (mainly petroleum), and the necessity to develop innovative materials architectures are some of the main drivers to push the use of biobased compounds extracted from the biomass. Following this mainstream, starch, as a natural polymer from renewable resources, has experienced considerable development in the past decades in nonfood and materials applications (Avérous and Halley 2014). Starch has strong advantages such as low cost, wide availability, renewability, and total compostability without toxic residues. By using conventional polymer processing techniques such as extrusion, native starch (also known as raw starch) in the form of granules can be transformed into a molten state with the presence of low content of "plasticizers" such as water and glycerol. This converted form of starch is known as "plasticized starch," "thermoplastic starch" (although its behavior is not totally thermoplastic but more thermo-mechano-plastic (Martin et al. 2003)), or abbreviated as "TPS," which can be produced into different end-use forms such as extruded, molded, thermoformed, or blown articles (Liu et al. 2009a).

Despite of the advantages mentioned above, starch-based plastic materials are known to have limitations such as poor processability and limited properties (e.g., weak mechanical properties, large evolution of properties during aging, and high water sensitivity). Formulation development could be the major key to solve these crucial problems. To give some examples, various starch-based blends and biocomposites (i.e., with fillers) have been developed, showing improved performance (Avérous 2004; Avérous and Halley 2009; Kalambur and Rizvi 2006a; Tang and Alavi 2011; Wang et al. 2003; Yu et al. 2006a) compared to the neat matrix. Recently, along with the exponential momentum of the development in polymer nanocomposites (Alexandre and Dubois 2000; Crosby and Lee 2007; Paul and Robeson 2008; Pavlidou and Papaspyrides 2008; Sinha Ray and Okamoto 2003; Sinha Ray and Bousmina 2005; Spitalsky et al. 2010), much attention has been focused on the use of nanosized fillers (at least one dimension in the nanometer range, i.e., 1–100 nm) in producing starch-based nano-biocomposite materials. Their nanosize can generate huge areas at the matrix–filler interface, which largely control the global macrostructures and associated global properties of the corresponding materials. Under certain conditions with the tailored nanofiller and/or organomodification of the nanofiller, nanocomposite materials can exhibit drastic improvement in mechanical behavior, thermal stability, flame retardancy, and gas barrier properties (Alexandre and Dubois 2000). Such property enhancement depends on the nature, geometry, surface area, and surface chemistry of the nanofiller (Sinha Ray and Okamoto 2003).

Unlike most conventional synthetic polymers, starch is a biopolymer directly extracted from biomass, which has unique chemical structure and processing behavior. Therefore, the preparation and properties of starch-based nano-biocomposites are inherently dissimilar to those of other polymer nanocomposite systems. Furthermore, the incorporation of appropriately tuned nanoparticles into starch as a biopolymer may not only enhance the conventional material performance of starch-based materials, but it could also provide new functionalities for new applications due to the resulting novel structures and functional groups. While this chapter aims to provide the basic knowledge of starch and starch-based nano-biocomposites, which should be helpful to those new to this area, it touches some of the most recent international research progress on this topic as well.

2 Starch Characteristics

2.1 Structure of Native Starch

The starch granule provides the main way of storing carbon and energy over long periods in green plants (Pérez et al. 2009). Starch granules are mainly found in seeds, roots, and tubers and display different shapes (spherical, lenticular, and polygonal) depending on their origins such as maize (corn), wheat, potato, and rice. In Fig. 1, an overview of starch granule structure is shown, which presents

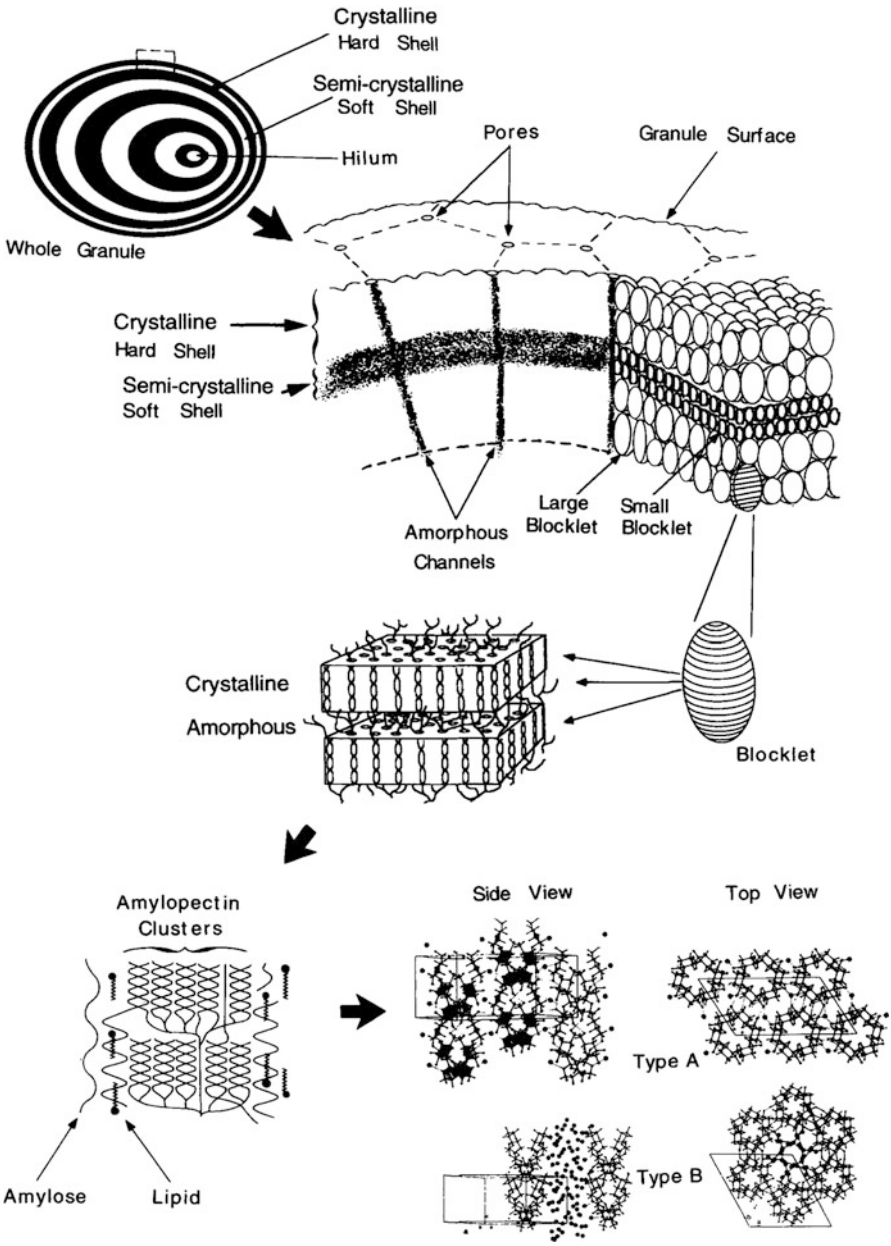

Fig. 1 Overview of starch granule structure. At the lowest level of granule organization (*upper left*), alternating crystalline (*hard*) and semicrystalline (*soft*) shells are shown (*dark and light* colors, respectively). Shells are thinner toward the granule exterior (due to increasing surface area to be added to by constant growth rate) and the hilum is shown off-center. At a higher level of structure, the blocklet structure is shown in association with amorphous radial channels. Blocklet size is smaller in the semicrystalline shells than in the crystalline shells. At the next highest level of

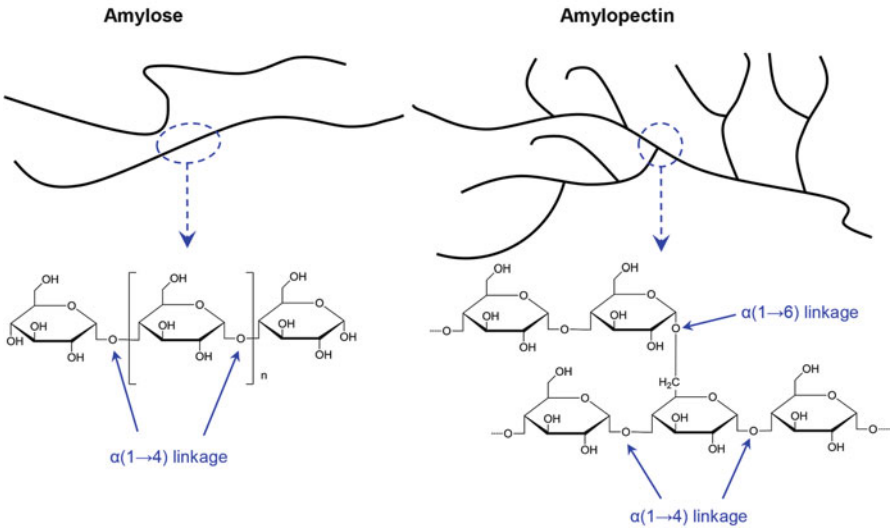

Fig. 2 Chemical structures of amylose and amylopectin molecules of starch

a concentric three-dimensional architecture from the hilum, with a crystallinity varying from 15 % to 45 % depending on the botanical source (Zobel 1988). The starch granule is well known to possess multilevel structures from macro- to molecular scales, i.e., starch granules (<1–100 μm), alternating amorphous and semicrystalline shells (growth rings) (100–400 nm), crystalline and amorphous lamellae (periodicity) (9–10 nm), and macromolecular chains (~nm) (Buléon et al. 1998; Jane 2009; Pérez et al. 2009; Pérez and Bertoft 2010).

In molecular level of structure, starch is a polysaccharide consisting of D-glucose units, referred to as homoglucan or glucopyranose. Figure 2 presents the two major biomacromolecules of starch, i.e., amylose and amylopectin. Amylose is a sparsely branched carbohydrate mainly based on α(1–4) bonds with a molar mass of 10^5–10^6 and can have a degree of polymerization (DP) as high as 600 (Pérez et al. 2009). The number of macromolecular configurations based on α(1–6) links is directly proportional to the amylose molar mass (Tako and Hizukuri 2002). The chains show spiral-shaped single or double helices with a rotation on the α(1–4) link and with six glucoses per turn, where the hydroxyl groups are mainly located toward the exterior of the helices. As a result, the core of the helix is mainly hydrophobic.

Fig. 1 (continued) structure, one blocklet is shown containing several amorphous crystalline lamellae. In the next diagram, amylopectin is shown in the lamellae. The next image is a reminder of the importance of amylose–lipid (and protein) components in the organization of amylopectin chains. At the highest level of order, crystal structures of the starch polymers are shown (Reprinted from Gallant et al. (1997), Copyright (1997), with permission from Elsevier. Redrawn in Gallant et al. (1997) from Imberty et al. (1988) and Imberty and Perez (1988))

On the other hand, amylopectin is a highly multiple-branched polymer with a high molar mass of 10^7–10^9. It is one of the largest natural polymers on earth (Pérez et al. 2009). Amylopectin is based on α(1–4) (around 95 %) and α(1–6) (around 5 %) links, with constituting branching points localized every 22–70 glucose units, generating a highly branched structure with a lot of pending chains of DP ≈ 15, which are mainly responsible for the materials' crystallinity (between 20 % and 45 %). This specific structure has a profound effect on the physical and biological properties (Pérez et al. 2009; Pérez and Bertoft 2010).

Besides, in starch granules, very small amounts of proteins, lipids, and phosphorus are also found depending on the botanical resource (Jane 2009; Pérez and Bertoft 2010). These components can interact with the carbohydrate chains during processing (e.g., Maillard reaction) and then modify the behavior of the starchy materials.

Depending on the source, amylose content of starch can be varied from <1 % to 83 % (Tan et al. 2007). The so-termed waxy starch contains little or no amylose, whereas high-amylose starch contains >50 % amylose. The amylose content has a great impact on the crystalline structure and degree of crystallinity (Tan et al. 2007), as well as on the thermal, rheological, and processing properties (Li et al. 2011a; Liu et al. 2006, 2011d; Wang et al. 2010a; Xie et al. 2009).

2.2 Gelatinization/Melting of Native Starch

When native starch granules are heated in water, their semicrystalline nature and three-dimensional architecture are gradually disrupted, resulting in a phase transition from the ordered granular structure into a disordered state in water, which is known as "gelatinization" (Atwell et al. 1988; Lelievre 1974; Ratnayake et al. 2008). The process of gelatinization is schemed in Fig. 3. Gelatinization is an irreversible process that includes, in a broad sense and in time/temperature sequence, granular swelling, native crystalline melting (loss of birefringence, as observed under polarized light), and molecular solubilization (Russo et al. 2009). Full gelatinization of starch under shearless conditions requires excess water, which Wang et al. (1991) have defined as >63 % for waxy maize starch, for example. If the water concentration is too high, the crystallites in starch might be pulled apart by swelling, leaving none to be melted at higher temperature. If the water concentration is limited, the swelling forces will be much less significant and the steric hindrance is high. Thus, complete gelatinization will not occur in the usual temperature range (Lai and Kokini 1991; Liu et al. 2005, 2006). However, as the temperature increases, starch molecules will become progressively more mobile and eventually the crystalline regions will be destructured (Donovan 1979). The process of gelatinization with low water content could more accurately be defined as the "melting" of starch (Lai and Kokini 1991).

The gelatinization/melting behavior of starch is quite different when shear treatment is applied (Xie et al. 2006). With abundant water, shear can enhance

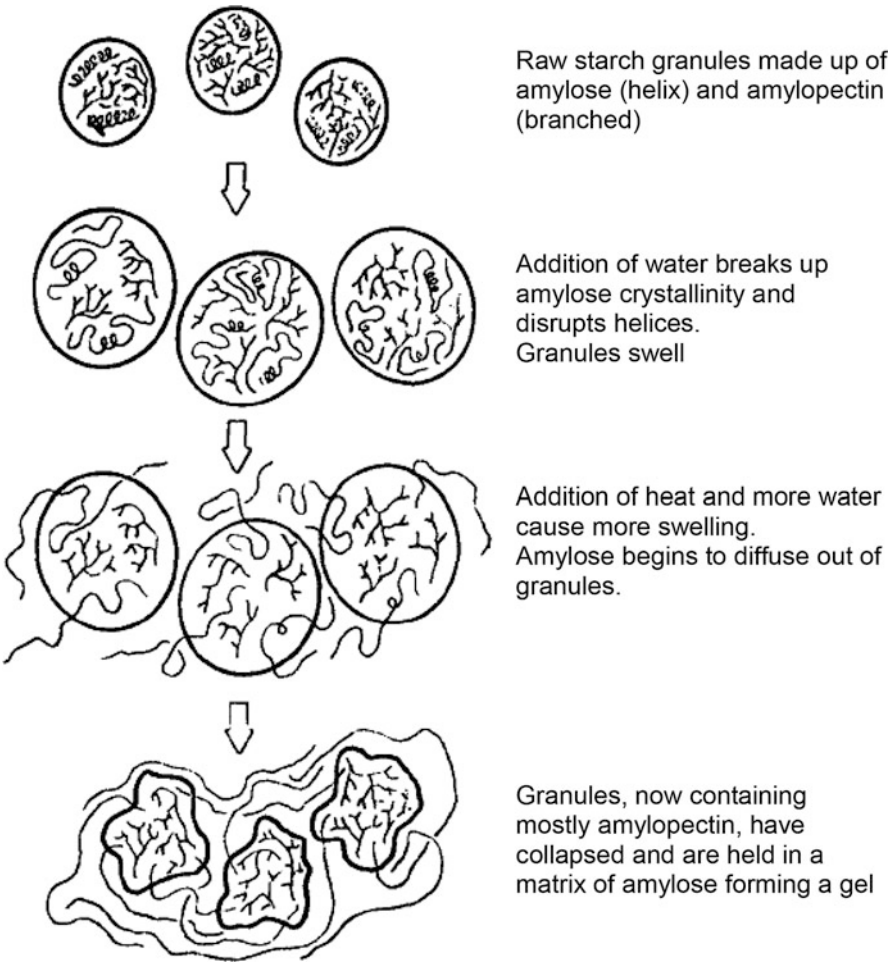

Fig. 3 Mechanism of starch gelatinization (Copyright © 1978 Wiley Periodicals, Inc. Reproduced from Remsen and Clark (1978) with permission)

the destructuration of starch granules (Chen et al. 2007; Yu et al.2006b). When the water content is limited, shear can assist the melting of crystallites (Wang et al. 2010a; Xie et al. 2008; Xue et al. 2008). The significance of such studies is that most processing techniques for starch involve shear treatment. In extrusion processing (which will be discussed below in Sect. 3.1), shear forces can physically destructure starch granules, allowing faster transfer and distribution of water into the material (Burros et al. 1987). Therefore, during extrusion, the loss of the crystallinity is not only caused by the water penetration but also by mechanical disruption due to the intense shear fields within the extruder (Barron et al. 2001; Wang and Zheng 1995; Zheng and Wang 1994; Zheng et al. 1995).

3 Starch-Based Materials

3.1 Processing Techniques

The techniques that have been used to process starch polymers, such as solution casting, internal mixing, extrusion, injection molding, and compression molding, are similar to those widely used for conventional synthetic thermoplastics. Solution casting has been frequently utilized in the literature as a method to prepare starch-based films for research purposes. However, this technique suffers from disadvantages such as low efficiency and the difficulty in scaling up from the lab scale to the industry and not being considered as a "green process" due to the use of toxic organic solvents and the great consumption of energy for solvent evaporation. Alternatively, extrusion processing is more aligned to modern industrial production. A single-screw extruder (SSE) can handle the high viscosity of starch and provide high processing pressure for continuous metering of starch through a die shape. A twin-screw extruder (TSE) has large operational flexibility (individual barrel zone temperature control, multiple feeding/injection, and screw configuration for different degree of mixing/kneading) and is useful to intensive mixing and compounding of other components into starch plastics. Another advantage of TSE is to allow the decoupling of the die flow and the mechanical treatment. In both SSE and TSE, the residence time and specific mechanical energy (SME) input can be controlled, and high-efficiency production can be achieved. Other processing techniques such as film blowing and injection molding are often combined with the extrusion. More details about the specifics of the processing techniques for starch polymers as well as the recent advances in the understanding of starch processing can be found elsewhere (Liu et al. 2009a; Xie et al. 2014).

A schematic of twin-screw extrusion process for the production of TPS is shown below in Fig. 4 (Xie et al. 2012). The native starch granules are introduced, preferably by a powder gravimetric feeder, into the extruder in a hungry way (i.e., the feeding capacity is less than the conveying capacity of the screws at the feeding port). Liquids (typically plasticizer) could be introduced in a following location, preferably using a pressure-injection way to ensure uniform mixing between the solid(s) and the liquid(s). The granules undergo exposure to high temperatures and pressures in the extruder, resulting in the disruption, and gelatinization/melting, of starch granules (Liu et al. 2006). After gelatinization, the TPS will undergo further melting and compression, which may be increased with increased use of high mixing (kneading or reversing) elements in the screw. It is important to note that degradation of starch molecules also occurs with the thermal mechanical treatment in the extruder, with amylopectin molecules suffering more than amylose (Li et al. 2014; Liu et al. 2010b). And the mechanism for the scission of the polymer chains is believed to preferentially take place close to the center of the molecule, causing the size distribution to narrow and converge toward a maximum stable size (Liu et al. 2010b). The TPS is forced through the extrusion line and finally out of a die at the end of the extruder at a controlled rate (possibly with the aid of a melt pump to further control the flow rate).

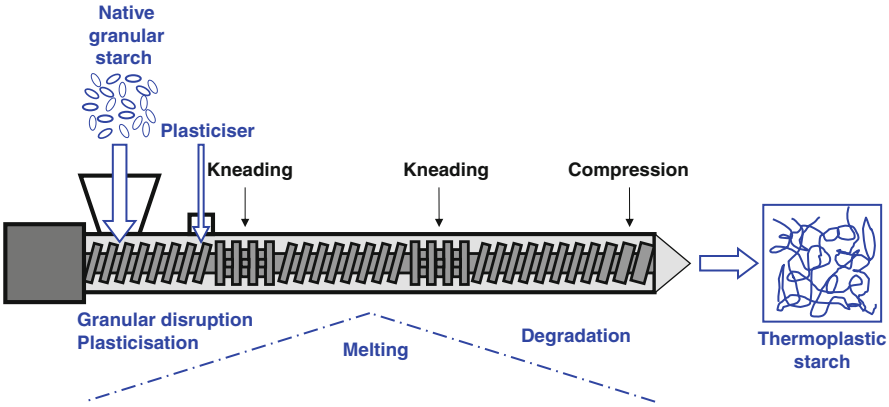

Fig. 4 Schematic representation of starch processing by extrusion (Reprinted from Xie et al. (2012), Copyright (2012), with permission from Elsevier)

3.2 Plasticizers

Water is indispensable for the thermal processing of starch. By reducing the moisture content, the melting temperature of starch would progressively increase, and that of dry starch is often larger than its degradation temperature as extrapolated by Flory Law (Liu et al. 2008; Russell 1987). Water functions by lowering the melting temperature and plasticizing the starch polymers. As a result, in practical processing, water acts as a volatile "plasticizer." Thus, unstable processing or undesirable foaming may be caused due to the evaporation of the water. Furthermore, the final products based on starch containing only water usually have poor mechanical properties especially due to the brittleness, because of its final temperature usually lower than its glass transition temperature (T_g) (Chaudhary et al. 2011b; Enrione et al. 2010; Forssell et al. 1997; Liu et al. 2011b, 2009b, 2010a; Lourdin et al. 1997) and/or resulting from the densification (happening below T_g) or retrogradation (also known as recrystallization, happening above T_g) (Atwell et al. 1988; Bulkin et al. 1987; Gudmundsson 1994; Liu and Thompson 1998). To overcome these issues, nonvolatile (at the processing temperature) plasticizers such as polyols (glycerol, sorbitol, glycol, etc.) (Da Róz et al. 2006; Enrione et al. 2010; Forssell et al. 1997; Gaudin et al. 1999; Kirby et al. 1993; Lin and Tung 2009; Liu et al. 2011d; Lourdin et al. 1997; Mathew and Dufresne 2002a; Nashed et al. 2003; Pushpadass and Hanna 2009; Pushpadass et al. 2009; Qiao et al. 2011; Rodriguez-Gonzalez et al. 2004; Shi et al. 2007a, b; Smits et al. 2003; Tan et al. 2004a, b; van Soest et al. 1994, 1996; Wang et al. 2009a; Yan et al. 2012; Zhang et al. 2008), nitrogen-based compounds (urea, ammonium derived, amines, etc.) (Dai et al. 2009b, 2010a, b; Ma and Yu 2004a, b, c; Ma et al. 2004, 2005, 2006; Shogren et al. 1992; Tung et al. 2011; Wang et al. 2009a; Yang et al. 2006a, b, c, 2007; Zhang et al. 2008; Zheng et al. 2009b), or citric acid (Shi et al. 2007b; Wang et al. 2007; Yu et al. 2005a) are utilized. In particular, citric acid has been regarded as an effective plasticizer for starch as the acidity of citric acid can promote the

fragmentation and disruption of starch granules, as well as the effective interactions with the C–O groups of starch (more than glycerol) and thus the restriction of hydrogen bonds between the hydroxyl groups of starch. Therefore, citric acid can result in a greater degree of the amorphous state and a low degree of recrystallization (or "retrogradation," a term specifically for starch) (Yu et al. 2005a).

3.3 Chemical Modification

Chemical modification of starch by substituting ester or ether groups for the hydroxyls is an effective way to improve the processing and product properties. For example, hydroxypropylated starch displays improved processability (lower viscosity) and mechanical properties (Chaudhary et al. 2008; Lafargue et al. 2007; Vorwerg et al. 2004); and acetylated starches with a degree of substitution of 2–3 are water insoluble and have good mechanical properties (Fringant et al. 1996, 1998; Jarowenko 1986; Mbougueng et al. 2012; Volkert et al. 2010; Yan et al. 2012; Zamudio-Flores et al.2010). However, it should be noted that chemical modification often decreases the polysaccharide molar mass, potentially leading to materials with less mechanical strength, and also the toxic chemical residues may modify the biodegradability and negatively impact the life-cycle assessment (LCA) of the final products.

3.4 Starch-Based Blends and Composites

To improve the performance such as moisture resistibility, mechanical properties, and long-term stability, several starch-based multiphase systems have been developed during the last two decades, such as blends or composites. Starch is often blended with other polymers (mainly biodegradable) such as poly(lactic acid) (PLA), polycaprolactone (PCL), poly(butylene succinate adipate) (PBSA), poly (butylene adipate-*co*-terephthalate) (PBAT), poly(vinyl alcohol) (PVA), and many more, as extensively reviewed in several papers (Avérous 2004; Kalambur and Rizvi 2006a; Liu et al. 2009a; Tang and Alavi 2011; Wang et al. 2003; Yu et al. 2006a).

Starch biocomposites can be produced with the reinforcement by cellulose fibers (potato pulp, bleached leafwood fibers, fibers from bleached eucalyptus pulp, and flax and jute fibers) (Alvarez et al. 2004; Averous and Boquillon 2004; Avérous 2002, 2007; Avérous et al. 2001; Carvalho et al. 2003; Curvelo et al. 2001; Dufresne et al. 2000; Funke et al. 1998; Lawton et al. 2004; Matsui et al. 2004; Romhány et al. 2003; Wollerdorfer and Bader 1998) and lignin fillers (Baumberger et al. 1998a, b; Baumberger 2002). When the fillers are nanoscaled, nanocomposites are obtained. They exhibit drastic modification in the properties of the matrix, like improvement in the mechanical properties and barrier properties, and/or changes in the thermal and electrical conductivity (Alexandre and Dubois 2000). Various kinds of starch-based nano-biocomposites will be discussed in the following sections.

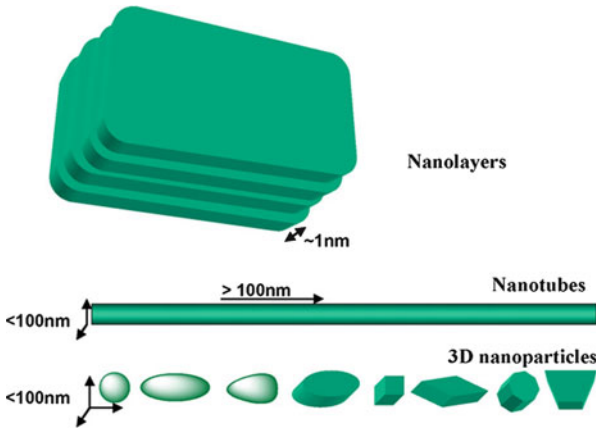

Fig. 5 Various types of nanofillers: nanolayers, nanotubes, and nanoparticles (Reprinted from Kumar et al. (2009), Copyright (2009), with permission from Elsevier)

4 Nanofillers

There are a diversity of nanofillers that can be used for the preparation of nanocomposites. Regarding their shapes, three distinct types of nanofillers can be observed (cf. Fig. 5) (Kumar et al. 2009):

(a) Nanoparticles: When the three dimensions of particulates are in the order of nanometers, they are referred as equiaxed (isodimensional) nanoparticles.
(b) Nanotubes: When two dimensions are in the nanometer scale and the third is larger, forming an elongated structure, they are generally referred as nanotubes, also known as nanowhiskers/nanofibers/nanorods.
(c) Nanolayers: The particulates are characterized by only one dimension in nanometer scale and are present in the form of sheets of one to a few nanometers in thickness and hundred to thousand nanometers in length.

Nevertheless, it should be noted that the term "nanoparticles" is also frequently used in broad sense in the literature to describe a nanofiller regardless of its shape.

The different nanofillers that have been examined for the use in starch-based nano-biocomposites are summarized in Table 1. They have different geometry (size and shape) and surface chemistry; therefore, different kinds of interactions between the nanofiller and the starch matrix and variation in the reinforcing capability are expected. Among them, phyllosilicates, especially montmorillonite (MMT), are most frequently utilized due to their appealing advantages such as wide availability, low cost, and low toxicity. In addition, polysaccharide nanofillers especially cellulose nanowhiskers and starch nanoparticles have also been widely used with one of the advantages in using them being the similar polysaccharide chemical structure of the nanofiller and the matrix, which could benefit the nanofiller–matrix interactions. The use of carbonaceous nanofillers (in particular carbon nanotubes (CNTs)) is also interesting to be incorporated into starch due to their superior reinforcing abilities

Table 1 Overview of the nanofillers used for starch-based nanocomposites

Category/ source	Nanofiller	Dimensional type	Remark
Phyllosilicates			
Clay minerals			
Kaolinite group	Kaolinite	Nanolayer	Non-expandable
	Halloysite	Nanolayer (actually in cylindrical shape)	Non-expandable
Smectite group	Montmorillonite	Nanolayer	Most expandable; most frequently used; natural sodium montmorillonite being a preferable choice due to the matching of polarity with starch
	Hectorite	Nanolayer	Expandable
Sepiolite group	Sepiolite	Nanolayer (actually in needle shape)	–
Synthetic clays	Somasif™ ME 100 fluorohectorite/ fluoromica	Nanolayer	Montmorillonite- or hectorite-type synthetic clay
	Laponite® B, Laponite® RD	Nanolayer	Hectorite-type synthetic clay
Mica group	Muscovite	Nanolayer	Non-expandable
	Paragonite	Nanolayer	Non-expandable
	Illite[a]	Nanolayer	Non-expandable
Polysaccharides			
Cellulose	Nanowhiskers/nanofibrils/ nanofibers from plant cellulose (flax, hemp, ramie, wood, pea hull, cassava bagasse, wheat straw) and microcrystalline cellulose (commercially available)	Nanotube/ nanoparticle	Tend to form aggregates; size, shape, and crystallinity largely dependent on the preparation method and conditions
	Nanorods from tunicin (animal cellulose)	Nanotube	
	Nanofibrils/nanofibers from bacterial cellulose	Nanotube	High crystallinity
Starch	Nanoparticles/nanocrystals from starch (waxy maize and regular maize)	Nanoparticle	Tend to form aggregates
Chitin	Nanoparticles from chitin	Nanoparticle	
Chitosan	Nanoparticles from chitosan	Nanoparticle	
Carbonaceous materials			
	Carbon nanotubes	Nanotube	–
	Graphite oxide	Nanolayer	–
	Carbon black	Nanoparticle	–

[a]Hydrous mica, considered to belong to the clay–mica group, sometimes categorized to the clay minerals

[b]"M^{II}" and "M^{III}" are metal cations, "A" is the anion, and "intra-" and "inter-" denote the intralayer domain and the interlayer space, respectively

as demonstrated in other polymer systems as well as their potentials for developing nanocomposites with new functionalities (e.g., electrical conductivity and electroactivity), although there have been a limited number of the related reports so far. CNT-reinforced nanocomposites have already shown great potentials in biomedical applications such as sensors, stimulators of bone cells, etc. (Harrison and Atala 2007; Lahiff et al. 2010; Tsai et al. 2007; Wang 2005; Wu and Liao 2007; Xiao and Li 2008), although the toxicity of CNTs appears still controversial (Famá et al. 2011; Valdés et al. 2009). Moreover, despite the long list of nanofillers in Table 1, some only appear in very recent reports, and their potential as nanofillers for reinforcing starch-based materials remains uncertain. For example, unfortunately synthetic nanolayers like LDH and brucite can hardly be intercalated by starch molecules (Wilhelm et al. 2003a), which greatly limited their usability.

Different kinds of starch-based nano-biocomposites could result from the use of a variety of nanofillers, which are discussed in the following sections separately.

5 Starch-Based Nano-biocomposites Reinforced by Phyllosilicates

5.1 Phyllosilicates

Phyllosilicates, or layered silicates, are an important group of minerals that includes the clay minerals, the micas, chlorite, serpentine, talc, etc. They possess some strong advantages such as wide availability, low cost, versatility, eco-friendliness, and low toxicity. They have different structure, texture, and/or morphology. Due to the complexity of the structure, it is no surprise to find the classification of phyllosilicates to be different according to the literature source. Table 1 lists the most commonly used phyllosilicates for starch-based nano-biocomposites in the literature.

Phyllosilicates mainly present three organizational levels depending on the observational scale, i.e., (a) the layer, (b) the primary particle, and (c) the aggregate (cf. Fig. 6) (Chivrac et al. 2009a):

(a) The layer is equivalent to a disk or a platelet with the width varying from 10 nm to 1 μm and the thickness of 1 nm. These layers, especially the widest, are flexible and deformable.
(b) The primary particle is composed of five to ten stacked platelets. The cohesion of the structure is assured by van der Waals and electrostatic attraction forces between the cations and the platelets. The stacking of these particles is perpendicular to the z direction and is disordered in the plane (x, y). The structure thickness is around 10 nm.
(c) The aggregate is the association of primary particles orientated in all the directions. The size of the aggregates varies from 0.1 to 10 μm.

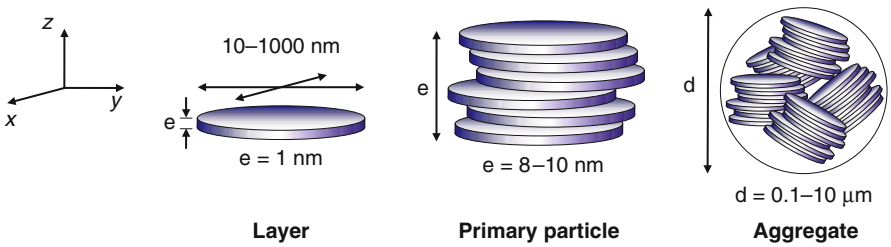

Fig. 6 Phyllosilicate multi-scale structure showing the individual clay platelet, a stack of a few platelets forming the primary particle, and the aggregate structure consisting of associated primary particles with their characteristic dimensions (thickness e and average diameter d) (Reprinted from Chivrac et al. (2009a), Copyright (2009), with permission from Elsevier)

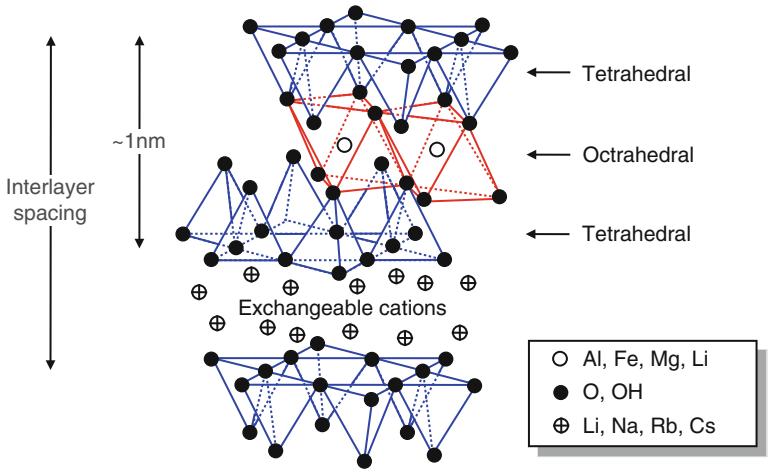

Fig. 7 Structure of 2:1 phyllosilicate (Adapted with permission from Sinha Ray et al. (2003). Copyright (2008) American Chemical Society)

The layer is the result of the condensation of tetrahedral sheets (T) and octahedral sheets (O) (Bergaya et al. 2012). Phyllosilicates are often referred to as 1:1 or 2:1. A 1:1 phyllosilicate would consist of one tetrahedral sheet and one octahedral sheet (T–O), and examples would be kaolinite and serpentine. A 2:1 phyllosilicate consists of an octahedral sheet sandwiched between two tetrahedral sheets (T–O–T), such as the smectite, illite, and chlorite (although chlorite has an external octahedral sheet often referred to as "brucite"). For a 2:1 phyllosilicate, the crystal structure is based on the pyrophyllite structure $Si_4Al_2O_{10}(OH)_2$ and can be described as a crystalline 2:1 phyllosilicate with a central alumina octahedral sheet sandwiched between two silica tetrahedral sheets corresponding to seven atomic layers superposed (cf. Fig. 7) (Hendricks 1942). This structure becomes $(Si_8)(Al_{4-y}Mg_y)O_{20}(OH)_4$, M_y^+ for MMT or $(Si_8)(Al_{6-y}Li_y)O_{20}(OH)_4$, M_y^+ for hectorite. The differences are mainly due to the isomorphic substitutions that take place inside the aluminum oxide layer (Jozja et al. 2003). These substitutions induce a negative charge inside the silicate platelet, which is naturally counterbalanced by inorganic cations (Li^+, Na^+, Ca^{2+}, K^+, Mg^{2+}, etc.) located in the interlayer spacing. The global charge varies depending on the phyllosilicate. For the smectite and the mica families, this charge varies from 0.4 to 1.2 and from two to four per unit cell, respectively. The charge amount is characterized by the cationic exchange capacity (CEC) and corresponds to the amount of monovalent cations necessary to compensate the platelet negative charge, which is usually given in milliequivalent per 100 g (meq/100 g). For instance, the CEC of MMT varies from 70 to 120 meq/100 g depending on their extraction site (Thomas et al. 1999).

The distance observed between two platelets of the primary particle, named interlayer spacing or *d*-spacing (d_{001}), depends on the phyllosilicate type. This value does not entirely depend on the layer crystal structure but also on the type of

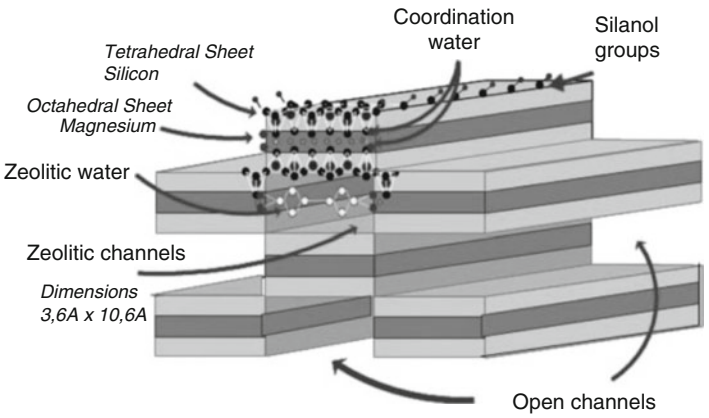

Fig. 8 Structure of sepiolite (Reprinted with permission from Duquesne et al. (2007). Copyright (2007) Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim)

the counter-cation and on the hydration state of the phyllosilicate. For instance, the d_{001} equals 1.2 nm in usual conditions, but the value becomes 0.96 nm for anhydrous MMT with sodium as the counterion. This increase is linked to the adsorption of one layer of water molecules between the silicate platelets (Alexandre and Dubois 2000).

Particularly, some phyllosilicates do not display a normal layered structure. Sepiolite is also a phyllosilicate and displays a kind of fibrous structure. In opposition to all the other phyllosilicates mentioned above which have continuous tetrahedral and octahedral sheets, sepiolite has a discontinuous magnesium oxide–hydroxide octahedral sheet between two-dimensional silica tetrahedral sheets that are continuous but exhibit regular inversions of tetrahedron orientation along one crystallographic direction (*b*). In fact, the lath-like fragments of T–O–T structure extend along the *c* axis, being connected by siloxane bridges (Fig. 8) (Bergaya et al. 2012; Duquesne et al. 2007). Some isomorphic substitutions occur inside these central layers creating a negative charge naturally counterbalanced by the presence of inorganic cations (Na^+, Ca^{2+}, etc.). The sepiolite channels are filled both with coordinated water molecules, which are bonded to the Mg^{2+} ions located at the edges of the octahedral sheets, and with zeolitic water, which is associated to the structure by hydrogen bonding. The discontinuity of the silica sheets gives rise to the presence of silanol groups (Si–OH) at the edges of the external surfaces of sepiolite nanoparticles (Chivrac et al. 2010d). Another example is halloysite, which has a structure similar to kaolinite but has a single layer of water molecules existing between the T–O sheets. It has structural constraints in the layers which cause them to curl and forms spheroidal aggregates (Bergaya et al. 2012).

The phyllosilicate multi-scale structure has different porosity levels, which drive its swelling ability. The water absorption occurs, thanks to the intercalated cation hydration, which lowers the attractive forces between the silicate layers (Sposito and Grasso 1999), and also thanks to the water capillarity phenomenon, which takes place in the interparticle and inter-aggregate porosities (Luckham and Rossi 1999; Mering 1946).

For a given pressure, this swelling is characterized by a d_{001} increase until an equilibrium distance (Cases et al. 1992). In general, the smaller the cation and the lower its charge, the higher is the phyllosilicate swelling. For MMT, the swelling decreases depending on the cation chemical type according to the trend $Li^+ > Na^+ > Ca^{2+} > Fe^{2+} > K^+$ (Powell et al. 1997, 1998; Tettenhorst 1962). The potassium cation is a specific case because its size is equal to the dimension of the platelet surface cavity. Thus, the potassium is trapped in these cavities, leading to the reduced hydration ability.

Swelling is typical enough of smectites to have provided their alternative name of "swelling clays" (Bergaya et al. 2012). In contrast, the other natural phyllosilicates lack the ability to swell in water, which greatly limits their application in the development of starch-based nano-biocomposites.

To enhance the intercalation/exfoliation process (which will be discussed in Sect. 5.2) in a polymer matrix, chemical modification of the phyllosilicate surface, with the aim to match the polymer polarity, is often carried out (Alexandre and Dubois 2000; Sinha Ray and Okamoto 2003). Cationic exchange is the most common technique, but other original techniques such as organosilane grafting (Dai and Huang 1999; Ke et al. 2000), the use of ionomers (Lagaly 1999; Shen et al. 2002), and block copolymers adsorption (Fischer et al. 1999) are also used.

The cationic exchange involves the substitution of inorganic cations by organic ones. These cations are often alkylammonium surfactants having at least one long alkyl chain. Phosphonium salts are also interesting silicate modifiers, thanks to their higher thermal stability, but they are not often used (Wilkie et al. 2001). The ionic substitution is performed in water because of the phyllosilicate swelling which facilitates the organic cation insertion between the platelets. Then, the solution is filtered, washed with distilled water (to remove the salt formed during the surfactant adsorption and the surfactant excess), and lyophilized to obtain the organomodified phyllosilicate. In addition to the modification of the phyllosilicate surface polarity, organomodification increases the d_{001}, which will also facilitate the polymer chain intercalation (Lagaly 1986). Using this technique, various organomodified MMTs (OMMTs) and hectorites used for the fabrication of starch-based nano-biocomposites (cf. Table 2) can be produced, which mainly differ in the counter-cation nature and the CEC. It is noteworthy that, in contrast to most synthetic polymers which are hydrophobic, starch possesses the nature of being highly hydrophilic as previously mentioned (cf. Sect. 2.1); however, most conventional organomodifiers increase the hydrophobicity of the phyllosilicate. Consequently, the compatibility with the starch matrix could be reduced using most of the commercial OMMT presented in Table 2. Thus, it is one of the key points to consider for the development of phyllosilicate-reinforced starch-based nano-biocomposites.

5.2 Nanocomposite Structures

Depending on the processing conditions and the matrix–nanolayer affinity, different structures can be obtained when a phyllosilicate (except sepiolite and halloysite) is associated with a polymer (cf. Fig. 9) (Alexandre and Dubois 2000; Avérous and

Halley 2009; Kumar et al. 2009; Paul and Robeson 2008; Sinha Ray et al. 2003; Sinha Ray and Okamoto 2003; Sinha Ray and Bousmina 2005; Tang et al. 2008b; Vaia and Giannelis 1997):

(a) *Phase-separated composite (microcomposite)*: the polymer chains have not penetrated into the phyllosilicate interlayer spaces, and the silicate layers are mainly stacked and aggregated. The aggregates are micron sized, and the corresponding behavior is close to a conventional composite. (In this case, the nanocomposite designation is actually incorrect.)
(b) *Intercalated nanocomposite*: the polymer diffusion into the phyllosilicate interlayer spaces leads to an increase in the d_{001}. This structure shows regularly alternating silicate layers and polymer chains.
(c) *Exfoliated nanocomposite*: the silicate layers are individually delaminated and homogeneously and fully dispersed into the matrix. (In some papers, this category is further divided into oriented–exfoliated and unoriented–exfoliated systems.)

5.3 Preparation Techniques

Normally, the incorporation of phyllosilicate nanolayers into a polymer matrix can be carried out with one of the three main techniques, i.e., (a) solution intercalation, (b) in situ intercalative polymerization, or (c) melt intercalation (Alexandre and Dubois 2000; Giannelis 1996; Mallapragada and Narasimhan 2006; Sinha Ray and Okamoto 2003; Sinha Ray and Bousmina 2005). It should be noted that these techniques might not be fully applicable to sepiolite and halloysite due to special structures as previously mentioned.

Solution intercalation process is based on a solvent system in which the polymer is soluble and the phyllosilicate is swellable and dispersible. The swelling of phyllosilicates is crucial for nanocomposite structure development, and thus swellable phyllosilicates (mainly smectite group clays) are preferably used (cf. Table 1). Starch, as the matrix, is first dissolved in an appropriate solvent. Water is often used since starch is usually gelatinized in water. In parallel, the phyllosilicate is swollen in the same or another solvent such as water, chloroform, or toluene to obtain a miscible solution. Sonication may be employed to assist the swelling and dispersion process. When the solution of starch and that of swollen phyllosilicate are mixed, the polymer chains intercalate and may replace the solvent molecules within the interlayer spaces of the aggregated phyllosilicate nanoparticles. Upon solvent removal, the intercalated structure remains, resulting in nanocomposite formation. Figure 10 is a schematic representation of solution intercalation for fabricating polymer–phyllosilicate nanocomposites (Pavlidou and Papaspyrides 2008).

For the preparation of starch–phyllosilicate nano-biocomposites, it is important to minimize the intercalation of the plasticizer (glycerol) in the phyllosilicates

(which will be detailed in Sect. 5.6). Regarding this, the mixing order of different ingredients (starch, nanofiller, and plasticizer) in solution processing could have some effect on the intercalation/exfoliation of silicate layers and thus the properties of the resulting nano-biocomposites (Pandey and Singh 2005). For this sample reason, Chung et al. (2010) introduced a new way to prepare well-dispersed starch–phyllosilicate nano-biocomposites by adding a dilute phyllosilicate dispersion to a solution of starch followed by coprecipitation in ethanol.

In situ polymerization is often used to make conventional nanocomposites. In this case, a phyllosilicate is swollen in a monomer solution, and then the monomer polymerization takes place, leading to a d_{001} increase, till in some cases a fully exfoliated morphology (Sinha Ray and Okamoto 2003). Since starch molecular chains are synthesized during plant growth and then extracted from the vegetal, in situ polymerization is limited to nano-biocomposites with chemically modified starch such as starch graft copolymer, which is synthesized in situ with a phyllosilicate (Al et al. 2008; Luo et al. 2005; Namazi et al. 2009; Wu et al. 2000; Zhou et al. 2011).

Compared with solution intercalation, melt intercalation has strong advantages such as the absence of solvents and the compatibility with current industrial polymer processing techniques, such as extrusion and injection molding. As a result, melt intercalation has often been used and described in the literature to produce starch–phyllosilicate nano-biocomposites.

Melt intercalation involves processing a mixture of a polymer with a phyllosilicate in a melt processing unit (e.g., extruder or internal mixer). During processing, the chains diffuse between the aggregated silicate layers to produce a (nano)structured system that is controlled by the processing conditions such as temperature, shearing, and residence time in the processing equipment. Shearing is necessary to induce platelet delamination from the phyllosilicate tactoids, and extended residence time is needed to allow the polymer chains to diffuse into the interlayer spaces and then to obtain exfoliated morphology (Dennis et al. 2001). Fornes et al. (2001) proposed a stepwise mechanism for describing the phyllosilicate dispersion and exfoliation under shear stress during melt processing (cf. Fig. 11). However, it should be noted that the strong shear and long residence time would also contribute to the degradation of the starch matrix. Therefore, it is necessary to balance the processing parameters to minimize the polymer chain degradation and to obtain a kind of well-exfoliated morphology.

More related to starch–phyllosilicate nano-biocomposites, Zhang et al. (2007) proposed a schematic depicting the main force components operating on a pair of adjacent silicate layers in melt processing (Fig. 12). The van der Waals force and the electrostatic attractive force act against silicate layer exfoliation, while the shearing force and the elastic force arising with starch molecular intercalation favor silicate layer exfoliation (Zhang et al. 2007). Both the molar mass of the polymer and the polar interactions between the phyllosilicate and the polymer could influence the polymer intercalation (Vaia and Giannelis 1997).

(2001), Copyright (2001), with permission from Elsevier)

5.4 Effect of Phyllosilicate Addition

Starch-based systems reinforced by phyllosilicates normally exhibit increases in tensile strength (Chivrac et al. 2008b, 2010d; Chung et al. 2010; Cyras et al. 2008; Dai et al. 2009a; de Carvalho et al. 2001; Gao et al. 2012; Hassan Nejad et al. 2011; He et al. 2012; Huang et al. 2004, 2005a, b, 2006; Huang and Yu 2006; Ibrahim 2011; Kvien et al. 2007; Lilichenko et al. 2008; Ma et al. 2007b; Majdzadeh-Ardakani et al. 2010; Maksimov et al. 2009; Mondragón et al. 2008; Müller et al. 2011; Park et al. 2002, 2003; Qiao et al. 2005; Ren et al. 2009; Tang et al. 2008b, 2008c; Wang et al. 2009b, 2010b; Xie et al. 2011), Young's modulus (Chaudhary 2008; Chen and Evans 2005; Chivrac et al. 2009b, 2010c, d; Chung et al. 2010; Cyras et al. 2008; de Carvalho et al. 2001; Hassan Nejad et al. 2011; He et al. 2012; Huang et al. 2004, 2005a, b; Huang and Yu 2006; Lilichenko et al. 2008; Ma et al. 2007b; Majdzadeh-Ardakani et al. 2010; Maksimov et al. 2009; Mondragón et al. 2008; Müller et al. 2011; Nejad et al. 2010; Pandey and Singh 2005; Ren et al. 2009; Wang et al. 2010b; Wilhelm et al. 2003b), storage modulus (measured by dynamic mechanical analysis [DMA]) (Kvien et al. 2007; Park et al. 2003; Wilhelm et al. 2003a, b), T_g (Chivrac et al. 2010a, c; Huang et al. 2006; Kvien et al. 2007; Nejad et al. 2010; Park et al. 2003; Wang et al. 2009d; Wilhelm et al. 2003b; Xiong et al. 2008; Xu et al. 2005), thermal stability (Chiou et al. 2007; Chivrac et al. 2010d; Cyras et al. 2008; Dai et al. 2009a;

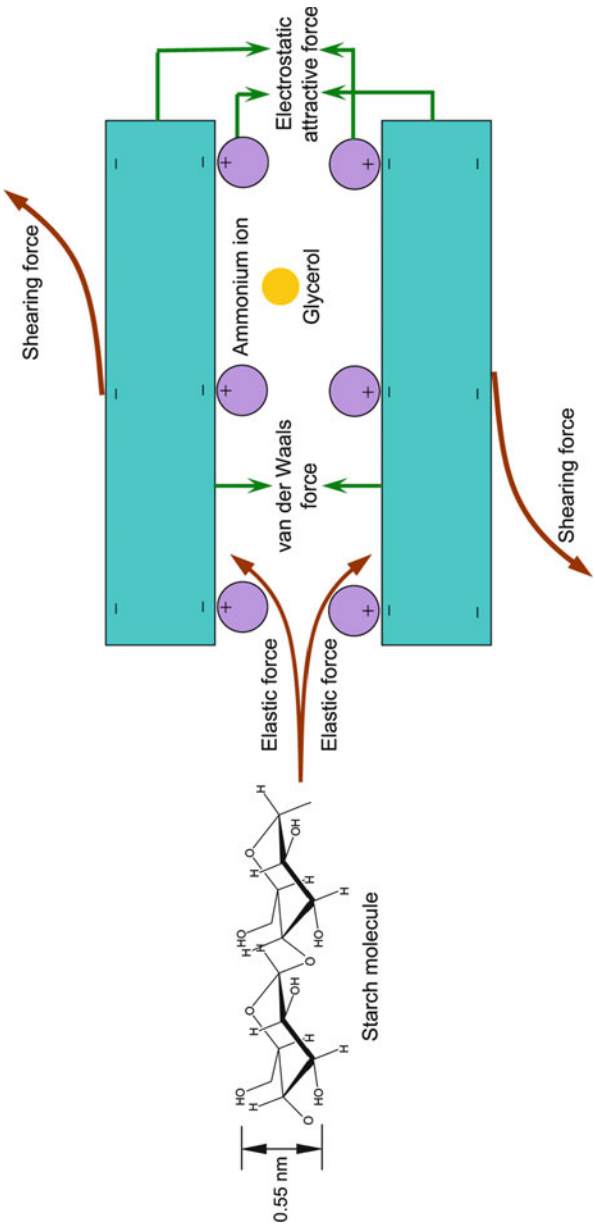

Fig. 12 Schematic representation of the intercalation process between starch and organomodified phyllosilicate (Reprinted from Zhang et al. (2007), Copyright (2007), with permission from Elsevier)

Huang et al. 2004, 2005a, b; Huang and Yu 2006; Ma et al. 2007b; Namazi et al. 2009; Pandey and Singh 2005; Park et al. 2002, 2003; Wang et al. 2009d; Wilhelm et al. 2003a, b; Xu et al. 2005; Zhou et al. 2011), moisture resistance (i.e., moisture uptake, water vapor permeability [WVP], etc.) (Chiou et al. 2006, 2007; Chivrac et al. 2010a; Cyras et al. 2008; Dai et al. 2009a; de Carvalho et al. 2001; Gao et al. 2012; Huang et al. 2004, 2005a; Huang and Yu 2006; Ibrahim 2011; Lilichenko et al. 2008; Maksimov et al. 2009; Müller et al. 2011; Pandey and Singh 2005; Park et al. 2002, 2003; Tang et al. 2008b, c; Wang et al. 2009b, 2010b), oxygen barrier property (Zeppa et al. 2009), and biodegradation rate (Magalhães and Andrade 2009), generally meaning improved performance, even though the elongation at break was observed to be reduced in most studies (Chivrac et al. 2008b, 2010c; Chung et al. 2010; Cyras et al. 2008; Dai et al. 2009a; de Carvalho et al. 2001; Hassan Nejad et al. 2011; Huang et al. 2004, 2005a, b; Ibrahim 2011; Ma et al. 2007b; Majdzadeh-Ardakani et al. 2010; Maksimov et al. 2009; Pandey and Singh 2005; Park et al. 2002, 2003; Qiao et al. 2005; Ren et al. 2009; Tang et al. 2008b, c; Wang et al. 2009b; Wilhelm et al. 2003b). While these changes could usually be ascribed to the structural reasons such as (a) the homogeneous dispersion of silicate layers in the starch matrix (Chivrac et al. 2010d; Chung et al. 2010; de Carvalho et al. 2001; Huang et al. 2005a, 2006 Huang and Yu 2006; Ibrahim 2011; Kampeerapappun et al. 2007; Kvien et al. 2007; Ma et al. 2007b; Majdzadeh-Ardakani et al. 2010; Nejad et al. 2010; Wang et al. 2009b, 2010b; Zhang et al. 2007), (b) the strong interactions (typically by hydrogen bonding) between the silicate nanofiller and the starch matrix (Chivrac et al. 2008b, 2010d; Cyras et al. 2008; Dai et al. 2009a; Huang et al. 2004; Ma et al. 2007b; Majdzadeh-Ardakani et al. 2010; Park et al. 2003; Ren et al. 2009; Tang et al. 2008c; Wang et al. 2009b, 2010b), and (c) the high aspect (width-to-thickness) ratio and thus the vast exposed surface of the silicate layers (Cyras et al. 2008; Huang and Yu 2006; Ibrahim 2011), the detailed mechanisms regarding the changes in different properties are summarized below from the literature:

- Glass transition: an increase in the T_g can be a result of the restriction of chain mobility due to nanofiller–polysaccharide interactions (Kvien et al. 2007; Xu et al. 2005).
- Mechanical properties: increases in Young's modulus, storage modulus (DMA), and tensile strength can be ascribed to (a) the facilitation of stress transfer from the starch matrix to the nanofiller as a result of the strong nanofiller–matrix interactions (Chivrac et al. 2008a; Chung et al. 2010; Tang et al. 2008c); (b) the formation of a physical cross-linking network as a result of the high nanofiller–matrix interactions, which strengthens the material through mechanical percolation (Park et al. 2003; Ren et al. 2009); and (c) the stretching resistance of the oriented backbones of the chains in the interlayer spaces (Cyras et al. 2008). Besides, a decrease in the elongation at break can be attributed to the decreased flexibility of the starch molecules in the presence of the nanofiller (Cyras et al. 2008; Ren et al. 2009; Tang et al. 2008c).

- Moisture resistance: the homogeneous dispersion of high-aspect-ratio silicate layers (a) introduces tortuous and thus longer pathways through the starch polymer matrix for the diffusion of water molecules (Cyras et al. 2008; Dai et al. 2009a; Ibrahim 2011; Lilichenko et al. 2008; Maksimov et al. 2009; Mondragón et al. 2008; Park et al. 2003; Tang et al. 2008c; Wang et al. 2009b, 2010b) and also (b) causes the shielding of the exposed water-sensitive hydroxyl groups of the starch (Müller et al. 2011; Wang et al. 2009b, 2010b), both of which contribute to a reduction in the moisture sensitivity.
- Oxygen barrier property: a higher oxygen barrier can be ascribed to the silicate layers inducing a higher tortuosity and longer diffusion pathways for oxygen molecules (Lilichenko et al. 2008; Maksimov et al. 2009; Zeppa et al. 2009).
- Thermal stability: improvement in the thermal stability can be due to several concomitant phenomena such as (a) the higher thermal stability of the inorganic phase (phyllosilicate) compared to the organic one (starch), (b) the phyllosilicate acting as a heat barrier which enhances the overall stability (Cyras et al. 2008; Ibrahim 2011), (c) the increase in the tortuosity of the diffusion pathways for oxygen and the combustion (pyrolysis) gas (Alexandre and Dubois 2000; Chiou et al. 2007; Chivrac et al. 2010d; Cyras et al. 2008; Namazi et al. 2009; Xu et al. 2005), and (d) the reorganization of the starch structure with less exposed hydroxyl groups and thus less susceptibility to degradation (Pandey and Singh 2005; Wang et al. 2010b; Wilhelm et al. 2003b).

In spite of the changes in the properties mentioned above, increased elongation at break (Chivrac et al. 2010d; Chung et al. 2010; Huang and Yu 2006; Huang et al. 2006; Kvien et al. 2007; Pandey and Singh 2005), decreased thermal stability (Magalhães and Andrade 2010), unchanged thermal stability (Qiao et al. 2005), decreased T_g (de Carvalho et al. 2001; Gao et al. 2012), and unchanged moisture resistance (Chivrac et al. 2010c) have also been observed in certain cases. Majdzadeh-Ardakani et al. (2010) found that the elongation at break first decreased with the phyllosilicate addition level of up to 6 %, while further increasing the nanofiller content causes an increase in the elongation at break. Some authors reported that the phyllosilicate addition reduced the melting temperature of glycerol-plasticized starch-based nano-biocomposites (Liu et al. 2011c), but increased that of sorbitol-plasticized starch-based nano-biocomposites (Chaudhary et al. 2011a; Kvien et al. 2007). Furthermore, breaking energy could either be increased (Huang et al. 2004, 2005a, b; Huang and Yu 2006; Ma et al. 2007b; Wang et al. 2010b) or decreased (Chivrac et al. 2010c; Huang et al. 2004) with the addition of a phyllosilicate. To address these discrepancies, it is useful to consider the crystalline structures in the materials as influenced by the nanofillers. Crystallinity and/or crystal size could affect the biodegradation (Magalhães and Andrade 2009), mechanical properties (Chivrac et al. 2010c, d; Chung et al. 2010; Majdzadeh-Ardakani et al. 2010), and moisture resistance (Cyras et al. 2008). Most typically, a higher crystallinity could embrittle nanocomposite materials with lower elongation at break values (Chivrac et al. 2010c, 2010d; Majdzadeh-Ardakani et al. 2010). Nevertheless, the literature shows that the recrystallization of

a starch-based material could either be restrained (Chung et al. 2010; Huang et al. 2004, 2005a; Liu et al. 2011c; Magalhães and Andrade 2009, 2010; Ren et al. 2009; Wang et al. 2009b; Zhang et al. 2007), unchanged (Zeppa et al. 2009), or enhanced (Chaudhary 2008; Müller et al. 2011) with the addition of a phyllosilicate.

5.5 Effects of Phyllosilicate Type and Content

Table 2 highlights various natural and organomodified MMT nanofillers that have been utilized in starch-based nano-biocomposite systems. It is important to note that the surface hydrophobicity of Cloisite MMT nanofillers follows the order $Na^+ <$ 30B $<$ 10A $<$ 25A $<$ 93A $<$ 20A $<$ 15A $<$ 6A. Although OMMT could provide much greater d_{001} than natural sodium MMT (MMT–Na^+ or Cloisite Na^+) to possibly facilitate starch molecular intercalation, it has been demonstrated that the structure of the resulting composites more highly depends on the hydrophilicity of MMT (Zhang et al. 2007). It has been shown that the incorporation of hydrophobic OMMT nanofillers such as Cloisite 15A, Cloisite 6A, Cloisite 10A, Nanomer I.30E, etc. (cf. Table 2 for designations and corresponding chemical structures) led to the formation of microcomposites (Chiou et al. 2005; Park et al. 2002; Tang et al. 2008c), as evidenced by the unchanged values of the d_{001}. When Cloisite 30B, a more hydrophilic OMMT, was utilized, higher d_{001} values were obtained, with a slight d_{001} shift and a strong decrease in the diffraction peak intensity, corresponding to higher dispersion (Chen and Evans 2005; Chiou et al. 2005, 2006; Park et al. 2003). Exfoliated nanocomposites have also been produced with MMT–Na^+ due to the more hydrophilic character of the Na^+-based nanofiller, which makes it more compatible with plasticized starch (Chen and Evans 2005; Chen et al. 2005; Chiou et al. 2005, 2006, 2007; Cyras et al. 2008; Huang et al. 2004; Pandey and Singh 2005; Park et al. 2002, 2003; Tang et al. 2008c; Zeppa et al. 2009; Zhang et al. 2007). Uniform dispersion of the MMT in the plasticized starch can be achieved in this case due to the polar interactions, especially hydrogen bonds formed between the hydroxyl groups of the MMT and the hydroxyl groups of the starch molecules (Huang et al. 2004; Park et al. 2002, 2003; Tang et al. 2008c).

Chiou et al. (2005) investigated the rheology during the solution processing of starch biocomposites filled by different MMT nanofillers. They demonstrated that the paste with Cloisite Na^+ displayed a larger increase in the rheological elastic modulus (G') at the temperature reaching 95 °C due to an intercalation process during the starch gelatinization, while the samples with the more hydrophobic MMT nanofillers had comparable modulus values to the neat starch sample (Chiou et al. 2005). More importantly, the high compatibility of MMT–Na^+ with a starch matrix and corresponding good dispersion could result in improved properties (as previously mentioned in Sect. 5.4) compared with those of other starch–OMMT hybrids (Park et al. 2002, 2003). In addition, these last authors also showed that MMT–Na^+ could shift the T_g of the starch-rich phase and the β-transition of the glycerol-rich phase of the starch matrix to higher temperatures (from 7 °C to 12 °C and from −64 to −53 °C, respectively), whereas the two relaxation temperatures were decreased for the other

starch–OMMT hybrids (Park et al. 2002, 2003). These results were clearly attributed to the matching of the surface polarity of and the interactions between the Cloisite Na^+ and the starch (Park et al. 2002). Moreover, Zhang et al. (2007) showed that while a starch-based biocomposite reinforced by MMT–Na^+ has a higher thermal decomposition temperature, that reinforced by Cloisite 93A displayed a reduced thermal stability, which was ascribed to the earlier decomposition of the organic alkylammonium on the clay. However, Magalhães et al. (Magalhães and Andrade 2010) proposed that the catalytic effect of acidic sites of MMT may also reduce the thermal stability of starch.

Though OMMT is normally less capable than natural MMT–Na^+ to bring about the nanostructure of starch-based biocomposites, some other reasons may account for the desired property improvement of starch–OMMT hybrids. For example, by water absorbance tests, Chiou et al. (2006) found that, while a MMT–Na^+ sample containing the most dispersed (exfoliated) nanoclays had the lowest water uptake, a Cloisite 30B sample also absorbed less water than the MMT–Na^+ sample containing intercalated clay. This might be due to Cloisite 30B being more hydrophobic than MMT–Na^+ (Chiou et al. 2006). Actually, for understanding the moisture sensitivity of a nanocomposite, it could be better to consider the water uptake capacity of each component (nanofiller, matrix, and plasticizer), especially when a hydrophilic nanofiller like MMT–Na^+ is used (Mondragón et al. 2008; Zeppa et al. 2009). However, proper organomodification of MMT may display even better reinforcing ability than natural MMT–Na^+. As reported by Qiao et al. (2005), the use of OMMT based on trimethyl dodecyl ammonium with acetylated starch matrix could result in a nano-biocomposite with higher tensile strength and storage modulus than the sample reinforced by MMT–Na^+. This was attributed to the higher dispersion and d_{001} of the OMMT in the acetylated starch matrix (Qiao et al. 2005). Remarkably, Chivrac et al. (2008b, 2009b, 2010a, b, c; de Carvalho et al. 2001) used cationic starch as a new phyllosilicate organomodifier to better match the polarity of a starch matrix and thus to facilitate phyllosilicate exfoliation process. The morphological analyses (X-ray diffraction [XRD] and transmission electron microscopy [TEM]) showed that MMT organomodified by cationic starch (OMMT–CS) (which can be prepared either in solution with ultrasonication or in a mixer with strong shear treatment, with the latter resulting in greater delamination of the clay platelets) allowed the preparation of well-exfoliated nano-biocomposites, compared to natural MMT–Na^+, which only led to the formation of intercalated nano-biocomposites (Chivrac et al. 2008b). As a result, the OMMT–CS could lead to greater stiffness without affecting the elongation at break. Such a behavior is not observed for most other starch-based nano-biocomposites reinforced by MMT–Na^+ (Chivrac et al. 2008b, 2009b).

Although Tang et al. (2008c) reported that the MMT content did not have any significant effect on the occurrence of intercalation or exfoliation as observed by XRD, it is worth noting that there can be an optimized level of MMT addition for the greatest improvement in properties such as mechanical properties (Huang and Yu 2006; Huang et al. 2006; Kampeerapappun et al. 2007; Mondragón et al. 2008; Park et al. 2003; Tang et al. 2008c), moisture barrier property (Chiou et al. 2007; Mondragón et al. 2008), and thermal stabilities (Park et al. 2003). A higher content of MMT might contribute to aggregates and stacks of MMT in a starch matrix

(Chung et al. 2010; Huang et al. 2004; Kampeerapappun et al. 2007; Majdzadeh-Ardakani et al. 2010; Park et al. 2003) and also to lower plasticization of the starch phase (Wang et al. 2009b).

Other clays (natural or synthetic) such as hectorite (Chen and Evans 2005; Kvien et al. 2007; Wilhelm et al. 2003a, b) and kaolinite (Chen and Evans 2005; de Carvalho et al. 2001; Wilhelm et al. 2003a) have also been incorporated into starch. As a non-swelling clay, kaolinite can hardly generate intercalation/exfoliation, and thus increases in the tensile strength and Young's modulus and a decrease in the WVP could be, though observed, limited (de Carvalho et al. 2001). A recent study reported that kaolinite could be intercalated by dimethyl sulfoxide (DMSO) which is an aprotic polar molecule, and thus the dispersion of kaolinite could be enhanced (Mbey et al. 2012). However, DMSO as a toxic solvent may cause health and environmental problems. Although natural hectorite might perform better than kaolinite for the formation of a nanocomposite structure (as shown by the increasing d_{001}) (Chen and Evans 2005; Wilhelm et al. 2003a), organomodified hectorite (Bentone 109) could only result in conventional composite like kaolinite (Chen and Evans 2005). Again, this can be explained by the dominant role of the hydrophilicity of a phyllosilicate in determining the structure of the resulting biocomposite. In addition, the CEC of nanofillers may also account for the alteration of some properties (Dean et al. 2007). For example, the CEC of MMT–Na^+ is 92 meq/100 g, whereas the CEC of fluoromica (FHT–Na^+) is only 70–80 meq/100 g. A larger CEC could contribute to a stronger water retention property which could influence the mechanical properties (Dean et al. 2007).

Chivrac et al. (2010d) initiated the use of sepiolite to reinforce starch-based materials and found the reinforcing effect of sepiolite was even better than that of MMT, as evidenced by the higher Young's modulus, elongation at break, and breaking tensile strength values, which was ascribed to the stronger interactions established between the sepiolite nanofiller and the polysaccharide chains. Nevertheless, when sepiolite was modified by cationic starch for better interactions with starch, the thermal stability of the nano-biocomposites could be deteriorated, due to the fast thermal decomposition of cationic starch (Chivrac et al. 2010d).

Halloysite, a hydrated kaolinite, has recently been tried to be incorporated into starch, but the mechanical strength of the resulting materials was not high enough to apply for packaging (Xie et al. 2011). This is because halloysite nanotubes are easily aggregated owing to its large specific areas and polar functional groups, and this causes halloysite nanotubes poorly dispersed in a polymer matrix. It was reported that this problem could be solved by ball-milling treatment together with polyethylene glycol (PEG) as the dispersing agent and water–ethanol mixture as the medium. PEG also improved the compatibility between the nanofiller and the starch phase, resulting improved tensile strength and Young's modulus (He et al. 2012).

5.6 Effect of Plasticizers/Additives

Glycerol has been a widely used plasticizer in the preparation of starch–phyllosilicate nano-biocomposites (Bagdi et al. 2006; Chen and Evans 2005;

Chiou et al. 2007; Chivrac et al. 2008a, b, 2009b, 2010a, b, c, d; Chung et al. 2010; Cyras et al. 2008; de Carvalho et al. 2001; Huang et al. 2004; Ibrahim 2011; Kampeerapappun et al. 2007; Lilichenko et al. 2008; Liu et al. 2011c; Magalhães and Andrade 2009, 2010; Majdzadeh-Ardakani et al. 2010; Maksimov et al. 2009; Mondragón et al. 2008; Müller et al. 2011; Pandey and Singh 2005; Park et al. 2002, 2003; Tang et al. 2008b, c; Wang et al. 2009b, d; Wilhelm et al. 2003b; Zeppa et al. 2009; Zhang et al. 2007). It has been demonstrated in the previous studies (Cyras et al. 2008; Park et al. 2002) that, because of the strong polar interactions between the hydroxyl groups from the starch polymer chains, from the glycerol, and from the silicate layers, glycerol and/or starch chains can enter into silicate interlayers to form intercalated starch–MMT nano-biocomposites. However, it was highlighted by Wilhelm et al. (2003a, b) that, for high glycerol-to-clay ratio, an intercalated structure could be formed in such systems with the d_{001} increasing to about 18.5 Å, a very well-known value which was attributed to the intercalation of glycerol instead of starch molecules, whereas a total exfoliation could be obtained in the absence of the plasticizer. Such a similar phenomenon has also been reported elsewhere with glycerol (Chivrac et al. 2010c; Zhang et al. 2007) and also with sorbitol (Chivrac et al. 2010c; Ma et al. 2007b). Such materials, with a very limited polymer chain intercalation, must rather be considered as conventional microcomposites (Chivrac et al. 2010c). Furthermore, the trapping of the plasticizer in the interlayer spaces could also induce a lower plasticization effect on the starch phase (Chivrac et al. 2010c; Müller et al. 2011).

Pandey and Singh (2005) examined the effect of mixing order on the intercalation of MMT–Na^+ in samples containing maize starch, water, and glycerol. They found that the nanofiller dispersion became highly heterogeneous and the product became more brittle when the starch was plasticized with the glycerol before filling with the clay due to the formation of a bulky structure resulting from electrostatic interactions between the starch and the plasticizer. However, if the glycerol was added after mixing the clay into the starch matrix, best dispersion and thus best mechanical properties could be obtained. This study demonstrated that glycerol and starch both have the tendency to penetrate into silicate interlayers, with glycerol being favored by its smaller size (Pandey and Singh 2005). The effect of glycerol content on the nanostructure of starch–MMT biocomposites has also been reported. In a study on MMT–Na^+-reinforced wheat starch–based biocomposites prepared by twin-screw extrusion, Chiou et al. (2007) showed that the addition of 5 wt % glycerol produced the mostly exfoliated nanoclay, whereas adding 10 or 15 wt % glycerol produced the intercalated nanoclay. Similarly, Tang et al. (2008b) reported that the degree of clay exfoliation increased as the glycerol decreased from 20 % to 5 %. As a result, the film with 5 % glycerol exhibited the lowest WVP (0.41 g mm/kPa h m^2), highest T_g (53.8 °C), and highest tensile strength (35 MPa), but a low elongation at break value (2.15 %). From these studies, it was proposed that samples containing higher glycerol concentrations had an increase in the starch–glycerol interactions, which competed with the interactions with the nanoclay surfaces (Chiou et al. 2007; Majdzadeh-Ardakani et al. 2010; Tang et al. 2008b). To address this issue, Chung et al. (2010) introduced a novel method

to prevent the intercalation of glycerol into silicate interlayer spaces: starch and clay were first well dispersed in a water solution at very low concentrations, which was then coprecipitated by ethanol, followed by hot-pressing with glycerol. This method was reported to lead to good dispersion of the clay in the starch matrix (Chung et al. 2010).

Chiou et al. (2007) proposed that the hydrophilic nature of glycerol could negate the improved water resistance of starch-based nano-biocomposites containing exfoliated MMT. This issue has been extensively addressed by Chivrac et al. (2010a), who investigated the effect of plasticizer (glycerol) content on the structure of starch-based nano-biocomposite materials and on their moisture barrier properties (permeability, water sorption, and diffusivity). It was shown that the relatively high plasticizer content (23 wt % glycerol) could induce a phase separation, with plasticizer-rich and starch-rich phases, resulting in the nanoclay being preferentially located in the starch-rich domains (Chivrac et al. 2010a). As a result, a preferential pathway for water transfer was more likely to be created in the very hydrophilic glycerol-rich domains where the nanoclay platelets were almost totally absent. Thus, even if exfoliated morphology was achieved, the heterogeneous clay distribution and phase separation phenomenon explained the lack of improvement and even the decline in the moisture barrier property for these glycerol-plasticized starch-based nano-biocomposites (Chivrac et al. 2010a).

Other plasticizers such as sorbitol (Chivrac et al. 2010c; Kvien et al. 2007; Ma et al. 2007b), citric acid (Wang et al. 2009b), urea (Chen et al. 2005; Huang and Yu 2006; Huang et al. 2006; Ren et al. 2009; Tang et al. 2008b; Wang et al. 2010b; Zeppa et al. 2009), formamide (Huang et al. 2004, 2005a, b, 2006; Ma et al. 2007b; Tang et al. 2008b; Wang et al. 2010b), *N*-(2-hydroxyethyl)formamide (Dai et al. 2009a), ethanolamine (Huang et al. 2005a, b; Huang and Yu 2006; Ren et al. 2009; Zeppa et al. 2009), or their combinations have been used in the preparation of starch–phyllosilicate nano-biocomposites and have been proved to be effective in enhancing the dispersion and exfoliation of silicate layers. Also, 1-allyl-3-methylimidazolium chloride, a hydrophilic ionic liquid (IL), which can be considered as a plasticizer, has been experimented for the preparation of starch-based nano-biocomposites with promising results (Wang et al. 2009c). Nevertheless, some systems mentioned above are highly eco-toxic and cannot be used to develop safe "green" materials. However, the use of these latter plasticizers may avoid the disturbance of small polyols in the intercalation/exfoliation of silicate layers, as mentioned before. As a result, the starch-based nano-biocomposites plasticized by these plasticizers usually have improved properties. For example, Tang et al. (Tang et al. 2008b, c) demonstrated that a formamide- or urea-plasticized starch–MMT nano-biocomposite film exhibited a lower WVP, higher T_g, and higher tensile strength than a glycerol-plasticized nano-biocomposite film. Particularly, Chen et al. (2005) reported that the use of urea as the plasticizer enhanced the dispersion of ammonium-treated MMT in a starch matrix, making exfoliated starch–clay nano-biocomposites possible. This is due to the $-NH_2$ groups

from urea, which could develop strong interactions with the quaternary ammonium from the organoclay, providing better dispersion of the organoclay in the matrix (Chen et al. 2005).

Nevertheless, the strong plasticizer–nanoclay interactions might play a negative effect on the exfoliation in nanohybrid materials. In a study on wheat starch–based nano-biocomposites reinforced by OMMT–CS, Chivrac et al. (2010c) reported that a kind of exfoliated morphology was obtained with glycerol as the plasticizer, while an intercalated/exfoliated structure could be formed with Polysorb®, a glycerol and sorbitol mixture, or with only sorbitol. The sorbitol-plasticized starch-based nano-biocomposite displayed a slight decrease in the mechanical properties corresponding to a more aggregated structure compared with the glycerol-plasticized sample (Chivrac et al. 2010c).

For producing more desirable starch-based nano-biocomposites, phyllosilicates can be pretreated with glycerol (Wang et al. 2009b, d), ethanolamine (Huang et al. 2005a, b; Huang and Yu 2006), citric acid (Huang et al. 2006; Majdzadeh-Ardakani et al. 2010), urea (Wang et al. 2010b), 1-allyl-3-methylimidazolium chloride (Wang et al. 2009c), etc. before the compounding step. This pretreatment can increase the *d*-spacing and destruct the stacked layered structure of a phyllosilicate during a preprocessing procedure. As reported by Huang et al. (2005a, b, 2006; Huang and Yu 2006), when MMT–Na^+ was treated with citric acid or ethanolamine, the XRD peak of the MMT–Na^+ (001) crystal plane moved to a lower value, which indicates that the distances between the layers of the MMT–Na^+ widened, and the citric acid or ethanolamine had intercalated into the layers of the MMT–Na^+. This made it easy for the MMT–Na^+ to interact with plasticized starch to achieve total dispersion and exfoliation, as indicated by the disappearance of the diffraction peak d_{001} (Huang et al. 2005a, b, 2006; Huang and Yu 2006). A two-step processing method was recently utilized for the preparation of starch-based nano-biocomposites reinforced by plasticizer-modified MMT–Na^+ (Ma et al. 2007b; Wang et al. 2009b, d, 2010b; Zhang et al. 2007). In the first modification step, the plasticizer enlarged the *d*-spacing and destructed the stacked multilayer structure of the MMT–Na^+ effectively either by using high-speed emulsifying machine (Wang et al. 2009b, d) or by using a SSE (Ma et al. 2007b; Wang et al. 2010b; Zhang et al. 2007), and the resulting MMTs were propitious to form an intercalated or exfoliated nano-biocomposite in the melt extrusion processing in a second step. Nonetheless, the possible competition between the starch and the plasticizer for the intercalation might decrease the plasticization of starch, because the intense interactions (the hydrogen bonding and the ion–dipole) existed in these multiphase nano-biocomposites (Wang et al. 2009b, 2010b).

Alternatively, chitosan, an abundant polysaccharide, has been focused as a new eco-friendly compatibilizer to promote MMT platelet exfoliation in solution (Chung et al. 2010; Kampeerapappun et al. 2007). Unfortunately, the intercalation of chitosan was not observed since the molar mass of chitosan was too high (Kampeerapappun et al. 2007). However, it was assumed that this polycation can act as a compatibilizing agent leading to fewer clay aggregates and improved mechanical properties (Kampeerapappun et al. 2007).

5.7 Effects of Starch Type, Amylose Content, and Chemical Modification

The amylose content of starch or starch type was also reported to have a structural impact on starch-based biocomposites, even though the results were not consistent (Mondragón et al. 2008; Tang et al. 2008c). Mondragón et al. (2008) compared regular maize starch, high-amylose maize starch (maize starch with 70 % amylose), and waxy maize starch (almost pure amylopectin) and concluded that the plasticized waxy starch molecules were the easiest of them all to form an intercalated/exfoliated structure. The structural features corresponded with the mechanical properties as the tensile strength and Young's modulus of the nano-biocomposites tended to increase with the MMT content and experienced an incremental improvement following the order high-amylose < normal < waxy maize starch (Mondragón et al. 2008). In contrast, Tang et al. (2008c) reported that a regular maize starch–based film presented better barrier and mechanical properties than either a waxy starch– or high-amylose starch–based nano-biocomposite film. Besides, the WVP, tensile strength, and elongation at break of the films did not change significantly as the amylose content increased to >50 %. These results should be ascribed to complicated reasons including the degree of gelatinization and the starch crystallinity. Moreover, Chiou et al. (2005) reported that amylose, leached from the granules during the gelatinization when the temperature was higher than 95 °C, was intercalated into the MMT–Na^+ interlayer spaces, resulting in a large increase in the elastic modulus during rheological measurement. In addition, MMT–Na^+ samples containing wheat and normal maize starch had comparable elastic modulus values during the gelatinization, while both potato and waxy maize starch samples had elastic modulus values that decreased rapidly at higher temperatures. The results of the potato starch sample could be explained in part by a higher swelling capacity, while the waxy maize starch results could be explained by the lack of amylose resulting in fewer physical cross-links between the leached amylose, the starch granule, and the nanoclay (Chiou et al. 2005).

To seek better performance, various chemically modified starches have also been experimented to develop nano-biocomposites (Gao et al. 2012; Hassan Nejad et al. 2011; Kvien et al. 2007; Namazi et al. 2009; Nejad et al. 2010; Qiao et al. 2005; Wilhelm et al. 2003a; Xu et al. 2005). Chemical modification can result in starch derivatives with varied properties such as the molecular chain length and hydrophilicity, which could affect the interactions with a phyllosilicate. For example, Wilhelm et al. (2003a) showed that the substitution of an unmodified starch matrix by an oxidized starch gave rise to the d_{001} value of the nano-biocomposite, indicating that the short oxidized starch chains were easier to intercalate into the silicate interlayer spaces. They also found that the glycerol (the plasticizer) intercalation was minimized in the oxidized starch film where the intercalation of the oxidized starch chains was preferred (Wilhelm et al. 2003a). On the other hand, by replacing some hydroxyl groups of starch with less hydrophilic functional groups such as acetate groups, the polarity matching between the starch and a specific phyllosilicate can differ (Gao et al. 2012; Hassan Nejad et al. 2011; Namazi

et al. 2009; Nejad et al. 2010). For instance, Nejad et al. (2011, 2010) reported that OMMT (Dellite 67G or Dellite 43B), compared with MMT–Na^+ (Dellite LVF), matched better with hydrophobic starch derivatives (starch acetate, starch propionate, and starch propionate acetate laurate) as the matrices. As a result, very good dispersion and partially exfoliated structures were achieved.

5.8 Effects of Preparation Techniques and Processing Conditions

Namazi et al. (2009) compared solution intercalation and in situ polymerization methods for preparing starch-*g*-PCL nano-biocomposites reinforced by Cloisite 15A. Their result showed that, even though the d_{001} could be varied by the clay addition level and swelling/process time, the diffusion and intercalation of copolymer into the interlayer spaces were generally better by solution intercalation than by in situ intercalative method (Namazi et al. 2009).

Chiou et al. (2006) examined the effects of moisture content, temperature, and screw speed in a twin-screw extrusion process of wheat starch–based biocomposites reinforced by MMT–Na^+ and Cloisite 30B. They found that the moisture content was the major factor affecting the MMT–Na^+ dispersion; an increase in the water content led to intercalation and eventual exfoliation (for the sample with 47 wt % moisture) of the nanoclay. The results were explained by the greater degree of gelatinization at a higher moisture content, which allowed more leaching of hydrophilic amylose and amylopectin molecules from the granules to penetrate into the MMT–Na^+ interlayer spaces (Chiou et al. 2006). However, the other processing parameters like temperature and screw speed had little effect on the MMT–Na^+ dispersion (Chiou et al. 2006). For the samples based on Cloisite 30B, only an increase in the temperature produced slight intercalation of the nanoclay, while changes in the moisture content and screw speed did not produce intercalation. This was ascribed to the incompatibility of starch with the rather hydrophobic Cloisite 30B (Chiou et al. 2006). For both Cloisite Na^+ and 30B samples, intercalation did not depend on the SME (Chiou et al. 2006).

Dean et al. (2007) investigated the effects of the levels of phyllosilicates (1–3.2 %) and plasticizer (13–20 %), types of phyllosilicates (MMT–Na^+ and sodium fluorohectorite), dispersion methodologies, and processing conditions on the degree of intercalation/exfoliation of the starch-based nano-biocomposites. Three different mixing regimes were studied, i.e., (a) dry blending of the components prior to extrusion, (b) conventional mixing of the phyllosilicate in solution prior to high-speed mixing with starch and extrusion, and (c) ultrasonic treatment of the phyllosilicate in solution prior to high-speed mixing with starch and extrusion. It was shown that the use of ultrasonics was only advantageous in terms of phyllosilicate dispersion at medium nanofiller concentrations for the MMT–Na^+ samples and at higher nanofiller concentrations for the sodium fluorohectorite samples due to the difference in the cationic exchange capacity. When the levels of the phyllosilicate, water, and starch were optimized, an exfoliated structure could be produced via conventional standard mixing (Dean et al. 2007). This seems in

contrast with a recent study (Majdzadeh-Ardakani et al. 2010) where starch-based nano-biocomposites were reinforced by either MMT–Na^+, Cloisite 30B, or citric acid–modified MMT–Na^+ and were prepared via a solution casting method. The authors of this publication (Majdzadeh-Ardakani et al. 2010) reported that a combined mechanical and ultrasonic mixing mode led to the most dispersion of the silicate layers in the nano-biocomposites and thus the highest Young modulus, irrespective of the clay type, compared to a process involving only one mixing mode, either mechanical or ultrasonic. This is due to the contribution of both dispersive (the breakup of the silicate agglomerates to individual silicate layers, provided by the ultrasonic device) and distributive (a spatial uniformity of all the components in system, provided by the mechanical mixer) mixing mechanisms (Majdzadeh-Ardakani et al. 2010).

5.9 Effect of Blending with Other Polymers

In order to produce starch-based nano-biocomposites with better properties, starch has been blended with different biodegradable and nonbiodegradable polymers, including PLA (Arroyo et al. 2010; Lee and Hanna 2008, 2009; Lee et al. 2007b, 2008a, b), PCL (Ikeo et al. 2006; Kalambur and Rizvi 2005, 2006b, 2004; Perez et al. 2008, 2007, 2008a, b; Vertuccio et al. 2009), PVA (Dean et al. 2008, 2011; Majdzadeh-Ardakani and Nazari 2010), PBAT (Nayak 2010; Raquez et al. 2011), PBSA (Bocchini et al. 2010), and some trademarked polyesters (Ikeo et al. 2006; McGlashan and Halley 2003; Park et al. 2007). In addition, starch–natural rubber nano-biocomposites have also been studied (Mondragón et al. 2009). Some of these studies (Nayak 2010; Perez et al. 2008, 2007; Pérez et al. 2008a, b; Raquez et al. 2011), though also quite interesting, will less be discussed in the present paper since they involved nano-biocomposites of which the matrix contained starch as a minor component (e.g., Mater-Bi® Z, containing 18 % starch, 75 % PCL, and 7 % additives).

McGlashan and Halley (2003) successfully prepared starch–polyester nanocomposite films by melt extrusion and film blowing. They found that the addition of MMT to the matrix could make the processing more stable: the die and die lip temperature could be lowered without detrimentally affecting the film blowing process (McGlashan and Halley 2003). The reason could be the exfoliated MMT acting as a barrier for plasticizer migration and evaporation. This also contributed to the products with greater stability with storing time (McGlashan and Halley 2003). Ikeo et al. (Vertuccio et al. 2009) suggested that the addition of MMT–Na^+ could improve the compatibility between starch and PCL. Besides, Dean et al. (2011) suggested there was a "nanostabilization" effect of MMT–Na^+ in starch–PVA blends, meaning the starch recrystallization could be disrupted by the nanofiller, which reduced the rate of embrittlement over time, in agreement with a previous study (McGlashan and Halley 2003).

In some studies (Arroyo et al. 2010; Avella et al. 2005; Bocchini et al. 2010; Dean et al. 2008; Majdzadeh-Ardakani and Nazari 2010; McGlashan and Halley 2003), systematic investigations were carried out to find out the effects of the

second polymer content, the nanofiller type and content, and some other parameters on the properties of the nanocomposites and also to find out the optimized applicable products. Nanocomposites based on starch blends are also expected to show improved characteristics such as mechanical properties (increases in the storage modulus (Bocchini et al. 2010; Vertuccio et al. 2009), Young's modulus (Arroyo et al. 2010; Avella et al. 2005; Dean et al. 2008, 2011; Ikeo et al. 2006; McGlashan and Halley 2003; Mondragón et al. 2009; Pérez et al. 2007), and tensile strength (Arroyo et al. 2010; Avella et al. 2005; Dean et al. 2008, 2011; Ikeo et al. 2006; McGlashan and Halley 2003; Mondragón et al. 2009; Pérez et al. 2007)). However, it is quite significant to note that the incorporation of another polymer (usually being relatively hydrophobic) would modify the hydrophilic/hydrophobic balance of the material. As a result, MMT–Na^+ would probably not match anymore the polarity of the blend. In the study by McGlashan and Halley (2003), it was proposed that the organic constituents of the OMMT consisted of alcohols and hydrogenated tallow could be more thermodynamically compatible with the polyester in the matrix. Lee and co-workers (Lee and Hanna 2008, 2009; Lee et al. 2007b, 2008a, b) carried out a series of studies on nanocomposite foams based on tapioca starch and PLA by melt intercalation using different MMTs. Their results showed that Cloisite 30B, instead of MMT–Na^+, could result in the greatest extent of intercalation (Lee et al. 2007b). The greatest enlargement in the d_{001} of the Cloisite 30B in the nanocomposite was caused by the strong hydrogen bonding between the hydroxyl groups of the matrix and the hydroxyl groups of the Cloisite 30B organomodifier (Lee et al. 2007b). Therefore, the functional properties of the nanocomposite filled with Cloisite 30B were generally better than those of the Cloisite Na^+ counterpart at a nanoclay addition level of 3 wt % (Lee et al. 2007b). Similarly, in another study by Bocchini et al. (2010) who experimented with systems based on starch and PBSA with different ratios and filled with either MMT–Na^+ or Cloisite 30B as the nanofiller, only Cloisite 30B could result in an exfoliated structure because of the high affinity between the Cloisite 30B and the PBSA. Majdzadeh-Ardakani and Nazari (2010) compared starch–PVA nanocomposites reinforced by either MMT–Na^+, Cloisite 30B, or citric acid–modified MMT. The results showed that the citric acid–modified MMT led to better mechanical properties in comparison with the MMT–Na^+ and Cloisite 30B because of the strong interactions between the citric acid and the starch–PVA polymer chains (Majdzadeh-Ardakani and Nazari 2010).

Despite of the above discussion, the properties can be not only dependent on the degree of intercalation/exfoliation. Dean et al. (2008) prepared a series of plasticized starch–PVA nanocomposites reinforced by MMT–Na^+ which exhibited intercalated and highly exfoliated structures and investigated the key interactions in these products. Their results showed that the relative concentration of the PVA and MMT–Na^+ could be directly correlated to the change in the d_{001} (Dean et al. 2008). Although good dispersion of the nanoclay platelets was important in improving the mechanical properties in these nanocomposites, the interfacial interactions between the nanofiller and the matrix played also a key role. The more agglomerated biocomposites containing both the MMT–Na^+ and PVA showed significant

increases in the tensile strength (up to 67 % increase) and Young's modulus (up to 85 % increase) as compared to the better dispersed biocomposites without PVA. The improvement in the properties could be attributed to both the interfacial interactions and the disruption of the starch retrogradation (recrystallization process) (Dean et al. 2008).

Starch is known to often show problems of compatibility with other polymers, which can also be an issue in materials based on nano-biocomposites. In a study on starch–PLA nano-biocomposites, Arroyo et al. (2010) found that the MMT–Na^+ was preferentially located in the starch phase or at the blend interface, which could reduce the interactions between the plasticized starch and PLA phases in the compatibilized blends resulting in lower stress transfer from the PLA matrix to the plasticized starch dispersed phase. In another study on starch–natural rubber nano-biocomposites, Mondragón et al. (2009) revealed that the MMT–Na^+ nanolayers were mainly dispersed in the natural rubber domains forming a well-ordered intercalated structure. This could be ascribed to the reasons related to the high molar mass and the matching polarity of the natural rubber (Mondragón et al. 2009). Of course, some studies have addressed the compatibility issue, and methods such as high-energy ball milling (for starch–PCL nano-biocomposites (Vertuccio et al. 2009)) and reactive processing (for starch–PCL nano-biocomposites (Ikeo et al. 2006; Kalambur and Rizvi 2005, 2006b, 2004) and starch–PBAT nano-biocomposites (Nayak 2010; Raquez et al. 2011)) have been employed, which showed to be quite effective.

5.10 Toward Some Applications

There have been some studies on starch graft copolymer–phyllosilicate superabsorbent nano-biocomposites with excellent water absorbency and retention properties (Al et al. 2008; Luo et al. 2005; Wu et al. 2000; Zhou et al. 2011), which can be applied in industrial, agricultural, and horticultural applications. The graft copolymer could either be starch-*graft*-polyacrylamide (Wu et al. 2000), starch-*graft*-acrylic acid (Al et al. 2008), or starch-*graft*-poly[acrylamide-*co*-(acrylic acid)] (Luo et al. 2005; Zhou et al. 2011). The addition of a low-cost phyllosilicate which is abundant of –OH groups into the starch matrix is expected to improve the morphological homogeneity, water absorbing property, and gel strength because the cross-linking network can be improved with homogeneous dispersion of MMT (Luo et al. 2005). Wu et al. (2000) compared the water absorbency values of starch-*g*-polyacrylamide nano-biocomposites filled with either bentonite (MMT), kaolinite, or sericite (mica) and found that the best result was obtained with kaolinite which had the right hydration and distension to form the most suitable cross-linking density. On the other hand, several studies (Al et al. 2008; Luo et al. 2005; Zhou et al. 2011) indicated that increasing the phyllosilicate content or phyllosilicate-to-monomer ratio would first increase and then decrease the water absorbency of the nano-biocomposites, which was also ascribed to the reasons related to cross-linking density. When the cross-linking density was high, the space in the network would

become small with an adverse effect to absorb water (Al et al. 2008; Luo et al. 2005; Wu et al. 2000; Zhou et al. 2011). Furthermore, Al et al. (2008) showed that this kind of materials could also be useful in the removal of a dye (safranine T) from an aqueous solution.

Xu et al. (2005) prepared starch acetate–based nano-biocomposite foams reinforced by different OMMTs by melt extrusion and found the nano-biocomposite foams showed a decrease in the cell size. The incorporation of OMMT also significantly decreased the compressibility of the nano-biocomposite foams but did not substantially affect their spring index (Xu et al. 2005). Chen et al. (2005) prepared novel starch-based nano-biocomposite foams with ammonium-treated MMT as the nanofiller and urea as the plasticizer. Spontaneously formed regular foam structure with 84 % porosity was obtained due to the ammonium surfactant of the clay which produces ammonia gas acting as an internal blowing agent (Chen et al. 2005).

Wang et al. (2009c) prepared starch-based nano-biocomposites filled with MMT, with the use of IL both as the plasticizer for the starch and the modifier for the MMT. They found that the MMT and water contents exerted an important influence on the conductance of the nano-biocomposite films, with the maximum conductance being $10^{-0.3}$ S/cm with the MMT content of 9 wt % and the moisture content of 23 wt % (Wang et al. 2009c), which was higher than alkali metal–doped plasticized starch (Ma et al. 2007a). This makes IL-plasticized starch-based nano-biocomposites to be a promising alternative for the development of new solid electrolytes, which had a wide variety of potential applications such as antistatic plastics, electronic shielding, biosensor, environmentally sensitive membranes, etc. (Wang et al. 2009c). Studies (Wang and Zhao 2006; Zhao et al. 2008) have been carried out to investigate the electrorheological activity of a novel ternary kaolinite–dimethyl sulfoxide–carboxymethyl starch (CMS) nano-biocomposite as an electrorheological fluid (which could produce an instantaneous, reversible change in rheological properties when exposed to an electric filed in the flow direction), which was influenced by the degrees of intercalation and substitution.

6 Starch-Based Nano-biocomposites Reinforced by Cellulose Nanowhiskers/Nanoparticles

6.1 Cellulose Nanowhiskers

Cellulose, which is the most abundant biopolymer on earth and can be obtained from various sources such as plants, animals, and bacteria, is a linearly condensed polymer consisting of β-1,4-linked D-anhydroglucopyranose units (cf. Fig. 13). Depending on the source, the DP ranges from 2,500 to 15,000 (Kumar et al. 2009). Often associated with hemicellulose and lignin, cellulose is the main constituent of wood, flax, ramie, hemp, or cotton (Chivrac et al. 2009a).

Since polysaccharides such as cellulose normally have a semicrystalline structure, the most common method to prepare polysaccharide nanofillers is by acid hydrolysis, which can remove the amorphous regions and leave the highly

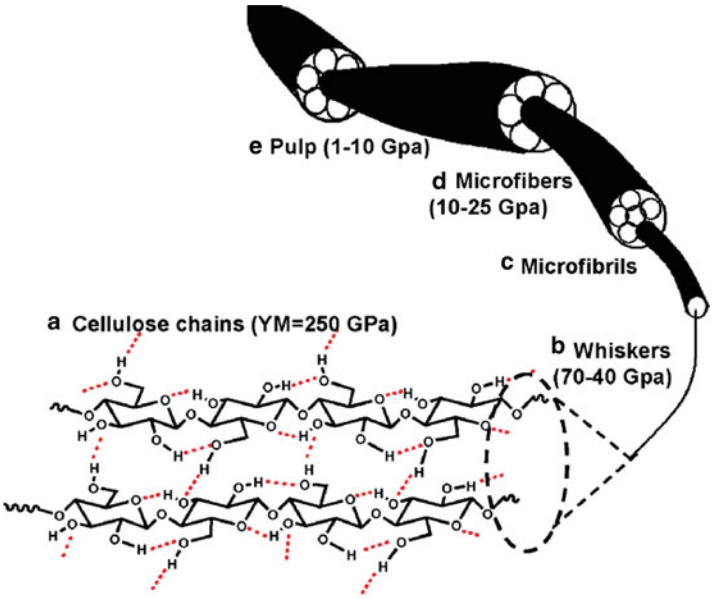

Fig. 13 Schematic representation of cellulose chemical structure and fibrillar organization (Reprinted from Kumar et al. (2009), Copyright (2009), with permission from Elsevier)

crystalline parts of the material. The resulting nanocrystals occur as rodlike particles or whiskers, whose dimensions depend on the nature of the polysaccharide (Dufresne 2008).

CNWs (also cellulose nanofibers, which are typically cellulose nanocrystals; cf. Fig. 13) can be isolated from biomass like flax (Cao et al. 2008a), hemp (Cao et al. 2008b), ramie (Lu et al. 2006), peal hull (Chen et al. 2009a, b), cassava bagasse (Teixeira et al. 2009), and tunicate (a sea animal) (Angles and Dufresne 2000, 2001; Mathew and Dufresne 2002b; Mathew et al. 2008), or from microcrystalline cellulose (Chang et al. 2010c; Kvien et al. 2007), through acid hydrolysis with a concentrated mineral acid (typically sulfuric acid) under strictly controlled conditions of time and temperature (Angles and Dufresne 2000; Azizi Samir et al. 2004, 2005; Bondeson et al. 2006; Cao et al. 2008a, b; Chen et al. 2009a, b; Dong et al. 1996; Lu et al. 2006; Mathew and Dufresne 2002b; Teixeira et al. 2009). Acid action results in a decrease of the amorphous parts by removing the polysaccharide material closely bonded to the crystallite surface and breaking down portions of glucose chains in most accessible, nanocrystalline regions and by acid hydrolysis of cellulosic materials. Generally, the final geometrical characteristics depend on the cellulose origin and the acid hydrolysis process conditions such as time, temperature, and purity of the materials (Kumar et al. 2009). Tunicin (animal cellulose) nanowhiskers have a comparatively high aspect ratio (*L*/*D*: 50–200), which could enhance the interfacial phenomena between this nanofiller and a polymer matrix (Xie et al. 2013).

Chen et al. (2009b) investigated the effect of the hydrolysis time on the length (L), diameter (D), and L/D of the resulting CNWs from pea hull fiber. The authors showed that the chemical removal of hemicellulose and lignin from the original pea hull fiber was mostly complete in the first 4 h of acid hydrolysis and that 8 h of hydrolysis was long enough to remove most of the amorphous regions in the pea hull fiber, when the CNWs showed the highest L/D value (36). However, if the hydrolysis time was too long (particularly 24 h), the crystalline regions could be destroyed (Chen et al. 2009b).

Though direct acid hydrolysis is frequently used to prepare CNWs, other methods have been employed to produce this kind of nanofiller as well, as some examples listed below:

- The precipitation of a NaOH/urea/H_2O solution of microcrystalline cellulose by dropwise addition of an ethanol/HCl aqueous solution; particularly, the resulting material is in the form of particles (Cai and Zhang 2005; Chang et al. 2010c).
- The disintegration of the plant fiber cell wall by mild enzymatic hydrolysis combined with mechanical shearing and high-pressure homogenization (Mohanty et al. 2005; Paakko et al. 2007; Svagan et al. 2009).
- The extraction from wheat straw using steam explosion, acidic treatment, and high shear mechanical treatment (Kaushik et al. 2010).
- The production by *Acetobacter* bacteria; enzyme hydrolysis may be applied further (Grande et al. 2008, 2009; Wan et al. 2009; Woehl et al. 2010).

It is worth noting that, regardless of the preparation method, a high crystallinity of the nanofiller is generally encouraging because the higher the crystallinity, the higher the Young modulus of the nanofiller (Kumar et al. 2009) (cf. Fig. 13), which is beneficial to mechanical property improvement in the resulting nano-biocomposites. Complementary treatments in addition to the traditional hydrolysis may further decrease the contents of hemicellulose and lignin, disintegrate the bundles, and increase the crystallinity of CNWs. In a study by Kaushik et al. (2010), for example, the crystallinity increased from 54 % for untreated wheat straw to 67 % for the chemically treated sample and to 80 % for the CNWs treated both chemically and mechanically. Nevertheless, nanoparticles or nanowhiskers were not fully crystalline in some studies (Cai and Zhang 2005; Chang et al. 2010c).

Though much less frequently, commercially available CNWs (e.g., Celish, Daicel Chemical Industries Co. Ltd., Japan) have also been used in some studies to develop starch-based nano-biocomposites (Sreekala et al. 2008).

6.2 Preparation Techniques

A solution casting method has been mostly used to prepare starch-based nano-biocomposite films, which were then conditioned at specific temperature and relative humidity conditions. For the predominant use of the solution casting method, two reasons might account:

– Cellulose nanowhiskers/nanoparticles tend to aggregate due to the association by strong hydrogen bonding in the presence of high density of the –OH groups (Cao et al. 2008a, b; Kaushik et al. 2010).
– The nanofiller is prepared in aqueous condition, with the resulting dispersion (without either sedimentation or flocculation, as a consequence of charge repulsion due to the surface sulfate groups created during the sulfuric acid treatment) easy to be incorporated into a starch solution (Angles and Dufresne 2000; Cao et al. 2008a, b; Chen et al. 2009a, b; Kvien et al. 2007; Lu et al. 2006; Mathew and Dufresne 2002b).

In a solution for preparing starch-based nano-biocomposites, the key point is to fully gelatinize starch and to break nanofiller aggregates and create a homogeneous dispersion state. For the dispersion of nanowhiskers/nanoparticles in a starch matrix, some additional treatments such as ultrasonication and homogenization might be helpful (Chang et al. 2010c; Kaushik et al. 2010).

As far as bacterial cellulose nanowhiskers (BCNWs) are concerned, some special preparation methods were practiced when this kind of nanofiller is used as reinforcement. In a study by Wan et al. (2009), pellicles of BCNWs were incorporated into glycerol-plasticized starch via a solution impregnation method (Wan et al. 2009). Grande et al. (2008, 2009) developed a bioinspired bottom-up technique to produce self-assembled nano-biocomposites of cellulose synthesized by *Acetobacter* bacteria and native starch. As a final step, in order to produce starch–BCNW nano-biocomposite sheets, the BCNW–starch gels were hot-pressed and the starch phase underwent a "second gelatinization" (Grande et al. 2008, 2009). This technique took advantages of the way some bacteria "extrude" cellulose nanofibers and of the transport process that occurs during gelatinization of starch. The interesting solution preparation method could result in nano-biocomposites with a coherent morphology (Grande et al. 2008, 2009).

Contrary to most studies where the preparation processes were carried out in solution conditions, Teixeira et al. (2009) used a batch mixer equipped with roller rotors to hot melt (140 °C) a mixture of starch, the plasticizer, stearic acid, and the nanofiller with low moisture content (previously adjusted to 20 %), which was then hot-pressed at 140 °C into sheets. This preparation technique is promising since it is close to the way that the thermal processing of plasticized starch-based materials is normally carried out.

6.3 Effect of Cellulose Nanowhisker Addition

With homogeneous dispersion of CNWs within a starch matrix, property enhancement could often be observed. According to the different reports, the mechanical properties (tensile strength and Young's modulus), thermal property (T_g), and moisture resistance generally show improvement (Angles and Dufresne 2000, 2001; Cao et al. 2008a, b; Chang et al. 2010c; Chen et al. 2009a, b; Grande et al. 2009; Kaushik et al. 2010; Kvien et al. 2007; Lu et al. 2006; Mathew and Dufresne 2002b; Mathew et al. 2008; Svagan et al. 2009; Teixeira et al. 2009;

Wan et al. 2009; Woehl et al. 2010). The improvement in different properties can be linked to the morphology of nano-biocomposites which showed not only good dispersion of nanofillers in the matrix but also good adhesion between the nanofiller and the matrix. This can be explained by the chemical similarity between starch and cellulose and the hydrogen-bonding interactions existing at the nanofiller–matrix interface (Cao et al. 2008a; Chen et al. 2009b; Lu et al. 2006). Specifically, the main reasons for such improvements are summarized below:

- Mechanical properties: improvement in the mechanical properties (but usually at the expense of the elongation at break) can be benefited by (a) the formation of a rigid network of the CNWs connected by hydrogen bonds, the mutual entanglement between the nanofiller and the matrix, and the good bonding and thus the efficient stress transfer from the matrix to the nanofiller (Kaushik et al. 2010; Siqueira et al. 2008) and by (b) the increase in the overall crystallinity of the system resulting from the nucleating effect of the CNWs (Mathew and Dufresne 2002b; Mathew et al. 2008). (The latter point (b) has been in dispute since the hindrance, by the CNW dispersion and CNW–matrix interfacial adhesion, of the lateral rearrangement of the starch polymer chains, and hence the hindrance of the recrystallization, was observed in some studies (Kaushik et al. 2010).)
- Glass transition: an increase in the T_g of the starch-rich domains can be ascribed to (a) the occurrence of intermolecular interactions between the starch and the stiff CNWs, which restricted the mobility of the amorphous starch polymer chains in contact with the CNW surface (Cao et al. 2008b; Chen et al. 2009a; Lu et al. 2006); to (b) the increased crystallinity upon the CNW addition, which also restricted the mobility of the amorphous starch polymer chains (Mathew and Dufresne 2002b; Mathew et al. 2008); and to (c) the relocation of the plasticizer(s) (including water) from the starch matrix to the CNW surfaces (detailed in Sect. 6.5), which decreases the plasticization effect on the amorphous regions of the bulk starch matrix (Angles and Dufresne 2000, 2001).
- Moisture resistance: the reasons for the improvement include (a) the less hydrophilic nature of cellulose and the geometrical impedance created by the CNWs, (b) the constraint of the starch swelling due to the presence of the CNW network (initial moisture absorption may also contribute to the establishment of strong hydrogen bonds), (c) the resistance of the diffusion of water molecules along the nanofiller–matrix interface due to the strong adhesion between them (Angles and Dufresne 2000; Luo et al. 2006; Mathew and Dufresne 2002b; Sreekala et al. 2008; Svagan et al. 2009; Wan et al. 2009), and (d) the decrease in the mobility of the amylopectin chains, resulting from an increase in the T_g or the crystallinity (Angles and Dufresne 2000).

It is noteworthy that a high level of nanofiller addition is not necessarily good because of the aggregation which results in the reduction in the matrix homogeneity and cohesion. This could affect the properties in an inverse trend (Chen et al. 2009a). Moreover, one controlling factor which needs to be emphasized here is the moisture content (usually related to the relative humidity during post-processing conditioning).

The moisture plays a key role in controlling the abovementioned properties of the nano-biocomposites by assisting in the formation of the hydrogen bonding between the CNWs and by (together with the other plasticizers) increasing the mobility of the starch chains which is favorable either for its recrystallization during the conditioning process or for the decrease in its T_g (Angles and Dufresne 2000, 2001; Mathew and Dufresne 2002b; Mathew et al. 2008).

In addition to the properties mentioned above, Chen et al. (2009a, b) reported that nano-biocomposites filled with CNWs showed transparency (tested by light transmittance in the wavelength range of 200–800 nm) very close to or even slightly higher than that of the pure starch matrix, which was attributed to the nanosize and the homogeneous dispersion of the nanofiller.

In the meantime, the addition of CNWs to a starch matrix could probably result in a decrease in the thermal stability (as observed by the thermal decomposition temperature) of the nano-biocomposites (Chen et al. 2009a, b; Kaushik et al. 2010). The reason might be that, for the CNWs prepared by sulfuric acid treatment, the presence of acid sulfate groups decreased the thermal stability of the cellulose by dehydration; thus, the decrease in the thermal decomposition temperature of the CNWs also decreased the thermal stability of the starch matrix by the incorporation of this nanofiller (Chen et al. 2009a, b; Roman and Winter 2004; Teixeira et al. 2009). Interestingly, such a phenomenon also occurred when hydrochloric acid was used for the acid hydrolysis of cellulose; however, this point was not reasonably explained by the authors (Kaushik et al. 2010). In contrast in another study (Chang et al. 2010c), when a non–acid hydrolysis method was used, the nano-biocomposites showed improved thermal stability.

6.4 Effect of Nanofiller Preparation

Compared to microcomposites based on plasticized starch and common cellulose fibers, the global behaviors of CNW-reinforced materials are primarily driven by the nanofiller–matrix interface. Chen et al. (2009a, b) systematically investigated the effect of the acid hydrolysis time (t) during the CNW preparation on the structure and performance of pea starch–based nano-biocomposites reinforced by pea hull fiber–derived nanowhiskers. Firstly, they found that the starch–CNW nano-biocomposites ($t = 4$–24 h) generally exhibited much better properties, i.e., the higher tensile strength, elongation at break, Young's modulus, T_g, transparency, and moisture resistance except for the thermal stability (the lower thermal decomposition temperature, due to the reason already discussed before), than the microcomposites obtained with the native pea hull fibers (without acid hydrolysis) (Chen et al. 2009a). These were related to the smooth and compact morphology of the starch–pea hull fiber nanowhisker films, while the starch–pea hull fiber composite film showed cracks, holes, and fiber-like aggregates (even though the CNWs could also show aggregates at high content) (Chen et al. 2009a). Secondly, they discovered that, though there were no apparent differences in the results of Fourier transform infrared spectroscopy (FTIR) and XRD of the nano-biocomposites filled with CNWs obtained at different

hydrolysis times ($t = 4$–24 h), the morphological results revealed the smoother cross section of the 8 h hydrolyzed CNW nano-biocomposite sample than those of the other nano-biocomposite films (Chen et al. 2009b). The more homogeneous dispersion of the CNWs within the starch matrix and the fewer outstanding particle-like CNWs on the cross section of the sample indicated that, in this nano-biocomposite sample, the CNWs (obtained after 8 h of acid hydrolysis) were wrapped more tightly by the starch matrix (Chen et al. 2009b). It was suggested that this stronger adhesion between the CNWs and the starch matrix resulted from the highest aspect ratio of the CNWs after 8 h hydrolysis and contributed to the superior properties of the nano-biocomposite such as transparency, tensile strength, and elongation at break (Chen et al. 2009b).

Woehl et al. (2010) studied the effect of enzyme hydrolysis of bacterial cellulose (to prepare CNWs) on the structure and mechanical properties of the resulting starch-based nano-biocomposites. Their results showed that hydrolysis for 60 min decreased the DP of the cellulose without changing its crystallinity index or promoting a significant mass loss. However, the nano-biocomposites reinforced by such CNWs displayed the most improved mechanical properties than those with CNWs hydrolyzed for either shorter or longer time (Woehl et al. 2010). The authors proposed two mechanisms for the enzyme-treated CNWs, i.e., (a) the elimination of less organized regions between the fibers that entangled them to each other in the original material, thus allowing much better dispersion of the reinforcing agent into the starch matrix, and (b) the reduction of defects in the surface of the fibers that could act as crack propagators (Woehl et al. 2010). However, they also mentioned that longer hydrolysis time could lead to gradual hydrolysis and weakening of the crystalline regions of the CNWs, resulting in worsening mechanical properties (Woehl et al. 2010), which is in agreement with the study by Chen et al. (2009b).

A noteworthy fact is that the preparation of CNWs may also result in non-cellulose components, which could be, together with the CNWs, incorporated into a starch matrix and affect the properties of the resulting nano-biocomposites. Teixeira et al. (2009) prepared CNWs from cassava bagasse (mainly composed of water (70–80 wt %), residual starch, and cellulose fibers) by acid hydrolysis and found that sugars (mainly glucose and sucrose) could be originated from starch hydrolysis during the acid extraction. For glycerol-plasticized nano-biocomposites, these sugars caused considerable reduction in the T_g of the starch-rich domains and inhibited the formation of V_H-type crystalline structure, as agreed by the increased elongation at break (Teixeira et al. 2009). This is because the chemical similarity between the starch and the sugars (such as glucose) could favor the interactions between them, reducing the specific interactions between the starch matrix and the CNWs, which resulted in very high mobility of the starch chains (Teixeira et al. 2009).

6.5 Plasticizer Relocation and Transcrystallization Phenomena

Dufresne and co-workers (Angles and Dufresne 2000, 2001) have undertaken a series of studies on plasticized waxy maize starch–based nano-biocomposites reinforced by tunicin nanowhiskers. The results indicated that, though the strong

interactions between CNWs such as hydrogen bonding (which could be affected by the moisture content) could lead to a rigid network, which was responsible for the improved mechanical performance, some effects could tamper the reinforcement induced by the CNWs (Angles and Dufresne 2000, 2001):

- The accumulation of the plasticizer in the vicinity of the cellulose/amylopectin interfacial zone (because of the stronger interactions of either the water or glycerol with the cellulose than with the starch, as demonstrated by the contact angle measurements), enhanced in moist conditions.
- The coating of the CNWs by a soft plasticizer-rich interphase as a result of the previous effect.
- Especially in highly moist conditions, the abovementioned plasticizer accumulation, and the presence of the CNWs as a nucleating agent, could improve the ability of the amylopectin chains to crystallize, leading to the formation of a highly oriented layer, i.e., transcrystalline zone, around the CNWs.

These effects could then interfere with the inter-CNW hydrogen-bonding forces and hinder the stress transfer at the nanofiller–matrix interface and thus compromise the mechanical properties of the ensuing nano-biocomposites (Angles and Dufresne 2000, 2001).

However, by the substitution of sorbitol for glycerol as the plasticizer, no evidence of the preferential migration of the plasticizer toward the cellulose and the transcrystallization phenomenon of the amylopectin on the CNW surfaces could be observed; instead, only a single glass transition was observed for the nano-biocomposites (Mathew and Dufresne 2002b; Mathew et al. 2008). In this case, strong interactions among the CNWs, starch matrix, sorbitol, and water and a rigid three-dimensional network of the CNWs were formed, benefiting the mechanical enhancement (Mathew and Dufresne 2002b; Mathew et al. 2008).

While Dufresne and co-workers (Angles and Dufresne 2000, 2001) used waxy maize starch as the matrix and tunicin nanowhiskers as the nanofiller in their systems, it would be probable that the plasticizer relocation and transcrystallization phenomena also happen in other CNW-reinforced systems, as one example demonstrated by Teixeira et al. (2009).

7 Starch-Based Nano-biocomposites Reinforced by Starch Nanoparticles

7.1 Starch Nanoparticles

As previously presented in Sect. 2.1, starch has multilevel structures. A review by Le Corre et al. (2010) has summarized starch SNPs prepared by different methods, mainly (a) starch nanocrystals resulting from the disruption of amorphous domains from semicrystalline granules by acid hydrolysis and (b) starch nanoparticles produced from gelatinized starch.

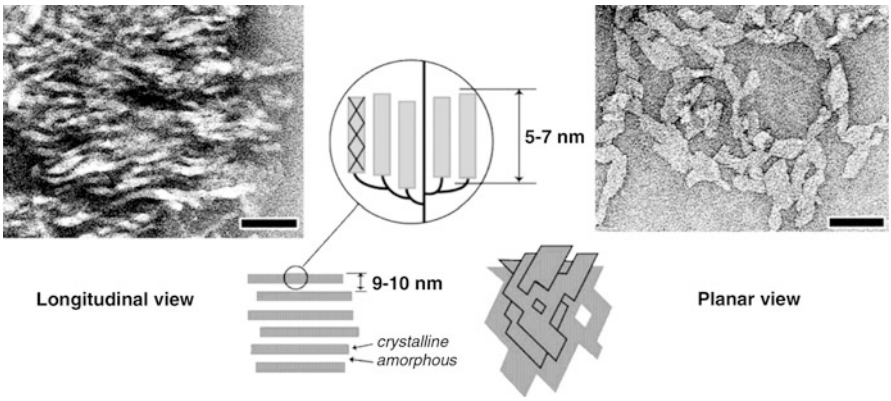

Fig. 14 TEM images of starch nanocrystals: longitudinal and planar views (Reprinted with permission from Putaux et al. (2003). Copyright 2003 American Chemical Society)

Starch nanocrystals can be obtained by acid (normally sulfuric acid) hydrolysis of native starch granules by strictly controlling the temperature, acid concentration, starch concentrations, hydrolysis duration, and stirring speed (Angellier et al. 2004; García et al. 2009; Putaux et al. 2003; Viguié et al. 2007; Zeng et al. 2011). Figure 14 shows one of the first observations of starch nanocrystals by TEM with longitudinal and planar views. The starch nanocrystals prepared by acid hydrolysis have a strong drawback since they gelatinize in hot water which could be a problem when preparing plasticized starch nano-biocomposites.

In the second method, SNPs were prepared by dropwise delivering ethanol as the precipitant into a gelatinized starch solution with constant stirring, followed by centrifugation, washing with ethanol, and oven-drying. The resulting SNPs free from water were further modified by citric acid in a dry preparation technique. The so-formed amorphous citric acid–modified SNPs could not be swelled or gelatinized in hot water because of the cross-linking induced by the citric acid (Ma et al. 2008c). The reaction between the SNPs and the citric acid decreased the aggregation of the SNPs, and the size of the SNPs was reduced (Ma et al. 2008c).

7.2 Preparation Techniques

Similarly as for those reinforced with cellulose nanowhiskers/nanoparticles, solution casting is most commonly used to prepare starch-based nano-biocomposite films reinforced with SNP, which were then conditioned at specific temperature and relative humidity conditions. The reasons for this could be:

– SNPs tend to aggregate due to the association by strong hydrogen bonding in the presence of high density of the –OH groups (Angellier et al. 2006; García et al. 2009, 2011; Viguié et al. 2007).

- The structure of SNPs may be destroyed (gelatinized) at high temperature (e.g., during extrusion), which tampers the reinforcing ability (Angellier et al. 2006; Viguié et al. 2007).
- The nanofiller is prepared in aqueous condition, with the resulting dispersion (without either sedimentation or flocculation, as a consequence of charge repulsion due to the surface sulfate groups created during the sulfuric acid treatment) easy to be incorporated into a starch solution (Angellier et al. 2006; García et al. 2009, 2011; Viguié et al. 2007).

In a solution for preparing starch-based nano-biocomposites, the key point is to fully gelatinize starch and to break SNP aggregates and create a homogeneous dispersion state. SNPs may be added to a gelatinized starch solution at reduced temperature to avoid gelatinization (Angellier et al. 2006; Viguié et al. 2007).

7.3 Effect of Starch Nanoparticle Addition

The nano-biocomposites generally showed increased values of the strength at break, Young's modulus (Angellier et al. 2006; Ma et al. 2008c; Viguié et al. 2007), and T_g (of the starch-rich domains) (Angellier et al. 2006; Ma et al. 2008c; Viguié et al. 2007) and decreased values of the WVP (García et al. 2009; Ma et al. 2008c), indicating improved performance. However, some unfavorable property changes were also observed, e.g., higher water uptake percentage (García et al. 2009) and lower thermal decomposition temperature (García et al. 2009, 2011).

Compared with CNWs, SNPs should have strong affinity with a starch matrix due to the same chemical structure. As a result, good interfacial interactions (nanofiller–nanofiller and nanofiller–matrix) by hydrogen bonding and hence a strong reinforcing effect of SNPs could be expected (Angellier et al. 2006; Ma et al. 2008c; Viguié et al. 2007). Besides, SNPs, acting as a nucleating agent, could facilitate the recrystallization process of the starch polymer chains at the interface, as demonstrated by the increases in the melting temperature and in the melting enthalpy, indicating the increase in the size of the crystalline domains and in the global crystallinity, respectively. However, at high nanofiller content, SNPs seem to hinder the formation of crystalline domains possibly because of an increase in the viscosity in the nano-biocomposite (Viguié et al. 2007). Starting from these points, the mechanisms accounting for all the property changes are summarized below:

- Mechanical properties: increases in Young's modulus and strength at break and a decrease in the elongation at break result from (a) the good interfacial interactions and the strong reinforcing effect of the SNPs (Angellier et al. 2006; Ma et al. 2008c; Viguié et al. 2007) and (b) the increased crystallinity in the starch matrix (Angellier et al. 2006; Viguié et al. 2007).
- Glass transition: an increase in the T_g (of the starch-rich domains), indicating the restraint of the starch polymer chain mobility and the reduction in the free

volume, was due to the presence of the SNPs (a) which function as physical joints, bringing the adjacent starch polymer chains closer and strengthening the intermolecular interactions (Angellier et al. 2006; Ma et al. 2008c; Viguié et al. 2007), and (b) which increase the crystallinity in the starch matrix (Angellier et al. 2006; Viguié et al. 2007).

- Moisture resistance: a reduction in the WVP is ascribed to (a) the less hydrophilic nature of the SNPs (especially citric acid–modified SNPs, of which the hydrophilic –OH groups were substituted by hydrophobic ester groups (Ma et al. 2008c)) and to (b) the tortuous pathways introduced by the SNPs for water molecules to pass through (García et al. 2009; Ma et al. 2008c).
- Thermal stability: a decrease in the thermal decomposition temperature is attributed to (a) the sulfate groups on the acid-hydrolyzed SNPs (García et al. 2009, 2011; Roman and Winter 2004), the reason similar to that for the nano-biocomposites reinforced by CNWs as discussed before; another reason might be (b) the strong interactions between the SNPs and the glycerol (García et al. 2009, 2011), which will be discussed in detail hereafter.

7.4 Effect of Plasticizer

Regarding some property deterioration and result discrepancy in the literature, it is believed that a starch–SNP nano-biocomposite is a complex system governed by more than the nanofiller. One major factor affecting the structure and properties of the nano-biocomposites could be the plasticizer.

By comparing the data of starch–CNW nano-biocomposites and those of starch–SNP nano-biocomposites reported in the literature, it would be interesting to note that the reinforcing effect of waxy maize SNPs in plasticized starch generally is higher than that of tunicin nanowhiskers (Angellier et al. 2006; Angles and Dufresne 2001), even though tunicin nanowhiskers have a higher aspect ratio than SNPs. Nevertheless, this should not be surprising by understanding that starch–tunicin nanowhisker nano-biocomposites have the problems of the plasticizer relocation and transcrystallization (cf. Sect. 6.5), which undermine the interactions between the tunicin nanowhiskers and the starch matrix. It should be reasonable to think that these phenomena are quite limited for starch–SNP nano-biocomposites because of the same chemical nature of the filler and matrix and thus the same affinity of plasticizers such as glycerol and water for both components (Angellier et al. 2006). As a result, Angellier et al. (2006) suggested that strong interactions between the SNPs and between the nanofiller and matrix could be established. The same study (Angellier et al. 2006) also proposed that the same chemical nature of the nanofiller and matrix possibly results in "crystallization" (co-crystallization?) occurring at the nanofiller–matrix interface, which was favorable for mechanical property improvement. These could possibly explain the results from this group of people (Angellier et al. 2006; Viguié et al. 2007) showing that, for waxy maize starch–waxy maize SNP nano-biocomposites, the relative reinforcing effect of the SNPs was more significant when the plasticizer content

(glycerol or sorbitol) was high. Nonetheless, Viguié et al. (2007) from the same research group had to admit a possible "transcrystallization" phenomenon occurring for starch–SNP nano-biocomposites plasticized by sorbitol regarding their DMA results. Anyway, the authors also suggested that there was an increase in the crystallinity (double helices) during aging, which enhanced the mechanical stiffness (though intramolecular crystallites could result in a reduction of intermolecular interactions and in the cohesion of the matrix and thereby result in cracks) (Angellier et al. 2006; Viguié et al. 2007).

Despite the same chemical nature of plasticized starch and SNPs, García et al. (2009) suggested that the large number of –OH groups on the surfaces of SNPs, which were mainly the crystalline zones of hydrolyzed waxy starch, led to more association of the SNPs with glycerol molecules through hydrogen bonding than with the cassava starch matrix. This contributed to the cassava starch matrix having more –OH groups available to interact with moisture, as compared to the unfilled film. As a result, an increase in the water uptake with the SNP addition was observed (García et al. 2009). In another study where waxy maize starch was used as the matrix, García et al. (2011) suggested that the SNPs were mainly located in the glycerol-rich domains of the matrix. They compared a nano-biocomposite without glycerol plasticization and the plasticized one and found the former displayed a rather smooth and homogeneous surface associated with a brittle fracture, while the latter showed a nanometric fibrillar structure, as shown in the images of scanning electron microscopy (SEM). The peculiar structure was referred as "nanothreads" which resulted from the association of the aggregated SNPs through the glycerol. They proposed that the nanothreads were formed by the SNPs, glycerol, and transcrystallized amylopectin. The nanothreads which have high concentration of –OH groups become a preferential path for water vapor diffusion, resulting in an increase in the WVP (García et al. 2011).

8 Starch-Based Nano-biocomposites Reinforced by Chitin/Chitosan Nanoparticles

8.1 Chitin/Chitosan Nanowhiskers/Nanoparticles

Chitin is the second most abundant polysaccharide produced in nature after cellulose, appearing as ordered crystalline microfibrils forming structural components in the exoskeleton of arthropods or in the cell walls of fungi and yeast, but also being produced by a number of other living organisms in the lower plant and animal kingdoms, serving in many functions where reinforcement and strength are required (Rinaudo 2006). It is an acetylated polysaccharide composed of *N*-acetyl-D-glucosamine units linked by β(1→4) linkages (cf. Fig. 15). Chitosan is obtained from chitin by deacetylation. Interestingly, chitosan shows antibacterial activity (Dutta et al. 2009).

Chitin nanowhiskers of slender parallelepiped rods can be made from different chitin sources such as crab shells (Gopalan Nair et al. 2003), shrimp shells

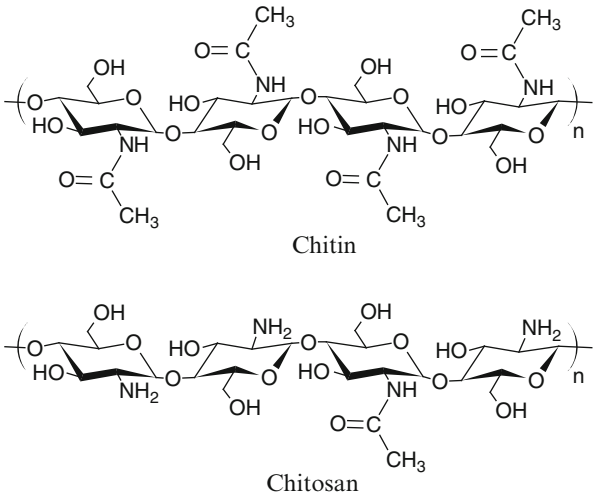

Fig. 15 Chemical structures of chitin and chitosan

(Sriupayo et al. 2005), squid pens (Paillet and Dufresne 2001), and tubes of *Tevnia jerichonana* (Saito et al. 1997) and *Riftia pachyptila* tube worms (Morin and Dufresne 2002). They are obtained by deproteinization in a boiling alkaline (KOH) solution and then hydrolyzing the sample with a boiling HCl solution with vigorous stirring. Besides, Chang et al. (2010b) introduced a modified method to prepare chitin nanoparticles, in which two identical acidic treatments were applied followed by repeated disruption/dispersion processes with sonication. The chitin nanoparticles obtained had a low crystallinity because acid hydrolysis converted some of the crystalline regions into amorphous parts (Chang et al. 2010b). The use of chitin nanoparticles has been reported in starch-based nano-biocomposites, whereas chitin nanowhiskers have hardly been used in this case so far.

Besides, for transforming chitosan into a nanofiller, a very simple and mild method based on ionotropic gelation between chitosan and sodium tripolyphosphate was used: chitosan was dissolved into an acetic acid solution, followed by the dropwise addition of sodium tripolyphosphate into the solution with vigorous stirring and sonication (Chang et al. 2010a; Shu and Zhu 2000; Tsai et al. 2008). This method involves physical cross-linking by electrostatic interactions (instead of chemical cross-linking), which avoids possible toxicity of reagents and other undesirable effects (Shu and Zhu 2000).

8.2 Nanocomposites Reinforced by Chitin/Chitosan Nanoparticles

The use of chitin and chitosan nanoparticles in starch-based nano-biocomposites has been recently described. Chang et al. (2010b) investigated chitin nanoparticle–reinforced starch-based nano-biocomposites and found that the chitin nanoparticles could be uniformly dispersed in the starch matrix at low loading

levels (e.g., 2 wt %), while, at a higher level (5 wt %), conglomeration of the chitin nanoparticles occurred. However, the tensile strength, storage modulus (DMA), T_g, and WVP of the starch–chitin nanoparticle nano-biocomposites showed improvement with the addition of the nanofiller at loading levels up to 5 wt %, due to the good interfacial interactions between the nanofiller and the starch matrix (Chang et al. 2010b). The same group of people (Chang et al. 2010a) carried out another similar study, whereas chitosan nanoparticles instead were used as the nanofiller. Similarly, the nanofiller addition resulted in increases in the tensile strength, storage modulus (DMA), T_g, WVP, and thermal decomposition temperature. The mechanisms of the property improvement in both studies are similar to those for starch–SNP nano-biocomposites. It should be noted that the aggregation of the nanoparticles at high content could deteriorate the reinforcing effect of the nanofiller, as demonstrated by the decrease in the tensile strength when the content of chitosan nanoparticles was higher than 6 wt % (Chang et al. 2010a).

9 Starch-Based Nano-biocomposites Reinforced by Carbon Nanotubes

9.1 Carbon Nanotubes

CNTs are tubular derivatives of fullerenes but exhibit properties quite different from those of the closed cage fullerenes such as C_{60}, C_{70}, C_{76}, etc. CNTs can be visualized as a sheet of graphite that has been rolled into a tube. Unlike diamond, where a three-dimensional diamond cubic crystal structure is formed with each carbon atom having four nearest neighbors arranged in a tetrahedron, graphite is formed as a two-dimensional sheet of carbon atoms arranged in a hexagonal array. In this case, each carbon is covalently bonded to three neighboring carbon atoms through sp^2 hybridization in such a way to form a seamless shell. "Rolling" sheets of graphite into cylinders forms CNTs (Falvo et al. 1997; Kumar et al. 2009; Nicole 2007; Schadler 2003; Wilder et al. 1998). The properties of nanotubes depend on the atomic arrangement (how the sheets of graphite are "rolled"), the diameter and length of the tubes, and the morphology or nanostructure. This rolling can be from one (single-wall carbon nanotubes (SWCNTs)) or more (multiwall carbon nanotubes (MWCNTs)) cylindrical shells of graphitic sheets, with the latter being simply composed of concentric SWCNTs held together with relatively weak van der Waals forces (Kis and Zettl 2008; Kumar et al. 2009; Thostenson et al. 2001). The special topologies are responsible for the unique and interesting properties of CNTs. Due to their high mechanical strength, capillary properties, and remarkable electronic structures, a wide range of potential uses have been reported within the field of materials science research (Kumar et al. 2009).

Though CNTs have already been widely used for other polymer nanocomposite systems (Kumar et al. 2009; Spitalsky et al. 2010), the use of CNTs as the nanofiller to develop starch-based nano-biocomposites has just been initiated, and mostly MWCNTs were involved (Cao et al. 2007; Famá et al. 2011; Liu et al. 2011e;

Ma et al. 2008d) (with the only exception that Bonnet et al. (2007) used SWCNTs in their initial study). This may be due to the lower price and more abundance of MWCNTs than SWCNTs. Besides, MWCNTs also exhibit high aspect ratio (as high as 1,000) and excellent mechanical (with Young's modulus as high as 1 TPa), thermal, and electrical properties (Ajayan 1999; Curran et al. 1998; Qi et al. 2003).

The effectiveness of utilizing CNTs for nanocomposites strongly depends on two main factors: (a) homogeneous dispersion of nanotubes throughout the matrix without destroying the integrity of them and (b) adequate interfacial adhesion between the phases (Kumar et al. 2009; Ruan et al. 2003). These are difficult to achieve especially in the fabrication of starch-based nano-biocomposites regarding the highly hydrophilic nature of starch. For these purposes, chemical modifications such as surface modification with the aid of surfactants, functionalization of endcaps, and functionalization of sidewalls can be helpful (Cao et al. 2007; Kumar et al. 2009). However, care must be taken since these types of procedures might destroy the extended networks on the CNT surfaces, diminishing their mechanical and electronic properties (Famá et al. 2011). The modification methods for CNTs to be incorporated into a starch matrix mainly include:

- The treatment by a surfactant (e.g., sodium dodecyl sulfate (Ma et al. 2008d) and sodium dodecyl benzene sulfonate (Bonnet et al. 2007))
- The carboxylation by strong acids (e.g., sulfuric acid and nitric acid) (Cao et al. 2007; Liu et al. 2011e)
- The wrapping by an aqueous solution of a starch–iodine complex (Famá et al. 2011)

The last method is especially interesting regarding starch-based nanocomposites. This method was initiated by Star et al. (2002), in which the helical conformation of amylose was initially formed by complexation with iodine (or bromide (Casey et al. 2005)), and then a subsequent treatment with SWCNTs displaced the iodine molecules inside the helix. The other methods for the wrapping of CNTs with starch (either amylose or amylopectin) have also been reported (Fu et al. 2007; Kim et al. 2003; Lii et al. 2003; Stobinski et al. 2003; Yang et al. 2008). While the original purpose of these studies was just to improve the dispersion stability of CNTs in aqueous solutions, the described methods may be of great interest for the preparation of starch–CNT nanocomposites since it could be a very smart solution to address the two main issues mentioned earlier, namely, the homogeneous dispersion of nanotubes and a good interfacial adhesion between the phases.

While it is relatively easy to prepare modified CNTs in a non-covalent way (e.g., the wrapping with starch and the modification by a surfactant), the covalent modification of CNT surfaces seems more promising since strong interactions between the CNTs and the starch are expected for the dispersion of the CNTs into a starch matrix and the enhancement of the nanofiller–matrix interface. The successful grafting of different polysaccharides such as chitosan (Wu et al. 2007), cellulose acetate (Ke 2010), and starch (Yan et al. 2011) onto the CNT surfaces has already been reported, although these kinds of modified CNTs have never been

tried into starch-based nano-biocomposites. Starch-grafted MWCNTs, prepared by covalently grafting starch onto carboxylated MWCNTs (Yan et al. 2011), are especially interesting in regard to the same chemical nature of the grafts and the starch matrix. Nevertheless, one should bear in mind that covalent sidewall functionalization usually destroys the extended networks on the CNT surfaces, diminishing their mechanical and electronic properties (Famá et al. 2011).

9.2 Preparation Techniques

Starch–CNT nano-biocomposites were mostly prepared by a convenient solution process assisted by sonication and strong stirring, which are necessary to achieve dispersion of CNTs in a solvent. However, care should be taken since the sequence of adding ingredients might affect the nanofiller dispersion, the gelatinization/plasticization, and thus the final structure of the nano-biocomposite. Summarized from the literature, three ways of solution preparation process were practiced:

(a) The nanofiller was first dispersed in a water solution (with surfactant or starch–iodine complex) and treated with sonication, and then starch and glycerol were added to the same solution with strong stirring and increased temperature for gelatinization, followed by casting (Bonnet et al. 2007; Famá et al. 2012, 2011; Liu et al. 2011e; Ma et al. 2008d).
(b) The nanofiller was dispersed in water with sonication; in parallel, starch and glycerol were dispersed in water with increased temperature and strong stirring for gelatinization. After that, the two dispersions were mixed with stirring, followed by casting (Cao et al. 2007).

By the first method, there might be an anti-gelatinization/plasticization effect of the nanofiller, which deteriorates the cohesion of the starch matrix and thus the final properties (Liu et al. 2011e). For better gelatinization of starch, the second method could be better.

9.3 Effect of Carbon Nanotube Addition

The incorporation of MWCNTs generally increased the ultimate tensile strength (Cao et al. 2007; Famá et al. 2011; Ma et al. 2008d), Young's modulus (Cao et al. 2007; Famá et al. 2011; Ma et al. 2008d), T_g (Cao et al. 2007; Famá et al. 2012, 2011), and thermal decomposition temperature (Liu et al. 2011e) and decreased water sensitivity (Cao et al. 2007; Famá et al. 2012), showing improved performance. Homogeneous dispersion of the nanofiller in the matrix and strong interactions between the nanofiller and the matrix can account for the property enhancement (Cao et al. 2007; Famá et al. 2012, 2011; Liu et al. 2011e; Ma et al. 2008d), which relies on the proper MWCNT modification. Specially, the reasons for the variation in the different properties by the incorporation of MWCNTs are summarized below:

- Glass transition: a shift in the T_g (of the starch-rich phase) to higher temperature can be attributed to the occurrence of interactions between the starch and the stiff MWCNTs, which reduced the flexibility of the starch molecular chains in contact with the MWCNT surfaces (Cao et al. 2007). Moreover, a depression in the loss tangent (tan δ) in DMA indicates the reduction in the number of the mobile chains during the relaxation process (Famá et al. 2012; Rao and Pochan 2006).
- Thermal melting: a reduction in the melting enthalpy could reflect the restraint of the starch recrystallization, with the reason being the good dispersion of the MWCNTs and the formation of MWCNT–starch interactions spatially preventing the starch molecules from moving, interacting, and crystallizing again (Cao et al. 2007; Ma et al. 2008d).
- Mechanical properties: higher values of the tensile strength and Young's modulus can be ascribed to (a) the formation of an isotropic, three-dimensional nanotube network by the MWCNT interactions, which inhibits the crack propagation (Ma et al. 2008d); (b) the interfacial adhesion between the MWCNTs and the starch matrix, which allows the effective stress transfer from the matrix to the nanofiller (Ma et al. 2008d); and (c) the increase in the T_g, which contributes to the increase in the stiffness (Famá et al. 2012, 2011).
- Thermal stability: there are several reasons for an increase in the thermal decomposition temperature: (a) MWCNTs are more stable than starch, and (b) a barrier effect of the nanotubes and their formed aggregates hinders the diffusion of the degradation products from the bulk of the polymer into the gas phase (Chatterjee and Deopura 2006; Liu et al. 2011e; Yang et al. 2005).
- Moisture sensitivity: a reduction in moisture sensitivity can be associated with (a) the nanofiller–matrix interactions which suppress the swelling of the starch matrix when submitted to a highly moist atmosphere (Cao et al. 2007), (b) the relatively low water sensitivity of MWCNTs which reduces the moisture sensitivity of the whole nano-biocomposite system (Cao et al. 2007), and (c) the increase in the T_g (for the starch-rich phase) which significantly decreases the free volume where the water diffusion occurs (Famá et al. 2012; Pinnavaia and Beall 2000).

While a small amount of MWCNT addition can result in significant improvement in the properties, a high loading level of MWCNTs may have some counter-effect. For example, for starch-based nano-biocomposites reinforced with MWCNTs treated by a surfactant, Ma et al. (Ma et al. 2008d) found that the maximum value of the tensile strength occurred at the 3.8 % level of MWCNT addition, while, in another study by Liu et al. (2011e), the optimized addition level of carboxylated MWCNTs was 1.5 %. Noting that starch was added to the MWCNT solution during the preparation of nano-biocomposites, it was suggested that high content of the MWCNTs could not only deteriorate the plasticization of starch which destructed the efficient load transfer from the starch matrix to the ultra-strong MWCNTs (as demonstrated by SEM and FTIR) but also destructed the continuity of the starch matrix (Liu et al. 2011e).

It is worth noting that there have been discrepancies over the trends of the property changes with the MWCNT addition. For example, while it is no surprise to observe a decrease in the toughness or elongation at break with the loading of a nanofiller like MWCNTs into a starch matrix, which was attributed to the spatial restraint of the slippage movement of the starch molecules with good dispersion of the MWCNTs, yielding the increasingly brittle samples (Ma et al. 2008d), there have also been some exciting reports showing that MWCNTs could enhance the toughness (Famá et al. 2011) or elongation at break (Cao et al. 2007; Famá et al. 2011; Liu et al. 2011e) in addition to the tensile strength and Young's modulus. Again, this is a consequence of the homogeneous dispersion of the MWCNTs in the starch matrix and the really strong interfacial adhesion, resulting from the proper nanofiller modification, which will be further detailed.

9.4 Effect of Nanofiller Modification

The effects of two kinds of modification of MWCNTs, namely, carboxylation and starch–iodine complex wrapping, are discussed here regarding their effect on the nanofiller dispersion and interface adhesion and thus the property changes.

For the carboxylated MWCNTs, the acid-treatment process can incorporate various polar groups (carboxylic, carbonyl, and hydroxyl groups), which can improve the hydrophilicity and reduce the agglomeration of the MWCNTs (Cao et al. 2007; Liu et al. 2011e). Interestingly, Liu et al. (2011e) showed that, compared with water, glycerol containing much hydroxyl groups could dramatically increase the dispersion of these MWCNTs in a solution and restrain their agglomeration (Liu et al. 2011e). As a result, the hydrogen-bonding interactions and thus the compatibility between the acid-treated MWCNTs and a starch matrix could be enhanced, resulting in improvement in the mechanical performance of starch–MWCNT nano-biocomposite films (Cao et al. 2007). It was shown that the tensile strength and Young's modulus did not come at the expense of the elongation at break (which usually exists in conventional filled polymer systems), which increased from 30 % to 42 % with the MWCNT addition level up to 1 % and then slightly decreased with higher MWCNT content (which might be due to some degree of aggregation of the MWCNTs) (Cao et al. 2007). Furthermore, the carboxyl groups on the surface of the MWCNTs could increase the interfacial interactions between the MWCNTs and the starch matrix, which improved the degradation activation energy (Liu et al. 2011e).

Very recently, Famá et al. (2012, 2011) experimented with starch-based nano-biocomposites reinforced by MWCNTs wrapped with starch–iodine complex, where the starch used to wrap the MWCNTs was the same as the one used as the matrix. The SEM results showed that, because of the wrapping, the failure around an MWCNT agglomerate occurred within the matrix rather than between the MWCNTs and their starch coating, indicating strong MWCNT–starch adhesion (Famá et al. 2011). As a consequence, the efficient load transfer from the matrix to

the nanofiller was attained, and the high tensile strength and elongation at break of the MWCNTs were transferred to the biocomposites (Famá et al. 2011). Therefore, the good interfacial adhesion obtained avoided the formation of holes and kept a high deformation, resulting in an increase in the toughness (defined as the work done to break a sample which is determined by integrating the stress–strain curve) with the nanofiller loading (Famá et al. 2011). This work is remarkable since very small content of MWCNTs, i.e., 0.055 %, could result in great changes in the material performance as a result of the exceptionally well-dispersed MWCNT and optimized interfacial adhesion (Famá et al. 2011).

9.5 Electrical Conductivity

Besides the properties discussed above, the addition of CNTs into a starch matrix gives the resulting nano-biocomposite electrical conductivity (Liu et al. 2011e; Ma et al. 2008d). For this purpose, an amorphous state of the starch matrix should be advantageous because the recrystallization of starch could reduce the good dispersion of the MWCNTs in the matrix (Ma et al. 2008d). On the other hand, the electrical conductivity can be influenced by the water content and the MWCNT content of the nano-biocomposites (Liu et al. 2011e; Ma et al. 2008d). As demonstrated in a study by Ma et al. (2008d), higher water content would result in an increase in the electrical conductivity in a very sensitive way, with the conductivity (y) versus water content (x) relationship being described with a second-order polynomial ($y = B_2x^2 + B_1x + B_0$); an increase in the MWCNT content decreased the sensitivity of conductivity of the nano-biocomposites to water (both the monomial coefficient B_1 and the binomial coefficient B_2 approached more to zero), until an electrical percolation threshold was reached when the effect of water content was eliminated. If the water content was fixed at 0 %, the electrical conductivity firstly observed a gradual increase with increasing the MWCNT content and then a stepwise increase when a specific level (3.8 wt %) of MWCNT content was reached (Liu et al. 2011e; Ma et al. 2008d). The reasons accounting for these phenomena are:

(a) Although water is advantageous to improve the conductivity of a starch matrix (Meyer 1998) by improving the movement of the starch polymer chains (Van Soest and Knooren 1997), the introduction of MWCNTs and good dispersion of the MWCNTs in the matrix spatially restrained the movement of the starch polymer chains even at high water content (Ma et al. 2008d).
(b) While the gradual increase in the conductivity with the increase in the MWCNT content at a low MWCNT addition level (<2.85 wt %) was due to the formation of a conductive network through hopping and tunneling processes (Lee et al. 2007a), the creation of an interconnected structure of the MWCNTs allows a very high percentage of electrons to flow through the sample at an applied electric field at the MWCNT content higher than a specific value (Ma et al. 2008d).

10 Starch-Based Nano-biocomposites Reinforced by Graphite/Graphite Oxide

10.1 Graphite and Graphite Oxide

Graphite is composed of layers of graphene which has a structure of one-atom-thick two-dimensional individual sheet composed of sp^2-hybridized carbon (Geim and Novoselov 2007). It combines the lower price and the layered structure of phyllosilicates with the superior thermal and electrical properties of CNTs. As a result, graphite can also be used to produce nanocomposites with competitive multifunctional properties (Jiang et al. 2010; Kim and Macosko 2009; Wei et al. 2009). While as-prepared graphite cannot be dispersed in water or organic solvent, which makes the fabrication of nanocomposites difficult, graphite oxide (GO) is hydrophilic and can form strong physical interactions with a polymer like starch due to its various oxygen functional groups including hydroxyls, epoxides, carbonyls, and carboxyls (Li et al. 2011b). Therefore, GO can be regarded as a promising nanofiller for the development of high-performance starch-based nano-biocomposites. On the other hand, because of the layered structure of GO just like that of a phyllosilicate, a GO-reinforced polymer nanocomposite is expected to have an intercalated or exfoliated structure, and the mechanisms for discussing phyllosilicate-reinforced polymer nanocomposites might also be useful to explain the property variation of GO-reinforced nanocomposites.

10.2 Nanocomposites Reinforced by Graphite Oxide

Li et al. (2011b) pioneered the work on starch-based nano-biocomposites reinforced by GO, of which the content was up to 2 wt %. GO was first dispersed in a water solution and treated with sonication, and then starch and glycerol were added to the same solution with strong stirring and increased temperature for gelatinization, followed by casting (Li et al. 2011b). They found that hydrogen bonding formed between the GO and the starch matrix, as revealed by FTIR, and that the nanofiller was well dispersed (exfoliated) when the GO loading was low, whereas aggregation occurred when the GO loading was high, as demonstrated by XRD and atomic force microscopy (AFM) (Li et al. 2011b). With increasing the GO loading level, the tensile strength, Young' modulus, and thermal decomposition temperature were continuously increased, the ultraviolet (UV) transmittance and elongation at break were decreased, and the moisture uptake percentage first decreased to a lowest value and then slightly increased (Li et al. 2011b). For the improvement in the mechanical properties, the good dispersion of the GO within the starch matrix and the strong interfacial interactions between the GO and the matrix were responsible for the stress transfer from the matrix to the nanofiller, although they also restrained the slippage movement of the starch molecules, which resulted in the decrease in the elongation at break (Li et al. 2011b). For the variation in water resistance, the layered structure of the nanofiller provided tortuous pathways, and the strong nanofiller–matrix interactions reduced the diffusion of water molecules in the materials (Li et al. 2011b).

11 Starch-Based Nano-biocomposites Reinforced by Carbon Black

11.1 Carbon Black

CB is a very fine powdered form of amorphous elemental carbon with a high surface area-to-volume ratio. It plays an important role in the improvement in the mechanical and/or electrical properties of high-performance polymeric materials (typically rubber), due to the formation of a physically bonded flexible filler network and strong polymer–filler couplings, which refer to a high surface activity and specific surface of the filler particles (Donnet et al. 1993; Kluüppel et al. 2007; Kraus 1965; Payne 1962, 1963, 1964, 1965a, b). As the most widely used conductive filler for polymers, a high-structural CB (original millimeter-sized CB particles) consists of many primary nanoparticles fused together in a grapelike aggregate (Norman 1970). Due to the high surface tension, flocculation in a quiescent melt can be formed by dispersing the CB aggregates during processing, which promotes the formation of a conductive network (Böhm and Nguyen 1995). As demonstrated in other polymer systems, this process depends on the compatibility between CB and the matrix, which is related to the similarity of the surface tension of them (Miyasaka et al. 1982; Sumita et al. 1991), and the flocculation process, which relies on the viscosity of the matrix (Breuer et al. 1997; Tchoudakov et al. 1996; Yu et al. 2005b). In Sect. 11.2, the development of novel starch–CB nano-biocomposites by different processing techniques will be discussed.

11.2 Nanocomposites Reinforced by Carbon Black

Ma et al. (2008a) compared two preparation methods, i.e., melt extrusion and solution casting with microwave radiation, on the properties of starch-based nano-biocomposites reinforced by CB. It was revealed that the samples prepared by solution method contained the CB in good dispersion, whereas isolated agglomerates of the CB particles existed in those prepared by melt extrusion. As a consequence, the former approach shows better tensile strength, WVP, and electrical conductivity. It was suggested that the CB particles could act as physical cross-linking points of the starch molecules, which resulted in the increased tensile strength, although the dispersion of the CB particles in the matrix also spatially restrains the slippage movement of the starch molecules, resulting in a decrease in the elongation at break (Ma et al. 2008a). A decrease in the WVP arises from the longer and tortuous diffusive pathways with the dispersion of the CB in the matrix (Ma et al. 2008a). Moreover, the CB could form an electrical conductance network in the matrix (Ma et al. 2008a). The same research group (Ma et al. 2008b) also investigated the effect of the glycerol content on the samples prepared by solution casting with microwave irradiation and found that lower glycerol content (and thus lower viscosity) facilitated the flocculation of the CB during the solution process and thus a better electrical conductive network in the biocomposite.

12 Nanocomposites Reinforced by Metalloid Oxides, Metal Oxides, and Metal Chalcogenides

Metalloid oxides (e.g., silicon dioxide [SiO_2] and antimony trioxide [Sb_2O_3]), metal oxides (e.g., zinc oxide [ZnO], titanium dioxide [TiO_2], and hydrous zirconium dioxide [$ZrO_2{\cdot}nH_2O$]), and metal chalcogenides (e.g., cadmium sulfide [CdS] and cadmium selenide [CdSe]) are grouped together in this section because of their similar chemical categories, preparation methods, and nanofiller reinforcement mechanisms. Novel applications are expected for starch-based nano-biocomposites reinforced by this type of nanofillers. Particularly, metal oxides and chalcogenides are normally semiconductor materials. The incorporation of such a filler into a polymer matrix can result in nanocomposites to be used as components for photovoltaic solar cells, light-emitting diodes, photodiodes, and gas sensors (Godovsky 2000). In addition, Sb_2O_3 is an excellent UV filter (Tigau et al. 2005). Thus, nanocomposites filled with Sb_2O_3 might find applications in UV light-emitting devices and solar cell technology (Chang et al. 2009; Zheng et al. 2009a). Furthermore, TiO_2, particularly in the anatase form, shows a photocatalytic activity under UV light and is suitable for developing nanocomposites for environmental purification (Yun et al. 2011).

The paragraphs below will firstly provide general discussion on starch-based nano-biocomposites reinforced by different metalloid oxides, metal oxides, and metal chalcogenides. Then, nano-biocomposites based on starch blended with PVA, and reinforced by SiO_2, will be separately discussed regarding the particular intermolecular interaction and network structure in such a multiphase system.

12.1 Nanofillers and Preparation Techniques

In order to fabricate a starch-based nano-biocomposite reinforced by a metalloid oxide, metal oxide, or metal chalcogenide, only solution methods have been used, which are listed below:

(a) The nanoparticles (SiO_2 (Wu et al. 2009b; Xiong et al. 2008) and TiO_2 (Yun et al. 2011)) are directly added into a starch matrix dispersion.
(b) The nanoparticles (ZnO (Ma et al. 2009; Yu et al. 2009) and Sb_2O_3 (Chang et al. 2009; Zheng et al. 2009a)) are firstly synthesized with a stabilizing template, and then the resulting encapsulated nanoparticles are incorporated into a starch dispersion.
(c) The nanoparticles (SiO_2 (Tang et al. 2008a; Yao et al. 2011), TiO_2 (Liao and Wu 2008), CdS (Radhakrishnan et al. 2007), and CdSe (Zhao et al. 2008)) are directly synthesized in a starch dispersion, which acts not only as the stabilizer but also as the matrix of the resulting nano-biocomposite (sol–gel method).

The first method has only been applied to nano-SiO_2, which is a kind of amorphous powder with a molecular structure that is a three-dimensional net, the

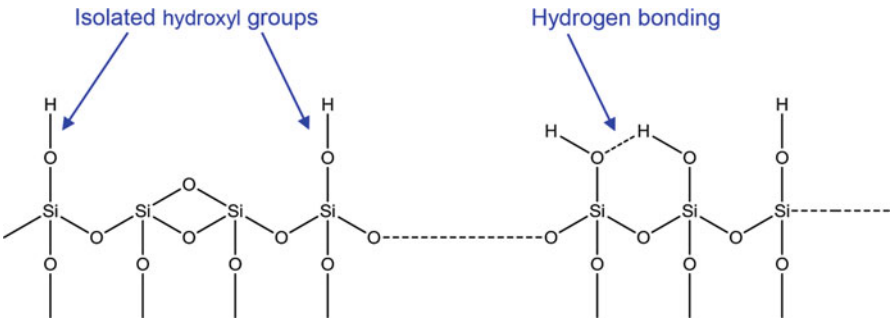

Fig. 16 Structure of nano-SiO_2

structure of which is shown in Fig. 16. Nano-SiO_2 deviates from a stable silicon–oxygen structure for the lack of oxygen in its surface. Its molecular formula is SiO_{2-x}, in which x ranges from 0.4 to 0.8 (Tang et al. 2009; Xiong et al. 2008). Because of its small size (30–60 nm), large specific surface area (>400 m^2/g), high surface energy, as well as a lot of unsaturated chemical bonds and hydroxyl groups on the surface, nano-SiO_2 is easy to disperse into a polymer matrix (Tang et al. 2009; Wu et al. 2009b; Xiong et al. 2008). However, the direct addition of nano-SiO_2 into a starch slurry normally requires intensive sonication and/or shearing; otherwise, large aggregates of the nanoparticles will remain, resulting in less improved or even deteriorated properties (Frost et al. 2011; Wu et al. 2009b). A better solution to achieve good dispersion of SiO_2 nanoparticles in a starch matrix is by using the third method (Tang et al. 2008a; Yao et al. 2011). It is worth noting that the sol–gel method has recently been extended to a reactive extrusion (REX) process for producing starch–PVA nano-biocomposites (Frost et al. 2011), which will be detailed in Sect. 12.3.

The nanoparticles of metal oxides and chalcogenides are mainly prepared by the second and third methods. For the nanoparticle synthesis in the second method, polysaccharides such as native starch (Rodriguez et al. 2008), soluble starch (Chairam et al. 2009; Li et al. 2007; Ma et al. 2009; Radhakrishnan et al. 2007; Vigneshwaran et al. 2006; Wei et al. 2004), and CMC (Chang et al. 2009; Liu et al. 2011a; Yu et al. 2009; Zheng et al. 2009a) have been shown to be good stabilizers. Polysaccharides can form complexes with divalent metal ions due to their high number of coordinating functional groups (hydroxyl and glucoside groups) (Taubert and Wegner 2002) and present dynamic supramolecular associations facilitated by inter- and intramolecular hydrogen bonding, which can act as templates for metal nanoparticle growth (Raveendran et al. 2003). As a result, metal ions can preferentially be associated with a polysaccharide, of which the nucleating effect can promote the initial crystal growth of the metal oxide, improve the stability of the nanoparticles in water, and prevent the aggregation of the nanoparticles (Chang et al. 2009; Ma et al. 2009; Yu et al. 2009; Zheng et al. 2009a). After synthesis, there is normally strong binding in the ZnO nanoparticles, although no obvious formation of covalent bonds occurs between

the stabilizer (soluble starch or CMC) and the ZnO (Ma et al. 2009; Yu et al. 2009). In contrast, for the CMC-stabilized $ZrO_2 \cdot nH_2O$, interaction exists between the ZrO_2 and the C–O groups of the CMC (Liu et al. 2011a; Pawlak and Mucha 2003). On the other hand, by using the third method, the average size (3.6–5 nm) of CdS nanoparticles can be dependent on the initial concentration of cadmium acetate during the sample preparation (Radhakrishnan et al. 2007).

12.2 Effects of the Addition of Metalloid Oxides, Metal Oxides, and Chalcogenides

As reported in the literature, uniform dispersion of a nanofiller in a starch matrix and strong interfacial adhesion through hydrogen bonding between the nanoparticles and the matrix could normally be achieved, especially for polysaccharide-encapsulated metal nanoparticles due to the similar chemical structures of the stabilizer and the matrix (Chang et al. 2009; Liu et al. 2011a; Ma et al. 2009; Yu et al. 2009; Zheng et al. 2009a). As a result, improvement in the performance could be normally observed, even though some aspects of property deterioration have also been reported. The details are summarized below:

- Mechanical properties: increases in the tensile strength (Chang et al. 2009; Liu et al. 2011a; Ma et al. 2009; Wu et al. 2009b; Yu et al. 2009; Yun et al. 2011; Zheng et al. 2009a), Young's modulus (Ma et al. 2009; Yu et al. 2009), and the storage modulus (DMA) (Ma et al. 2009; Yu et al. 2009) and a decrease in the elongation at break (Chang et al. 2009; Liu et al. 2011a; Zheng et al. 2009a) have been reported. These could be ascribed to the decreased mobility of the polymer chains in the presence of the nanofiller, which has strong interactions with the matrix (ZnO (Ma et al. 2009; Yu et al. 2009), $ZrO_2 \cdot nH_2O$ (Liu et al. 2011a)).
- Glass transition: an increase in the T_g (Ma et al. 2009; Yu et al. 2009) could result from the reduced free volume with the presence of the nanoparticles which act as physical joints (ZnO (Ma et al. 2009; Yu et al. 2009)).
- Water resistance: a decrease in the WVP with the addition of ZnO (Ma et al. 2009; Yu et al. 2009), ZrO_2 (Liu et al. 2011a), or Sb_2O_3 (Chang et al. 2009) nanoparticles was reported, which was ascribed to the introduction of the nanoparticles providing fewer and more tortuous pathways for water molecules to diffuse. However, Radhakrishnan et al. (2007) observed an increase in the water uptake of starch–CdS nano-biocomposites at specific relative humidity and attributed this phenomenon to the higher exposed hydroxyl groups in the presence of the nanoparticles which broke the intermolecular interactions of the starch matrix.
- Melting/crystallinity: lower melting temperature but higher melting enthalpy was observed for starch–CdS nano-biocomposites by Radhakrishnan et al. (2007), who proposed that, though the CdS nanoparticles have a nucleating effect for the starch chain recrystallization (facilitated by the water diffusion), smaller crystals and broader melting crystal size distribution were also generated.

- Thermal stability: a decrease in the thermal decomposition temperature but an increase in the residual weight at the end of thermal decomposition was observed for nano-biocomposites reinforced by $ZrO_2 \cdot nH_2O$ (Liu et al. 2011a), CdS (Radhakrishnan et al. 2007), CdSe (Božanić et al. 2009), and Sb_2O_3 (Chang et al. 2009). While Liu et al. (2011a) and Chang et al. (2009) ascribed this to the poor thermal stability of the CMC in the nanoparticles, Radhakrishnan et al. (2007) and Božanić et al. (2009) explained that the increased hydroxyl groups (due to the presence of the nanoparticles which broke the intermolecular interactions of the starch matrix) could result in thermal condensation between them, which could consequently direct the reaction toward carbonization instead of the formation of volatile components (Zhang et al. 2002),
- UV–visible light absorbance/transmittance: compared to the pure starch matrix, nano-biocomposites reinforced by ZnO (Ma et al. 2009; Yu et al. 2009) and Sb_2O_3 (Chang et al. 2009) displayed increased UV–Vis absorbance due to the quantum confinement effect of the nanofiller, and both the starch–CdS (Radhakrishnan et al. 2007) and starch–CdSe (Božanić et al. 2009) nano-biocomposite films showed improved light transparency.

A higher addition level of nanofiller may result in the agglomeration of nanoparticles (Chang et al. 2009; Liu et al. 2011a; Ma et al. 2009; Yu et al. 2009; Zheng et al. 2009a), which is unfavorable for the performance improvement of the nano-biocomposites. In a study on the starch–SiO_2 nano-biocomposites for textile applications, for example, Wu et al. (2009b) found that the best tensile strength and wear resistance could be achieved when the nano-SiO_2 addition level was 4 % and 3 %, respectively, with the reasons being the even distribution of the nanoparticles and the strong nanofiller–matrix interactions at these levels, while the lubricating effect of the rigid nanofiller could also contribute to improved abrasion resistance.

12.3 Starch–Poly(vinyl Alcohol)–Silicon Dioxide Nanocomposites

There have been a series of studies (Frost et al. 2011; Tang et al. 2009, 2008a; Xiong et al. 2008; Yao et al. 2011) on SiO_2-reinforced nanocomposites in which starch and PVA were the matrix. This may improve the mechanical properties and water resistance of starch–PVA films which are still lower than those of conventional polymers (Tang and Alavi 2011).

Xiong et al. (2008) utilized a solution casting method to prepare this kind of nanocomposites. It was found that the addition of nano-SiO_2 resulted in the formation of hydrogen bonds in the hybrid materials, whereas the intermolecular hydrogen bonding of the starch was decreased. Meanwhile, chemical bonds of C–O–Si were also formed in the nanocomposites. These contributed to the increased miscibility and compatibility between the starch and the PVA. In addition, the addition of the nano-SiO_2 had no influence on the crystalline type of the films, but decreased the crystallinity because of the disturbance of the parallel arrangement of the starch–PVA chains. As a result of the structural changes, the

nanofiller played a key role as cross-linking points and restricted the movement of the chains. Therefore, the tensile strength, elongation at break, and light transmittance were increased and the water absorption was decreased. Nevertheless, biodegradation as a whole was not affected though there was a lower degradation rate at the early stage. Following this study, Tang et al. (2009) further investigated the effect of the nano-SiO_2 content (1–5 wt %, on the basis of starch and PVA) on the changes in the properties of the nanocomposites. They found that 3 wt % was the optimized level of the nano-SiO_2 for the best tensile strength and the lowest water absorption. The reduced tensile strength with the higher nano-SiO_2 content was due to the intensification of the elastic collision of the nanoparticles which showed aggregation and had phase separation with the matrix. In addition, the high surface energy and plenty of free hydroxyl groups of the nano-SiO_2, which is beneficial to interact with water, might have a counter-effect on moisture resistance when the nanofiller content was high (Tang et al. 2009).

Tang et al. (2008a) and Yao et al. (2011) used a sol–gel method to fabricate starch–PVA–SiO_2 composites, in which tetraethyl orthosilicate (TEOS) was used as the precursor to obtain SiO_2 in situ in the polymer solution. A network structure in the composites was formed by combining the SiO_2 with the starch–PVA with hydrogen and C–O–Si bonding (Tang et al. 2008a; Yao et al. 2011). The trends of changes in the properties (mechanical properties, water sensitivity, light transmittance, and biodegradation) with the SiO_2 content (Tang et al. 2008a; Yao et al. 2011) were similar to those in the previous studies (Tang et al. 2009; Xiong et al. 2008). Using the same principle, Frost et al. (2011) made the first trial of using a continuous REX process to produce films of such composites, where the TEOS-to-SiO_2 conversion efficiency was up to 41.3 % and the actual SiO_2 content was up to 1.24 wt %. The resulting films had spherical SiO_2 agglomerates of size ranging from 20 to <1 μm, which were responsible for the increased tensile strength, Young's modulus, and storage modulus (DMA).

In addition to product property improvement, it is noteworthy that SiO_2 can also be used to adjust the viscosity of a polymer and thus to improve the miscibility of this polymer with starch in a melt blending process (Bélard et al. 2009). More details are given in a recent review paper (Xie et al. 2012).

13 Nanocomposites Reinforced by Layered Double Hydroxides

The LDH structure is referred to as the natural hydrotalcite and described by the ideal formula $[M^{II}_{1-x}M^{III}_{x}(OH)]_{intra}[A^{m-}_{x/m} \cdot nH_2O]_{inter}$, where "$M^{II}$" and "$M^{III}$" are metal cations, "A" is the anion, and "intra" and "inter" denote the intralayer domain and the interlayer space, respectively (Leroux and Besse 2001). The structure consists of brucite-like layers constituted of edge-sharing $M(OH)_6$ octahedra (cf. Fig. 17) (Hofmeister and Platen 1992; Leroux and Besse 2001). Partial "M^{II}" and "M^{III}" substitution induces a positive charge for the layers, balanced with the presence of the interlayered anions (Leroux and Besse 2001).

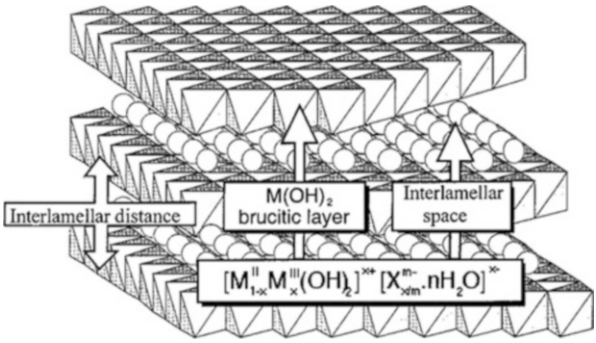

Fig. 17 Scheme of the typical LDH structure (Reprinted with permission from Leroux and Besse (2001). Copyright 2001 American Chemical Society)

Chung and Lai (2010) compared an LDH synthesized in a starch matrix (unmodified maize starch or acid-modified maize starch), which involved fast LDH nuclei precipitation followed by a hydrothermal treatment that simultaneously leached the starch molecules from the granules and aged the LDH nuclei, with one synthesized without the starch matrix. They found that the presence of starch during the synthesis effectively inhibited the stacking of the clay sheets, with the crystal size corresponding to approximately seven brucite-like layers (Chung and Lai 2010). However, no intercalated structure in the starch–LDH biocomposites was indicated, with the reason being ascribed to the rigid structure of the polysaccharide chains (Chung and Lai 2010). The LDH tended to present aggregated morphology in the unmodified maize starch, whereas almost individual dispersion of the LDH was observed in the acid-modified starch. This is due to the lower viscosity of the acid-modified starch. Unfortunately, even the acid-modified starch–LDH biocomposites only showed an increase in Young's modulus, whereas the crystallinity, tensile strength, moisture sensitivity, and transparency were hardly affected. These results could be possibly attributed to the poor interaction between the LDH and the matrix (Chung and Lai 2010).

Alternatively, Wu et al. (2011) used carboxymethyl cellulose sodium (CMC) as a stabilizer to synthesize an LDH, of which the size and number of the stacked sheets were similar to that in the study by Chung and Lai (2010). However, starch-based biocomposites reinforced by this LDH at a low loading level (6 wt %) were reported to show obviously improved mechanical properties (increased tensile strength) and water resistance (decreased WVP) (Wu et al. 2011). There are two reasons for the improvement: (a) because polysaccharides could form complexes with metal ions due to the high number of coordinating functional groups (hydroxyl and glucoside groups) (Taubert and Wegner 2002), strong associations between the metal ions and the CMC occurred for the nucleation and initial crystal growth of the LDH, and thus the LDH was successfully encapsulated by the CMC and (b) the hydrophilic CMC component and the smaller size of each LDH stack allowed the LDH to be well dispersed in the starch matrix and good interactions between the nanofiller and the matrix were formed because of the CMC component (Wu et al. 2011). However, the biocomposites displayed a decrease in the thermal decomposition temperature because the weak thermal stability of the CMC could

weaken the interactions between the LDH filler and the starch matrix and facilitate the decomposition of the starch (Wu et al. 2011). Furthermore, high LDH content (8 wt %) could result in the agglomeration of the nanofiller in the matrix and thus reduce the mechanical properties and WVP (Wu et al. 2011).

14 Nanocomposites Reinforced by α-Zirconium Phosphate

Synthetic α-ZrP (i.e., $Zr(HPO_4)_2 \cdot H_2O$) exhibits similar structural characteristics to natural MMT clay but has advantages such as high purity and ion exchange capacity and ease of intercalation and exfoliation (Clearfield et al. 1972; Clearfield and Berman 1981; Sun et al. 2005; Wu et al. 2009a). In addition, the particle size and aspect ratio can be manipulated by varying the reaction conditions (Wu et al. 2009a). Wu et al. (2009a) investigated starch-based nano-biocomposite films reinforced by α-ZrP at different loading levels. The results from XRD and SEM indicated that the plasticized starch and the α-ZrP interacted and formed strong hydrogen bonds, resulting in improved compatibility. Compared with the neat plasticized starch, the nano-biocomposite films showed increases in the tensile strength and elongation at break, decreases in the crystallinity and moisture uptake, and a slight decrease in the transparency. The improvement in the mechanical properties was due to the much enhanced nanofiller–matrix interaction since α-ZrP has huge surface area The decrease in the moisture sensitivity was attributed to the decreased number of –OH groups available for the interaction with migrating water molecules. Nevertheless, higher content of the nanofiller could contribute to an adverse effect on the improvement in the properties due to the phase separation and the aggregation of the nanofiller, but not as much to reach back the values of the pure starch film. Besides, the maximum thermal decomposition temperatures of the nano-biocomposite films decreased with an increase in the α-ZrP content, which could be ascribed to the increase in the acidity of the α-ZrP with the increase in the temperature, which induces the decomposition of the glycoside bonds (Wu et al. 2009a).

15 Nanocomposites Reinforced by Hydroxyapatite

The use of HA is mainly for making biomaterials for biomedical applications such as clinical orthopedics because HA has the chemical and crystallographic similarity to the inorganic component of natural bone and has excellent biocompatibility, bioactivity, and osteoconductivity (Murugan and Ramakrishna 2004). The successful use of injection molding to produce HA-reinforced starch–EVA nanocomposites with high mechanical performance for temporary tissue replacement applications has been demonstrated (Reis et al. 1997). Besides, like metalloid oxides, metal oxides, and metal chalcogenides, rodlike nano-HA crystals can be synthesized with controlled shape and size using soluble starch as a template (via an in situ biomimetic process) (Meskinfam et al. 2011; Sadjadi et al. 2010). The bioactivity and biocompatibility of the resulting biocomposites were verified (Meskinfam et al. 2011;

Sadjadi et al. 2010). Sundaram et al. (2008) reported the fabrication of a porous scaffold biomaterial made from nano-HA, gelatin, and starch displaying the appropriate enhanced mechanical properties for bone repair and regeneration.

16 Conclusion

Starch-based nano-biocomposites are novel multiphase systems that can be tuneable via the type, geometry (size and shape), and surface chemistry of the nanofiller, the type/amylose content and chemical modification of the starch, the type and content of the plasticizer(s) and additive(s), and the processing steps and conditions.

A wide variety of nanofillers have been examined with starch matrix. Phyllosilicates have been mostly utilized to develop starch-based nano-biocomposites due to their advantages such as wide availability, low cost, and high aspect ratio and thus vast exposed surface area. In this group of nanofiller, smectite group clays especially MMT are most popular due to their swelling nature and large availability. In addition, polysaccharide nanofillers (typically CNWs and SNPs) represent the second most popular group of nanofillers to realize starch-based nano-biocomposites because of their abundance in nature, the biological sources, and the chemical similarity to starch. Unfortunately, the preparation of these biobased nanoparticles is time consuming and involves acid hydrolysis in multiple steps which is not eco-friendly. Furthermore, studies have also been carried out for incorporating many other nanofillers such as carbonaceous nanofillers (typically CNTs), metalloid oxides (e.g., SiO_2 and Sb_2O_3), metal oxides (e.g., ZnO, TiO_2, and $ZrO_2{\cdot}nH_2O$), and metal chalcogenides (e.g., CdS, CdSe). One of the advantages in utilizing such nanofillers is that they can provide new functionalities to starch-based materials in addition to the general reinforcement. Unfortunately, some of these last nanoparticles (e.g., the CNTs) may have a detrimental impact on the human health and the environment (Helland et al. 2007; Klaine et al. 2008; Lam et al. 2006; Oberdörster et al. 2007). Finally, some much less frequently employed nanofillers are LDH, α-ZrP, and HA.

With the incorporation of the nanofiller, starch-based materials generally show improvement in some of their properties such as mechanical properties (typically tensile strength, Young's modulus, and storage modulus), T_g (of the starch-rich domains), thermal stability, moisture resistance, gas/solvent barrier property, and biodegradation rate. The improvement can be fundamentally ascribed to the homogeneous dispersion of the nanofiller in the matrix and the strong interface adhesion, which can contribute to the formation of a rigid nanofiller network and influence the molecular and crystalline structures in the matrix. Regarding the dispersion, intercalation or even exfoliation is desired for the nano-biocomposites reinforced by layered nanofillers, which can be assisted by some pretreatment/activation methods. To achieve good nanofiller dispersion and strong interface adhesion, the compatibility between the nanofiller and the matrix is the key point to address, although intensive processing means such as shearing, stirring, and sonication

could also help. When phyllosilicates are used, the best nanofiller could be those containing Na^+ or cationic starch as the counter-cation due to better polarity matching with the starch matrix. Besides, while polysaccharide nanofillers normally do not have starch compatibility issues, some modifications have to be used for many other types of nanofillers to increase the compatibility with starch which has a hydrophilic nature. In all these systems, the interactions between the nanofiller and the matrix are usually achieved by hydrogen bonding. However, the nanofiller–matrix interactions can be affected by more factors such as the plasticizer(s)/additive(s), the starch chemical modification, the presence of other polymer(s) in the matrix, and the processing conditions. In spite of the discussion above, some property changes could not be exclusively attributed to the dispersion of the nanofiller in the matrix and the nanofiller–matrix interactions. Typical examples are the moisture resistance, which could be counter-affected by the hydrophilicity of the plasticizer(s) and the nanofiller, and the thermal stability, which could be counter-affected by the functional groups or the modifying/stabilizing polymer of the nanofiller. Furthermore, the nanofiller plays an important role in determining the properties of the nano-biocomposite. The extent of improvement can be related to the aspect ratio/surface area, chemistry, and mechanical properties of the nanofiller, which may have a relationship with its mixing preparation and modification of final structure and properties. A typical example is that the geometry (size and shape) and the crystallinity of cellulose nanowhiskers are highly dependent on the preparation method and conditions, influencing the final performance properties of the nano-biocomposites.

Nevertheless, how the nanofiller affected the crystalline structure and crystallinity of the starch matrix has not been unambiguously elucidated across the literature. Several reasons might account for this: (a) the crystalline structure and crystallinity of starch-based materials can be highly affected by the formulation (e.g., the amylose content of the starch and the type and content of the plasticizer), the processing conditions (e.g., temperature, pressure, shearing, and orientation), and the storing conditions (e.g., time, temperature, and relative humidity); (b) phase separation of the plasticizer, the starch, and/or the nanofiller may exist in the system, with the different domains showing different recrystallization/anti-crystallization behaviors; and (c) effective means are lacking in the accurate thermal and structural characterization of starch. It is significant to note that some of these reasons may also account for the discrepancies in some of the other results such as T_g and moisture resistance.

With improved properties that are comparable to those of traditional petroleum-based polymers such as polyethylene and polypropylene, starch-based nano-biocomposites can be designed into various products such as blown/casting films, extruded sheets, expanded foams, and thermoformed shapes. These can greatly enhance and widen the current applications of starch-based materials. In addition to the general reinforcement, some nanofillers have been reported to provide new functionalities to starch-based materials, such as superabsorption, electroactivity, electroconductivity, electrorheological behavior, UV shielding, drug releasing, scaffolding (in tissue engineering), and environmental purification. Consequently,

starch-based nano-biocomposites have been or are expected to be applied in a wide range of fields such as packaging, agriculture, medicine, and electronics. Furthermore, the renewable resource and inherent environmental friendliness of such materials can justify its wide use for a sustainable future.

In the future research, it is still very important to test new nanofillers to be incorporated into starch for developing promising nano-biocomposites with excellent performance and new functionalities to be competitive in the materials world. Specifically, maintaining homogeneous dispersion of the nanofiller in the matrix and having strong interface adhesion are the key prerequisites. Good dispersion of the nanofiller results in a greater contact area; otherwise, the filler is not a nanofiller (but micron-sized aggregates) and the composite can only be regarded as microcomposite instead of nanocomposite. As pointed out by Schaefer and Justice (Schaefer and Justice 2007), the current nanocomposites are often not "nano enough," resulting in the elusive realization of anticipated properties. They discovered that large-scale disorder is ubiquitous in nanocomposites regardless of the level of dispersion, leading to substantial reduction of mechanical properties (modulus) compared to predictions based on idealized filler morphology (Schaefer and Justice 2007). This problem should also be addressed when developing starch-based nano-biocomposites since heterogeneous dispersion of the nanofiller and phase separation unfortunately also existed in some of the studies examined in the current review. While the manipulation of chemistry might help to some extent, the future research should also address the importance in using processing techniques like extrusion, film blowing, and injection/compression molding, which are more aligned to the efficient industrial production. With such processing, intensive thermomechanical treatment is normally involved, which could possibly play the dominant role in controlling the morphology and structure and thus the performance of starch-based nano-biocomposites. Thus more research is needed regarding how to achieve a well-dispersed structure without adding a detrimental effect to the final properties by starch molecular degradation under thermomechanical treatment.

Chemically Modified Natural Polysaccharides to Form Gels

50

John Garner and Kinam Park

Contents

Abstract

Polysaccharides have been utilized for a wide variety of industrial, cosmetic, food, and medical applications. The presence of functional groups on polysaccharides has been exploited for chemical modification to prepare polymers with unique properties. Various polysaccharides form hydrogels through physical or chemical cross-linking, and many of them possess environmentally responsive properties, known as smart hydrogels. Polysaccharide-based smart hydrogels are ideal for biomedical and pharmaceutical applications due to their inherent biocompatibility, degradability, and environment sensitivity, such as pH, temperature, and specific biomolecules.

Keywords

Polysaccharides • Chemical modification • "Smart" hydrogels • Chemically cross-linked • Physically cross-linked

1 Overview on Polysaccharides

Polysaccharides are polymeric carbohydrates in which a large number of carbohydrate repeating units are linked together by glycosidic bonds. In nature these are typically used for energy storage (e.g., starch and glycogen) or for mechanical structure (e.g., cellulose and chitin). Polysaccharides can be divided into homopolysaccharides (homoglycans) having the monosaccharide repeating unit and heteropolysaccharides (heteroglycans or hemicelluloses) having different types of repeating units. In general, these polysaccharides can be either linear by containing, for example, only 1,4-β-glycoside bonds (e.g., cellulose) or branched by containing a mixture of 1,4-β-glycoside bonds as well as other bonds such as 1,6-α-glycoside bonds (e.g., glycogen). Polysaccharides may also contain sugars which are missing an oxygen from a given position (deoxy sugars), sugars with amine units (amino sugars), and sugars with sulfate/sulfonate moieties (sulfate/sulfonate sugars). The presence of the amine and sulfate/sulfonate groups allows for other chemical modifications. Table 1 briefly highlights a few examples of different types of polysaccharides.

A hydrogel is a network of polymer chains which absorb water but do not dissolve due to either physical or chemical cross-links. As polysaccharides are already polymeric in nature and possess a plurality of nucleophilic moieties (hydroxyls and sometimes amines) along their backbone, they are easily converted into hydrogels. This, along with their typically low price and natural biodegradability, makes them attractive starting materials for forming various hydrogels. Linear homoglycans are typically used for mechanical stiffness and strength in hydrogel applications (Chang et al. 2009, 2010; Sannino et al. 2009). Branched and linear heteroglycans, such as locust bean gum, xanthan gum, and others, tend to form supermolecular complexes based on their respective chain entanglement which naturally leads to strong gel formation even without modifications beyond a simple heating–cooling cycle (Fernandes 1991; Lundin and Hermansson 1995; Mannion et al. 1992; Urayama et al. 2008). Notably, aminoglycans possess an amine unit which acts as a stronger nucleophile than hydroxyl units, allowing for a

Table 1 Types of polysaccharides and examples

Linear homoglycans	Branched homoglycans	Linear heteroglycans		Branched heteroglycans
Amylose/ cellulose	Amylopectin	Alginate	Chitin	Galactomannans
Chrysolaminarin	Dextran	Gellan	Chitosan	Guar gum
Curdlan	Schizophyllan	Laminarin	Carrageenan	Locust bean gum
	Scleroglucan	Pullulan	Chondroitin sulfate	Xanthan gum

		Xylan		

From references Pigman et al. (1950), McNaught and Wilkinson (1997), Matthews et al. (1999), McMurry (2000); BeMiller (2007), Varki et al. (2009), Heinze et al. (2012)

greater flexibility in chemical modifications. Additionally, the amine unit is weakly basic, making the polymer pH sensitive (Qu et al. 2000; Risbud et al. 2000; Wang et al. 2004). Figure 1 shows examples of polysaccharide structures.

2 Chemical Modifications

With a plurality of nucleophilic groups ranging from alcohols to amines as well as highly reactive acid moieties, polysaccharides represent an ideal platform for a wide array of chemical modifications. However, there are some drawbacks which must be considered for chemical modification of polysaccharides. First, polysaccharides inherently have poor solubility in organic solvents, and thus, they must be processed, at least initially, in highly polar solvents or water. Second, the presence of a multitude of nucleophilic moieties makes it rather difficult to control the extent of modification, i.e., degree of substitution. Third, polysaccharides are susceptible to hydrolysis, although fairly resilient.

2.1 Ether Conjugation

Most chemical modifications of polysaccharides generally rely on the plurality of nucleophiles present along the chain in the form of hydroxyl or amine units. Several hydrogel-forming modifications, particularly of water-insoluble cellulose, have been used to generate water-soluble/gel-like cellulose derivatives for many years. Most of these reaction require cellulose to be activated by conversion to alkali cellulose (cellulose which has been treated with sodium hydroxide) prior to subsequent conjugation (Fig. 2). Once formed into alkali cellulose, the material can be transferred into a variety of derivatives including carboxymethylcellulose (formed by reacting alkali cellulose with sodium monochloroacetate), hydroxyethyl cellulose (formed by reacting alkali cellulose with ethylene oxide), hydroxypropyl cellulose (formed by reacting alkali cellulose with propylene oxide), and methyl-cellulose (formed by reacting alkali cellulose with methyl chloride). Additionally, combinations of modifying agents, e.g., propylene oxide and methyl chloride, can be used to generate polysaccharides with multiple modifications, e.g., hydroxypropyl methylcellulose. These ether derivatives of cellulose are popular for use as thickeners and gums, as they form physical hydrogels (BeMiller 2007).

Carboxymethylcellulose (CMC, Fig. 3a), also known as sodium carboxymethylcellulose to reflect its deprotonated state, notably has high water solubility and is utilized traditionally in foods and other household applications as a thickener and emulsifier. Due to the presence of the carboxymethyl moiety, this material has a pKa of roughly 4.0 (Abu-Ghoush et al. 2009) and can be converted between protonated and deprotonated forms by changing solution pH. Naturally it is fully water soluble and usually does not form a hydrogel. CMC, however, has the capacity to form hydrogels by ionic interaction with multivalent cations such as iron (III) and calcium (Yakup Anca 2000; Davidson et al. 2013). Additionally CMC

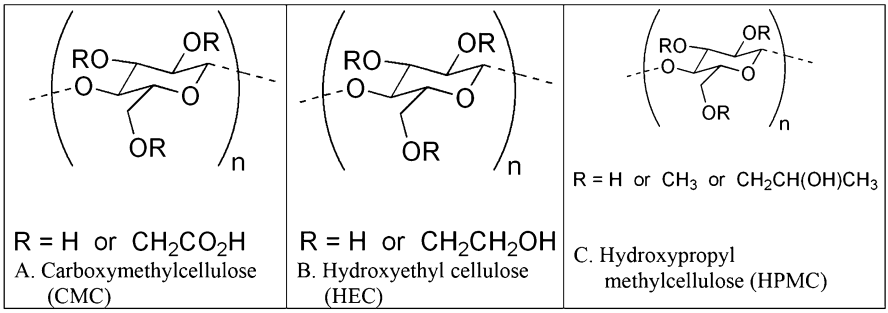

Fig. 3 Examples of chemically modified cellulose. (**a**) Carboxymethylcellulose (CMC). (**b**) Hydroxyethyl cellulose (*HEC*). (**c**) Hydroxypropyl methylcellulose (*HPMC*)

hydrogels can be achieved by a multitude of further chemical modifications including reactions with dialdehydes (Rokhade et al. 2006), divinyl sulfone (Sannino et al. 2004), and diepoxies (Kono et al. 2013), as well as with interaction with radiation (Wach et al. 2001) and other methods. CMC hydrogels tend to display pH sensitivity due to the presence of the carboxymethyl units. In deprotonated state, i.e., at high pH, CMC hydrogels swell more rapidly due to both higher hydrophilicity of the anionic COO^- and the lack of hydrogen bonding which occurs in the protonated state (Barbucci et al. 2000). Figure 3 also shows the repeating units of hydroxyethyl cellulose (HEC) and hydroxypropyl methylcellulose (HPMC). Methylcellulose, despite the hydrophobic modification, has improved water solubility over cellulose, because the modification prevents the polysaccharide chains from forming crystalline domains that prevent solubility of native cellulose.

Methylcellulose possesses a thermal sensitivity and exhibits a lower critical solubility temperature (LCST) between 40 °C and 50 °C (Ruel-Garipy and Leroux 2004). LCSTs of HPC and HPMC are known to be ~42 °C (Winnik et al. 1992) and 69 °C (Joshi 2011), respectively. HEC does not display a thermal sensitivity (Kan et al. 2004). An additional ether-type addition of cellulose is ethyl(hydroxyethyl)cellulose (EHEC). It forms into a gel upon cooling; however, when mixed with surfactants such as sodium dodecyl sulfate (SDS) or cetyltrimethylammonium bromide (CTAB), the solution becomes a reverse thermogel capable of transitioning around body temperature (Ruel-Garipy and Leroux 2004). Ether-modified celluloses are highly stable and can be utilized for further chemical modifications (Lee et al. 2005).

3 Chemically Cross-Linked Polysaccharide Hydrogels

Polysaccharide hydrogels can be generated by chemically cross-linking the polysaccharide using permanent covalent bonds. This can be done in a one-step process by direct addition of a cross-linking agent or can be done in a two-step process in which the polysaccharide is modified to contain activated groups (such as vinylic groups)

and then subsequently cross-linked in a second step. The benefits of the first method are speed and ease of a "one-pot"-type reaction, though the second type offers more flexibility as the activated polysaccharide can be subsequently combined with other monomers or components to create complex multicomponent hydrogels with varying properties.

3.1 Direct Cross-Linking Methods

There are several methods and conditions under which polysaccharides can be cross-linked directly to form into chemically conjugated hydrogels. One method which utilizes no chemicals is the application of high-energy ionizing radiation. This method has been utilized previously to cross-link water-soluble polysaccharide derivatives, such as carboxymethyl starch, carboxymethylcellulose, carboxymethyl chitin, and carboxymethyl chitosan, by exposing paste-like suspensions of each to electron beams or gamma irradiation. In this condition, water hydrolysis products create free radicals that interact with the polysaccharide chains which can induce chemical reactions between the chains leading to cross-linking (Yoshii et al. 2003). Recently, gamma radiation was applied to solutions of carboxylated locust bean gum to create superabsorbent hydrogels. It should be noted that the cross-linking reaction by exposure of polysaccharide to radiation competes against degradation of the polysaccharide which places some limits on this method in terms of exposure and cross-linking degree (Hayrabolulu et al. 2013).

Chemicals which may be applied to directly cross-linking polysaccharide primarily include multifunctional moieties which are reactive towards nucleophiles. One example of this is cross-linking by dialdehydes. Figure 4 shows a schematic overview of an aldehyde–nucleophile reaction commonly used for cross-linking. Typical aldehydes and nucleophiles react in a rapid and spontaneous manner at room temperature allowing for simple one-step reactions. Typically, this has been done with low molecular weight dialdehydes. For example, chitosan is reacted with a variety of phthalaldehydes that cross-link preferentially with the amines (Hirano and Takeuji 1983). Another example is the reaction of glutaraldehyde with alginate to form hydrogels to control delivery of pesticides for agricultural uses. Alginate does not contain amine units but the aldehyde reaction can also occur with other nucleophiles such as alcohol units (Kulkarni et al. 2000).

In addition to low molecular weight dialdehydes, large multifunctional aldehydes can be utilized to achieve this reaction. Recently, an interesting variation of this chemistry was used to create an in situ forming aldehyde-linked hydrogel. In this

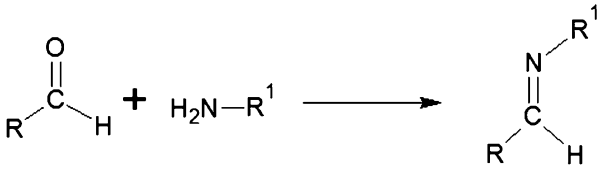

Fig. 4 Example of aldehyde reaction with a nucleophile

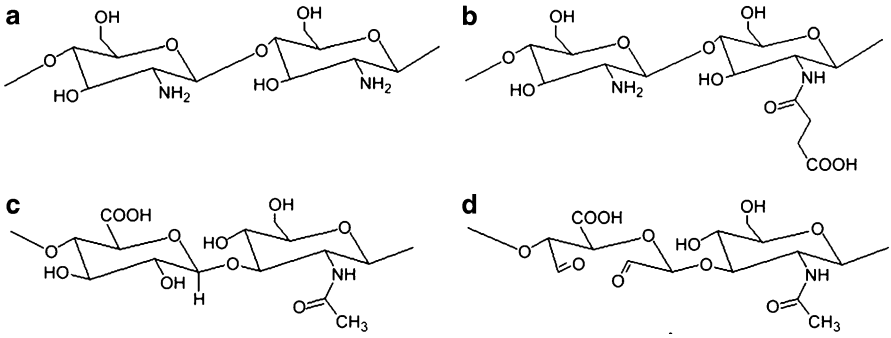

Fig. 5 Chemical structures of chitosan (**a**), *N*-succinyl-chitosan (**b**), hyaluronic acid (**c**), and aldehyde hyaluronic acid (**d**) (Reproduced with permission from Tan et al. (2009))

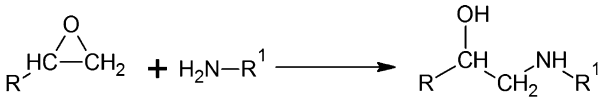

Fig. 6 Reaction between amine and epoxide

technique, chitosan was reacted with succinic anhydride to add carboxylic acid moieties along the backbone. This allowed the chitosan to remain soluble at higher pH. Separately, hyaluronic acid was reacted with sodium periodate in the dark to generate aldehyde units along the backbone of the hyaluronic acid (Fig. 5). When solutions of these polymers were combined, they reacted spontaneously to form a strong cross-linked hydrogel. This reaction, also known as a Schiff base reaction between and amine and an aldehyde, proceeded rapidly in 1–4 min to form a hydrogel system which is biodegradable and biocompatible enough to support growth of bovine chondrocytes on the surface of the hydrogel (Tan et al. 2009). Similarly, aldehyde-converted dextran was reacted with chitosan to form a chemically cross-linked hydrogel. Bovine serum albumin (BSA) was released in a controlled manner from the matrix showing promise for potential use as a drug delivery material as well as for tissue engineering and cell culture (Cheng et al. 2013).

Another method of cross-linking polysaccharides to form hydrogels is to apply epoxide moieties to the polysaccharide. In the presence of nucleophiles, epoxide rings undergo ring opening to conjugate to the nucleophile. Due to ring strain, epoxides are highly susceptible to nucleophilic attack, and thus, this reaction proceeds quite easily even at room temperature with no catalysts. An example schematic of this reaction is shown in Fig. 6. Examples of this cross-linking reaction include reactions involving amine-bearing polysaccharides, such as chitosan, with ethylene glycol diglycidyl ether or epichlorohydrin (Wan Ngah et al. 2002). In this case, the amine serves as the nucleophile. Additionally, alcohol units can be used as the nucleophile in reactions, for example, between poly(ethylene glycol) diglycidyl ether and hyaluronic acid (Collins and Birkinshaw 2008). In general, the amine group is a much more suitable nucleophile for this and other reactions. The hydroxyl reaction may occur but is very slow unless the pH is quite high (Lawal et al. 2011).

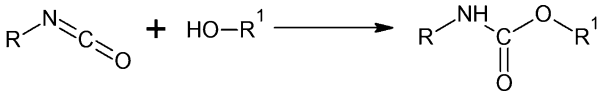

Fig. 7 Generalized isocyanate reaction to form urethane linkage

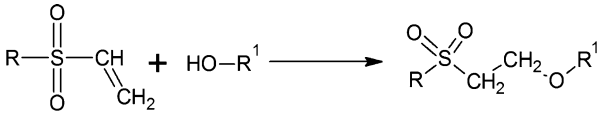

Fig. 8 Generalized vinyl sulfone–alcohol reaction

Polysaccharides can be cross-linked as well by utilizing difunctional isocyanates to form polyurethanes. A generalized schematic of this reaction is shown in Fig. 7. Similar to previous items, the urethane moiety (R-N=C=O) is susceptible to reacting with nucleophiles. It has a higher reactivity towards alcohols, allowing for easier reactions along this route. There are, however, some drawbacks for reacting polysaccharides directly with isocyanates, as this reaction typically does require increased temperatures, specific solvents, and catalysts. This reaction is also highly susceptible to the presence of water which leads to degradation of the isocyanates into carbon dioxide gas. Due to polysaccharides' crystallinity, poor solubility, tendency to contain water, susceptibility to temperature, and acid/alkaline, native polysaccharides are poorly suited for conversion into PEU hydrogels. Typical modifications include depolymerization or alkylation, although this often leads to plastics instead of thermogels (Donnelly et al. 1991). Despite this, there are examples of hydrogels generated utilizing this chemistry typically when mixed with other alcohol/amine-bearing ingredients. For example, urethane reactions have been utilized to cross-link mixtures of chitosan, poly(ethylene glycol) (PEG), and alcohol-terminated polydimethylsiloxane (Rodkate et al. 2010). Additionally, hyaluronic acid has been cross-linked utilizing star-shaped polyethers with isocyanate groups on the distal arms to form biodegradable hydrogels for drug delivery applications (Dhanasingh and Groll 2012).

Another method of cross-linking is by utilizing divinyl sulfone. A generalized schematic of this reaction is shown in Fig. 8. Divinyl sulfone operates as a Michael's type reaction acceptor and is reactive preferentially towards nucleophiles such as amines and thiols. Vinyl sulfone can also react with alcohols at high pH. This reaction has been done with hyaluronic acid to form hydrogels (Collins and Birkinshaw 2008). This vinyl-sulfone-linked hyaluronic acid has been investigated for drug delivery as well as for use as biocompatible coatings and tissue scaffolds. In addition to direct divinyl sulfone, a variety of sulfone-terminated PEGs have been used for this as well. The presence of the hydrophilic PEG spacer leads to an overall lower cross-linking density which allows for greater swelling and faster drug release (Hahn et al. 2004). HPC has also been reacted with divinyl sulfone at high pH (pH~12) to form a temperature-responsive hydrogel which shrinks upon warming. This system was investigated for its potential to serve as an actuator or "artificial muscle" (Hinkley et al. 2004). In addition to divinyl sulfone and PEG/vinyl sulfone, vinyl sulfone macromers have also been produced. To create this, mercaptoalkanoic

acid was modified with divinyl sulfone to yield vinyl sulfone alkanoic acid which was subsequently conjugated to dextran using *N*,*N*′-dicyclohexylcarbodiimide (DCC) and 4-(dimethylamino)pyridinium 4-toluenesulfonate (DPTS) as catalyst. This formed dextran/vinyl sulfone with varying degrees of substitution was reacted with thiol-terminated PEGs linear and star shaped. This in situ reaction formed dextran–PEG hydrogels rapidly which were biodegradable over the course of 3–21 days based on the degree of substitution (Hiemstra et al. 2007). These examples highlight some of the capabilities of this versatile reaction mechanism.

3.2 Activated Cross-Linking Methods

The above sections highlight a variety of methods for generating polysaccharide hydrogels directly in a "single-step" reaction. This chemical method is robust and simple. There is often a requirement for the hydrogel to include other monomers or be reacted in a certain manner. Thus, it becomes desirable to first convert the polysaccharide into an activated form. Typically, this takes the form of attaching vinyl groups onto the polysaccharide which can subsequently participate in radical chain reaction. Several of the linking chemistries are similar to those described above but will be highlighted briefly with an emphasis on their functionality.

3.2.1 Epoxide–Acrylate

One common method is to react polysaccharide with epoxide–acrylates to generate a vinylically reactive macromer. The initial reaction typically involves an epoxy reaction between glycidyl methacrylate and glycidyl acrylate with a polysaccharide. The epoxide ring opens against one of the polysaccharide nucleophiles (alcohol or amine) binding the vinyl group to the nucleophile. Since this reaction occurs easily at room temperature with no need for a catalyst, the vinyl group remains unreacted, allowing for the subsequent material to be purified and mixed with other reagents easily. Examples of this include the grafting of glycidyl methacrylate onto cashew gum (Guilherme and Reis 2005), galactomannan (Reis et al. 2003), dextran (Hennink et al. 1996; De Smedt et al. 1995), and hyaluronic acid (Leach et al. 2004). This allows these macromers to be subsequently reacted into semisynthetic hydrogels. Recently, this technique has been applied to synthesize biocompatible cryogels for cell growth and seeding. The components used were low molecular weight hyaluronic acid–methacrylate generated by reacting glycidyl methacrylate with autoclaved hyaluronic acid (having reduced chain length) as well as full molecular weight hyaluronic acid–methacrylate. Dextran–methacrylate was synthesized by dissolving dextran in dimethyl sulfoxide (DMSO) and reacting with glycidyl methacrylate utilizing 4-(dimethylamino) pyridine as a catalyst. Solutions of the thus formed polysaccharide–acrylates were then dissolved in water and degassed by sparging/ultrasound. They were then frozen and irradiated directly with electron beam irradiation to achieve cross-linking. The resultant cryogels were found to be highly biocompatible and readily allowed for ingrowth of 3T3 cells (Reichelt et al. 2014).

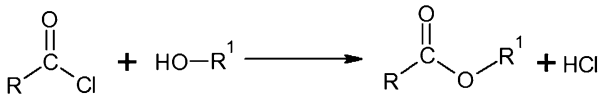

Fig. 9 Generalized acyl chloride–nucleophile reaction. If "R" is acrylate or methacrylate, the resultant molecule is capable of participating in radical chain polymerization

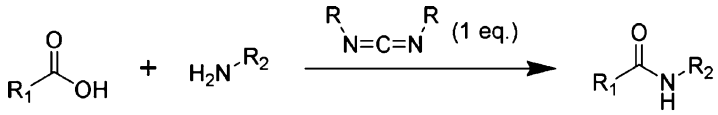

Fig. 10 Example of generic carbodiimide-mediated reaction between an acid and an amine

3.2.2 Vinyl-Oyl Chloride

Vinyl groups can also be attached to polysaccharide using vinyl-oyl chlorides, such as acryloyl chloride and methacryloyl chloride, both of which are readily commercially available. The acyl chloride moiety is highly reactive towards any nucleophile including alcohol and water, and thus, care must be taken to ensure that the reaction is performed under anhydrous conditions. The resultant formation of HCl limits the reaction from proceeding, and so typically this reaction is performed in the presence of an HCl scavenger such as triethylamine (Fig. 9) (Tran et al. 2011). This reaction has been previously applied to acrylate starch which had been previously modified to contain sulfate groups to provide hydrophilicity. This reaction was performed at 60 °C in DMF utilizing pyridine as an acid scavenger. The resultant modified starch was subsequently combined with a comonomer, acrylic acid, and initiated via ammonium persulfate/*N*,*N*,*N*′,*N*′-tetramethylethylenediamine redox pair utilizing a blowing agent sodium bicarbonate to simultaneously increase the rate of reaction by raising pH and generate carbon dioxide gas bubbles. The formed superporous hydrogel (SPH) was capable of absorbing up to 200 times its weight in water (Kuang et al. 2011).

3.2.3 Carbodiimide Conjugation

Conjugation of polysaccharides can also be accomplished via carbodiimide-mediated chemistry. A carbodiimide is any reagent with the N=C=N moiety typically close to the middle of the reagent. Popular carbodiimides include *N*,*N*′-dicyclohexylcarbodiimide (DCC) (preferably in hydrophobic solvents) and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) (preferable in aqueous or polar solvents). The reaction initiates with the acid end cap of the material reacting with the carbodiimide to form an unstable *O*-acylisourea intermediate. The intermediate proceeds to react with nucleophiles (preferentially with amines over hydroxyls) forming an amide bond with a side product being an insoluble organo-urea which is typically removed by filtration (Fig. 10) (Monagle 1962). This chemistry has been applied to forming polysaccharide gels by reacting hyaluronic acid with *N*-(3-aminopropyl)methacrylamide hydrochloride utilizing EDC as a carbodiimide reagent. The resulting hyaluronic acid derivative (Fig. 11) had chemical conjugates

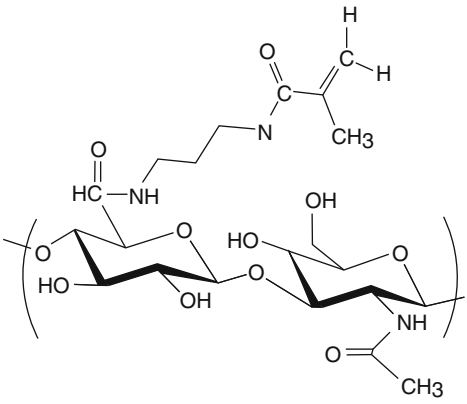

Fig. 11 Hyaluronic acid conjugated to methacrylate units by carbodiimide-mediated attachment (Reproduced with permission from Kim and Park (2002))

between the carboxylic acid units of the hyaluronic acid and the aminopropylmethacrylamide, allowing for subsequent cross-linking with poloxamer diacrylate to form a thermally sensitive, chemically cross-linked hydrogel which served well as a scaffold for controlled release of human growth hormone (Kim and Park 2002).

3.3 Enzymatic Methods

One of the more unusual chemistries recently applied to adding vinyl reactive groups is the utilization of biological enzymes to catalyze the conjugation of vinyl acrylate onto dextran in order to activate it for subsequent use in radical chain-initiated reaction. Solutions of proleather and lipase were utilized to catalyze the reaction between dextran and vinyl acrylate. The subsequent dextran acrylate was then cross-linked to form hydrogels which showed good biocompatibility and biodegradability (Ferreira et al. 2002, 2004).

4 Physically Cross-Linked Polysaccharide Hydrogels

Physically cross-linked polysaccharide hydrogels are formed through chain entanglement, ionic interactions, hydrogen bonding, and hydrophobic interactions.

4.1 Chain Entanglement

Polymer chains of polysaccharides can intertwine to form physical cross-links. The "gum" series of polysaccharides form chain-entangled hydrogels upon simple heating and cooling of their solutions. Xanthan gum is a heteropolysaccharide composed of a 1-4-linked β-D-glucose backbone. This backbone has a trisaccharide side chain composed of two mannoses and one glucuronic acid at every other residue. Locust bean gum is a 1-4-linked β-D-mannan backbone with 1-6-linked

α-D-galactose side groups. When respective solutions of these two gums are mixed and heated, the chains gain motility, allowing for them to intertwine. Upon cooling a gel is formed which is highly resilient to redissolution except for at extremely high temperatures (Higiro et al. 2006). These kinds of gels are typically used in the food industry as viscosity modifiers for a wide variety of products as well as for forming edible films and other substances (Aydinli and Tutas 2000). Although chain entanglement is not typically a desired method of physical cross-linking in semisynthetic polysaccharides, it is often a contributing factor along with other modes of physical cross-linking.

4.2 Ionic Interaction

Several anionic polysaccharides react to form hydrogels directly by interaction with multivalent cation metals, such as calcium (Olivas and Barbosa-Canovas 2008; Betigeri and Neau 2002), iron (Kroll et al. 1996), and others. Cationic polyglucosamines have the capacity to react with polyanions, such as sodium tripolyphosphate(Betigeri and Neau 2002), to form gels. Most notable examples of this kind of cross-linking include cross-linking interaction between sodium alginate and calcium chloride as well as the cross-linking interaction between chitosan and sodium tripolyphosphate. These ionic interactions have the capacity to form hydrogels very quickly, so fast that discrete beads of alginate/calcium or chitosan/tripolyphosphate can be formed by simply dripping the polysaccharide solution into the polyvalent ion solution.

4.2.1 Alginic Acid–Calcium

Alginic acid (Fig. 1a) is a linear copolymer comprised of blocks of (1-4)-linked β-D-mannuronate (M) and the C-5 epimer α-L-guluronate (G) residues, respectively. Alginic acid is extracted from the cell walls of brown algae and used for a wide variety of medical, food, and industrial purposes as a water-absorbent gum/thickener. When processed at high pH utilizing sodium hydroxide or potassium hydroxide, it is converted to sodium alginate or potassium alginate. In this form, it is freely water soluble at low concentrations (Remminghorst and Rehm 2009). When a solution of alginate interacts with calcium, the sodium or potassium exchanges with calcium. Divalent calcium ions interact with two carboxyl groups of alginate to form ionic cross-links and a gel (Fig. 2). This versatile chemistry can be applied for a wide variety of applications including drug delivery (McLennan et al. 2000) and medical devices/tissue scaffolds (Christensena 2011; Livnat et al. 2005).

4.2.2 Chitosan/Tripolyphosphate

An analogous situation occurs with a cationic polysaccharide (chitosan) which interacts with tripolyphosphate to form a hydrogel (Vimal et al. 2013). Chitin is found naturally as the structural component in the exoskeleton of crab, shrimp, and insects. This material is readily available in bulk at an extremely low price from commercial fishing industry. Shell pieces are chopped/ground and then soaked in

hydrochloric acid and deproteinized typically by hot alkali treatment with refluxing sodium hydroxide. This, along with oxidization procedures using oxidizing agents (e.g., KMnO4 + oxalic acid + H2SO) to remove pigmentation, allows for chitin to be isolated from shells. Subsequently, chitin can be converted to chitosan by deacetylation of the chain using alkali treatment (Abdou et al. 2008). Chitin can also be extracted from fungal sources as well (Rane and Hoover 1993; Zikakis 1984). Chitosan is inherently water insoluble at neutral and high pH due to the deprotonated form of the amine units along the chain. When exposed to low pH (typically pH < 5, easily achieved with even 1 % acetic acid), however, the chitosan becomes protonated and fully soluble in water. When this chitosan solution is exposed to a multivalent anion, such as sodium tripolyphosphate which is dibasic, a chemical cross-link is formed between the chains, creating a polysaccharide hydrogel held by ionic influences (Mi et al. 1999). This hydrogel can occur with other materials to create mixed hydrogels as well as has the capacity to have anionic materials, such as alginate, absorb onto the hydrogel due to ionic attraction. These capabilities make this type of hydrogel desirable for microparticle drug delivery systems (Ko et al. 2002). The mechanical strength, in the absence of reinforcement, of chitosan/tripolyphosphate is not as high as that of other ionic polysaccharide hydrogels such as calcium ion-cross-linked alginate. For this reason, it is not typically used for devices or other larger structures (Shu and Zhu 2000).

4.2.3 Other Ionic Polysaccharides

Although chitosan and alginate are the most popular materials for generating ionic polysaccharide hydrogels, any polysaccharides which have a plurality of charges along its backbone can be used for this purpose. Carrageenan (Fig. 1) is a family of polysaccharides which have anionic sulfonate (SO^{3-}) groups present along their backbone. These anionic sulfonate groups have also been used as sites for ionic cross-linking with divalent and trivalent counterions as well as by interaction with other natural polymers such as gelatin. Gellan gum forms thermoreversible gels in the presence of divalent counterions. Scleroglucan, when derivatized to introduce carboxylic acid units, can be cross-linked by calcium ions to form hydrogels (Coviello et al. 2007). Ionically cross-linked polysaccharide hydrogels are inherently sensitive to both pH and ionic strength of the media. Since it is the balance between ions that generates these gels, changes in pH can shift the protonation degree of the ions. When applied in vivo or in a sink system over time, the low molecular weight cross-linking ion (e.g., calcium and tripolyphosphate) leaches out of the system, and eventually the hydrogel redissolves.

4.2.4 Polyelectrolyte Complex

A polyelectrolyte complex forms when two polymers having opposite charges interact. This is a popular method of forming an ionic gel with polysaccharides as they typically contain or can be modified to contain opposing charges. These ionic interactions are stronger than other interactions, such as van der Waals or hydrogen bonding. Polysaccharide polyelectrolyte complexes are formed by interacting a polycation (e.g., chitosan) with an anionic polysaccharide. Anionic polysaccharides

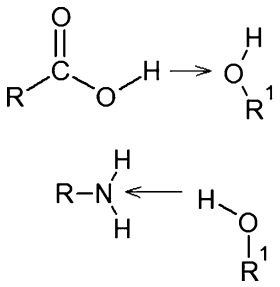

Fig. 12 Examples of hydrogen bonding of carboxylic acid and amine with alcohol units. *Arrows* indicate hydrogen bonds

include alginic acid, hyaluronic acid, chondroitin sulfate, carboxymethylcellulose, dextran sulfate, pectin, and xanthan. Polysaccharide polyelectrolyte complexes can also be formed with proteins, such as gelatin, fibroin, albumin, keratin, or collagen, or anionic synthetic polymers such as polyacrylic acids (Bhattarai et al. 2010).

4.3 Hydrogen Bonding

Hydrogen bonding is a strong electromagnetic attraction between hydrogen and an electronegative atom such as oxygen or nitrogen. As shown in Fig. 12, hydrogen bonding in polysaccharides is common due to the presence of several participatory groups such as alcohols, carboxylic acids, and amines (Blackburn 2004). Hydrogen bonding is an environmentally sensitive process. For hydrogen bonding to occur, the hydrogen-bearing groups must be appropriately protonated for carboxylic acid or deprotonated for amine (Fig. 12) and at an appropriate temperature with a low salinity for a strong hydrogen bond to form. Agarose only forms hydrogen bonds at relatively low temperatures, and chitosan only forms these bonds at pH higher than 5 (Francis Suh and Matthew 2000). Semisynthetic polysaccharides, such as carboxymethylcellulose, also undergo hydrogen bonding in a pH-sensitive manner (Barbucci et al. 2000). Hydrogen bonding is sensitive towards other components in the solution, such as urea, which disrupt this form of physical bond and reduce its capacity to gel a material (Moon et al. 2012).

4.4 Hydrophobic Physical Cross-Linking

One effective way of forming a hydrogel is to attach hydrophobic units to the chain for hydrophobic association. The hydrophobic association is primarily due to the lack of attraction between water and the hydrophobic moieties rather than any attraction among hydrophobic moieties (Chandler 2005). The presence of an excess of hydrophobic moieties will simply yield a water-insoluble polymer (Miyamoto et al. 1995). One good example of this is cellulose acetate with high levels of acetate conjugation. They are water-insoluble plastics used for a variety of films, photographic and consumer purposes (Kamide 2005). The thermal sensitivity is strongly tied to the relative content of hydrophobic and hydrophilic portions of the polymer,

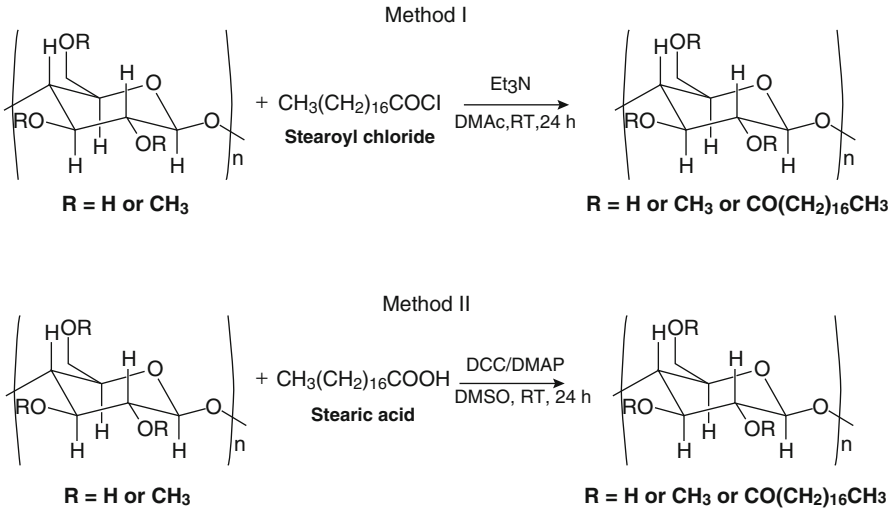

Fig. 13 Synthetic methods for generating stearate-modified methylcellulose (Reproduced with permission from Lee et al. (2005))

and thus, it can be controlled by adjusting the hydrophobic content of a polysaccharide. Methylcellulose, which has thermogelation properties but with a relatively high transition temperature, can be modified to contain additional stearate (C18 fatty acid) groups along the chain. Stearoyl chloride was reacted with methylcellulose in the presence of triethylamine (which serves as an HCl scavenger). In another method, stearic acid was reacted with methylcellulose utilizing carbodiimide-mediated chemistry and dimethylaminoethylpyridine (DMAP) as a catalyst. Both of these conjugation techniques were successful in generating hydrophobically modified cellulose (Lee et al. 2005) (Fig. 13). Similarly cellulose has been reacted with hydrophobic modifiers, such as 1,2-epoxydecane and butyl isocyanate, to form thermogelling derivatives based on hydrophobic associations (Miyamoto et al. 1995). Additionally reacetylated chitosan can serve as a thermogel based on hydrophobic modifications as well (Li et al. 2013).

5 Stimuli-Responsive Polysaccharide Hydrogels

An increasingly popular field of research is into "smart" or "environmentally sensitive" hydrogels. This is a popular field both for polysaccharide hydrogels and hydrogels in general. The phrase "smart" typically refers to hydrogels which undergo a change in their physical bonds or attraction towards water due to a change in the environmental factor, such as pH, ionic strength, temperature, light, and presence of specific molecules, such as glucose or enzymes. In some instances, the phrase is applied to hydrogels which undergo chemical changes such as those which are sensitive towards enzymatic hydrolysis of a specific enzyme which may be utilized for drug delivery.

Stimuli-responsive polysaccharide hydrogels display a phase transition behavior. There are two (or three for un-cross-linked polymers) different phases these responsive hydrogels can exist in as defined by the Flory–Huggins theory (Bromberg and Ron 1998). The polymer–solvent interaction creates osmotic pressure ($\Delta\pi_{mix}$) attracting the polymer chains to the solvent, thus driving the polymer to either expand or, if there are no other bonds holding it together, to ultimately dissolve. Additionally, there are polymer–polymer interactions related to the strength of the polymer chain attraction for each other as an elastic force ($\Delta\pi_{elast}$). These forces in a given polymer system are always in balance, and the following equation applies:

$$\Delta\pi = \Delta\pi_{mix} + \Delta\pi_{elast} = 0$$

In a general hydrogel system, the opposing forces balance and thus define the swelling of the hydrogel. However, in a responsive system, the relative balance of these forces is affected by a specific stimulus. As this occurs, the system transitions through three stages (Harsh and Gehrke 1991):

1. Precipitate stage ($\Delta\pi_{mix} \ll \Delta\pi_{elast}$): There is maximum polymer–polymer interaction with minimal polymer–solvent interaction, and thus, the polymer is precipitated from the solution and behaves in a hydrophobic manner resisting water infiltration.
2. Gel stage ($\Delta\pi_{mix} \sim \Delta\pi_{elast}$): The opposing interaction forces are close to balance with one another. The polymer chains retain enough interaction to hold the hydrogel together as one piece but still be highly hydrated with water. Depending on the system, this transition may be very sharp or broad.
3. Solution/fully swollen stage ($\Delta\pi_{mix} \gg \Delta\pi_{elast}$): The polymer–solution interaction is maximized, and the polymer either completely dissolves (in the situation where the physical bonds were holding it together) or in the case of a chemically cross-linked hydrogel expands to reach their maximum swelling.

This general theory applies to the interaction of physical bonds with the environment, but with several exceptions and nuances. For example, altering the relative attractive forces is a reversible change, whereas breaking of chemical bonds by enzymes or formation of chemical bonds by light is an irreversible change. Additionally, the method in which these interactions change depends drastically on the system being altered. Several types will be detailed and highlighted with examples below (Qiu and Park 2001).

5.1 Enzymatic/Special Molecule Sensitivity

In general, polysaccharide hydrogels display enzymatic sensitivity in that they are degraded by the enzyme which is a nonreversible change to the polymer backbone. A good example of this is the degradation of dextran-based hydrogels by dextranases leading to increased release of the drug payload. This method was used as a means to develop a hydrogel for controlled protein delivery based on enzymatic

degradation rate (Hennink et al. 1997). One valuable aspect of this application is towards colon-specific drug delivery where dextranases are present in higher concentrations than elsewhere in the body (Hovgaard 1995). Additionally "dual-sensitive" hydrogels have been made by forming interpenetrating polymer networks (IPNs) consisting of oligopeptide-terminated PEG and dextran. This requires the presence of both papain and dextranase to degrade the hydrogel and release the drug under very specific conditions.

There are a wide range of hydrogels which display sensitivity towards a variety of biomolecules including glucose, peptides/proteins, nucleic acids, and other materials (Miyata et al. 2002). Glucose sensitivity can be achieved by incorporation of concanavalin A (Con-A), which is a carbohydrate-binding protein with a strong affinity for glucose. A dextran–PEG-based cross-linked hydrogel incorporating Con-A was made to provide glucose sensitivity. As part of forming this, hydrogel dextran was modified using glycol methacrylate to form dextran–methacrylate, and Con-A was modified by Michael's addition with ethylene glycol acrylate–methacrylate. These were reacted with PEG-dimethacrylate to form a chemically cross-linked hydrogel. In the absence of glucose, Con-A is attracted to the dextran chain and binds to this chain. When glucose is present, however, it competes for this binding and as such increases the swelling of the hydrogel, thus making the hydrogel as a whole sensitive towards glucose. The goal of this type of research is to generate an intelligent pump which releases certain quantities of insulin based on the glucose content in the blood (Yin et al. 2010).

5.2 pH Sensitivity

Some hydrogels exhibit pH sensitivity primarily due to the presence of ionizable groups. Several natural polysaccharides, such as alginic acid and chitosan, already have ionizable groups available and display pH sensitivity. Weak acid, such as –COOH, present in hydrogels ionizes at high pH and thus swells to a greater degree or dissolves. On the other hand, hydrogels containing weak bases, such as amines, become ionized at low pH for higher swelling or dissolution. In all cases, the sensitivity towards pH is related to the materials' acidity constant which defines the equilibrium state of the ionized fraction at a given pH. The equilibrium constants for weak acids and weak bases can be written as shown in Table 2. K_a and K_b are the acidity constant and basicity constant of the weak acid and weak base, respectively. A weak acid at low pH (where $[H^+]$ is high) is primarily in the protonated (non-ionized) form which is not water soluble (or not swellable). At high pH, it is primarily in the deprotonated (ionized) form which is water soluble (or swellable).

Table 2 Equilibrium constants for weak acids and weak bases

Weak acids	Weak bases
$HA \leftrightarrow H^+ + A^-$	$B + H_2O \leftrightarrow BH^+ + OH^-$
$K_a = \frac{[H^+][A^-]}{[HA]}$	$K_b = \frac{[BH^+][OH^-]}{[B]}$

A weak base dissolves (or swells) at low pH, but become water insoluble (or not swellable) at high pH. Due to the wide range of pH, it is common to convert the K_a and K_b values into pK_a and pK_b, the sum of which for a conjugate acid/base pair equals 14 in an aqueous system. One simple and practical implication of pH sensitivity with natural polysaccharides is that chitosan is normally insoluble in water at neutral pH. It dissolves quite easily, however, in dilute acids (e.g., 0.1 M acetic acid) due to ionization of the amine units along its backbone (Rinaudo et al. 1999).

Polyelectrolyte complex beads formed by mixing chitosan and alginate have been utilized to control the release of bitter gourd extract in a pH-dependent manner (Lin et al. 2014). Sometimes the pH-sensitive portion of the hydrogel is not from the polysaccharide. Radical chain polymerization of acrylic acid was performed in the presence of tragacanth gum. During this reaction, the initiator abstracts a hydrogen atom from tragacanth gum chain, and poly(acrylic acid) initiates from this point leading to a grafted polymer. Due to the presence of the plurality of –COOH units along the poly(acrylic acid) chain, the system displayed a reduced swelling and drug release at low pH (Singh and Sharma 2014).

5.3 Thermal Sensitivity

A gel can react towards changes in solution temperature in two primary ways. The first is referred to as the "normal" thermogel response in which heating of the solution improves overall polymer solubility. The increase in temperature reduces chain entanglement and hydrogen bonding, leading to either dissolution (for a physically cross-linked gel) or increased swelling for a chemically cross-linked gel. This type of response is common for gels made from gelatin or mixtures of xanthan and locust bean gum (Acharya et al. 2010; Carafa et al. 2011). Typically, however, when one refers to a thermogel or thermally sensitive hydrogel, this is not the response they are indicating. Responsive thermogels are generally considered to be "inverse" thermogels. In this situation, heating of the solution leads to a change in the water–polymer entropy or physical bonding that leads, counterintuitively, to gelation or shrinking of the hydrogel at increased temperature. As temperature increases, hydrogen bonding decreases while hydrophobic interaction increases.

Generally, the process of thermogelation is considered to be driven by entropy relative to the water–polymer attraction system. When water molecules are associated with the polymer chain, they are highly organized leading to a decreased entropy relative to the entropy of free water. The attractive force of water–polymer binding energy is an enthalpic term (ΔH_f, heat of fusion). The energy of the system as a whole can be generally described by the Gibbs free energy equation as follows:

$$G = H - TS$$

where G, H, S, and T are Gibbs free energy, enthalpy, entropy, and temperature, respectively. At low temperatures, the entropy drive is reduced, and the heat of fusion (ΔH_f) dominates so that the water molecules prefer to be associated with the polymer

chain and the physically cross-linked hydrogel dissolves freely while a chemically cross-linked hydrogel swells to its maximal extent. As temperature increases, the total energy of the system, as described by Gibbs free energy of the system, favors the entropic term rather than the enthalpic term, and the water molecules prefer to be in unorganized form in free solution rather than bound to the polymer chain (Oesterhelt et al. 1999; Harris 1992; Wang et al. 1997). The condition at which these two forces are in balance is referred to as the lower critical solubility temperature (LCST), and it is at that point that the material gels to a solid. The nucleophilic groups along the polysaccharide chain bond strongly to water. Thus, the requirement to generate a thermogel is simply to modify the polysaccharide to introduce hydrophobic moieties (Li et al. 2010; Kuang et al. 2006; Zhai et al. 2012).

Several examples have already been discussed, including methylcellulose, HPMC, etc. Chitosan, dextran, pullulan, and carboxymethyl curdlan have been hydrophobically modified to form thermogels (Lee et al. 2005; Hennink and van Nostrum 2012; Jeong et al. 2002). Polysaccharide hydrogels can also be generated relying on an additional, typically synthetic polymer for providing the thermogelation property. Examples of this include graft polymers of alginate with poloxamer (a known synthetic thermogel containing blocks of polypropylene oxide and polyethylene oxide) (Chen et al. 2011) and hyaluronic acid with poly(*N*-isopropylacrylamide) (PNIPAM) (Mortisen et al. 2010). In both these situations, the polysaccharide provides general hydrophilicity as well as other desired properties (biodegradability, biocompatibility), while the thermogel (poloxamer or PNIPAM) provides the thermogelling property.

Thermal gelation LCST is sensitive towards other components present in the solution. For instance, some materials (NaCl, KF, $(NH_4)_2SO_4$, and poly(ethylene glycol)) lower the LCST due to their water structure formation properties (Lee et al. 2005). Conversely, the addition of hydrotropic agents, materials which reduce water structure formation such as salicylate, diethylnicotinamide, urea, etc., will raise the LCST. This property can be controlled by the degree of hydrophobic modification. For example, methylcellulose has thermal sensitivity with LCST of $>45\ ^\circ C$. This makes the methylcellulose useful for some applications, such as food preparation as a batter viscosity modifier (Sanz 2005), but physiologically not applicable as a tissue scaffold or drug delivery gel. To lower the LCST of methylcellulose, additional hydrophobic groups may be added. Stearate (C18) groups were introduced to methylcellulose of 14,000–40,000 Da and a degree of methyl substitution around 1.6–1.9. Stearates were conjugated onto a methylcellulose chain at 0.3 or 1.6 mol%. The original methylcellulose could not thermogel at 33–37 °C, regardless of NaCl concentration, but that the stearate-modified methylcellulose could gel easily at these conditions (Lee et al. 2005).

Chitosan can also be converted into a thermogel by carefully controlling the degree of deacetylation. A highly controlled thermogelling glycol chitin was generated by reacetylating the chitin chain to contain the desired quantity of acetylation units (Li et al. 2013). This was done by reacting glycol chitosan with acetic anhydride at room temperature for varying reaction times to achieve varying degrees of reacetylation (Fig. 14). Glycol-modified chitosan has enhanced water

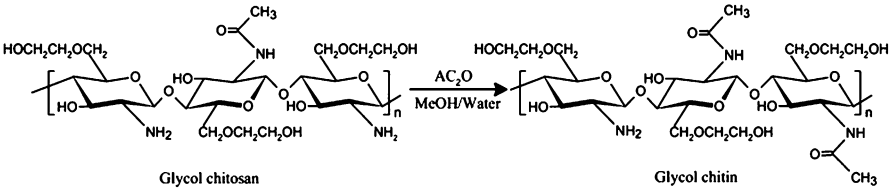

Fig. 14 Reacetylation reaction of glycol chitosan with acetic anhydride (Image reproduced with permission from Li et al. (2013))

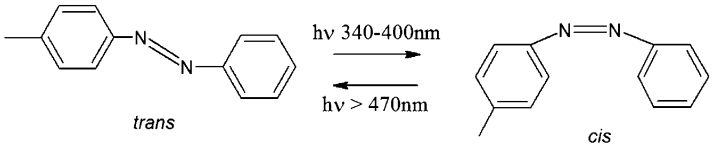

Fig. 15 The cis/trans conversion of [4-(phenylazo)phenyl]carbamate upon exposure to light Yashima et al. (1995)

solubility over conventional chitosan due to glycol unit which allows the polymer to dissolve at high pH. Further modification to add the acetyl units achieves a material which carefully balances the hydrophobic interactions leading to gel formation and the hydrophilic attractions which lead to solution formation. The formed hydrogel was found to be rapidly gelling allowing for gelation upon injection into a warm body. With higher degrees of acetylation, the polysaccharide was more susceptible to degradation in the presence of lysozymes. The material displayed good biocompatibility and allowed for controlled release of doxorubicin, a chemotherapeutic agent, over 13 days. Overall this research showed that there is good promise for modified chitosan to be utilized as thermogels in the fields of drug delivery and tissue engineering. A great deal of these properties (biodegradability, biocompatibility) can be attributed to the polysaccharide itself which lends the use of these materials to medical applications.

5.4 Light Sensitive

Light-sensitive hydrogels refer to the hydrogels with reversible sensitivity towards light without light-induced chemical cross-linking. A typical strategy to form a light-sensitive hydrogel is to utilize a thermally sensitive polymer and then incorporate a material which generates heat from light such as melanin (Ninh et al. 2014) or graphene oxide (Lu et al. 2014). Photosensitive moieties, such as [4-(phenylazo) phenyl]carbamate which switched between cis and trans upon exposure to either UV light or light >470 nm, can be grafted to cellulose/amylose (Fig. 15) (Yashima et al. 1995). This light-sensitive moiety has been utilized to modify HPMC which, in the presence of cyclodextrin, forms a photosensitive hydrogel. Another method

of inducing light sensitivity is to conjugate a light-inducible zwitterion, such as spiro benzopyran or spiro napthoxazines, which undergoes reversible ring opening upon light impingement. This method has been utilized to convert methylcellulose, dextran, and other polysaccharides into a form that had varying water/organic solubility based upon light exposure. More information can be found in a review article (Wondraczek et al. 2011).

6 Conclusion

The possibilities for generating hydrogels out of polysaccharide precursors are boundless. The inherent biocompatibility/biodegradability as well as the presence of a plurality of nucleophilic groups along the polysaccharide backbone provides many benefits. Polysaccharides can be modified, allowing for both chemical and physical hydrogels. Several natural as well as modified polysaccharides display sensitivity to environmental conditions such as temperature, pH, salinity, and light, allowing for the generation of environmentally responsive or "smart" polysaccharide hydrogels. The many capabilities of polysaccharide hydrogels are useful for applications to industrial, cosmetic, food, and healthcare fields.

Contents

Abstract

Phytochemical and pharmacological investigations identified that polysaccharides are major active compounds in *Fructus Corni*, which is a well-known traditional Chinese medicine, which shows various beneficial effects, such as immune regulation, antioxidation, antitumor, and antiaging functions. This chapter summarizes the techniques of polysaccharide extraction and purification from *Fructus Corni*, as well as their structural determination and related bioactivities. The prospects of future investigations and polysaccharide use are also discussed.

Keywords

Fructus Corni • Polysaccharides • Extraction • Structure • Pharmacological activities

Abbreviations

AChE	Acetylcholinesterase
ALAT	Alanine aminotransferase
ALT	Alanine transaminase
ANOVA	Analysis of variance
Bcl-2	B-cell lymphoma 2
BHT	2,6-Di-tert-butyl-4-methylphenol
CD4	Cyclin-dependent kinase 4
$CD4^+$	Cluster of differentiation 4
$CD8^+$	Cluster of differentiation 8
DEAE-C	Diethylaminoethyl-cellulose
EAE	Enzymatic assisted extraction
EC50	Concentration for 50 % of maximal effect
GC	Gas chromatography
HDF	Human dermal fibroblast
HPGPC	High-performance gel permeation chromatography
HPLC	High performance liquid chromatography
HWE	Hot water extraction
IL-2	Interleukin 2
IL-4	Interleukin 4
IR	Infrared spectroscopy
MAE	Microwave-assisted extraction
MAP	Microwave-assisted process
MDA	Malondialdehyde
MS	Mass spectrometry
MTT	3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide
MUAE	Microwave and ultrasound assisted extraction
NBT	Nitroblue tetrazolium
NGF	Nerve growth factor
NMR	Nuclear magnetic resonance
RIA	Radioimmunoassay
RSM	Response surface methodology
RT-PCR	Reverse transcription polymerase chain reaction
SGPT	Serum glutamic-pyruvic transaminase
SOD	Superoxidase dismutase
TCA	Trifluoroacetic acid
TFA	Trifluoroacetic acid
UAE	Ultrasonic assisted extraction

1 Introduction

Cornus officinalis Sieb. Et Zucc. is a plant species known also as Japanese cornel, Japanese cornelian cherry, or cornelian cherries, which is one of the traditional and valuable Chinese medicinal plants and is scientifically classified into the *Cornus* genus, Cornaceae family, Cornales order, Magnoliopsida class and Magnoliophyta phylum. *Cornus officinalis* is mainly distributed in China, Korea, and Japan at latitudes between 26° and 37°40′ parallel north and altitudes from 600 to 1,400 m (optimal at 800–1,000 m) above sea level. The optimal cultivation climate is a yearly average temperature of 14.9 °C, lowest average temperature −14 °C, frost-free season ~230 days, and rainfall >822.3 mm (Chen et al. 2012). *Cornus officinalis* are deciduous trees or shrubs usually 4–10 m tall; their bark is light brown, with a feature of flaky stripping; their twigs are green, with a slender cylindrical shape that is glabrous covered with sparsely pubescent winter buds, while mature branches become blackish brown; winter buds are located terminal or axillary, displaying an ovate to lanceolate shape and covered with yellowish brown pubescent. Blade elliptic or long elliptic leaves grow in an opposite direction and are usually 5- to 12-cm long, 2.5- to 4.5-cm wide, green and glabrous at the upper face, and light green and covered with lean white paste sparsely pubescent at the lower face; leaves usually have 6–7 pairs of arcuate recurved lateral veins and are covered with densely pale brown floccose between veins; the petiole is thin and cylindrical, with a length of 0.6–1.2 cm and covered with slightly posted rusty pilose. *Fructus Corni* flowers in March–April, which precedes the leaves opening, and the flowers are clustered in umbels that are grown on apical branchlets or axils; flowers are small and bisexual; each flower has 4 crack calyxes yellowish green, 4 crack petals yellow, and 4 stamens; the fleshy disk is annular; below is the ovary with 2 rooms. *Fructus Corni* fruits in September–October, with oblong drupe that is 1.2- to 1.7-cm in length and 5- to 7-mm in diameter, with a red to purplish red color; nuclear bone, narrowly elliptic, ~12 mm, with a few irregular ribs (Fig. 1).

The dried fruit (*Fructus Corni*, Shan Zhu Yu in Chinese) of *Cornus officinalis* has been used for at least 2,000 years in Chinese herbal medicine and is officially listed in the Chinese Pharmacopoeia (2010). It has been used to invigorate the liver and kidney, to maintain kidney essence, to reduce urination, and to reduce perspiration and hemorrhage (China Pharmacopoeia Committee 2010). It has also been used in hygienic food and for cosmetic purposes (Cao et al. 2012). A number of functional compounds, including iridoid glycoside, aglycone, tannins, polysaccharides, organic acids, and esters, have been isolated and identified from *Fructus Corni* (Liu et al. 2011). Among them, polysaccharide is recognized as one of the major active compounds responsible for a wide range of healthy properties and thus has attracted ever-increasing attention (Tomshich et al. 1997; Ammar et al. 2010). Modern pharmacological investigations have indicated that polysaccharides of *Fructus Corni* have various bioactivities, including immunomodulatory (Du et al. 2008a; Miao et al. 2002), antioxidant (Li et al. 2003a, 2010; Zhang et al. 2008), antitumor (Zou et al. 2012), anticancer (Wang et al. 2012a, b), antiaging (Fu et al. 2007;

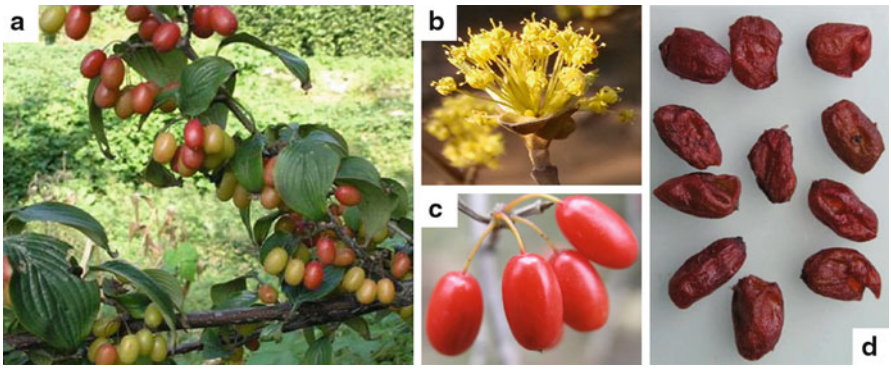

Fig. 1 (**a**) Tree, (**b**) flowers (**c**) fruits, (**d**) dried fruits of *Cornus officinalis*.

Wang et al. 2008a; Ou et al. 2010; Zhou et al. 2011), and sexual function effects (Shao et al. 2010). Because immunological modulation is believed to be involved in the prevention of various diseases such as cancer or pathogenic infections, the modulation function of polysaccharides on the immune system is particular interesting. Moreover, the physical–chemical properties of polysaccharides, such as the molecular weight, primary structure, solution conformation, and polymer charges, might play an important role in determining their affinity on various receptors and thus affect their biological activities and ultimately their biological effects on various diseases. Therefore, it is critically important to optimize their extraction, isolation, and purification from *Fructus Corni* in order to determine their structures for a better understanding of the underlying molecular mechanisms of their beneficial effects.

2 Extraction and Purification Processes

The application and further investigation of polysaccharides rely on an efficient extraction and isolation from *Fructus Corni*, a process that is theoretically affected by various factors, such as extraction temperature, pressure, pH, and ionic strength of the solvent. Commonly, aqueous solvents, such as water or basic aqueous solutions, in combination with various extraction "helpers" are used for polysaccharide extraction. Moreover, because polysaccharides of *Fructus Corni* exist as a structural compound of the cell wall, the nature of the cell wall structure constitutes a basic determinant for the selection of a suitable extraction method. Based on the structure and water solubility of *Fructus Corni* polysaccharides, the basic rule is to break the cell wall from outer layer to the inner layer with mild-to-strong conditions (for example, by varying solvent pH and temperature). In principle, polysaccharide extraction can be performed using water at room temperature, which is followed by a centrifugation process to remove nonsolubilized material that can be further extracted using hot water or other aqueous solutions. Acidic solutions can be employed for those water insoluble polysaccharides.

2.1 Hot-Water Extraction

Hot-water extraction (HWE) is the most commonly used technology for polysaccharide extraction in industrial applications. To improve the extraction efficiency of HWE, various reports have been reported in order to optimize the potential parameters, such as the extracting temperature and time, the ratio of solid-to-solvent and the number of extraction times all affecting the extraction of polysaccharides (Guo et al. 2010; Ye and Jiang 2011; Zhang et al. 2014a; Bin 2010). Zhang et al. (2007a; Zhang and Zhang 2007) performed HWE by selecting the extraction temperature, extraction time, and ratio of solvent to material as extraction parameters to optimize the extraction process using a uniform experimental design, which is a kind of space-filling design used for computer or industrial experiments when the underlying model is unclear. A uniform scattering of its design points on the experimental domain is desired by the uniform experimental design (Khattree et al. 2003). To determine the content of polysaccharides, Zhang et al. used a widely applied stable and simple method called phenol–vitriolic colorimetry (Dubois et al. 1956; Han et al. 2014; Wang et al. 2012c; Zhao et al. 2014), which employs the phenol–sulfuric-acid reaction, i.e., phenol undergoes sulfonation in situ, and the phenol–sulfonic acid generates a decreased color intensity for many hexoses and pentoses (Masuko et al. 2005). The final determined optimum extraction conditions were as following: temperature 100 °C, extraction time 180 min, and ratio of solvent to material 36 (mL/g). Extraction yield and polysaccharide content were 199.36 mg/g and 16.04 %, respectively.

By use of orthogonal arrays (or Taguchi methods) of L_9 $(3)^4$, which are frequently employed in industrial experiments to investigate the effect of several control factors, Li et al. (2003b) investigated also the factors, including extraction temperature and time, ratio of solvent to material, and material size, which all affect the extraction process. Usually, for an orthogonal array, columns for the independent variables are "orthogonal" to one another; thus, this method has the advantage of being easy to perform for large-scale analysis but with less experimental effort, and conclusions are valid over the entire region spanned by the control factors and their settings. In the work of Li et al. (2003b), the single-factor experiments were assayed and then the levels of parameter were selected. Based on polysaccharide content, range analysis was performed. The authors concluded that the optimal processing conditions for HWE were temperature 80 °C, extraction time 120 min, ratio of solvent to material 16 mL/g, and size of material particle 300–450 μm. According to the results of orthogonal arrays, another parameter – number of extractions–was further investigated; it was concluded that 4 extractions is the best.

In order to evaluate interactive effects among various parameters, response surface methodology (RSM) is used to optimize the process parameters. RSM is a collection of mathematical and statistical techniques based on the fit of a polynomial equation to the experimental data. It can be well applied when a response or a set of responses of interest are influenced by several variables (Bezerra et al. 2008). Using this method, Du et al. (2008b) optimized the extraction process by investigating the effects of extraction temperature, extraction time, and ratio of solvent to material on the extraction yield. After analyzing the data with MATLAB 7.0

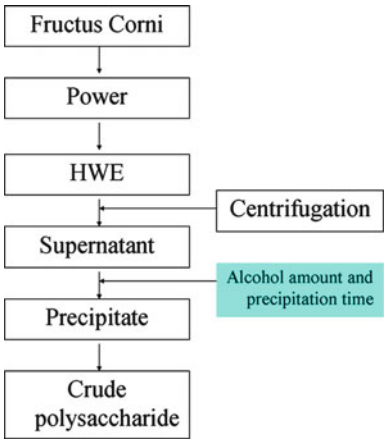

Fig. 2 Diagram of the process of hot-water extraction (*HWE*) of polysaccharides from *Fructus Corni*

software, the optimum extraction conditions were temperature 84 °C, extraction time 142 min, and water volume 276 mL for 20 g of raw material. The value of polysaccharide extraction yield from *Fructus Corni* was 89.79 μg/mL, which is in good agreement with the predicted value of 89.34 μg/mL by the RSM model. Based on these results (Du et al. 2008b), another study, reported by Wang (2008), further investigated the amount of alcohol that should be used for polysaccharide precipitation and the length of precipitation during the extraction of polysaccharides from *Fructus Corni*. The diagram of the extraction process is presented in Fig. 2. In this work, five levels of different factors were performed using RSM, and the experimental data variances were statistically analyzed using MATLAB 7.0 designed for the analysis of variance (ANOVA). The results indicated that the quadratic polynomial model is significant ($P < 0.05$), thus suggesting that the experimental data fit well with the model. By analyzing regression equation and inverse matrix, it was determined that 652 mL of alcohol should be used for 100 mL supernatant and the precipitation should take place for 59.7 h. Under such extraction conditions, the content of crude polysaccharide is determined to be 35.22 g/100 mL.

Although HWE is simple and safe, the disadvantage of this method is a rather low extraction yield and a long extraction time at high temperature, which could accelerate degradation of polysaccharides and thus constitutes a further contribution to low extraction efficiency.

2.2 Ultrasonic-Assisted Extraction

Ultrasonic-assisted extraction (UAE) is an emerging technique that is believed to have various advantages over traditional extraction methods and is regarded as one of the simplest extraction techniques. The mechanism of UAE involves two types of physical phenomena: diffusion through cell walls (acoustic cavitation effect) and washing out the cell contents once cell walls are broken. Ultrasound wave can facilitate swelling and hydration of cell walls, leading to an enlargement of the

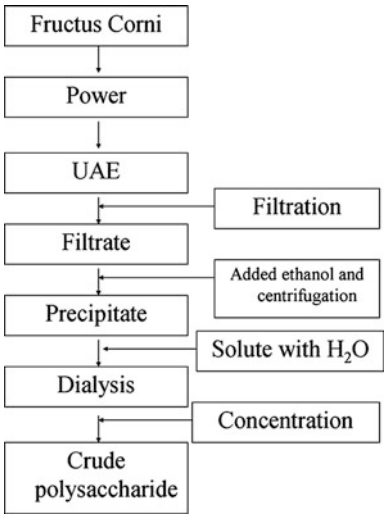

Fig. 3 Process of ultrasound-assisted extraction (*UAE*) of polysaccharides from *Fructus Corni*

pores formed on cell walls. This consequence will further contribute to cell disruption and diffusion of content from the plant-cell walls and ultimately washing out of the target compounds (Vinatoru 2001; Hromadkova et al. 1999; Yang et al. 2008a). Accumulated evidence suggests that the process parameters, including ultrasound frequency, ultrasound power, ratio of solvent to material, extraction time and temperature, number of repeated extractions, as well as the size of the material, must all be optimized to improve polysaccharide extraction efficiency.

UAE has been applied widely in traditional Chinese medicine to extract both single and combined medical herbs (Tian et al. 2013; Fan et al. 2012; Teng and Choi 2014). Its application on polysaccharide extraction has been described in a number of reports (Wen et al. 2011; Tahmouzi 2014; Chen et al. 2014). Figure 3 summarizes an extraction process described by Lei and Li (2013) who used UAE to extract polysaccharides from *Fructus Corni*. The process variables, such as ultrasonication time, extraction temperature, and ratio of solvent to material were used to investigate the extraction of polysaccharides in single-factor experiments, which provided the basis for a further orthogonal design based on three levels of different parameters. The data were finally analyzed by ANOVA, and the results showed that the optimal process parameters were 40 min of ultrasonic pretreatment, extraction temperature 80 °C, and ratio of solvent to material 30, which led to an average polysaccharide extraction yield of 5.29 %. Compared with conventional HWE, UAE uses less energy and has a higher extraction efficiency. In a study reported by Zhang and Kong (2007), a different ultrasonic device was used, but the whole extraction process was quite similar to that of Lie et al. (Fig. 3). Factors including extraction time, extraction temperature, and ratio of solvent to material were investigated using orthogonal design at three levels. The final optimized extraction condition was 60 min of ultrasonic pretreatment, extraction temperature 80 °C, and ratio of solvent to material 20, which is slightly different from the results of Lei and Li (2013). Although the

reason for this discrepancy between the two reports for optimized conditions is not known, it might be reasonable to assume that the differences in ultrasonic devices might generate a different acoustic cavitation effect, thus resulting in a different extraction yield. Therefore, the ultrasound power and frequency should be further investigated, which was not addressed in either study.

2.3 Microwave-Assisted Extraction

Microwave-assisted extraction (MAE), also called microwave-assisted process (MAP), or simply microwave extraction, is a newly evolved technique that combines microwave and traditional solvent extraction. Applied microwaves heat the extraction solvents and plant tissues during the process because the penetrated microwave energy into raw materials and extraction solvent generates a volumetrically internal heat source due to molecular friction. Thus, the mass transfer of target compounds is accelerated as a consequence of an increased extraction kinetic. The advantages of MAE include a shorter extraction time, less solvent, lower cost, and a higher extraction rate compared with traditional extraction methods (Rodriguez-Jasso et al. 2011; Eskilsson and Björklund 2000; Srogi 2006). Generally, a selective and quick extraction of natural chemical ingredients can be achieved by MAE, which thus can be regarded as a cost-effective and environmentally friendly extraction method (Zhang et al. 2014b; Taghvaei et al. 2014; Barrera Vázquez et al. 2014). In our previous work, extraction of polysaccharides from *Fructus Corni* using UAE was investigated using a single-factor design and orthogonal test. Various factors, such as microwave power, length of microwave treatment, ratio of solvent to material, and extraction time were optimized to improve the extraction yield of polysaccharides. Based on the results of single-factor experiments, orthogonal test design were carried out using $L_9(3^4)$. The optimal extraction parameters were concluded to be the following: microwave treatment for 10 min with a power of 560 W after a preextraction for 70 min, with the ratio of material to water 1:25 (g/mL). The average yield was 10.53 %, which is higher than using traditional extraction methods (Wu et al. 2011). In another study, RSM was used to investigate the interactions of various factors affecting polysaccharide extraction from *Fructus Corni* using MAE. After employing the single-factor designs to obtain different levels, extraction conditions were optimized using RSM, and the final optimized extraction conditions were as following: soak time 120 min, microwave power 456 W, solvent-to-material ratio 33 (mL/g), and microwave extraction time 3.2 min. Using these optimal extraction parameters, the extraction yield of polysaccharides was 11.12 % (Hu et al. 2011).

2.4 Enzymatic-Assisted Extraction Technique

Another alternative environmentally friendly extraction method is enzymatic-assisted extraction (EAE), which has the advantage that enzymes serve as ideal catalysts because they hold inherent abilities to specifically and region-selectively catalyze

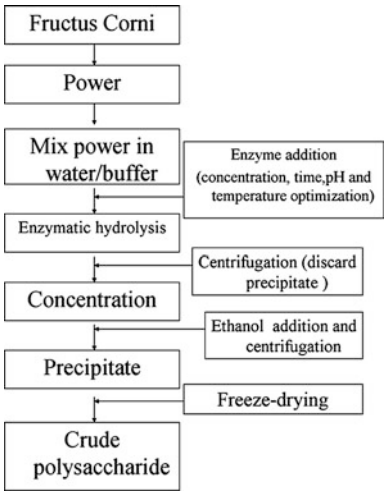

Fig. 4 Process of enzyme-assisted extraction (*EAE*) of polysaccharides from *Fructus Corni*

the degradation or disruption of cell walls and membranes, thus accelerating the mass transfer of target compounds into extraction solvent and as a consequence enabling a better release and more efficient extraction of bioactive compounds (Bahramian et al. 2011). Therefore, this method is regarded as an eco-friendly, greener, and cleaner chemical tool for food industry and pharmaceutical companies to extract new compounds. In comparison with conventional extraction methods, EAE exhibits properties of faster extraction, higher recovery, reduced solvent usage, and lower energy consumption. Enzymes such as pectinases, cellulases, and hemicellulases have been widely used for pretreatment of plant material prior to conventional methods for extraction (Puti et al. 2012), which can also significantly reduce the amount of solvent requirement. Application of EAE has been proved to be effective for natural ingredients, such as phenolic compounds, oils, and pigments when aiming for high extraction yields (Wu et al. 2005; Le and Le 2012; Jiao et al. 2014; Sowbhagya and Chitra 2010). Accumulated reports exist also for the application of EAE for polysaccharide extraction (Bahramian et al. 2011; Jiang 2014; Wang 2014; Qian 2014; Zhu et al. 2014). To obtain a more effective enzyme-assisted extraction, it must be optimized first by using a single enzyme or a combination of various enzymes, as well as optimal operation parameters such as temperature, pre- and actual extraction time, enzyme concentration, and optimal pH depending on the sources of plant materials selected. Figure 4 provides a summary of the application of EAE for crude polysaccharide extraction from *Fructus Corn*. Cheng et al. (2010) used a combination of various enzymes, including cellulase, pectic enzymes, and neutral proteases. The extraction process was optimized for the pretreatment of *Fructus Corni*, and the amount of used cellulase, pectic enzyme, and neutral protease was studied based on orthogonal test. The results showed that the amount of enzyme is 2.0 % cellulase, 2.0 % pectic enzyme, and 1.5 % neutral protease. Furthermore, the length of time for pretreatment, solvent pH, and temperature were all optimized using RSM. Data were analyzed using Design-Expert 7.0 software. ANOVA indicated that the quadratic polynomial model

is significant ($p < 0.01$), thus clearly indicating that the model fit well with the response. Moreover, the coefficient of multiple determination (R^2) is 0.9555, suggesting that a very high correlation was obtained. The determined optimum conditions for enzyme hydrolysis were temperature 50 °C, treatment for 69 min, and pH 3.8, with an extraction yield of 5.54 %. In another study by Chang (2011), the effect of pectin enzymes, variables such as the ratio of solvent to material, extraction time, extraction temperature, and amount of enzyme were investigated using the orthogonal test. Based on a single experiment, three levels of different parameters were selected, and the results showed that the extraction temperature was the most significant factor and extraction time is less significant compared with the others. This study determined the optimal extraction conditions were ratio of solvent to material 5 (mL/g), extraction time 6 h, extraction temperature 80 °C, and amount of pectin enzyme 0.55 g/L. Obviously, there is a discrepancy compared with the results of Cheng et al. (2010), thus further addressing the importance of thorough optimization of EAE depending on the selected enzymes for polysaccharide extraction from *Fructus Corn*.

2.5 Ultrasonic Microwave-Assisted Extraction

Considering the obvious advantages of both UAE and MAE techniques, particularly their abilities to reduce the extraction time and the consumption of solvent (Sporring et al. 2005), it is highly attractive to consider the combination of both methods to take advantage of UAE-enhanced mass transfer in inter- and intrafiber pores and MAE-intensified heat transfer. Thus, the combination of UAE and MAE is assumed to produce a high yield within a short reaction time. To this end, microwave- and ultrasound-assisted extraction (MUAE) has been developed to accelerate the extracting process and to improve extraction efficiency of natural ingredients (Cheng et al. 2011; Zhang and Liu 2008; Gergely et al. 2000; Chen et al. 2010). Optimization of MUAE-based polysaccharide extraction from *Fructus Corni* was reported by Shi (2014), who performed pretreatment of *Fructus Corni* powder using MAE prior to UAE. Variables including ultrasound time, temperature, ratio of solvent to material, and concentration of ethanol were evaluated using orthogonal array design. It was found that ultrasound time is the most significant factor for polysaccharide extraction, and the ratio of solvent to material is the least significant based on ANOVA analysis. The final determined optimal extraction conditions were extraction time 80 min, extraction temperature 60 °C, ratio of solvent to material 14 (mL/g), and concentration of ethanol 65 %, with a yield of 16.83 %.

3 Purification of *Fructus Corni* Polysaccharides

Extracted polysaccharides from plant materials using the above-mentioned methods are usually not pure enough for a direct characterization; therefore, commonly, further purification steps must be performed to remove undesired substances, such as proteins, phenolic compounds, amino acids, or monosaccharides.

In general, phenolic compounds can be eliminated by performing a methanolic extraction step (Palacios et al. 2011), which could even increase the effectiveness of extraction (Park et al. 2009). While remove of proteins can be achieved by performing a protease treatment followed by a trifluoroacetic acid (TCA, 10–20 %, w/v) precipitation or a direct TCA precipitation, both finally followed by centrifugation to remove aggregated proteins.

To purify polysaccharides, as the final step, various techniques, including ethanol precipitation (a ratio of 2:1, v/v) or combined with concentrated sodium chloride solutions to favor precipitation, fractionation by ammonium sulfate precipitation based on the molecular size of polysaccharides (Ragaee et al. 2008; Li et al. 2006), acidic precipitation with acetic acid, ion-exchange chromatography, gel filtration, and affinity chromatography (Jin et al. 2012), can be applied. In general, gel chromatography, such as size-exclusion chromatography, separates polysaccharides based on their molecular weights, while ion-exchange filtration separates neutral from acidic polysaccharides by changing elution buffers. To date, polysaccharides isolated from *Fructus Corni* are mainly neutral and acidic. Yang et al. (2008b) separated an acidic polysaccharide, which has a molecular weight of 8.7×10^4 Da, using ion-exchange chromatography packed with positively charged diethylaminoethyl-cellulose (DEAE-C) resin. In another study reported by Yang et al. (2008b), a neutral polysaccharide composed of glucose, galactose, xylose, and fucose with a molecular weight of 2.47×10^4 Da was identified using DEAE-C and a Sephadex G-200 column.

4 Physiochemical and Structural Features

The physiochemical and structural features of a polysaccharide are defined by its molecular weight, chain composition, configuration and conformational isomers, sequence order of monosaccharide residues, presence and position of branches, presence of glycosidic linkages, as well as number and location of appended noncarbohydrate functional groups (Johansson et al. 2006; Zhang et al. 2007b). Current available techniques to characterize the structural details of polysaccharides include both chemical and analytical methods. Chemical methods are usually used as the first step and followed by analytical strategies for a detailed determination. For example, to determine the chain composition of monosaccharides, acid hydrolysis using such compounds as trifluoroacetic acid (TFA), H_2SO_4, or HCl, is first applied then followed by monosaccharide profile determination using high-performance liquid chromatography (HPLC) or gas chromatography (GC) coupled with mass spectrometry (MS) (Agrawal 1992). For complex products, an *O*-methylation of polysaccharides is preferred to prepare samples for MS analysis because the *O*-methylated polysaccharides have the advantage of increased stability of ions and sensitivity during MS detection. While nuclear magnetic resonance (NMR) spectroscopy has a poor sensitivity in structural determination, it is a helpful tool for determining the configuration of polysaccharides (Laws et al. 2008; Wang et al. 2008b). Other biophysical techniques, like infrared spectroscopy

(Calonje et al. 1996; Kulicke et al. 1997), multiangle laser light scattering (Jelsma and Kreger 1975), or X-ray crystallography (Lee et al. 2010) can also be used for the structural determination of polysaccharides, but all have disadvantages of a high cost and limited availability. At this point, it is interesting to mention that chemical dyes that specifically interact with certain conformations can be applied under certain cases. For example, calcofluor, a chemofluorescent stain, can nonspecifically bind to β-linked polysaccharides, producing an intense green fluorescent sample, and therefore could enable distinction of the β-configuration of polysaccharides from that of α-configuration (Ko and Lin 2004). Other examples include detection using aniline blue in solution for single-helix conformation (Ogawa et al. 1994) and Congo red in alkaline solutions for glucans with high degrees of β-(1 → 6)-glycosidic bonds, which is usually arranged into a triple helix and can thus lead to a complex formation between the polysaccharide and the dye molecule through hydrogen-bond formation and/or hydrophobic interactions (Yang et al. 1999).

The molecular weight and composition of monosaccharides from polysaccharides isolated from *Fructus Corni* seem to vary, as evidenced by various reports (summarized in Table 1), which might be due to different purification processes or the sources of raw materials. Yang et al. (1999) isolated a water-soluble polysaccharide (Co-4), which has a molecular weight of 24,700 Da as determined using high-performance gel-permeation chromatography (HPGPC). The composition of this polysaccharide was determined using thin-layer chromatography, paper chromatography, GC–MS, and ^{13}C-NMR techniques, and results showed that it is composed of glucose, galactose, xylose, and fucose. Another polysaccharide, SZYP-2, separated by Chen et al. (2002) using HWE, macroporous resin decoloration, ethanol precipitation, and BUTYL-Sephadex G-200-column chromatography, is composed of rhamnose, arabinose, galactose, and glucose in a molar ratio of 1:3.3:3:3.8. Furthermore, another two polysaccharides, PFCC-I and PFCA-Ⅲ, were isolated from *Fructus Corni* by Li et al. (2003a, b), which they derived from physiochemical characterization and antioxidation activity investigation. The molecular weight of PFCC-I and PFCA-Ⅲ was determined to be 75,700 and 17,400 Da, respectively. The composition of monosaccharide includes xylose and glucose in a molar ratio of 18.8:81.2 for PFCC-I, while for PFCA-Ⅲ, it is composed of rhamnose, arabinose, and glucose in a molar ratio of 13.74:50.54:35.72. FCP5-A is an acidic polysaccharide that was isolated from *Fructus Corni* using water extraction and column chromatography by Yang et al. (2008b). Monosaccharide analysis using gas chromatography showed that FCP5-A has a molecular weight of 87,000 Da and is composed of rhamnose, arabinose, galactose, and galacturonic acid in a molar ratio of 1:5.7:0.6:1.2. While a CSZP polysaccharide with a molecular weight of 81,000 Da was separated by Wei and Cui (2006) using HWE, DEAE-32 ion-exchange chromatography and Sephacryl n300 HR gel filtration chromatography, its structure and the composition of monosaccharide still needs determination.

In contrast to the determination of molecular weight and composition of monosaccharide for those isolated polysaccharides from *Fructus Corni*, greater

Table 1 Polysaccharides isolated from *Fructus Corni*

No.	Compound name	Molecular weight (Da)	Composition of monosaccharide	Structures	Reference
1	Co-4	24,700	Glucose, galactose, xylose, and fucose	(1 → 4)β-D-glucan	(Yang et al. 1999)
2	SZYP-2		Rhamnose, arabinose, galactose, and glucose in the molar ratio of 13.3:3:3.8	Ara(1 → 4)Rhm (1 → 4)Ara(1 → 2,4)Rhm(1 → 3) Glc(1 → 3)Gal (1 → 4)Gal(1 → 6)Glc(1 → 2,6) Glc(1 → 4,6)Glc	(Chen et al. 2002)
3	PFCC-I	75,700	Xylose and glucose in the molar ratio of 18.8:81.2		(Li et al. 2003a)
4	PFCA-III	17,400	Rhamnose, arabinose, and glucose in a molar ratio of 13.74:50.54:35.72		(Li et al. 2003b)
5	FCP5-A	87,000	Rhamnose, arabinose, galactose, and galacturonic acid in molar ratio of 1:5.7:0.6:1.2	Rha(1 → 4)Gal with side chain attached to O-4 of Rha	(Yang et al. 2008b)
6	CSZP	81,000			(Wei and Cui 2006)

efforts are required to determine structure and molecular conformation of polysaccharides. Structural analysis of a water-soluble polysaccharide (Co-4) showed that Co-4 contains a backbone composed of 1,4-linked β-D-glucan residues, with branches attached to O-6 in some residues. The branches contain α-D-Xyl (1→,α-D-Xyl(1 → 2)) α-D-Xyl(1→),β-D-Glc(1→,β-D-Gal(1 → 2)) α-D-Xyl(1→,Fuc (1 → 2) β-D-Gal(1 → 2) α-D-Xyl(1 →)) (Yang et al. 1999) (Fig. 5). The structural feature of SZYP-2 was assayed by capillary gas chromatography. The glycosidic linkages of SZYP-2 is Ara(1 → 4)Rhm(1 → 4)Ara(1 → 2,4)Rhm(1 → 3) Glc(1 → 3)Gal(1 → 4)Gal(1 → 6)Glc(1 → 2,6)Glc(1 → 4,6)Glc (Fig. 6) (Chen et al. 2002). The structural feature of an acidic polysaccharide (FCP5-A) from *Fructus Corni* was also investigated using various strategies, including infrared spectroscopy (IR), GC, partial hydrolysis with acid, uronic acid reduction, methylation, GC-MS, and ^{13}C-NMR analysis. The results indicate that a backbone is composed of 1,2-linked Rha and 1,4-linked Gal, with branches attached to O-4 of rhamnosyl residues. The branches contain highly branched arabinan and short linear 1,3-linked galactan (Fig. 7) (Yang et al. 2008b).

5 Bioactivity of Polysaccharides from *Fructus Corni*

5.1 Immunomodulatory Activity

Polysaccharides are one of the main classes of bioactive substances identified in fungi, algae, and higher plants. They display broad immunomodulatory activity properties (Kouakou et al. 2013; Yao et al. 2009). *In vitro* cell culture analysis revealed that polysaccharides could improve the biological activity of interleukin 2 (IL-2), a protein that regulates the activities of white blood cells (leukocytes, often lymphocytes) responsible for immunity; in other words, IL-2 constitutes a part of the body's natural response in discriminating "own" and "not own" factors under microbial infection conditions. This result thus provides clear evidence of the specific immunomodulatory

activity of polysaccharides from *Fructus Corni* on immune cells (Jiang et al. 2010). In another study (Du et al. 2008a), it was demonstrated that polysaccharides from *Cornus officinalis* both in crude and processed form showed a beneficial effect on an immune-suppressed rat model induced by cyclophosphamide. The polysaccharides showed an enhanced effect on nonspecific immunity, specific humoral immunity, and specific cellular immunity when applied in immune-depressed mice; the processed form possesses a dramatically increased function. Improved effects of processed polysaccharides are in agreement with another study performed by Yao et al. (2009), who used a low-immunity mice model. After 9 days of polysaccharide treatment, the blood sample was taken from the eye pit to analyze the concentration of serum agglutinin, which was used as an indicator to see whether *Fructus Corni* polysaccharides can improve humoral immunity. The data demonstrated that compared with unprocessed polysaccharides, the processed form significantly improves the concentration of serum agglutinin and thus can benefit the body-specific immune function.

5.2 Antioxidant Activity

Free radicals induced by oxidative stress are believed to be one of the leading causes of aging and various diseases, including cardiovascular diseases, cancer, multiple sclerosis, Parkinson's disease, autoimmune disease, and senile dementia (De Lima et al. 2004; Lu et al. 2010; Zeng et al. 2014). Accumulated evidence suggests that natural polysaccharides function as a promising antioxidant (Zhang et al. 2008; Sun et al. 2014; Zhao et al. 2013; Li et al. 2003c). Isolated polysaccharides from *Cornus Officinalis* Seib. et Zucc were further fractionated using ethanol precipitation at various concentrations to investigate the antioxidant activities of different polysaccharides (Zhang et al. 2008). The antioxidation capacity of fractionated polysaccharides was measured using methods based on Fenton reaction, a commonly used nitroblue tetrazolium (NBT) photo-reduction method. It was found that the polysaccharides precipitated by 50% ethanol had the strongest free radical scavenging activity at a polysaccharide concentration of 1.2 mg/mL, with a scavenging rate for hydroxyl free radical and superoxide anion of 89.9 % and 87.1 %, respectively. Polysaccharides prepared with 90 % ethanol precipitation can inhibit lipid oxidation, even showing a comparable antioxidant activity against autoxidation of lard stored in an oven with that of 2,6-Di-tert-butyl-4-methyl phenol [$C_{15}H_{24}O$, (BHT), also known as antioxidant 264], a widely used natural antioxidant in food chemistry.

In vitro evaluation of purified polysaccharides PFCC-I and PFCA-Ⅲ from *Fructus Corni* as a potential antioxidant (Li et al. 2003a, b; Ou and Liu 2007) found that PFCA-III not only showed a strong protection activity on axunge and gingili against oxidation, but also showed scavenging actions towards Fenton-reaction-generated hydroxyl free radicals as well as superoxide anions generated by a pyrogallol autoxidation system. The EC50 of PFCA-III on hydroxyl free radicals was 430 mg/L, and the scavenging rate of PFCA-III on superoxide anion was 21.5 % at a concentration of 100 mg/L. The EC50 of PFCC-I on hydroxyl free radical and superoxide anion was 80 and 34.9 μg/mL, respectively.

5.3 Antitumor Activity

Because of the immunological enhancing property of polysaccharides, they have also been widely used in tumor therapies, as confirmed by biochemical/medical evidence (Bejima et al. 2000). This is because polysaccharides can activate various immune responses in the host without observed harmful body effects. Using an S180 rat model, the antitumor effects and underlying immunologic mechanism of polysaccharides from *Fructus Corni* were found to noticeably restrain tumor growth in S180 rats ($P < 0.01$) (Zou et al. 2012). Further mechanism analysis revealed that the expression of the cluster of differentiation 4 ($CD4^+$) T-helper white blood cells was increased while the expression of $CD8^+$ T cells in peripheral blood was decreased, indicating an improved immunity. In addition, an increase in IL-2, a protein that regulates the activities of white blood cells and serves as part of the body's natural response in discriminating between foreign ("nonself") and host ("self") organisms. A decrease in IL-4 was also recorded. All the above observed effects are in a dose- and concentration-dependent manner.

Effects of polysaccharides from *Fructus Corni* on apoptosis were also investigated (Wang et al. 2012a) using lung carcinoma A549 cells by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) assay, a colorimetric assay to assess cell viability. The results showed that polysaccharides of *Fructus Corni* displayed a strong inhibiting effect against cell multiplication. The expression pattern of apoptosis-related genes in lung carcinoma A549 cells was also analyzed using agarose-gel electrophoresis (AGE), which showed a ladder-shaped DNA strap with ~200 base-pairs of difference among various ladders. Further immunohistochemistry using streptavidin–peroxidase demonstrated that B-cell lymphoma 2 (Bcl-2, an important antiapoptotic protein involved in cell-death regulation) expression was down-regulated, while the expression of apoptosis regulator Bax (also known as Bcl-2-like protein 4, a protein that promotes apoptosis) was up-regulated, thus suggesting polysaccharides exert an antitumor effect. Increase of Bax expression in HeLa cells was also observed when the cells were treated with various concentrations of polysaccharides for 24 h (Wang et al. 2012b), which was correlated with a morphological change in the shape of HeLa cells, as observed using an upside-down microscope. Together, these results suggest that polysaccharides of *Fructus Corni* can indeed serve as an antitumor compound, as they promote Bax expression and thus induce tumor-cell apoptosis.

5.4 Antiaging Effect

Although aging is an inherently complex process, accumulation of oxidative stresses is believed to be an important contributor involved in the aging processes (Zhang et al. 2003; Jin et al. 2009). Antiaging effects of *Fructus Corni* have been recorded and demonstrated using both *in vitro* and *in vivo* methods. Ou et al. (2010) investigated the effects of polysaccharides of *Fructus Corni* using human dermal fibroblast (HDF) cell system and found that the cell viability of HDF can be improved by polysaccharides.

In another study, Wang et al. investigated HDF cell morphology after supplementation with polysaccharides of *Fructus Corni* from the 40th generation of HDF cell culture. They determined the cell activity by MTT assay and the expression pattern of key genes involved in aging, including cyclin D1 (a protein required for G1/S transition of cell cycle, whose aberrant behavior such as mutation or overexpression leads to altered cell-cycle progression and thus contributes to tumorigenesis) and cyclin-dependent kinase 4 (CD4, also known as cell-division protein kinase 4, which is a catalytic subunit of the protein kinase complex important for cell-cycle G1-phase progression, and mutations of this protein lead to tumorigenesis) using reverse transcription polymerase chain reaction (RT-PCR). They found that polysaccharide treatment increased cell activity and the content of CDK4 messenger RNA (mRNA) but decreased the content of cyclin D1 mRNA. These data suggest that a possible mechanism of antiaging effect of polysaccharides of *Fructus Corni* is to regulate the expression of cyclin D1 and CDK4 in HDF-senescence-model cells.

Using aging in a rat model induced by D-galactose (Zhou et al. 2011; Qin et al. 2011), it was found that polysaccharide treatment enhanced the antioxidation activity of superoxide dismutase (SOD), inhibited lipid peroxidation, and decreased the activity of acetylcholinesterase (also known as AChE, or acetylhydrolase, a hydrolase that hydrolyzes the neurotransmitter acetylcholine involved in a range of central nervous system diseases), and up-regulated the mRNA level of nerve growth factor (NGF, a small protein important for growth, maintenance, and survival of certain target nerve cells). In an aging mouse model of kidney deficiency (Fu et al. 2007), polysaccharides of *Fructus Corni* were observed to prolong the swimming time of mice with weight loading and the ability of antihypoxia, to promote SOD activity and to decrease the content of malondialdehyde (MDA, a naturally occurring reactive species and indicative marker for oxidative stress). All these results suggest that polysaccharides of *Fructus Corni* can be used as antiaging reagents to benefit body health.

5.5 Sexual Function Effect

Shao et al. (2010) demonstrated that polysaccharides of *Fructus Corni* increase the sexual function of hemicastrated rats, possibly by adjusting the hypothalamus–pituitary–gonadal axis. In that study, polysaccharides at various doses were given to Sprague–Dawley (SD) rats with right testis extirpated. Both mating and erective tests were assessed. The level of serum sex hormone testosterone was increased, as determined with radioimmunoassay (RIA). It was found that the incubation period of penis erection and the mounting period were shortened in the group treated with *Fructus Corni* polysaccharides and the percentage of mounting rats increased. Significant increase in the organ coefficient of foreskin gland and seminal vesicle-prostate gland as well as sperm count and vigor were observed ($P < 0.01$). All results suggest that polysaccharides have a positive effect on sexual function. In another study (Jiang et al. 2013), *Fructus Corni* polysaccharides were shown to benefit damaged testis in a dose-dependent manner, as investigated on rats in which

testis-tissue damage was induced by a warm bath. This conclusion was based on the investigation of morphological changes in testis organ, sperm amount and motility in epididymis, SOD activity, MDA content, and germ-cell apoptosis after 14 days of intragastric treatment of SD rats with *Fructus Corni* polysaccharides.

5.6 Hepatoprotective Activity

Yao et al. (2009) reported that the administration of *Fructus Corni* polysaccharides at a dose of 10 g/kg body weight prevents liver injury induced by CCl_4. The contents of the alanine transaminase [ALT, also called serum glutamic–pyruvic transaminase (SGPT) or alanine aminotransferase (ALAT), a transaminase enzyme clinically measured as a specific indicator of liver inflammation for diagnostic evaluation of hepatocellular injury to determine liver health] in serum of injured mice and MDA in injured liver tissue decreased, while an increased SOD activity in injured liver tissue was observed. It was therefore hypothesized that *Fructus Corni* polysaccharides have a nourishing effect on liver and kidney. A similar hepatoprotective effect of processed *Corni Fructus* extracts on D-galactose-induced liver injury in mice was also observed Jiang et al. (2013).

6 Conclusion

Despite accumulated investigations dealing with the extraction of polysaccharides from *Fructus Corni*, and mounting evidence suggests that polysaccharides have important pharmacological activities, the underlying molecular mechanisms of how the chemical structures of polysaccharides correlate with their respective bioactivities are still ill-defined, particularly because of the lack of detailed chemical structures and their chain conformations. Therefore, future extensive investigations focussing on such mechanisms are urgently required for application for pharmaceutical purposes. Moreover, although traditionally *Fructus Corni* has been used as a common method to nourish liver and kidney, and although it is believed that polysaccharides function as one of the bioactive compounds involved in that function, the specific utilization of *Fructus Corni* polysaccharides remain to be determined. Considering the wide application of polysaccharides from other sources being used in the food industry, it is reasonable to assume that *Fructus Corni* polysaccharides and their derived specific products hold high potential for broad applications in food or for pharmacological purposes pending extensive scientific investigations.

Bioactivity of Chitosan Derivatives

52

Mani Prabaharan

Contents

Abstract

Chitosan, a natural-based polymer obtained by alkaline deacetylation of chitin, is composed of glucosamine and *N*-acetylglucosamine monomers. Chitosan and its derivatives have a great potential for a wide range of applications in biomedical, pharmaceutical, food, cosmetics, and environmental fields due to its biodegradability, biocompatibility, nontoxicity, and versatile chemical and physical properties. For a breakthrough in utilization, especially in the biomedical field, chemical modification of chitosan will be a key point that can introduce desired properties and enlarge the field of the potential applications of chitosan. Different approaches have been reported to prepare chitosan derivatives and chitosan oligomers with low, medium, and high molecular weights. In this chapter, the properties such as biodegradation, antimicrobial activity, anti-inflammatory and tissue regeneration activity, wound-healing properties, antioxidant activity, and antitumor activity of chitosan and its derivatives are discussed in detail.

Chitosan • Bioactivity • Antimicrobial activity • Tissue engineering • Antioxidant • Wound healing

1 Introduction

Chitin, which is the most abundant biopolymer in nature after cellulose, is a polysaccharide that is widely spread among marine and terrestrial invertebrates and lower forms of a plant kingdom (Jayakumar et al. 2011). Chitosan is a poly (aminosaccharide), normally obtained by alkaline deacetylation of chitin as shown in Fig. 1. This naturally occurring polymer has a repeating structural unit of 2-acetamido-2-deoxy-β-D-glucose (Prabaharan et al. 2008). Chitosan is semicrystalline and the degree of crystallinity is a function of the degree of deacetylation. Chitosan allows specific chemical modifications since it has primary amine groups at the C-2 position and primary alcoholic groups at the C-6 position of its monomeric units. These reactive sites enable the grafting of a large variety of properly functionalized molecules (Prabaharan and Mano 2005b; Jayakumar et al. 2005). Chitosan is available in a variety of useful forms, and its unique chemical and biological properties such as biodegradability, bioactivity, and biocompatibility make it very attractive biomaterials. It is extensively used in many types of applications such as treatment of wastewater, chromatographic support, enzyme immobilization, wound-healing dressing, dental application, adhesion bandages for surgery, and drug-delivery system (Prabaharan et al. 2007; Prabaharan and Mano 2005a, 2007). The unique properties of chitosan, such as biodegradability, non- toxicity, antimicrobial activity, and polycationic nature, make it suitable for a number of applications.

Bioactivity of chitosan and its derivatives is associated with several phenomena, including biodegradation, stimulation of natural resistance, and direct action against pathogens. Biocompatibility has been defined as an ability of the biopolymers to perform with an appropriate host response in the specific application (Struszczyk 2002). The presence of these phenomena in the formation of chitosan can be linked to the type of chitosan, pathogens, or organisms attacked. Action of chitosan and its derivatives depends on the type of existing hazards, like infection of phytopathogenic bacteria and fungi, viruses or plant growth stimulation, wound healing, and the structure of chitosanous agents (Struszczyk 2002). Bioactivity and biocompatibility of chitosan and its derivatives is a function of several phenomena related mainly to their structural parameters such as average molecular weight, degree of deacetylation, distribution of both *N*-acetylglucosamine and glucosamine in polymer chain, crystallinity, porosity, charge character, and type of existing hazards (Struszczyk 2002). This chapter focuses on the biological activities of chitosan and its derivatives, which are correlated with their structures and physicochemical properties. This overview provides insights into these activities and for developing chitosan and its derivatives with special biological activity.

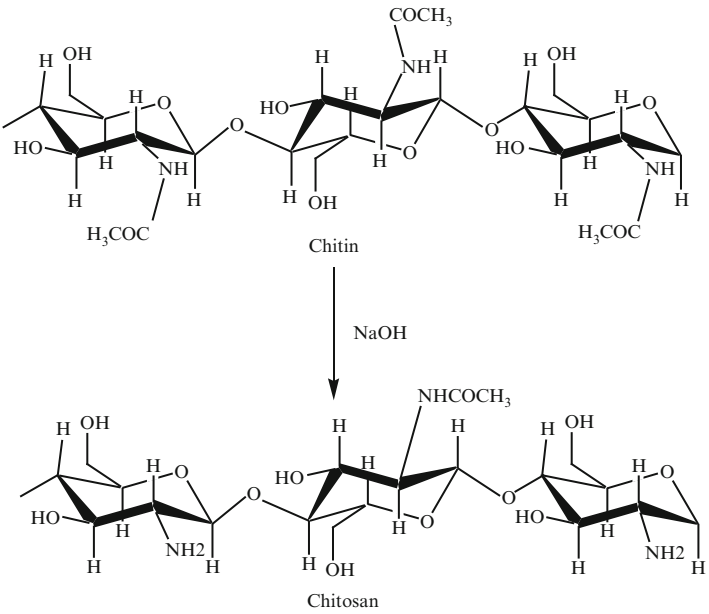

Fig. 1 Reaction scheme for the preparation of chitosan from chitin

2 Biodegradation of Chitosan

Chitosan and its derivatives are degraded by various lysozymes, which are present in plants and animals. A residual number of acetyl groups and the free hydroxyl group at C3 of the sugar units are required in order to observe reasonable hydrolysis rates (Tokura et al. 1984). Chitin deacetylase, detected in many fungi and insect species, catalyzes the hydrolysis of *N*-acetamido bonds in chitin to produce chitosan (Tsigos et al. 2000). Chitinases are another type of enzymes that are present in plant seeds, tubers, and flower organs, and they are associated with stimulation of self-defense in response to an exogenous attack by plant pathogens and/or contact with chitooligosaccharides (Santos et al. 2007). They have been detected in extracellular, cytosolic, and microsomal fractions from those organisms.

The presence of chitinases in human serum plays a defensive role against chitin-containing pathogens (Overdijk et al. 1996). Papain, an enzyme that is used in the food industry for the tenderization of meat by controlled hydrolysis of muscle protein, may be applied as a hydrolyzing agent of chitosan. This enzyme degrades long chain chitosan at room temperature, producing low molecular oligosaccharides, which show a number of attractive biological actions and can be used as elicitors of plant defense mechanisms against pathogens, accelerators of the root nodule formation, antitumor agents, material for synthesis of biologically active compounds, anti-inflammatory drug, etc. (Kobayashi et al. 1997).

The biodegradability of thiolated chitosans in comparison to unmodified chitosan was reported by Laffleur et al. (2013). In this study, two chitosan–thioglycolic acid conjugates and one chitosan–mercaptonicotinic acid conjugate were obtained. The obtained chitosan–thioglycolic acid conjugate displayed 267.7 μmol and 116.3 μmol of immobilized thiol groups. With 325.4 μmol immobilized thiol groups, chitosan–mercaptonicotinic acid conjugate displayed the most content of thiol groups. The enzymatic degradability of these thiomers was investigated by viscosity measurements with a plate–plate viscometer. In rheological studies subsequently the modification proved that chitosan–thioglycolic acid conjugates with a higher coupling rate of thiol groups were not only degraded to a lesser extent by 20.9–26.4 % but also more slowly. Chitosan–mercaptonicotinic acid was degraded by 31.4–50.1 % depending on the investigated enzyme and even faster than unmodified chitosan. According to these results the biodegradability can be influenced by various modifications of the polymer which showed in particular that the rate of biodegradation is increased when mercaptonicotinic acid is the ligand, whereas the degradation is hampered when thioglycolic acid is used as ligand for chitosan.

Enzyme-degradable dextran–chitosan hydrogels with aligned pores were prepared via unidirectional freezing followed by cryogelation method (Wu et al. 2013). In this study, microtubular pores from 20 to 100 μm were obtained in the swollen state of the hydrogels. It was found that chitosan can be hydrolyzed by chitosanase solution into short oligosaccharide fragments that leads to collapse and degradation of the gel network. In this study, the degradation rate was found to be optimized by adjusting the hydrogel composition and chitosanase concentration. Recently, Costa Pinto et al. (2014) studied the degradation of poly(butylene succinate) and chitosan using lipase and lysozyme, respectively. In this study, the subcutaneous implantation of the scaffolds was performed to assess tissue response. The type of inflammatory cells present in the scaffold was determined histologically and immunohistochemistry. The results showed that the water uptake of the scaffolds was found to be increased in the presence of lipase or lysozyme. The lysozyme combined with lipase had a notable effect on the in vitro degradation of the scaffolds. The in vivo implantation study showed a normal inflammatory response in the presence of neutrophils and macrophages, lymphocytes, and giant cells.

3 Antimicrobial Activity

Chitosan and its derivatives are found to have antimicrobial properties. They have several advantages over commercial disinfectants such as a high antibacterial activity, broad spectrum of activity, and a low toxicity over animal and plant cells (Liu et al. 2001). The antimicrobial action of the chitosan and its derivatives depends on the following factors: (i) target organism, (ii) intrinsic factors of the chitosan (positive charge density, molecular weight, hydrophobic and hydrophilic characteristics, chelating capacity), (iii) physical state factors, and (iv) environmental factors (ionic forces, pH, temperature, time) (Badawy and Rabea 2011).

3.1 Action Against Plant Pathogens

Since chitosan and its derivatives have antimicrobial and plant defense elicit function, they are considered as useful pesticides in the control of plant diseases. Chitosan's inhibition was observed on different development stages such as mycelia growth, sporulation, spore viability and germination, and the production of fungal virulence factors (Badawy and Rabea 2011). The experimental data indicate that chitosan or its oligosaccharides may inhibit the transcription or accumulation of RNA. Chitosan induces different mechanical defensive reactions in plant cells, such as plugging intercellular spaces with amorphous electron opaque substances, accumulation of chitinases, synthesis of proteinase inhibitors, lignification, induction of callous synthesis, and the formation of cell wall appositions, which may be implicated in restricting fungal invasion (Ghaouth et al. 1992). It is also known that the positively charged amine groups in chitosan form complexes with the cell DNA, which limit the growth of fungus (Li et al. 2011). Chitosan can also induce a set of plant genes known as disease resistance response and pathogenesis-related genes. Some of these genes encode enzymes for secondary pathways of phytoalexins and hydrolytic enzymes such as RNAase, chitinase, and B-glucanase, thionins or plant defensins, and peroxidases that are directly antimicrobial or capable of generating phenolic polymers such as lignin (Hadwiger 1999).

The fungicidal activity of chitosan samples was tested against plant pathogenic bacteria of *Agrobacterium tumefaciens*, *Corynebacterium fascians*, *Erwinia amylovora*, *E. carotovora*, *Pseudomonas solanacearum*, and *Sarcina lutea* (Badawy et al. 2006). The results indicated that chitosans with higher molecular weight were more potent in bactericidal activity than low molecular weight chitosan. The oligochitosans prepared by enzymatic depolymerization were found to be more effective than the original chitosan in inhibiting mycelial growth of nine phytopathogens: *F. graminearum*, *Phytophthora capsici*, *Verticillium dahliae*, *A. solani*, *B. cinerea*, *C. orbiculare*, *Exserohilum turcicum*, *F. oxysporum*, and *Pyricularia oryzae* (Xu et al. 2007). Hirano and Nagao (1989) reported the effect of high and low molecular weight chitosan on different fungal species, and they found that the best fungicidal activity on mycelia occurred in media supplemented with low molecular weight chitosan. Meng et al. (2010) reported that both of chitosan (350 kDa) and oligochitosan (6 kDa) strongly inhibited spore germination and mycelial growth of two phytopathogenic fungi *A. kikuchiana* Tanaka and *Physalospora piricola* Nose.

Chittenden and Singh (2009) tested the control of two sapstain fungi *Leptographium procerum* and *Sphaeropsis sapinea* by a combination of chitosan or chitosan oligomer and an albino strain of *Trichoderma harzianum*. There was no mycelial growth of the fungi regardless of chitosan concentrations used when *L. procerum* or *S. sapinea* was simultaneously inoculated with *T. harzianum*. The dose response of chitosan or chitosan oligomer was found to be apparent when *T. harzianum* was not inoculated with test fungi. There was a greater growth reduction at higher concentrations (0.075–0.1 %) of chitosan, and overall chitosan oligomer was more effective than chitosan aqueous solution. The results of this study showed that chitosan controlled the germination of spores and the combination of chitosan and *T. harzianum* inhibited spore germination.

Chitosan shows an antiviral activity against plant viruses. It was found that chitosan inhibited the productive infection caused by the bacteriophage. The efficiency of inhibition of bacteriophage was found to be depending on the final concentration in the medium (Kochkina et al. 1995). Major factors of suppressing phage infections by chitosan are phage particle inactivation and inhibition of bacteriophage reproduction at the cellular level. Obviously, chitosan may be used for induction of phagoresistance in industrial microorganism cultures to prevent undesirable phagolysis caused by inoculum contamination by virulent bacteriophages or by spontaneous prophage induction in lysogenic culture.

Anusuya and Sathiyabama (2013) investigated the defense proteins present in the exudates from water-imbibed and chitosan-imbibed seeds of chickpea. The results showed that chickpea seeds immersed in chitosan released a higher amount of proteins in the exudates when compared to the seeds immersed in water. The exudate obtained from chickpea seeds immersed in chitosan solution exhibited a new isoform of chitinase, chitosanase, and protease inhibitors. These exudates have shown an in vitro inhibitory effect on the growth of the fungus, *Fusarium oxysporum f.sp. ciceri*. These results suggest that seed exudates protect seeds during their germination from soil pathogens.

Antimicrobial properties of chitosan coatings and chitosan enriched with bioactive compounds and essential oils were determined by in vitro and in vivo assays on minimally processed broccoli (Alvarez et al. 2013). The efficiency of chitosan with bioactive compounds and essential oils in improving the safety of broccoli was tested against the native microflora. Also, its effects on the survival of *Escherichia coli* and *Listeria monocytogenes* inoculated in broccoli were evaluated. In vitro assays performed in tea tree, rosemary, pollen, and propolis demonstrated significant inhibitory effects on *E. coli* and *L. monocytogenes* counts, while pomegranate and resveratrol presented reduced activity. In vivo application of these bioactive compounds on broccoli exerted a bacteriostatic effect on mesophilic and psychrotrophic populations except for rosemary. The application of chitosan or enrichment with bioactive compounds and essential oils resulted in a significant reduction in mesophilic and psychrotrophic counts. Between 5 and 7 days, significant reductions of mesophilic and psychrotrophic counts were observed in samples treated with chitosan with bioactive compounds. The enrichment with bioactive compounds improved the antimicrobial action of chitosan. The application of these coatings did not introduce deleterious effects on the sensory attributes of broccoli. The results showed that chitosan coatings enriched with bioactive compounds and essential oils were a good alternative for controlling not only the microorganisms present in broccoli but also the survival of *E. coli* and *L. monocytogenes*.

Different types of chemically modified chitosan derivatives were reported as improved antimicrobial active compounds. For example, Muzzarelli et al. (2001) prepared chemically modified chitosans and tested their antifungal activities against *Saprolegnia parasitica*. Results showed that *S. parasitica* did not grow normally on the first day for methylpyrrolidinone chitosan and *N*-phosphonomethyl chitosan, and on the second day for *N*-carboxymethyl chitosan, a tightly packed precipitate was present at the bottom of the test tubes instead of the fluffy fungal material as in

the control. In contrast, *N*-dicarboxymethyl chitosan was found to favor fungal growth, while dimethylaminopropyl chitosan did not significantly differ from the control.

N,*N*,*N*-Dimethylalkyl chitosans as quaternary and water-soluble chitosan compounds were recently prepared to test their antimicrobial activities against the plant pathogenic bacteria *A. tumefaciens* and *E. carotovora* and fungi *B. cinerea*, *F. oxysporum*, and *P. debaryanum* (Badawy 2010). Quaternary chitosans enhanced the antibacterial activity, and *N*,*N*,*N*-dimethylpentyl chitosan was found to be active with MIC 750 and 1,225 mg/L against *A. tumefaciens* and *E. carotovora*, respectively. Both of *N*,*N*,*N*-dimethylpentyl chitosan and *N*,*N*,*N*-dimethyloctyl chitosan were active in fungal mycelial growth inhibition of *B. cinerea*, *F. oxysporum*, and *P. debaryanum*.

Charged derivatives of chitosan, *N*-sulfofurfuryl chitosan and *N*-[(2-hydroxyl-3-trimethylammonium)propyl]chitosan chloride, were prepared by Channasanon et al. (2007). The bioactivity of these films on the treated PET substrate was tested against selected proteins having a distinctive size and charge. It has been demonstrated that the proteins adsorbed onto the assembled film in a multilayer fashion, implying that the diffusion of the proteins within the multilayer structure has occurred. Since both *N*-[(2-hydroxyl-3-trimethylammonium)propyl]chitosan chloride and *N*-sulfofurfuryl chitosan are soluble over a broader pH range and possess different bioactivity from chitosan, these two charged derivatives can be potential candidates for biomedical applications.

3.2 Action Against Animal Pathogens

Several mechanisms of antimicrobial action of chitosan have been suggested in the literature. One of the mechanisms is the interaction between the positive charge of the chitosan and the negative charge of the microbial cell wall for the agglutination of the microbial cells and inhibition of growth (Senel et al. 2000; Avadi et al. 2004). It was also reported that when interacting with the bacterial cell, the chitosan promotes displacement of Ca^{2+} of the anionic sites of the membrane resulting in cell damages. Other studies proposed that the antimicrobial action is closely related to the physical–chemical properties of the polymer and the features of the cell wall of the microorganism (Costa Silva et al. 2006). It was reported that chitosan with low molecular weight penetrates in the cell and is linked to the microorganism DNA inhibiting the transcription and consequently the translation, whereas the high molecular weight chitosan acts as a chelant agent, binding to the cell membrane (Pedro et al. 2009).

Chung et al. (2004) have observed that the chitosan presents a better bactericidal and bacteriostatic action for Gram-negative bacteria than Gram-positive due to the composition of phospholipids and carboxylic acids of the bacterial cellular wall. These results proposed that the effects of the chitosan are distinct in Gram-positive and Gram-negative bacteria. In the Gram-positive bacteria, the chitosan of high molecular mass may form films around the cell that inhibit the absorption of

nutrient. In the Gram-negative bacteria, chitosan of low molecular mass penetrates more easily that may cause riots in the metabolism of these microorganisms. It was observed that the antimicrobial activity of chitosan is directly related with the absorption of the polysaccharide to the bacterium that will cause alterations in the cellular wall structure, consequently, in the permeability of the cellular membrane (Ikinci et al. 2002; Goy et al. 2009).

Chitosan microparticles have been shown to reduce *E. coli* shedding in a cattle model. However, the underlying mechanism of chitosan microparticles on reducing the shedding of this pathogen remains unclear. To understand the mode of action, Jeon et al. (2014) studied molecular mechanisms of antimicrobial activity of chitosan microparticles using in vitro and in vivo methods. They report that chitosan microparticles are an effective bactericidal agent with capability to disrupt cell membranes. Binding assays and genetic studies showed that outer membrane protein OmpA of *E. coli* is critical for chitosan microparticles binding, and this binding activity is coupled with a bactericidal effect of chitosan microparticles. This activity was also demonstrated in an animal model using cows with uterine diseases. Chitosan microparticles treatment effectively reduced shedding of intra-uterine pathogenic *E. coli* (IUPEC) in the uterus compared to antibiotic treatment. It was found that chitosan microparticle treatment did not induce bacteriophage or Shiga toxins in *E. coli* that suggests that chitosan microparticles can be a potential candidate to treat infections caused by this pathogen.

The antibacterial activities of *N*-alkylated disaccharide chitosan derivatives against *E. coli* and *S. aureus* were investigated (Yang et al. 2005). The results showed that the antibacterial activity of chitosan derivatives was affected by the degree of disaccharide substitution (DS) and the kind of disaccharide present in the molecule. Regardless of the kind of disaccharide linked to the chitosan molecule, a DS of 30–40 %, in general, exhibited the most pronounced antibacterial activity against both test organisms. *E. coli* and *S. aureus* were the most susceptible to cellobiose–chitosan derivatives and maltose–chitosan derivatives, both with DS values of 30–40 %, among the various examined chitosan derivatives. Although the disaccharide chitosan derivatives showed less antibacterial activity than native chitosan at pH 6.0, they exhibited higher activity at pH 7.0. The antibacterial activity of the chitosan derivatives against *E. coli* increased as the pH increased above 5.0 and reached a maximum around pH 7.0–7.5. The effect of pH on the antibacterial activity of chitosan derivatives against *S. aureus* was not as significant as that observed with *E. coli*. Population reductions of *E. coli* or *S. aureus* in nutrient broth increased markedly when the concentration of chitosan derivatives was increased from 0 to 500 mg/kg, while no marked increase in population reduction was found with further increases, even up to 2,000 mg/kg. From these studies, it is clear that although there are many reports discussing chitosan's antimicrobial activity in different conditions with conflicting results, they all confirmed that chitosan and its oligosaccharides have strong antimicrobial effects and are safe for human use.

Recently, Jena et al. (2012) synthesized chitosan-stabilized silver nanoparticles and analyzed their activities. In this study, silver nanoparticles were synthesized

using chitosan as both a stabilizing and a reducing agent. Chitosan–silver nanoparticles exhibited potent antibacterial activity against different human pathogens and also impeded bacterial biofilm formation. SEM analysis indicated that chitosan–silver nanoparticles kill bacteria by disrupting the cell membrane. Chitosan–silver nanoparticles showed no significant cytotoxic or DNA damage effect on macrophages. Propidium iodide staining test pointed out that active endocytosis of chitosan–silver nanoparticles resulted in reduced intracellular bacterial survival in macrophages. This study indicates that chitosan-based silver nanoparticles kill bacteria without harming the host cells at a specific dose.

4 Anti-inflammatory and Tissue Regeneration Activity

The anti-inflammatory activity of chitosan is due to the acid hydrolysis of chitosan to glucosamine hydrochloride or its sulfate, phosphate, and other salt preparation by salt conversion. These monosaccharides are structural units of the proteoglycans contained in connective tissue and cartilage. These tissues can be repaired and regenerated by absorbing these monosaccharides directly when they are damaged or inflamed (Olivier et al. 2004). Therefore, these monosaccharides are an effective treatment for preventing and curing rheumatoid arthritis as well as bone hyperplasia and are used as antiarthritic drugs in clinical practice. Moreover, unlike some common antiarthritic steroidal anti-inflammatory drugs or analgesic and anti-inflammatory drugs, these monosaccharides have no side effects and can be taken for a long period. The clinic experiments indicated that taking glucosamine for 2 weeks can eliminate arthritic pain and improve movement in patients suffering from severe arthritis.

Chung et al. (2012) studied the anti-inflammatory effects of low molecular weight chitosan oligosaccharides prepared from high molecular weight chitosan by enzymatic digestion against allergic reaction and allergic asthma in vivo and in vitro. The low molecular weight chitosan (<1 kDa), consisting of glucosamine $(GlcN)_n$, $n = 3–5$, was found to be capable of inhibiting both antigen-stimulated degranulation and cytokine generation in rat basophilic leukemia RBL-2H3 cells. In this study, the protective effect of low molecular weight chitosan against ovalbumin-induced lung inflammation in asthma model mice was also examined. Oral administration of low molecular weight chitosan (16 mg/kg body weight/day) resulted in a significant reduction in both mRNA and protein levels of interleukin-4, interleukin-5, interleukin-13, tumor necrosis factor-α in the lung tissue, and bronchoalveolar lavage fluid compared to those in the ovalbumin-sensitized/challenged asthma control group. These results showed that the oral administration of low molecular weight chitosan is effective in alleviating the allergic inflammation in vivo and thus can be a good material for the development of a potent therapeutic agent against mast cell-mediated allergic inflammatory responses and airway inflammation in allergic inflammatory diseases.

Chitosan–tobermorite composite membrane was prepared by solvent casting a mixture of chitosan and tobermorite from acetic acid solution (Hurt et al. 2014).

The bioactivity and biocompatibility of the composite were evaluated with respect to its potential for use as a biodegradable guided tissue regeneration membrane. The in vitro bioactivity of the composite membrane was confirmed by the formation of crystalline bone-like substituted hydroxyapatite on the surface of the embedded tobermorite particles in simulated body fluid. The tobermorite began to degrade on contact with simulated body fluid, and its alkaline dissolution products buffered the acidic breakdown products of the chitosan polymer. MG63 osteosarcoma cell viability was enhanced by up to 30 % in the presence of the chitosan–tobermorite membrane. These results indicated that the chitosan–tobermorite composite may be a suitable material for tissue regeneration applications.

5 Wound-Healing Properties

Chitosan can facilitate wound healing by stimulating granulation tissue formation or reepithelialization. It can influence the formation of postsurgical adhesions and the repair of surgical incisions and anastomosis since it improves reepithelialization and wound healing (Dai et al. 2011). The role of chitosan in wound healing was found to be associated with their immune stimulating property, which involves higher production of macrophages that release cytokines necessary for the healing process (Okamoto et al. 2003). The wound-healing property of chitosan oligomers is due to their ability to stimulate fibroblast production by affecting the fibroblast growth factor and subsequent collagen production in order to facilitate the formation of connective tissues (Howling et al. 2002).

The nanofibrous composite chitosan/collagen membrane for wound-healing application was reported by Chen et al. (2008). The composite membrane was found to promote wound healing and induce cell migration and proliferation. The results showed that the composite chitosan/collagen membrane was found to be better in wound healing than commercial wound-healing materials. A wound dressing material based on chitosan/collagen with high liquid absorbing, biocompatibility, and antibacterial properties was designed by Wang et al. (2008). In their study, different weight ratios of collagen to chitosan, which were pre-grafted with acrylic acid or *N*-isopropyl acrylamide (NIPAAm), were used to immobilize on the polypropylene nonwoven fabric to construct a durable wound dressing membrane with high water absorbing, easy removal, and antibacterial activity. The results showed that NIPAAm-grafted and collagen-/chitosan-immobilized polypropylene nonwoven fabric showed a better healing effect than acrylic acid-grafted and collagen-/chitosan-immobilized polypropylene nonwoven fabric. The excellent remodeling effect in histological examination with respect to the construction of vein, epidermis, and dermis at 21 days after skin injury was observed when the wound was treated with this composite fabric.

A bilayer composite film consists of an upper layer of a soybean protein nonwoven fabric and a lower layer of a genipin-cross-linked chitosan film was developed as a wound dressing material by Liu et al. (2008). In this study, the degree of cross-linking and the in vitro degradation rate of the genipin-cross-linked

chitosan films was found to be controlled by varying the concentration of genipin. The contact angle analysis showed that the genipin-cross-linked chitosan film is not highly hydrophilic, and therefore, the genipin-cross-linked chitosan layer is not entangled with the soybean protein nonwoven fabric, which forms an easily stripped interface layer between them. It was observed that this wound dressing material provides adequate moisture, thereby minimizing the risk of wound dehydration, and exhibits good mechanical properties.

6 Antioxidant Activity

Chitosan and its derivatives have antioxidant properties. They act as antioxidants by scavenging oxygen radicals, and it is dependent on their molecular weights as well as their degree of deacetylation (Park et al. 2003). Low molecular weight chitosan oligomers are preferred than that of higher molecular weights for the activity. Highly deacetylated (90 %) chitosan oligomers also act as scavengers of hydroxyl, superoxide, alkyl, as well as highly stable DPPH radicals tested in vitro. It is reported that chitosan and their derivatives act as hydrogen donors to prevent the oxidative sequence (Je et al. 2004a, b).

Liu (2008) reported the antioxidant activity of chitosan in vitro and in vivo. The results showed that 0.02 % chitosan had antioxidant effects in lard and crude rapeseed oil, but the activity was less than ascorbic acid. When the concentration was increased, chitosan and ascorbic acid had similar activities; chitosan could significantly reduce serum FFA and MDA concentrations and elevate SOD, CAT, and GSH-PX activities, the latter being the major antioxidant enzymes in the body, indicating that chitosan regulated the antioxidant enzyme activities and reduced lipid peroxidation.

The cellular antioxidant effects of chitosan oligosaccharides produced by acidic hydrolysis of crab chitin were identified (Ngo et al. 2008). This study showed that chitosan oligosaccharides have free radical scavenging effects in a cellular system. It was observed that chitosan oligosaccharides can inhibit myeloperoxidase activity and decrease free radical oxidation of DNA and membrane proteins. Furthermore, they stimulate an increase in intracellular GSH levels. Based on the results, the authors concluded that chitosan oligosaccharides have free radical scavenging effects, acting in both indirect and direct ways to inhibit and prevent biological molecular damage by free radicals in living cells. Hence, chitosan and chitosan oligosaccharides can be used as a scavenger to control radical-induced damage to cellular systems and promise further applications in the future. Li et al. (2014) investigated the in vitro antioxidant activity of chitosan scaffold material by the chemiluminescence signal generated from the hydroxyl radical (•OH) scavenging assay. The results showed that the free radical scavenging ability of chitosan scaffold probably depends on the chitosan concentration and its molecular weight.

In recent years, more attention has been given on the preparation of chemically modified chitosan derivatives for the improved antioxidant activity. For example, modified chitosans with 3,4-dihydroxy benzoyl groups and 3,4,5-trihydroxy

benzoyl groups were synthesized and their antioxidant activity before and after sonication was investigated by the radical scavenging activity method using 1,1-diphenyl-2-picrylhydrazyl (DPPH) (Taghizadeh and Bahadori 2014). The results showed that the DPPH scavenging free radical capacity of chitosans with 3,4-dihydroxy benzoyl and chitosans with 3,4,5-trihydroxy benzoyl groups increased up to 89 % and 74 % respectively, when the concentration reached 6 μg/ml. The ultrasonic treatment of chitosans with 3,4-dihydroxy benzoyl and chitosans with 3,4,5-trihydroxy benzoyl groups after 30 min decreased the DPPH free radical scavenging activity but ultrasonic treatment of chitosan increased the DPPH free radical scavenging activity. Lee et al. (2014) reported the antioxidant and antimicrobial activities of chitosan–caffeic acid, chitosan–ferulic acid, and chitosan–sinapic acid conjugates with different grafting ratios. The antioxidant activities of the conjugates were found to be increased compared to the unmodified chitosan, by 1.79–5.05-fold (DPPH scavenging assay), 2.44–4.12-fold (hydrogen peroxide scavenging assay), and 1.34–3.35-fold ($ABTS^+$ radical scavenging assay). The conjugates showed excellent lipid peroxidation inhibition abilities in a linoleic acid emulsion system. The conjugates exhibited antimicrobial activity against various clinical isolates, standard methicillin-resistant strains, and foodborne pathogens.

7 Antitumor Activity

The anticancer activities of charged chitooligosaccharides were reported using three cancer-cell lines namely HeLa, Hep3B, and SW480 (Huang et al. 2006). Cell-viability studies showed that highly charged chitooligosaccharides could significantly reduce cancer-cell viability, regardless of their charge. Fluorescence microscopic observations and DNA-fragmentation studies confirmed that the anticancer activity of these charged chitooligosaccharides were due to necrosis. It was reported that chitooligosaccharides inhibited tumor growth through an increase in immune effects (Suzuki et al. 1986). Moreover, the chitooligosaccharides (DP4-7) showed strong inhibition of ascites cancer in BALB/c mice, whereas (GlcNAC)6 and (GlcN)6 showed strong inhibiting effects on S-180 and MM156 solid tumor growth in syngeneic mice.

The inhibitory effect of chitosan salts and chitosan gel with high molecular weight on cancer growth was observed (Guminska et al. 1996). Chitosan gel with a high degree of deacetylation showed a greater inhibition than chitosan salts with the same molecular weight and lower degree of deacetylation. These results indicate that chitosan blocks metabolic cascades connected with the transmission of signals from the cell membrane into its interior and leads to a specific inhibition of the tumor cell metabolism (Ignacak et al. 1998). Chitosan oligomers with degree of polymerization >6 with medium degree of deacetylation were found to be effective in blocking absorption of cholesterol and lipids in the intestinal tract. This observation might be due to the protonation of chitosan and thereby forming gels in the intestinal tract that entrap lipids and cholesterol (Razdan et al. 1997).

Kato et al. (2005) reported the mitomycin C (MMC) and chitosan derivative conjugates as antitumor materials. The MMC–*N*-succinyl-chitosan conjugates showed good antitumor activities against various tumor models due to their predominant distribution into the tumor tissue and sustained-release characteristics. Salah et al. (2013) determined anticancer activities of chitin, chitosan, and low molecular weight chitin using a human tumor cell line (THP-1). In this study, a molecular weight–activity relationship and an electrostatic interaction–activity relationship were determined. The cytotoxic effects of chitin and its derivatives were determined using a normal human fetal lung fibroblastic cell line (MRC-5). The results showed that when low molecular weight chitin is bound by YKL-40, an antiapoptotic effect of YKL-40 glycoprotein was found to be inhibited. Therefore, THP-1 cancer-cell death and MRC-5 were found to be proliferated.

Recently, Kim et al. (2013) reported the mechanism of the anticancer activity of water-soluble chitosan on the human leukemia cells (U937, K562, HL60, and THP-1). This study showed that water-soluble chitosan inhibited cell proliferation and induced apoptosis in leukemic cells via the mitochondria-dependent pathway. It was observed that this effect was accompanied by a marked increase in caspase activation and the cleavage of poly(ADP-ribose) polymerase. Water-soluble chitosan was found to decrease Bcl-2 expression in all leukemic cells and reversed the ectopic expression of Bcl-2 in U937 cells. Moreover, it suppressed the phosphorylation of Akt, thereby inhibiting cell proliferation. These observations suggest that water-soluble chitosan can inhibit proliferation and induce apoptosis in leukemia cells through the suppression of Bcl-2- and the Akt-dependent signaling pathways. From the above studies, it is clear that chitosan and its derivatives are potential candidates for tumor therapy.

8 Conclusion

Chitosan is a non-toxic, biocompatible and biodegradable biopolymer. Due to these properties, it is being widely used across a broad spectrum of industries like pharmaceutical, biotechnology, food, textile, cosmetic, etc. The applicability of the chitosan is directly related with its physicochemical properties such as degree of deacetylation, molecular weight, thermal stability, and degree of crystallinity. From this review, it is clear that chitosan and its derivatives have excellent antibacterial activity against plant and animal pathogens. Therefore, they can be used in a number of ways to reduce plant disease levels and prevent the development and spread of pathogens and hence the improved crop yield and quality. Based on the improved antibacterial activity, cell attachment ability, and oxygen permeability, it is clear that chitosan and its derivatives can be a promising candidate for wound dressing. To improve the wound-healing properties, chitosan-based membranes have been developed with different types of polymers such as collagen, acrylic acid, polypropylene, and *N*-isopropyl acrylamide. Due to their composite in nature, these membranes were found to have desired properties for wound-healing applications. While several studies have reported the antioxidant and antitumor activity

of chitosan and its derivatives, no clear information is available describing the detailed molecular mechanisms. Therefore, future research should be directed toward understanding the molecular mechanisms of these materials, which may help in the better understanding of the unknown biochemical functions of chitosan and its derivatives as well as to widen their potential applications.

Abstract

Gellan gum is an anionic extracellular bacterial polysaccharide identified in 1978 by CP Kelco (San Diego, USA). It is available in two forms in normal commercial production, native gellan gum and deacylated gellan gum. For deacylated gellan gum, acyl groups present in the native polymer are removed by alkaline hydrolysis resulting deacylated polymer which is known generically as "gellan gum." Gellan gum can form gels at low concentrations when hot solutions are cooled in the presence of gel promoting cations which provides it as a texture modifier to control the viscoelasticity in foods, as delivery vehicle in pharmaceuticals, and as cell encapsulation material in tissue engineering etc. Gellan gum has been extensively used as a culture medium in microbiology, as a rheology modifier in foods and cosmetics industries since the early stage of its

discovery. Recently, gellan gum as a natural polymer and its hydrogel show a wide range of application perspective in drug delivery and tissue engineering. Gellan gum is nontoxic, biocompatible, biodegradable and the resulting hydrogel is transparent and stable. However, gellan gum-based hydrogels have intrinsic defects such as lack of toughness and tissue tolerance as tissue engineering materials that restrict their use in biomedicine field. In order to solve these problems, quite a large number of studies on chemical modification of gellan gum have been carried out. In this chapter, the gelation behaviors, mechanism as well as various modification methods of gellan gum are summarized. Applications of gellan gum and modified gellan gum in food and biomedicine are highlighted.

Keywords
Hydrogel • Gelation Mechanism • Food • Chemical Modification • Biomedicine

1 Introduction

Gellan gum is a microbial polysaccharide derived from *Sphingomonas elodea* (ATCC31461), previously known as *Pseudomonas elodea*. It was recognized to have commercial potential (Sanderson 1990) in 1978, during an extensive screening program of soil and water bacteria by Kelco (San Diego, USA), the company that was also the first to produce xanthan as an industrial polysaccharide. The first applications of commercial gellan (Gelrite) were in growth media for microbial cultures, as a replacement for agar (Harris 1985; Lin and Cassida 1984). Gellan substrates have the advantages of clarity, purity, and the ability to withstand prolonged incubation at high temperature. Gellan was also identified (Morris et al. 2012; Shimomura and Kamada 1986) as a promising substitute for agar in plant tissue culture, because of the absence of impurities found in agar, the lower polysaccharide concentrations needed, and the greater clarity of the gels, allowing clearer observation of the development of roots and tissue (Arregui et al. 2003). Gellan gum was first used as a culture medium in horticulture because it formed a transparent gel (Ichi et al. 1986; Koda et al. 1988; Turner and Singha 1990).

Gellan gum has been approved for food use first in Japan in 1988, and then the approval propagated to USA in 1992, and then to the EU and many other countries. In 1989 a collaborative research group for gelation of gellan was organized in conjunction with the research group of polymer gels affiliated to the Society of Polymer Science of Japan. The common gellan was used to study its properties with various techniques. The results of the collaborative studies were published in special issues of *Food Hydrocolloids* (7, 361–456 in 1993), *Carbohydrate Polymers* (20, 75–207 in 1996), and *Progress in Colloid and Polymer Science* (114, 1–131 in 1999). It has been used as a texture modifier to control the viscoelasticity in foods and as a culture medium, as delivery vehicle in pharmaceuticals, and also in tissue engineering.

Recently, hydrogels from gellan gum show a wide range of application perspectives in drug delivery and tissue engineering. Gellan gum is nontoxic, biocompatible, and biodegradable and the resulting hydrogel is transparent and stable. The mechanical properties of gellan gum hydrogel are similar to those of normal human tissues under certain conditions. These advantages provide gellan gum versatile characteristics as a source of biomaterials. However, gellan gum-based hydrogels have intrinsic disadvantages such as lack of toughness and tissue tolerance as tissue engineering materials. These defects restrict their use in the biomedical field. In order to solve these problems, quite a lot of work on chemical and physical modification of gellan gum has been carried out. Modified gellan gum reveals a much more promising perspective in the development of biomedical materials.

2 Toxicity

In 1991, toxicological evaluation of gellan gum was done at the 37th meeting of the Joint FAO/WHO Expert Committee on Food Additives (JECFA) in Geneva WHO food additives series 28 (1991). The comments of the committee were as follows (Bajaj et al. 2007).

Gellan gum was shown to be poorly absorbed and did not cause any deaths in rats, which received a single large dose (5 g per kg of body mass) in the diet or by gavage. Short-term (90-day) exposure of rats to gellan gum at levels up to 60 g/kg in the diet did not cause any adverse effects. In prepubertal monkeys, toxicity of gellan gum was studied for 28 days at the highest dose level of 3 g per kg of body mass per day. Signs of any overt toxicity were not observed during this study. In reproduction and teratogenicity studies in rats in which gellan gum was given up to 50 g/kg in the diet, there was no evidence of interference with the reproductive process, and no embryotoxic or developmental effects were observed. Study in dogs, which were treated at dose levels up to 60 g/kg in the diet for 1 year, showed that there were no adverse effects that could be attributed to chronic exposure to gellan gum. In long-term carcinogenicity studies, gellan gum did not induce any adverse effects in mice or rats at the highest dose levels of 30 and 50 g/kg in the diet, respectively. Twenty-three-day dietary studies on humans revealed no significant effect on plasma biochemistry, hematological indices, urinalysis parameters, blood glucose, plasma insulin concentrations, or breath hydrogen concentration. No significant changes were seen in concentrations of HDL cholesterol, triglyceride, or phospholipid, but a decrease in serum cholesterol of ~12 % was noted. For the majority of volunteers participating in the human dietary study, an increase in fecal bulking was observed. Toxicological studies show that gellan gum is relatively nontoxic. An acute oral toxicity test on rat found that the LD50 of gellan gum is higher than 5,000 mg/kg, while a similar inhalation toxicity test caused no death in a group of ten animals, and an eye irritation test indicated gellan gum to be safe for eye contact. Thus, it was concluded that gellan gum produced no adverse effects and that increases in fecal bulking and decreases in serum cholesterol were desirable dietary attributes.

Gellan gum is also reported to shorten gastrointestinal transit time (Giavasis et al. 2000). As gellan gum is a relatively novel biopolymer, it is unlikely that the gut microflora have enzymes that can degrade the polysaccharide. However, there are reports of microbially produced gellan gum lyases (Giavasis et al. 2000; Kennedy and Sutherland 1994), and it will be interesting to see whether in the future gut microorganisms adapt to degrade this biopolymer.

3 Structure/Properties/Modification of Gellan Gum

3.1 Conformation

Gellan gum consists of a tetrasaccharide unit β-D-glucose, β-D-glucuronic acid, β-D-glucose, and α-L-rhamnose. X-ray diffraction studies of polycrystalline and well-oriented samples of the lithium, potassium, and calcium salts of gellan gum have shown that gellan adopts a double-helical structure with two left-handed threefold chains, each of which is translated by half a pitch (5.63 nm) with respect to the other (Chandrasekaran et al. 1988, 1992).

It is believed that gellan molecules take double-helical conformations in solutions at lower temperatures, and above a certain critical concentration, they form aggregates which act as junction zones resulting in a three-dimensional network.

The conformation of gellan gum in solutions has been studied by light scattering, optical rotation, and circular dichroism (Crescenzi et al. 1987; Milas et al. 1990). Since the potassium-type gellan molecules have a strong tendency to form aggregates, it was necessary to convert gellan gum to tetramethyl ammonium type or sodium type. It is necessary to mention here that almost all the commercially available samples are potassium type and contains different amounts of various cations because cations generally increase the gelling ability except when an excessive amount is added.

The collaborative researches reached to some conclusions; from optical rotation, light scattering, osmotic pressure, and intrinsic viscosity measurements, two disordered chains of deacylated sodium-type gellan at higher temperatures make a double helix at lower temperatures in dilute solution, and from rheological measurements gellan forms a gel under conditions favorable for the aggregation of double helices. The aggregation of double helices follows the coil-to-helix transition on further cooling above a certain gellan and cation concentrations.

Takahashi et al. (2004), using a sodium-type gellan gum, determined the molar mass by light scattering at 25 °C and 40 °C, and the molar mass ratio at these temperatures was shown to be 1.99~2.07. Furthermore, they got the persistence length 9.4 nm at 40 °C and 98 nm at 25 °C. These findings confirm that the gellan gum takes a double-helical conformation at lower temperatures and the helix–coil transition occurs at a temperature between 25 °C and 40 °C.

The helix–coil transition temperature was shown to be determined by the total concentration of cations as shown in Fig. 1 (Morris et al. 2012). The inverse of the midpoint temperature of the transition is a linear function of the logarithm of cation activity (Rochas and Rinaudo 1980). In solutions where the concentration of added

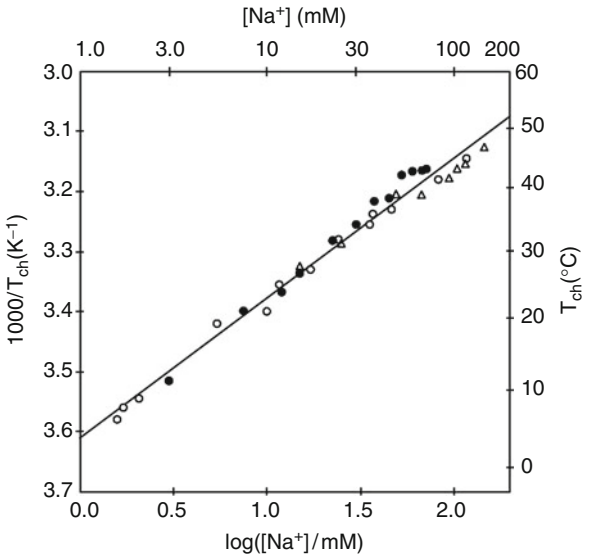

Fig. 1 Dependence of T_{ch} on total concentration of Na^+ (counterions to the polymer plus added NaCl, where present) observed for different independent measurements (Morris et al. 2012)

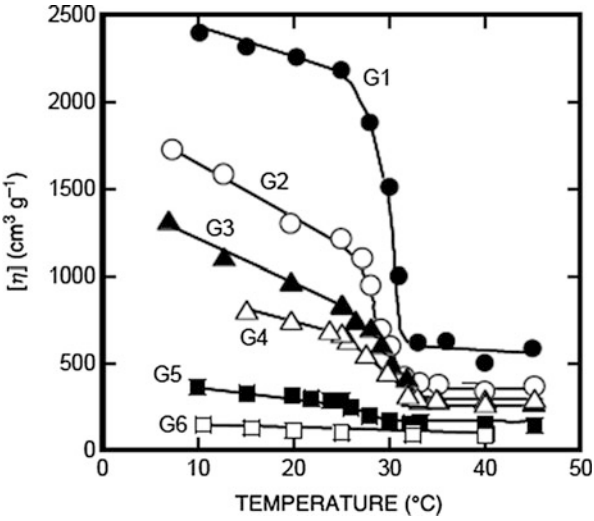

Fig. 2 Temperature dependence of intrinsic viscosity for Na–gellan aqueous solutions with 25 mM NaCl. Molar mass G1 > G2 > G3 > G4 > G5 > G6 (Ogawa et al. 2006)

salt is at least comparable to the polymer concentration and the activity coefficient is high or moderate, cation activity can be replaced by the total cation concentration without any serious loss of linearity, although the resulting plots have somewhat steeper slope than those obtained using the cation activity.

Ogawa et al. (2006) prepared six fractions of deacylated gellan samples with different molar masses which are converted to sodium type. The temperature dependence of the intrinsic viscosity for these six fractions is shown in Fig. 2.

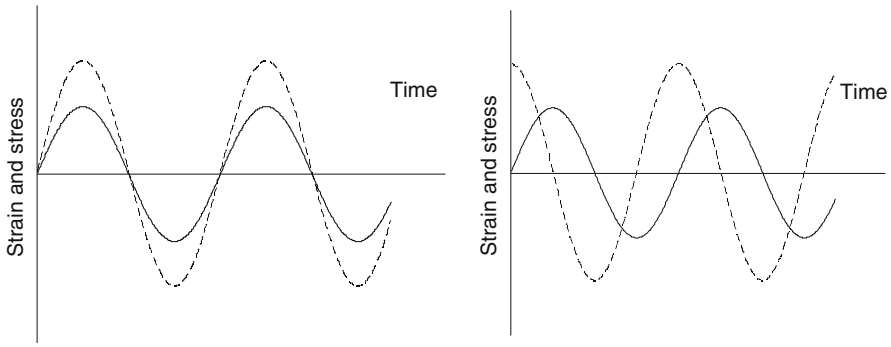

Fig. 3 Sinusoidal oscillation of strain (*solid line*) and stress (*dashed line*) for (**a**) a purely elastic solid and (**b**) a purely viscous fluid

3.2 Gelling Behavior

3.2.1 Rheology of Gellan Solutions and Gels

Dynamic oscillatory measurements are useful for gelation analysis since it is possible to shorten the measuring time so that samples remain unchanged with time during measurement. Figure 3 shows a sinusoidal oscillation of strain applied to (a) purely elastic solid and (b) purely viscous fluid and the resultant stress. If the material is perfectly elastic, the resultant stress wave is exactly in phase with the strain wave. On the other hand, if the material is purely viscous fluid, the resultant stress wave is exactly $\pi/2$ out of phase with the imposed deformation. The stress wave of the viscoelastic material has a phase difference δ ($0<\delta<\pi/2$).

In dynamic viscoelastic analysis, the storage and loss shear moduli, G' and G″, are obtained. The storage and loss Young's moduli E' and E'' are obtained by longitudinal oscillation. G' and E' are proportional to the elastic energy stored in viscoelastic material in a period of oscillation; G' and E' characterize solid-like response of the sample. G'' and E″ are proportional to the dissipated energy as heat in a period of oscillation; G'' and E″ characterize liquid-like response of the sample.

The variation of G' and G'' with frequency is known as the "mechanical spectrum" of the material. Typical mechanical spectra for polysaccharide solutions and gels are shown in Fig. 4.

A power law $G' \sim \omega^2$ and $G'' \sim \omega$ is found in dilute solutions of polysaccharide at low frequencies (Fig. 4d). Another rheological behavior where G' and G'' cross at a certain frequency, below which G'' is higher than G', is found in semi-dilute solution (Fig. 4c). In elastic polysaccharide gels, G' is higher than G'' at all frequencies examined and both moduli show a plateau even at low frequencies (Fig. 4a). At low frequencies, where there is sufficient time for entanglements to come apart within the period of oscillation, semi-dilute solutions respond predominantly by flow, and their mechanical spectra (Fig. 4c) are similar to those of dilute solutions (Fig. 4d). However, at higher frequencies, where there is less time for

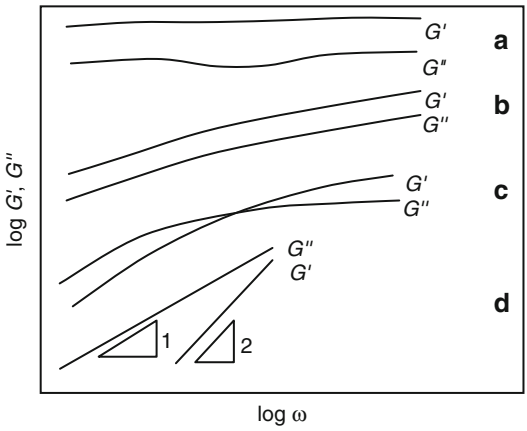

Fig. 4 Mechanical spectra for polysaccharide solutions and gels

disentanglement, the predominant response to the oscillatory strain becomes elastic distortion of the entangled network, and the mechanical spectra become similar to those observed for gels (Fig. 4a).

Some polysaccharide solutions show a gel-like behavior in mechanical spectra, but if subjected to a steady shear flow, they will apparently flow rather than fracture. In this case the behavior is called a "weak gel" type, where G' is higher than G'' at all frequencies examined and both moduli show only a slight frequency dependence (Fig. 4b). Some gellan solutions, sodium-type gellan solutions at lower temperature, for example, show "weak gel"-type behavior. Systems of this type show predominantly elastic (gel-like) response to small perturbations but cannot support their own weight and can be stirred and poured like normal solutions (Picout and Ross-Murphy 2003). "Weak gels" should not be confused with conventional gels that are "weak" only in the sense of having low moduli. Conventional gels, which are often described as "true gels," respond to high stress by fracturing, whereas "weak gels" flow. Mechanical spectra of "weak gels" normally differ from those of true gels in having greater frequency dependence of G' and G'' and smaller separation between the two moduli, but the main distinction is the difference in response to unidirectional stress or large strain. To avoid such confusion, other descriptions such as "structured liquids" have been used recently.

Although the term "weak gel" seems to have been used in many papers for a long time, the term "structured liquid" seems to be more logical. Polysaccharides that form true gels on cooling under quiescent conditions can also give dispersions of microscopic gel particles with "weak gel" properties if they are subjected to shear on cooling through the temperature range of the sol–gel transition (Norton et al. 1999). By applying this approach to gellan, Sworn et al. obtained "weak gel" networks capable of suspending small particles by mixing solutions of commercial gellan (Kelcogel) and NaCl at 80 °C and cooling (at 0.5 °C/min) to 25 °C under shear (at a constant shear rate of 100 s^{-1}) (Sworn et al. 1995). This is called "fluid gels" and can be also formed by dispersing gellan solution in oil phase at higher temperatures and then by lowering the temperature.

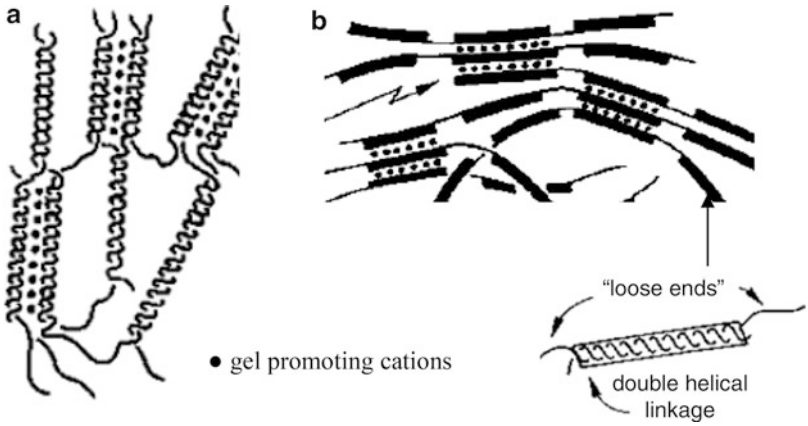

Fig. 5 Schematic model of gellan gel network proposed by (**a**) Robinson et al. (1991) and (**b**) Gunning and Morris (1990)

3.2.2 Gel Networks

Gel network and the origin of the elasticity of gellan gels have been investigated extensively. However, it has not been established well. Two schematic models proposed for the internal structure of gellan gels are shown in Fig. 5. The gel elasticity is often discussed based on the rubber elasticity. In rubber, disordered polymer chains are cross-linking, which leads to three-dimensional network formation. The main response to applied stress is stretching of the flexible regions of disordered polymer chains, and the elastic resistance to deformation comes predominantly from the consequent reduction in conformational entropy. The decrease of the mesh size (i.e., increase of number of cross-links) in the network leads to the increase of the elastic modulus. Some gellan helices are considered to play a role of junction zone which connects disordered polymer chains and make three-dimensional networks (Fig. 5a). Aggregates of helices are thought to form junction zones, out of which flexible gellan chains are released and connected with other junction zones, as proposed by "reel-chain" model (Nishinari et al. 1985). An alternative model has been proposed; the enthalpic elasticity rather than the entropic elasticity (rubber elasticity) dominates gellan gel elasticity (Morris 1995). In this model gellan helices form long "filaments" and networks are formed by lateral association of fibrillar strands (Fig. 5b). The elasticity of such networks would come predominantly from the increase in enthalpy on distortion of the aggregated filaments or the entire fibrillar network (Morris et al. 1999a).

It was shown that the helix–coil transition occurred in the self-supporting gellan gels (Nitta et al. 2001). They used cylindrically molded gels of a potassium-type gellan, and an endothermic DSC peak and a sigmoidal increase in circular dichroism at 202 nm were found on heating (Fig. 6). The gels kept the cylindrical shape up to highest temperature 60 °C at which the observation of longitudinal vibration could be made. Both storage and loss Young's moduli showed a sigmoidal decrease showing weakening of the network structure at this temperature range. The opposite

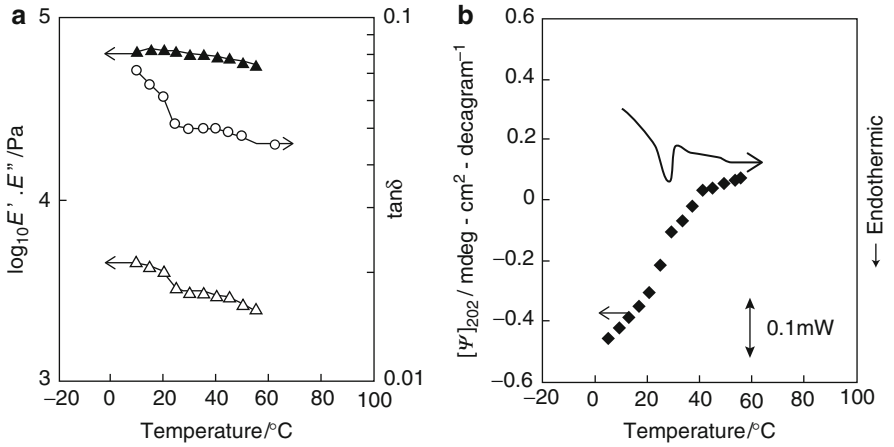

Fig. 6 (**a**) Temperature dependence of the storage modulus E' (▲),the loss modulus E'' (Δ), and mechanical loss tanδ (○) on heating and (**b**) the heating DSC curve (*solid curve*) and temperature dependence of the specific ellipticity at 202 nm (◆) on heating for 1.6 %(w/w) gellan gum gels. E' and E'' measurements were done after 15 min equilibration at each temperature. Heating rates of DSC and CD measurements: 0.5 ° C/min (Nitta et al. 2001)

tendency was observed on cooling. It is evident, therefore, that disordered chain sequences formed during heating of the gel have sufficient freedom of movement within the surviving cross-linked network to revert to the double-helix state on cooling.

Observations of chain release from gellan gels which were immersed in aqueous solutions (Hossain and Nishinari 2009; Tanaka and Nishinari 2007) suggested the existence of gellan chains that do not participate the network.

3.2.3 Effect of Ions

Kani et al. (2005) examined the effects of monovalent cations and anions on the conformation of gellan chains in aqueous solutions by optical rotation and fluorescence anisotropy measurement. They confirmed that the electrostatic shielding ability of cation species between intramolecular segments and intermolecular chains increased with increasing ionic radius. The coil–helix transition of gellan chains was affected by the cation concentration as shown in Fig. 1 rather than by the type of cation species; however, the latter was the predominant factor with respect to the aggregation of gellan chains. They found that the anion species F^- lowered the coil–helix transition temperature and suppressed the aggregation of gellan chains, while the anion species Cl^-, Br^-, and I^- showed no influence on the coil–helix transition temperature or the aggregation behavior.

The aggregation of gellan helices is inhibited by electrostatic repulsion between the helices. Monovalent cations are thought to screen electrostatic repulsion between the gellan helices and to promote double-helix formation and aggregation of the helices. The effectiveness is observed in order of $Cs^+ > K^+ > Na^+ > Li^+$ (Miyoshi and Nishinari 1999a). Aggregates lead to thermal hysteresis between the

temperatures at which helices form on cooling and aggregates melt on heating. The helix-forming temperature is usually from 30 °C to 40 °C, and the temperature increases with increasing cation concentration, while the aggregate melting temperature changes widely from 40 to over 90 °C depending on cation concentrations.

At low concentrations of monovalent cations, solutions of ordered gellan give mechanical spectra similar to those of solutions of disordered coils (Fig. 4c or d). On further increase in cation concentration, there is a region of "weak gel" response (Fig. 4b) before reaching the threshold concentration for formation of true gels. This progression is attributed to progressive suppression of electrostatic repulsion between the gellan double helices. For the true gel formation, at least 50 mM Na^+ or 20 mM K^+ is required (Morris et al. 2012).

Excessive addition of cations has been shown to decrease the elastic modulus and the fracture stress (Moritaka et al. 1991; Milas and Rinaudo 1996; Morris et al. 1999b). Morris et al. (1995) attributed this phenomenon to the formation of inhomogeneous structure in the presence of excessive amount of cations.

Divalent cations seem to bind directly with gellan molecules to form aggregates of gellan helices with the effectiveness of $Ca^{2+} > Mg^{2+}$. Firm gels are obtained above ~2 mM Ca^{2+}. Maximum gel strength is attained (Tang et al. 1996) when the concentration of divalent cations reaches ~100 % of stoichiometric equivalence to the carboxyl groups of the polymer. The gels induced by divalent cations have greater thermal stability than those induced by monovalent cations. A proposed interpretation is that divalent metal ions promote aggregation by site binding between pairs of carboxylate groups on neighboring helices, rather than by suppressing electrostatic repulsion by binding to individual helices.

3.2.4 Effect of pH

Gelling agents that form a gel at low pH are important to the production of, e.g., dessert jellies containing fruit juices. Gelling agents such as agarose and carrageenan show reduced gelling capacity at low pH, whereas gellan gum can form strengthened gels (Moritaka et al. 1995; Yamamoto and Cunha 2007). Moritaka et al. (1995) showed that the breaking stress of all gels increased with decreasing pH down to pH 4. The difference between the breaking stress of nonheated gels and that of gels reheated for **2** h at 90 °C became larger with increasing pH. Yamamoto and Cunha (2007) showed that failure stress increased at lower pH values, higher polysaccharide concentration, and with the application of heating before acidification. However, gels heated after acidification showed decreased failure stress. All the gels they examined were transparent and the water-holding capacity improved at higher concentrations and pH values or at lower pH values and gellan concentrations. Picone and Cunha (2011) examined the effect of pH (3.5, 5.3, and 7.0) on the formation of deacylated gellan gels by small and large deformation rheology and structural observation and found that formation and mechanical properties of gellan gels were directly dependent on the solution pH. An increase in pH led to the formation of a reduced number of junction zones and a decrease in molecular aggregation, reducing gel rigidity. Thus, they found that gels formed at neutral pH were more fragile and deformable than acid gels.

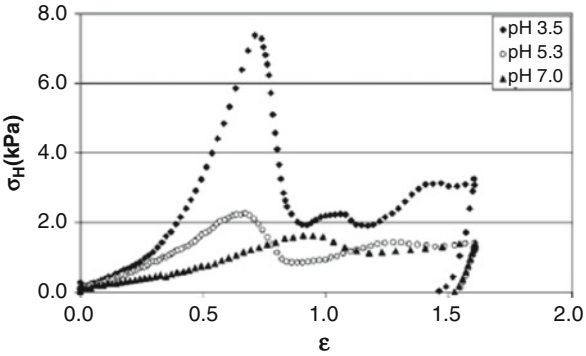

Fig. 7 Stress–strain curves of 1.5 (w/w) gellan gels at pH 3.5, 5.3, and 7.0 (Picone and Cunha 2011)

Gelation of gellan can also be induced by reduction in pH. Initial acidification from neutral pH to pH 3.5 causes a large increase in break stress as shown in Fig. 7 (Picone and Cunha 2011). They attributed it to a decreased formation of junction zones at higher pH values due to greater electrostatic repulsion between the gellan molecules, and thus, gels formed at neutral pH were more fragile and deformable than acid gels. However, by further decrease in pH to 2, the gels became extremely weak and turbid and showed phase separation of polymer and solvent (Moritaka et al. 1995). Indeed, precipitation by acid can be used as a method for isolation and purification of gellan (Sanderson 1990).

3.2.5 Effect of Sugars

Addition of sugars promotes conformational ordering and gelation of gellan. One obvious way in which high concentrations of sugars can promote association of polymer chains is by replacing most of the solvent. Much of the increase in the coil-to-helix transition temperature with increasing concentration of sugar could be explained in this way, but the value of the transition temperature for mixtures of gellan with the disaccharides (sucrose and trehalose) and glucose was still substantially higher than for equivalent concentrations of gellan alone (Miyoshi and Nishinari 1999b). The enhancements observed with sucrose, trehalose, and glucose were ascribed to sugar–water associations in competition with interactions between water and gellan.

Addition of sucrose increases Young's modulus, fracture stress, and fracture strain (i.e., with the gels becoming stronger and less brittle) at the compression tests as the concentration of sucrose is raised to 40 wt.%. On further increase in sucrose concentration to 60 wt.%, however, there is decrease in Young's modulus and a massive increase in fracture strain, with the gels remaining intact up to ~65 % strain. Figure 8 shows fracture stress and strain for gellan with no added sugar and in the presence of 60 wt.% sucrose (Kawai et al. 2008). The reduction in brittleness on incorporation of 60 wt.% sucrose is evident from the much greater deformation at break (stretch ratio 1.6~1.7) in comparison with the sample with no added sugar (stretch ratio 1.10~1.17). At high concentration of sugar, formation and aggregation of gellan double helices is inhibited probably due to "condensation" of sugar molecules around the polymer chains (Morris et al. 2012).

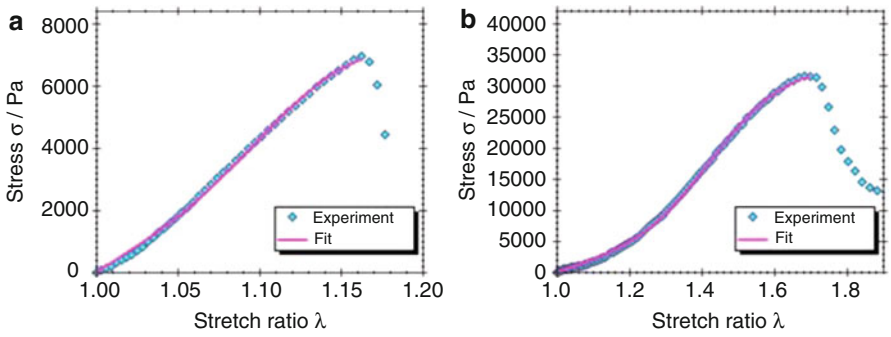

Fig. 8 Stress–strain curves of gellan gels obtained by experiments are plotted together with the calculated curves of a modified reel-chain model. (**a**) Gellan gel with the gellan concentration of 1.2 % without sucrose. (**b**) Gellan gel with 0.8 % gellan and 60 % sucrose (Kawai et al. 2008)

3.2.6 Effect of Acyl Substituents

The native gellan has an L-glyceryl substituent on O(2) of the 3-linked glucose residue of the tetrasaccharide sequence and, in at least some of the repeat units, an acetyl group at O(6) of the same residue (Kuo et al. 1986). In normal commercial production, both types of substituents are removed by treatment of the fermentation broth with hot alkali. Partial removal can be achieved by limiting the amount of alkali used. When hydrolysis is carried out in this way, at elevated temperature with the polymer in the disordered form, glyceryl substituents are liberated somewhat more rapidly than acetyl groups. Thus, it is possible to obtain samples differing widely in the proportion of repeat units carrying residual acetyl or glyceryl substituents.

High acyl gellan gives gels with lower modulus and lower hardness than those formed by commercial gellan gum, but the elasticity is much greater, and the "brittleness" values (strain at break) are also much greater (typically around 65 %, in comparison with ~30 %). In contrast to the ease with which gellan gum gels release fluid, the gels formed by high acyl gellan show no syneresis (Sworn 2009). As described below, the high acyl and deacylated forms also differ substantially in their response to changes in temperature and ionic environment. The conformational transitions that accompany formation and melting of high acyl gellan gels (1.0 wt.%) show no detectable thermal hysteresis, either in water or in 100 mM NaCl (Morris et al. 1996), and there are only small variations in melting temperature of the gels and in transition midpoint temperature from DSC heating scans (Mazen et al. 1999) on varying concentration of NaCl between 10 and 100 mM, in contrast to the massive changes in melting temperature observed for deacylated gellan over the same range of NaCl concentrations.

High acyl gellan shows higher transition temperatures in the DSC cooling scans (Morris et al. 1996) in comparison with deacylated gellan under the same conditions. The other noticeable difference is that the DSC peak is substantially wider for the high acyl form, indicating that the transition is less cooperative. Heating curves

Table 1 Physicochemical properties of gellan gum samples (Noda et al. 2008)

		GG1	GG2	GG4	GG6
Acyl content (HPIC)	Glycerate (%)	10.0	9.1	7.2	5.6
	Acetate (%)	3.0	2.8	2.7	2.5
	Total (%)	13.0	11.9	*9.9*	8.1
Cation content (ICP-OES)	Na (μmol/g)	5 %	600	674	622
	K (μmol/g)	0.82	ND[a]	ND[a]	ND[a]
	Ca (μmol/g)	4.25	3.75	7.5	5.75

Data are presented as means of duplicate
[a]Not detected

for the same samples, recorded in the same investigation but reported separately (Baird et al. 1992), were essentially equal and opposite to the cooling curves with again no indication of thermal hysteresis.

Noda et al. (2008) performed the rheological and structural studies using gellan samples with different acyl contents (Table 1). The temperature dependence of G' and tanδ is shown in Fig. 9. The thermal hysteresis between the sol-to-gel and the gel-to-sol transitions was observed, which became more apparent with decreasing acyl content from 13.0 % to 8.1 %. This is in good agreement with the previous finding that the conformational change from coil to helix and the subsequent intermolecular associations between the helices show detectable thermal hysteresis upon cooling and heating in the presence of gel-promoting cations (Morris et al. 1999b; Gunning et al. 1996). The sol-to-gel transition shifted to lower temperatures with decreasing acyl content – 65 °C, 62 °C, 60 °C, and 54 °C for GG1, GG2, GG4, and GG6, respectively – which agreed well with the result found in the absence of added cations (not shown), emphasizing the function of acyl groups, particularly glycerate, to stabilize the helical structures. At 20 °C, G' increased with decreasing acyl content, which was opposite to the result found in the absence of added cations (not shown). The unexpectedly large values of tanδ for GG6 at lower temperatures may be due to the slippage between the geometry and sample, which is difficult to avoid in rheological measurements of some gelling agents with relatively hard and brittle textures (e.g., deacylated gellan gum, kappa carrageenan, agar, etc.), showing syneresis when forming gel matrixes. Even if so, G' for GG6 was still much larger than those for the others, indicating highly developed gel structures.

Mixtures of high acyl and deacylated gellan give gels with textures that lie between the extreme brittleness of the deacylated form and the extreme extensibility of the high acyl form. There is no indication of the discontinuity in properties that would be expected from phase separation, which again strongly indicates an interpenetrating network structure (Morrison et al. 1999).

On cooling from high temperature, the mixtures show two regions of steep increase in G' (Kasapis et al. 1999), the first coincident with the sol–gel transition of high acyl gellan at high temperature and the second with the corresponding transition of the deacylated polymer at much lower temperature. Then, Kasapis et al. proposed a phase separation model for a 1 % mixed solution (0.5 % HA gellan and 0.5 % LA gellan) with NaCl at concentrations higher than 50 mM.

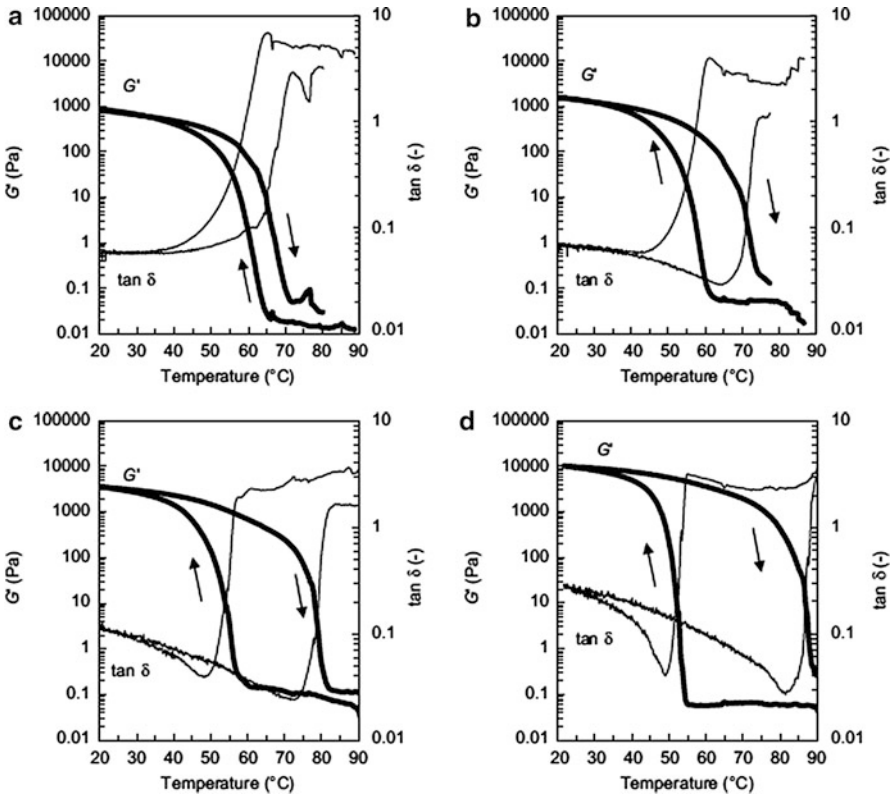

Fig. 9 Temperature dependence of dynamic viscoelasticities G' and tan δ for aqueous solutions of gellan gum in the presence of potassium. Aqueous solutions of each gellan gum sample were prepared at 1.0 w/w% in the presence of 0.1 M KCl. The solutions were placed into a double-wall Couette geometry as hot solutions at 90 °C. The geometry was preheated at 90 °C to avoid gelation in sample loading. After holding at 90 °C for 10 min, temperature decreased from 90 to 20 °C at a constant rate of 0.2 °C/min and then increased from 20 to 90 °C at the same rate. (**a**) GG1; (**b**) GG2; (**c**) GG4; (**d**) GG6. There was no difference in data from repeated measurements (Noda et al. 2008)

Matsukawa and Watanabe (2007) observed the good miscibility and transparency and no phase separation for the mixed solution of HA and LA without added salt. Therefore, they suggested that high acyl gellan chains show high preference for double-helix formation of the same kind of gellan chains in the homogeneous solution of mixed gellan species.

3.3 Mixture

3.3.1 Blending Gellan Gum with Other Polymers

Interactions between two different polymers can be classified as "associative" if they are thermodynamically more favorable than interactions between the individual

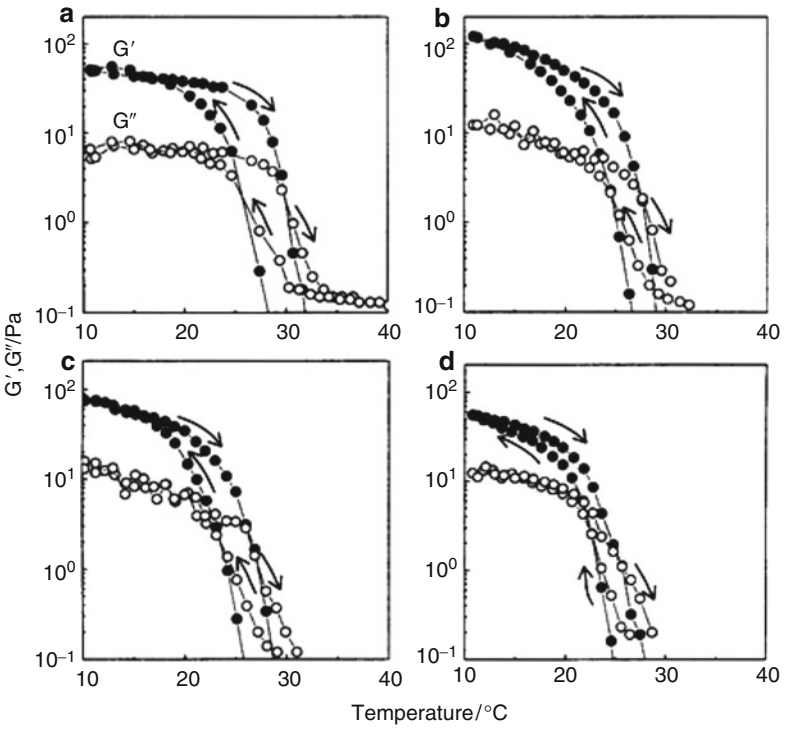

Fig. 10 Temperature dependence of storage and loss moduli of 1 % mixture of TSX and gellan on cooling and subsequent heating at 0.5 C/min and at 1.26 rad/s. TSX content: (**a**) 0.9, (**b**) 0.6, (**c**) 0.6, (**d**) 0.4 (Nitta et al. 2003)

polymers of each type and "segregative" if they are less favorable. The most common mechanism of association is electrostatic attraction between polyanions, such as negatively charged polysaccharides, and polycations, such as proteins below their isoelectric point. Segregative interactions can cause separation into a dispersed phase containing most of one polymer surrounded by a continuous phase containing most of the second polymer. The two phases may, however, run through one another, giving a bicontinuous structure. Alternatively, the two polymers may remain intimately mixed (without being confined to only part of the total volumes as in phase-separated bicontinuous networks) and form two separate gels permeating through one another, to give an IPN structure (Morris 1986, 1990).

Mixtures of Na^+ gellan with konjac glucomannan (KGM, MW950 kD) at a total polymer concentration of 0.8 wt.% in water were observed (Miyoshi et al. 1996a; Nishinari et al. 1996a) to give a sharp maximum in G' at a mixing ratio of 3:5 (i.e., 0.3 wt.% gellan plus 0.5 wt.% KGM) after cooling to low temperature (0 °C).

Tamarind seed xyloglucan (TSX) has the same backbone geometry as KGM, but the monosaccharide and disaccharide side chains confer the solubility on TSX. Mixtures of TSX with Na^+ gellan were examined (Fig. 10) (Nitta et al. 2003) at a

total polymer concentration of 1.0 wt.%, where the individual polysaccharides are nongelling. The mixtures converted from solutions to gels on cooling. Therefore, the gel was thought to be formed by a synergistic interaction. The temperature at the critical gel point increased with increasing content of xyloglucan, from 21 °C at 0.6 wt.% gellan gum plus 0.4 wt.% xyloglucan to 25 °C at 0.3 wt.% gellan gum plus 0.7 wt.% xyloglucan (Nitta et al. 2003; Nitta and Nishinari 2005).

Mixtures of K^+ gellan with kappa carrageenan, also in the K^+ salt form, were found to give two separate transitions in DSC, one at about the same temperature as for carrageenan alone and the other at higher temperature, about the same as for gellan gum alone, which seems to exclude the possibility of association between the two polymers (Nishinari et al. 1996b). This was attributed to phase separation, with consequent increase in the effective concentration of each polymer when confined to only part of the total volume. However, values of η* obtained for solutions prepared at a total polymer concentration of 0.25 wt.% with varying proportions of gellan gum and kappa carrageenan were substantially higher than those of the individual polymers, reaching a maximum at the ratio gellan gum/carrageenan = 2:8. At higher total concentrations of polymer (2–5 wt.%), where gels were formed, reaching minimum values at gellan gum/carrageenan = 1:1 can again be explained by phase separation, with the weaker network forming the continuous phase and the stronger gel confined to dispersed particles (Nishinari et al. 1996b). Unfortunately, the samples used for dilute solution studies and gel studies are not the same, and therefore, whether the occurrence of the synergistic interaction or phase separation depends on the difference in concentration or difference in the cation contents or not is not clear in this study and needs further clarification.

Phase separation has also been reported (Papageorgiou et al. 1994) for mixed gels of commercial gellan (Kelcogel) with calcium alginate. Incorporation of moderate concentrations of gellan gum (0.1–0.3 wt.%) increased the hardness (yield stress) of the gels formed by 2.0 wt.% alginate, but the breaking strain was unaffected, indicating that the brittle gellan gum network was distributed as dispersed particles embedded in a more elastic calcium alginate matrix. At higher concentrations of gellan gum (above 0.7 wt.%), however, the rheological response to addition of Mg^{2+} cations suggested a bicontinuous (phase-separated) network structure, although the possibility of phase inversion to a continuous gellan network surrounding dispersed particles of calcium alginate gel could not be eliminated conclusively.

Mixtures of K^+ gellan with agarose (Nishinari et al. 1994) showed separate DSC transitions for the two polysaccharides, as was also seen (Nishinari et al. 1996b) for kappa carrageenan–gellan mixtures, and a phase-separated network was again proposed. A subsequent study by (Amici et al. 2000), however, found no evidence of the large increase in turbidity expected to occur on phase separation or of biphasic structures in images obtained by confocal microscopy or TEM. Instead, the TEM micrographs showed a homogeneous distribution of both polymers, and rheological analysis was entirely consistent with interpenetrating networks of gellan and agarose.

Mixtures of Na^+ gellan with sodium and calcium salts of hyaluronic acid were studied by Mo et al. (2000). Gelation of mixtures of Na^+ gellan with Ca^{2+} hyaluronate

can, of course, be explained, at least in part, by interaction between the gellan component and Ca^{2+} cations from the hyaluronate, but substantial further research would be required to unravel the complexity of other possible macromolecular and ionic interactions in this system.

Mixtures of commercial gellan (Gelrite) with a wide range of starches (native and chemically modified) were studied (Sanderson et al. 1988). Gellan (0.5 wt.%) had little effect on the maximum viscosity generated by 4.5 wt.% starch during heating, in contrast to other hydrocolloids such as xanthan and carboxymethylcellulose which can give undesirably high values of peak viscosity. The starch pastes formed in the amylograph were cooled overnight and then sheared. The viscosities of the pastes containing gellan were reduced significantly by shearing, but remained higher than those of the corresponding pastes of starch alone, suggesting that gellan could be useful in preparation of a variety of starch-based fillings, which are generally prepared by cooking, stored in bulk, sheared during filling into their final containers, and allowed to recover viscosity on standing.

Direct association between gellan gum and gelatin by electrostatic attraction ("complex coacervation") was explored by Chilvers and Morris, using commercial gellan gum (Gelrite). The gelatin was obtained from pig skin by extraction with acid, giving an isoionic point of pH 8. Mixtures were prepared at a temperature (60 °C) well above the sol–gel transition temperatures of the individual polymers. Coacervate droplets (1–100 μm diameter) were formed at pH values in the range 3.5–5.0, where the gelatin had a net positive charge and the gellan gum a negative charge. The droplets gelled on cooling (Chilvers and Morris 1987).

The potential use of gellan gum–gelatin coacervates to encapsulate oils or solid particles was demonstrated by adding model substrates (paraffin oil, sunflower oil, aluminum powder, or beads of ion-exchange resin) to the biopolymer mixtures in the solution state, reducing pH into the range required for coacervation, and cooling to gel the coacervate layer that had formed around the core material. The resulting beads were then fixed with glutaraldehyde, washed, and dehydrated with isopropanol to yield concentrated slurries or free-flowing powders.

Bioartificial polymeric materials in the form of hydrogels were prepared starting from blends of PVA with gellan gum, using a procedure based on freeze–thawing cycles. Some results indicated that gellan gum favors the crystallization process of PVA allowing the formation of a material with a more homogeneous and stable structure than that of pure PVA hydrogels. Both the PVA melting enthalpy and the elastic modulus increased with increasing gellan gum content in the hydrogels; in addition, the higher the gellan gum content in the samples, the lower was the amount of PVA released. Gellan gum/PVA hydrogels were able to release human growth hormone (GH), and the release was affected by the content of the biological component. The amount of GH released was within a physiological range (Cascone et al. 2001a).

3.3.2 Films of Gellan Gum and the Mixtures with Other Polymers

Dried films cast from mixtures of commercial gellan (Kelcogel) with KGM (MW 1,320 kD) were studied (Xu et al. 2007). Maximum tensile strength was

observed when the KGM content of the films was around 70 %, which is in reasonable agreement with the mixing ratio of 3:5 gellan/KGM found (Miyoshi et al. 1996a; Nishinari et al. 1996a) to give maximum gel strength. The proposed interpretation was that KGM enhances the strength and thermal stability of gellan networks by binding to the surface of aggregated assemblies of double helices.

It was suggested that gellan gum–KGM films incorporating an antimicrobial agent (nisin) could be used in "active packaging" of food products to extend their shelf life (Xu et al. 2007).

Homopolymer films of gellan gum and PVA and blended films can be prepared by a solution casting method from a polymer solution in water of gellan and PVA. A single melt isotherm for the blends and the shift of onset, melt temperatures of the blends and a change in glass transition temperature were observed. A shift in the major signals of IR for OH absorption and with varied intensities in the FTIR spectra indicated cross-linked interaction by the polymers. The blended films had tensile strengths of 3.5–5.6 MPa and tear strengths of 15–30 g. The range of properties, both intermediate from the component polymers and extending beyond either individual components, suggests molecular interaction and cross-linking within the blends (Sudhamani et al. 2003).

Composite membranes based on gellan gum and poly(*N*-vinylimidazole) were prepared by using the method of solvent evaporation. The FTIR spectra evidenced ionic interactions between the two polymers, which contribute to the stabilization of the interpolymeric network in acid medium. The swelling behavior in media of various pH values was much dependent on the membrane compositions. This property would suggest the possibility of designing membranes with performances that might be anticipated by changing only the ratio between the two polymers (Alupei et al. 2006).

The membranes are soluble in basic medium regardless of their composition. The properties of the membranes indicate their potential application as biomaterials, especially as biodegradable materials or as supports for drugs in view of their controlled-release supports for including and releasing drugs in media of certain pH values (Alupei et al. 2006).

3.4 Texture, Syneresis, Flavor Release

3.4.1 Texture of Gellan Gels

In the texture profile analysis, five parameters are often examined: modulus, hardness, brittleness, elasticity, and cohesiveness. These parameters of gellan gels were also investigated and compared with gels formed by other gelling agents (Sanderson 1990; Gibson and Sanderson 1997). Hardness, which is defined as the maximum force generated in resistance to the compression and is usually equivalent to break stress, increased initially and then decreases on progressive reduction in pH or progressive addition of Na^+, K^+, Mg^{2+}, or Ca^{2+}. The brittleness value, which is identical to strain at break, decreased systematically with cation concentration (i.e., the gels become more brittle as more salt was added). The modulus, hardness, brittleness, elasticity, and cohesiveness of agar in traditional Japanese

food products could be matched well using gellan at much (two to three times) lower concentrations, although agar itself is a very efficient gelling agent (Sanderson et al. 1988).

Other gelling agents like agar and kappa carrageenan give firm and brittle texture, while gelation and the "synergistic" gels formed by mixtures of xanthan with plant polysaccharides such as locust bean gum (LBG) or konjac glucomannan give soft and flexible texture. The gels formed by commercial deacylated gellan (gellan gum) typically have brittleness values of around 25–30 %, giving firm and brittle texture. However, high acyl gellan gels give soft and flexible texture.

3.4.2 Syneresis

Gellan gels are comparatively stable when stored quiescently at ambient temperature or under refrigeration, but there may be some release of fluid (syneresis), particularly at polymer concentrations below ~0.2 wt.% (Gibson and Sanderson 1997). Syneresis is undesirable in most food products, and it may be necessary to add thickeners to prevent it.

Kubo et al. (2012) examined the syneresis of 0.15 % (w/w) deacylated potassium-type gellan gels in the presence of calcium ions from 1.6 to 25 mM and found that the syneresis increased from 2.4 % to 7.4 % with increasing calcium content. Syneresis can also cause problems of slippage when gellan networks are investigated by rheological measurements under shear (Morris et al. 1999b).

3.4.3 Flavor Release

It is well known in the food industry that perceived intensities of flavor and taste are lower for gelled products than for fluid products (such as sauces and drinks) incorporating the same objective concentrations of flavor compounds or "tastants" such as sugar or salt.

It is not well understood which factor governs the sweetness or saltiness of solid foods. Morris (1993) has proposed based on the study on gels with different rheological properties that the sweetness intensity increases with decreasing fracture strain because solid foods with low fracture strain are broken into small fragments and thus the total area is increased leading to the more contact of fragmented foods with taste buds. Clark (2002) showed a good correlation between the sweetness intensity with fracture stress and found two exceptions; gelatin gels which show a higher sweetness intensity in comparison with other gels with the same fracture stress because gelatin gels melt in the mouth and so showed a higher sweetness, and the other exception was a cohesive gel consisting of high acyl gellan/xanthan/locust bean gum, which showed a lower sweetness intensity because this mixed gel was not broken into small fragments, and thus Clark's explanation was not contradictory with Morris' proposal but rather complementary.

Gellan causes less suppression than most other gelling agents, or, as more commonly expressed, it has outstanding "flavor release" properties. One possible explanation (Gibson and Sanderson 1997), suggested by release of fluid when gellan gels are compressed, is that water is released from the gels during mastication, carrying with it flavor and taste compounds.

Moritaka et al. (1998) studied the relation between the texture and sweetness and milk flavor intensity of gellan jellies containing Pal Sweet (aspartame and maltose syrup) and milk powder. They found that sensory-evaluated hardness increased while smoothness decreased with increasing content of gellan gum. The sensory-evaluated milk flavor and sweetness increased with increasing content of sweetener and evaluated as higher for softer milk jellies. A jelly which was evaluated to have the strongest milk flavor contains less milk powder but with a higher content of sweetener. This phenomenon could be interpreted as the interaction between taste and aroma; sweetener intensified the milk flavor. Moritaka et al. (1999) also studied the relation between the texture and sweetness and lemon flavor intensity of gellan jellies containing Pal Sweet (aspartame and maltose syrup), citric acid, and lemon powder. Sensory-evaluated lemon flavor and sourness decreased with increasing sensory-evaluated hardness, which was well correlated with instrumentally determined hardness (fracture stress). It was observed that lemon flavor was evaluated higher for jellies with higher citric acid content. This may be again the result of the taste–aroma interaction; the sourness intensified the lemon flavor.

This cross-modal interaction between taste and flavor was recently reported by experimental psychologist groups. Hort and Hollowood (2004) showed that the sweet taste of sucrose solution intensified the banana flavor (isoamyl acetate, IAA) in the sensory evaluation based on the time–intensity method by varying the mixing ratio of sucrose solution, IAA solution, and water. Djordjevic et al. (2004) observed that the strawberry flavor intensified the sweetness of sucrose solutions and that the soy sauce flavor intensified the saltiness of salt solutions. They observed that this intensification occurred only by the imagination of the flavor of strawberry or soy sauce by the panelists without giving these flavors to their nasal cavity. They concluded that this cross-modal interaction occurred in the brain and not in the oral or nasal cavity.

Bayarri et al. (2001) investigated the influence of structure and rheological properties of gels of κ-carrageenan and gellan gels on the diffusion and perception of sweetener molecules. They found that the hydrocolloid used had an effect on the diffusion of sucrose and aspartame. The observed diffusion coefficients were higher in κ-carrageenan gels than in gellan gels. They attributed it to the incipient melting of κ-carrageenan gels. Bayarri et al. (2002) showed that fracture stress increased while the fracture strain decreased with addition of sucrose for concentrated gellan gels. Bayarri et al. (2005) also compared the influence of sucrose on gellan, *κ*-carrageenan, and *κ*-carrageenan/locust bean gum gels. They found that sucrose addition increased the fracture stress of all these gels, but this effect depended on the type and concentration of hydrocolloids. Addition of sucrose to soft gels did not influence the fracture strain, while sucrose addition to gels with higher hydrocolloid concentrations led to a slight decrease in the fracture strain.

Wang et al. (2014) examined the sucrose release from agar gels mainly based on uniaxial compression of cylindrically molded gels. The fracture stress increased with increasing agar concentration, while the concentration dependence of the fracture strain was different at different compression speeds. The number and total surface area of fragments increased with decreasing agar concentration.

Increasing the compression speed led to an initial increase followed by a monotonous decrease of both the number of fragments and their total surface area. The gel texture affected in a similar fashion both the sucrose release ratio and the total fragment surface area. The sucrose release ratio decreased with increasing agar concentration.

Sala et al. (2010) examined the effect of serum release on sweetness intensity in mixed whey protein isolate/gellan gum gels. With increasing gellan gum concentration, the size of the pores present in the protein network, the permeability, and the serum release increased, as well as the Young's modulus, the fracture stress, and the fracture strain. Increasing the sugar concentration induced an increase of the pore size, but resulted in a decrease of permeability and serum release. They found that serum release significantly boosted sweetness intensity; the sweetness scores for gels with 12 % serum release were found to be the same as for gels with 2 % serum release but with 30 % higher sugar concentration.

Sala and Stieger (2013) investigated the influence of the breakdown behavior on sweetness intensity of gelled model foods, emulsion-filled gelatin/agar gels with different fracture strains. They found that the sweetness intensity of the most brittle gel was almost twice as high as the sweetness intensity of the least brittle gel. They stated that the time to reach the sweetness intensity is important, i.e., the shorter the time, the higher the sweetness intensity. They suggested that the velocity of formation of new surfaces of the food in contact with the taste buds influences sweetness intensity in addition to the total surface which is generated during breakdown of the food.

4 Chemical/Physical Modifications of Gellan Gum and Their Effects

Gellan gum has found extensive applications in food and pharmaceutical industry because of their peculiar gelation, easy availability, biocompatibility, biodegradability, and cost-effectiveness. To improve its functional properties, a number of chemical and physical modification methods have been employed.

4.1 Comparison of Physical Gels and Chemical Gels

Physical gellan gum hydrogels, prepared with mono- or divalent cations, are used for the preparation of tablets, beads (Agnihotri et al. 2006), or microspheres in drug delivery systems. Chemical hydrogels of gellan gum are usually prepared via chemical cross-linking of the preformed physical networks, in order to enhance their mechanical properties and to obtain slower drug release profiles (Bhakoo et al. 1991). A novel gellan gum chemical hydrogel was obtained by cross-linking the polymer chains with L-lysine ethyl ester moieties and compared with the gellan gum physical hydrogels (Matricardi et al. 2009). The physical networks were much stronger than the chemical ones due to the formation of very tight junction zones

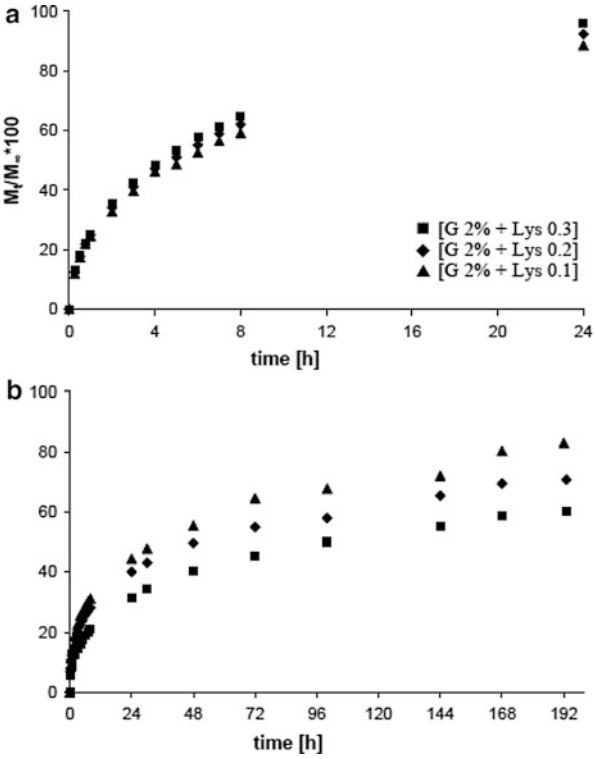

Fig. 11 Release profiles (37 °C, SIF) of DexFluo70: (**a**) from physical hydrogels; (**b**) from chemical hydrogels (in the legend G = Gellan) (Matricardi et al. 2009)

whose strength depends on the L-lysine ethyl ester content. On the other side, the chemical gels were weaker because of the applied cross-linking procedure: in fact the cross-linker was added when the polymeric chains were in a disordered conformation and therefore junction zone formation was forbidden. As a final effect the elastic modulus was lower of two orders of magnitude in comparison to those recorded for the physical networks. Of course, within the same kind of gel, physical or chemical ones, the storage modulus increased with the increase of the L-lysine ethyl ester content. In the physical gels the role of L-lysine ethyl ester was to decrease the electrostatic repulsions among the chains, and therefore the number of the junction zones was a function of the L-lysine ethyl ester content. In the chemical gel, obviously, the degree of cross-linking increases with the increase of L-lysine ethyl ester content. According to this model, also the yield stress and the compressibility parameters were affected by the kind and the degree of linkage among the polysaccharide chains (Matricardi et al. 2009).

The structural differences also influenced the delivery profiles in SIF (simulated intestinal fluid, phosphate buffer, pH = 7.4), in particular when high molecular weight model molecules were used. L-Lysine ethyl ester content does not affect significantly the delivery rate from the physical hydrogels, regardless of the steric hindrance of the guest molecules, due to the temporary nature of the junction zones (Fig. 11a). On the other side, for the chemical gels, quite different profiles were

recorded that were deeply influenced by the steric hindrance of the model molecule as well as by the L-lysine ethyl ester content, and a significant amount of the model molecule with the highest molecular weight still remains entrapped within the network even in 8 days (Fig. 11b) (Matricardi et al. 2009).

Injectable hydrogels are hydrogels capable of gelling in situ due to chemical and/or physical cross-linking development after injection. Because of the advantages over their conventional counterparts, injectable hydrogels have been found a great number of applications in tissue engineering, drug delivery, and cell and protein transplantation (Redouan et al. 2010; Jin et al. 2009; Bhattarai et al. 2010; Singh et al. 2009). The most attractive advantages are that they are easily deliverable by minimally invasive techniques and are capable of filling native or potential cavities by conforming to different shapes, which may be difficult to prefabricate (Aliyar et al. 2005).

Most recently, gellan gum-based physical hydrogels have been explored in tissue engineering because of their high biocompatibility, biodegradability, and injectability (Redouan et al. 2010; Oliveira et al. 2009a; Smith et al. 2007; Wang et al. 2008). However, substantial problems remain before the gellan gum hydrogels can become genuinely injectable for practical biological use – its gelation temperature is much higher than human body temperature (37°C) (Gong et al. 2009) and it gels in seconds in PBS medium, leaving no window of time for manipulation (Oliveira et al. 2009a). In addition, gellan gum physical hydrogels induced by cations tend to become weaker in physiological conditions due to the exchange of divalent cations by monovalent ones (Annaka et al. 2000).

An injectable, in situ physically and chemically cross-linkable gellan gum hydrogel is synthesized via gellan thiolation (Du et al. 2012). A chemical cross-linking was developed between gellan gum chains while the thiol groups underwent air oxidation in physiological conditions, giving a stable chemical hydrogel. The thiolation does not alter the gellan gum's unique 3D conformation but leads to a lower phase-transition temperature under physiological conditions and stable chemical cross-linking (Fig. 12). The possible mechanism behind the lower gelation temperature is due to the reduced cation binding sites on the gellan gum backbone and the steric effect of the attached small molecule. This gellan gum with decreased gelation temperature exhibited both physical gelling and chemical cross-linking ability, making it desirable for in vivo applications in tissue engineering (Du et al. 2012).

4.1.1 Carboxymethylation

Carboxymethylation of gellan gum was reported to improve its aqueous solubility, and so that the gelation of gellan can be controlled (Miyamoto et al. 1996). Carboxymethylation of gellan gum was found to increase its degree of crystallinity and surface roughness and diminish the cation-induced gelation and increase the solubility in water. Furthermore, carboxymethyl gellan gum showed 2.71-fold higher mucoadhesive strength than gellan gum. Evaluation of ex vivo ocular tolerance using chorioallantoic membrane of hen's egg and cytotoxicity screening on Vero cells using resazurin assay revealed that carboxymethyl gellan gum is

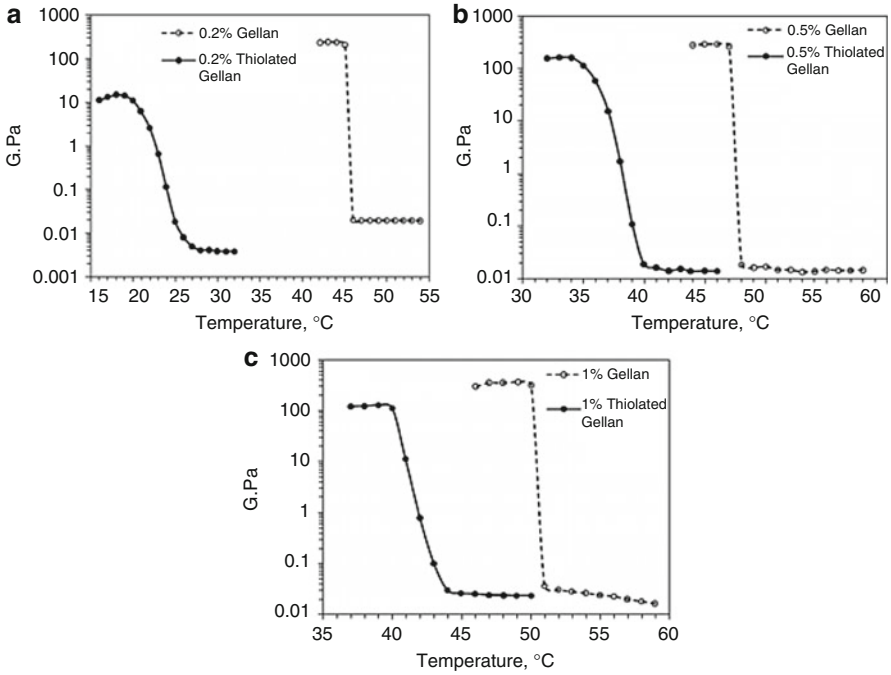

Fig. 12 Sol–gel transition of gellan (*dashed line*) and thiolated gellan (*solid line*) solutions in PBS at (**a**) 0.2 %, (**b**) 0.5 %, and (**c**) 1.0 % (w/v) upon cooling. Gellan solutions show high transition points (gelation temperatures) and narrow transition temperature ranges, while thiolated gellan solutions displayed decreased transition points and increased transition temperature ranges (Du et al. 2012)

non-irritant and biocompatible. Ionotiropically gelled beads of carboxymethyl gellan gum formulated using metformin as the model drug and calcium chloride as the cross-linking agent showed ex vivo bioadhesion of 100 % over 24 h. Further, it was observed that carboxymethyl gellan gum beads released metformin at a rate faster than gellan gum (Ahuja et al. 2013).

4.1.2 Oxidization

By regiospecific oxidation at C6 with NaOCl in the presence of 2,2,6,6-tetramethyl-piperidine-1-oxyl radical (TEMPO) and NaBr in aqueous solution at pH 10, the C6 primary hydroxyl groups of deacylated gellan gum were completely converted to carboxylate groups(Redouan et al. 2010). This original carbohydrate rhamnoglucuronan might find use as surrogates of ulvan, a sulfated cell wall polysaccharide extracted from green seaweeds (Ulva species), in pharmaceutical and medical areas (Redouan et al. 2010).

For tissue engineering purposes, gellan gum-based hydrogels need to be modified in order to meet the requirement of encapsulating living cells while maintaining their injectability, because the gelling point of this temperature-dependent gel is too

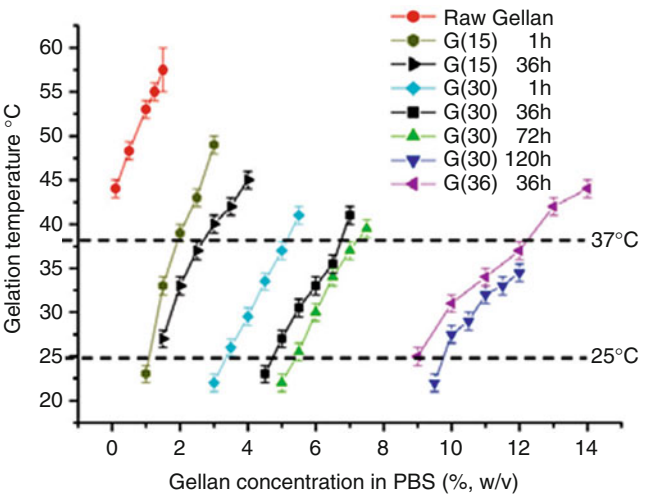

Fig. 13 Gelation temperatures of oxidized gellan with different reaction conditions (Gong et al. 2009).

high (above 42°C). Chemically scissoring (via oxidative cleavage) the gellan gum backbones can optimize the gelation temperature for injection as a result of downregulating their molecular size (Fig. 13) (Gong et al. 2009). Chondrocytes were then seeded into the modified gellan gum gels. Notably, chondrocytic constructs based on modified gellan gum gel were kinetically monitored for 150 days in comparison with those based on agarose gel, showing superiority for long-term cartilaginous development in terms of many aspects such as cell proliferation and specific matrix formation.

4.1.3 Amidation

Biomaterials have been designed as vehicles for cell transplantation in order to enhance cell survival after transplantation. In order to better mimic the extracellular matrix (ECM), biomaterials have been modified with several peptide sequences (Luo and Shoichet 2004; Tong and Shoichet 2001; Yu and Shoichet 2005) to influence biological processes, such as cell adhesion, growth, and development (Adams and Watt 1993; Schwarz et al. 1990). Cells transplanted in a material that mimics both the mechanical and chemical properties of native tissue have been shown to be more efficacious after transplantation (Cooke et al. 2010; Kim et al. 2012). Hydrogels are particularly appealing for soft tissue applications because they can be designed to match the mechanical properties and water content of these tissues. The gellan gum hydrogel is compelling because it can be injected in a minimally invasive way to form a gel in situ. But gellan gum hydrogel is a relatively bio-inert material. To enhance cell adhesion, the gellan gum (GG) was modified using Diels–Alder click chemistry with a fibronectin-derived synthetic peptide (GRGDS) (Silva et al. 2012). The GG–GRGDS had a profound effect on

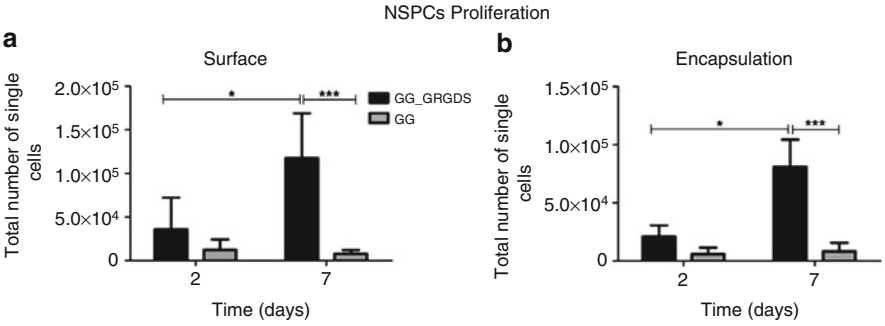

Fig. 14 Bioactivity of the GG–eGRGDS hydrogel. Proliferation analyses of NSPCs cultured either (**a**) on the surface of or (**b**) in the gel of the GG–eGRGDS (*black bars*) versus unmodified GG (*gray bars*) showed that on the 7th day a significantly higher number of single cells were found in the GG–eGRGDS. Moreover, only in the GG–eGRGDS was a significant increase in cell number observed from day 2 to day 7 (Silva et al. 2012)

neural stem/progenitor cell (NSPC) morphology and proliferation, distinct from that of NSPCs in GG alone, demonstrating the importance of GRGDS for cell–GG interaction (Fig. 14) (Silva et al. 2012).

4.2 Hydrophobization

In recent years, self-assembled nanohydrogels based on hydrophobically modified polysaccharides have been extensively studied due to their wide potential applications as drug delivery systems. As applied to drug delivery systems, natural polysaccharides have the advantages of their abundance in nature, low cost, safety, general biocompatibility, biodegradability, and high stability. Among all natural polysaccharides, gellan gum is a promising candidate for biomedical applications because of its peculiar physicochemical properties and its biocompatibility (Miyoshi et al. 1996b; Dreveton et al. 1996; Matricardi et al. 2009). Herein, gellan gum nanohydrogels (NHs) were prepared by self-assembly of the polymer chains, after an appropriate hydrophobic chemical derivatization with cholesterol and prednisolone moieties (D'Arrigo et al. 2012). The prednisolone moiety, linked to the polymer chains by means of a short hydrocarbon chain, simultaneously acts as a pharmacological agent and a promoter of NH formation, whereas cholesterol was chosen as a moiety able to promote the formation of reference NHs with no pharmacological activity. A slight decrease in cell viability was observed both for Ge–Pred and prednisolone treatments; at low concentrations, Ge–Pred showed a lower toxicity. However, it must be pointed out that in no case was cell viability reduced to less than 80 % (Fig. 15). This approach allows us to combine the advantages of nanotechnology, such as high stability, high carrier capacity, and feasibility of different routes of administration with an immobilized form of prednisolone that displays improved bioavailability, thus increasing its therapeutic effects and reducing its dosing frequency.

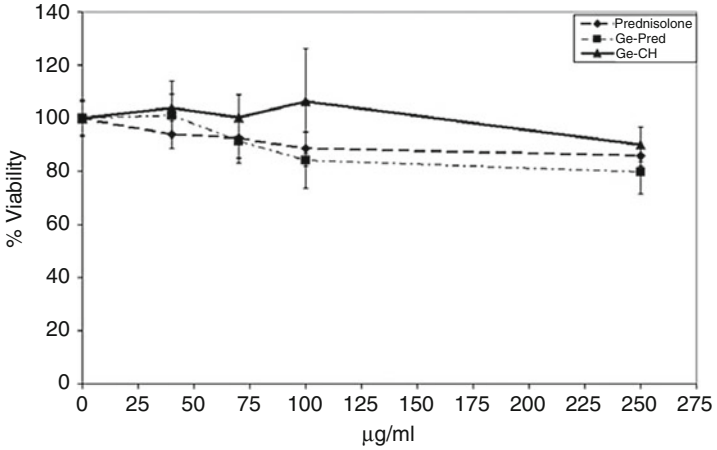

Fig. 15 Cell viability expressed as a function of the concentration of administered Ge–Pred (-), Ge–CH (:), or Pred (A). The viability of the control cells (without treatment) was set at 100 %. Each point is the mean SD of 16 replicates reaction scheme of the gellan gum–prednisolone synthesis (D'Arrigo et al. 2012)

4.3 Cross-linking

Over the past decades, great attention has been focused on biopolymer-based hydrogels for use as potential carriers in controlled drug delivery (Van Tomme et al. 2008; Coviello et al. 2007). Hydrogels are three-dimensional, hydrophilic, polymeric networks capable of imbibing large amounts of water or biological fluids (Peppas et al. 2000), resembling biological tissues. Because of this property, great interest was devoted to these systems for biomedical applications. Indeed, the physicochemical properties of the hydrogels can be tuned by varying the cross-linking degree (physical and/or chemical), thus making these networks suitable devices for a modulated drug delivery.

Recently, gellan gum has been investigated as a candidate material for biomedical engineering because of its biocompatibility and low cytotoxicity (Oliveira et al. 2010a; Silva-Correia et al. 2011). Although the polysaccharide can be cross-linked with Ca^{2+} ions, the mechanical properties of polysaccharide are fragile and less malleable (Ichibouji et al. 2009). When implanted, tissue calcification occurs, which limits the biomedical application of Ca^{2+}-cross-linked gellan gum. In addition, chemical cross-linkers can be cytotoxic due to dosage responses and cross-linker residues (Powell and Boyce 2006).

To develop a nontoxic method of cross-linking gellan gum that can be applied in biomedicine is the main purpose of these research works. Cross-linking via the photodimerization of polymeric systems has been utilized in various applications. So, a new photocrosslinkable gellan gum molecule that contains a cinnamate moiety can be designed and may be used for medicinal purposes (Lee et al. 2012). The reaction does not require the addition of a light-sensitive initiator. Cinnamate

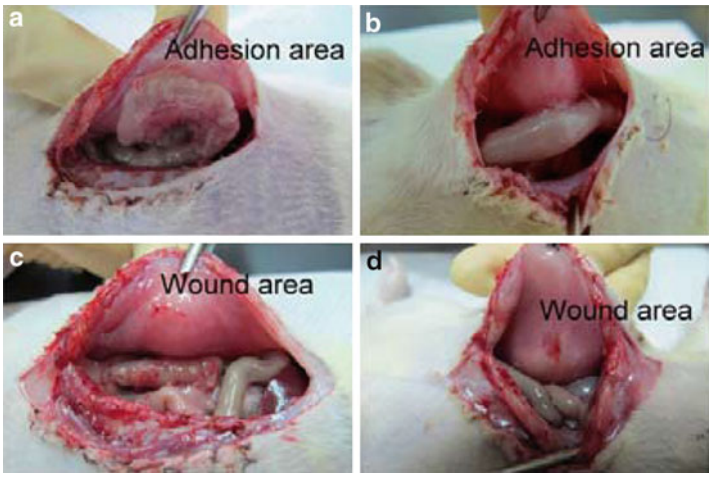

Fig. 16 Repair of the injured sites between the cecum and the peritoneal wall in the operated rats 3 and 7 days after surgery: (**a**) and (**b**) adhesion formation (control group) and (**c**) and (**d**) treated with gellan gum–cinnamate film without adhesion formation (Lee et al. 2012)

derivatives are natural compounds that possess anti-inflammatory and non toxic properties (Ballabeni et al. 2010). So, cinnamate functions not only as a cross-linking agent but also as an anti-inflammatory drug. The anti-adhesion films prepared from gellan gum–cinnamate polymers exhibited high gel contents (88 ± 2 %) and suitable mechanical properties. When implanted into rats, the gellan gum–cinnamate film exhibited the most promising anti-adhesion potential and anti-inflammation (Fig. 16). The gellan gum–cinnamate film thus has potential in clinical applications (Lee et al. 2012).

4.4 Graft Copolymerization

A graft copolymer is a macromolecular chain with one or more species of block connected to the main chain as side chain(s). Thus, it can be described as having the general structure, where the main polymer backbone, commonly referred to as the trunk polymer, has branches of another polymeric chain emanating from different points along its length (Zohuriaan-Mehr 2005). Graft copolymerization of synthetic polymers onto the polysaccharide backbone offers one of the best ways to use polysaccharides for controlled-release delivery. Graft copolymerization is an easier method to modify the structure of natural polymers and thus makes them attractive biomaterials in controlled-release applications since native polysaccharides may not be suitable in controlled drug delivery systems due to their substantial swelling and rapid enzymatic degradation in biological fluids (Soppimath et al. 2002). Acrylamide-grafted-gellan gum (AAm-g-GG) was synthesized using microwave-assisted ceric (IV) ion-induced grafting method (Fig. 17a). The acrylamide is toxic in nature, but from the toxicity study in mice, it is revealed that there is no morbidity

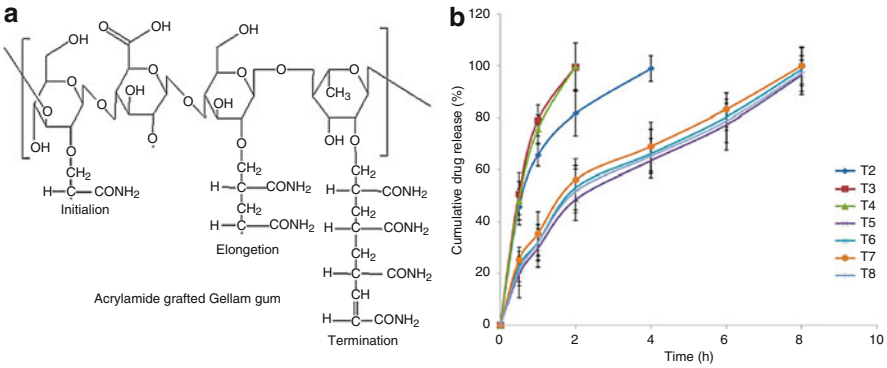

Fig. 17 (**a**) Acrylamide-grafted-gellan gum (AAm-g-GG), (**b**) Release profile of MTF from the tablet formulation containing different batches of AAm-g-GG (Vijan et al. 2012)

or mortality case during the LD50 study at a dose of 2,000 mg/kg body weight of AAm-g-GG. Sustained release tablet of metformin hydrochloride (MTF) was developed by using this grafted gum as a rate-controlling polymer. The release data could be fitted as a function of time $\sim t^n$. Cumulative release profiles of MTF from various formulations are shown in Fig. 17b, and the exponent n was found to be 0.363–0.556, thus indicating the release mechanism is Fickian or square root of time kinetics. Thus, microwave-assisted ceric (IV) induced graft copolymerization is an easy, efficient, less time-consuming, and reproducible (due to the supply of fixed energy form microwave) method for the development of graft copolymer which can be used as a rate-controlling polymer for the development of sustained release dosage form (Vijan et al. 2012).

Furthermore, a series of gellan gum unsaturated esters by addition of free radical polymerizable groups, which can be polymerized under mild conditions to design biodegradable three-dimensional networks having hydrogel properties, were synthesized by esterification under various conditions (Fig. 18). Different degrees of functionalization were obtained either homogeneously in water with acrylic acid or heterogeneously with acryloyl chloride and maleic anhydride in organic solvents. Maleic anhydride evidences a higher reactivity than the acryloyl chloride and acrylic acid, especially when the reactions of gellan gum esterification are carried out in DMF (Hamcerencu et al. 2008). Preliminary copolymerization experiments performed with acrylic monomers such as *N*-isopropylacrylamide and unsaturated gellan gum esters lead to thermo- and pH-stimulable hydrogels with adjustable cross-link density. Early results revealed that modified gellan gum-/*N*-isopropylacrylamide-based hydrogels are potential carriers in the design of controlled drug delivery systems.

4.5 Dual Interpenetrating Network

Hydrogels are promising candidates for tissue engineering scaffolds due to their high water content, high permeability to small molecules, biocompatibility, and

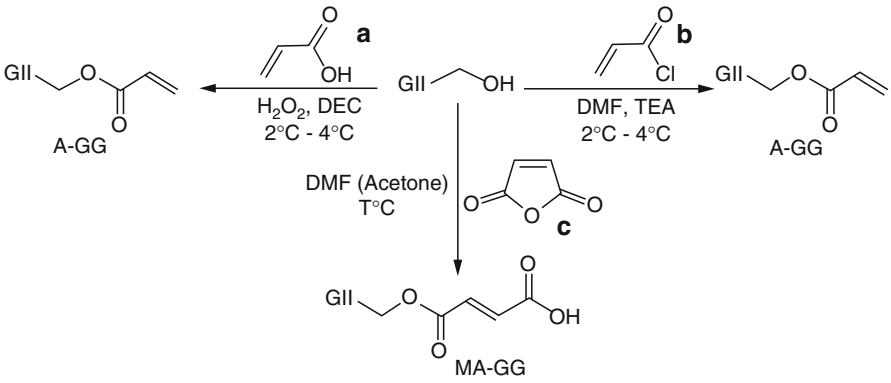

Fig. 18 Strategies for modification of gellan gum: (**a**) acrylic acid, (**b**) acryloyl chloride, (**c**) maleic anhydride (Hamcerencu et al. 2008)

mechanical properties which resemble natural tissues (Gong 2010; Lee and Mooney 2001; Peppas et al. 2006). However, hydrogels are often too soft and weak to be applied for a number of tissue engineering applications that require extensive load-bearing behavior. Therefore, developing hydrogels with high mechanical strength is a critical challenge for expanding the range of applications of hydrogels for tissue engineering scaffolds. Double-network (DN) hydrogels have attracted a great deal of attention for their high fracture toughness and high fracture stress (Gong et al. 2003; Nakayama et al. 2004). In the case of DN hydrogels, the first network is stiff and brittle, whereas the second is soft and ductile. In this scheme, the rigid network sustains the stress throughout the material, and the ductile network dissipates energy near the crack tip, preventing the fracture of gels (Na et al. 2004).

Gellan gum has been approved by the FDA as a food additive and has been recently receiving attention for tissue engineering applications (Gong et al. 2009; Oliveira et al. 2009b, 2010a). Gelatin is denatured collagen, which is a major constituent of the extracellular matrix. Due to the natural cell binding motifs, such as Arg-Gly-Asp (RGD), gelatin exhibits great biological properties such as cell adhesion and cell elongation, which makes it an attractive material for tissue engineering applications. So, both polymers can be modified into photocrosslinkable gellan gum methacrylate (GGMA) and gelatin methacrylamide (GelMA) and fabricated into DN hydrogels with high strength that can encapsulate cells (Fig. 19). In the DN hydrogels, GGMA is the rigid and brittle first network, and GelMA is the soft and ductile second network. As compared to single-network hydrogels, DN hydrogels exhibited higher strength, which approaches closer to the strength of cartilage. There is an optimal range of the cross-link density of the second network for high strength of DN hydrogels. DN hydrogels with a higher mass ratio of GelMA to GGMA exhibited higher strength, which shows promise in developing even stronger DN hydrogels in the future. Three-dimensional (3D) encapsulation of NIH-3T3 fibroblasts and viability test showed the cell

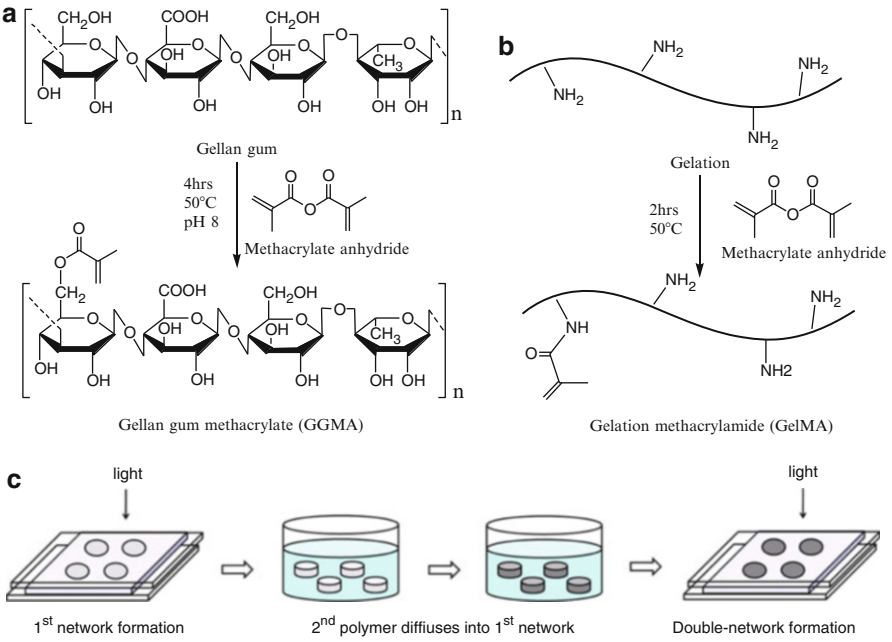

Fig. 19 Synthesis scheme of (**a**) gellan gum methacrylate (GGMA) and (**b**) gelatin methacrylamide (GelMA). (**c**) Fabrication of DN hydrogels through a two-step photocrosslinking process (Shin et al. 2012)

compatibility of the DN formation process. Given the high strength and the ability to encapsulate cells, the DN hydrogels made from photocrosslinkable macromolecules could be useful for the regeneration of load-bearing tissues (Shin et al. 2012).

Diltiazem hydrochloride is widely used in the treatment of angina pectoris and hypertension. It has a short half-life (3–4 h) and is administered three to four times daily (Shivkumar et al. 2006). The ion-exchange resins can be bound with diltiazem hydrochloride to form reversible complex. The advantages of using diltiazem–resin complex include reducing the bitter taste of drug, facilitating development of controlled-release dosage form, providing uniform drug absorption, and increasing stability by protecting the drug from hydrolysis. In addition, entrapping the diltiazem–resin complex within IPN matrix can modify the release rate of drug (Junyaprasert and Manwiwattanakul 2008). Diltiazem hydrochloride was bound to Indion 254, a cation exchange resin, and the resulting drug–resin complex was entrapped within IPN microcapsules of gellan gum and egg albumin prepared by ionotropic gelation and covalent cross-linking method (Fig. 20). The pure drug diltiazem showed rapid and complete dissolution within 60 min, while drug release from drug resinate was extended for 3 h and that from IPN microcapsules was still slower. The ionically cross-linked microcapsules were capable of releasing drug up to 9 h, and that from dual cross-linked microcapsules was extended up to 15 h. The microcapsules which were prepared with higher concentration of glutaraldehyde

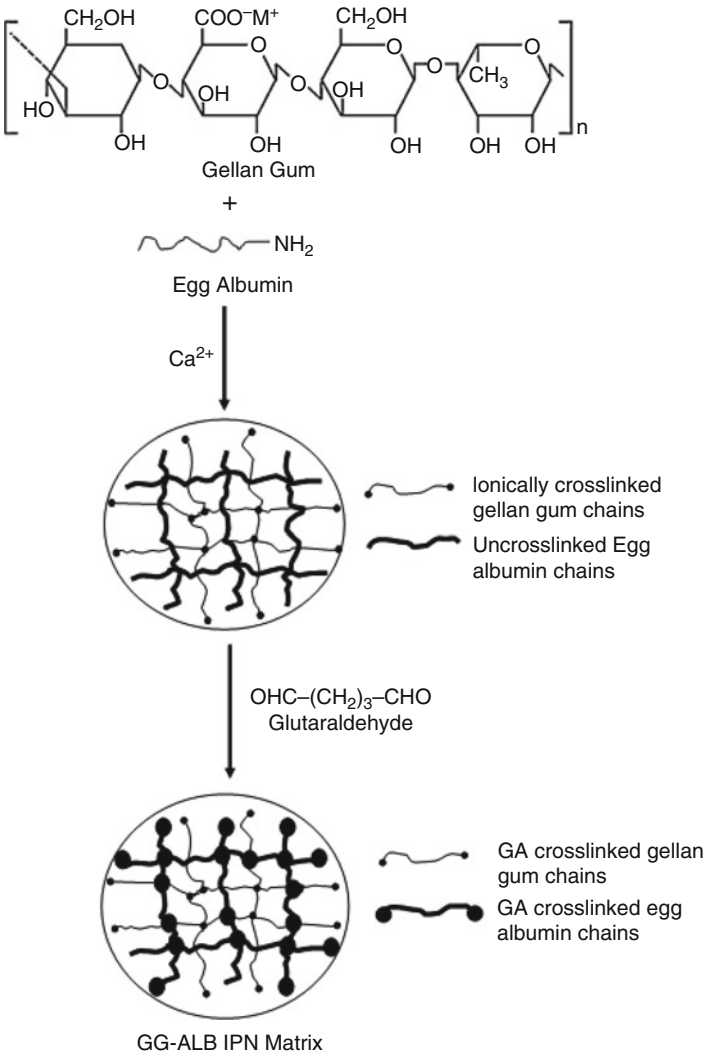

Fig. 20 Schematic representation of gellan gum–egg albumin IPN matrix (Kulkarni et al. 2011)

released the drug more slowly. The release data were fitted to an empirical equation to determine the transport mechanism (Kulkarni et al. 2011).

Gellan gum is a candidate material for cartilage tissue engineering, but its application is limited by the high gelation temperature and lack of mechanical strength (Coutinho et al. 2010). A double-network complex hydrogel with low gelation temperature ($T_{gelation}$) and high mechanical properties was prepared by mixed oxidized gellan gum with carboxymethyl chitosan (Fig. 21). The $T_{gelation}$ was lowered from 42°C to below physiological temperature by oxidation and further reduced by complexing with carboxymethyl chitosan. The complex hydrogel

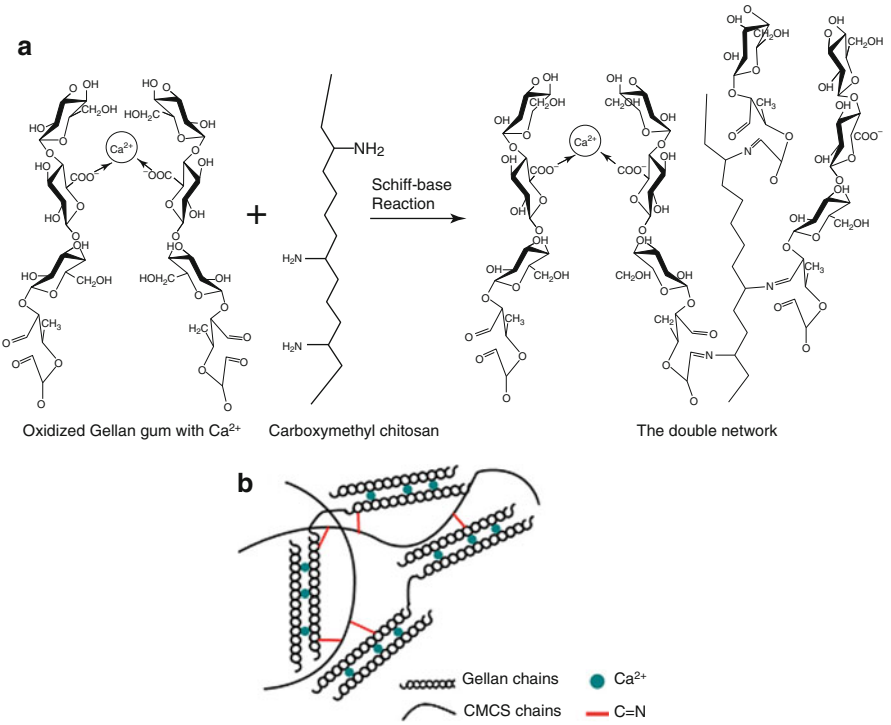

Fig. 21 (**a**) Schiff-base formation between amino groups of CM-chitosan and aldehyde groups of oxidized gellan gum. (**b**) The cross-linking mechanism of complex hydrogel (Tang et al. 2012)

showed an increased compressive modulus of 278 kPa and an ability to return to the original shape after release of the compressive load. In vitro chondrocyte encapsulation and proliferation experiments found that the complex hydrogel significantly enhanced the viability of the cells. These results suggest that the complex gel of gellan gum and carboxymethyl chitosan is a promising material for cartilage tissue engineering (Tang et al. 2012).

5 Applications of Gellan Gum and Its Modified Materials in Biomedicine

5.1 Applications in Food

Typical food applications of gellan are summarized in Table 2, which is taken directly from the CP Kelco booklet available online at the web address (http://www.appliedbioscience.com/docs/Gellan_Book_5th_Edition.pdf). Gellan is used as gelling agent for water-based dessert gels. In addition gellan is used to improve heat stability of other gelled products like aspic in which gelatin is usually used as gelling agent. Gellan can be an alternative for high methoxyl pectin, the gelling

Table 2 Typical food applications of gellan. http://www.appliedbioscience.com/docs/Gellan_Book_5th_Edition.pdf

Major food area	Typical products
Confectionery	Starch jellies, pectin jellies, fillings, marshmallow
Jams and jellies	Reduced calorie jams, imitation jams, bakery fillings, jellies
Fabricated foods	Fabricated fruits, vegetables, meats
Water-based gels	Dessert gels, aspics
Pie fillings and puddings	Instant desserts, canned puddings, precooked puddings, pie fillings
Icings and frostings	Bakery icings, canned frostings
Dairy products	Ice cream, gelled milk, yogurt, milkshakes, low-fat spreads, dips
Beverages	Fruit, milk-based, soy, and carbonated drinks
Films/coatings	Batters, breadings, coatings, adhesion systems

agent of general fruit jams. High methoxyl pectin requires high sugar level for gel formation. Reducing amounts of sugar is desired for jams and gellan can be used for this purpose. By applying gellan to starch jellies, the set time of starch jellies can be reduced. Gibson and Sanderson (1997) show many sample recipes for a low-solid fruit spread, a fruit pastille-type gel, a dessert jelly, and a milk jelly based on gellan gum.

For meat products, fat reduction is required from the viewpoint of preventing metabolic syndrome. On the other hand, fat plays an important role for taste and texture in meat products. Gellan was investigated whether it is possible to replace fat into carbohydrate polymers in meat products (Lin and Huang 2003; Totosaus and Pérez-Chabela 2009). Mixed gels of konjac and gellan were incorporated into reduced-fat (18%) frankfurters and compared with reduced-fat and high-fat (28%) controls for physicochemical, textural, and sensory properties and storage stability (Lin and Huang 2003). Water-holding capacity, sensory scores (firmness and juiciness) was improved by adding konjac and gellan compared to reduced-fat controls without added mixed gels (Lin and Huang 2003). Gellan was incorporated into low-fat and sodium-reduced meat batters with dicationic salts (Totosaus and Pérez-Chabela 2009). Inclusion of magnesium chloride showed better performance compared to calcium chloride in instrumental texture characteristics, which was attributed to differences of gellan gel structures (Totosaus and Pérez-Chabela 2009).

Among various polysaccharides, mainly cellulose derivatives methyl cellulose and hydroxypropylmethyl cellulose have been used to reduce the fat content in fried foods (Varela and Fiszman 2011). Some other trials to use gellan to reduce oil uptake during frying have been carried out. Addition of gellan to a traditional Indian deep-fat fried product *sev* consisting mainly of chickpea flour decreased oil content of final products without textural change (Bajaj and Singhal 2007).

In acidic condition, addition of gellan improves the stability of casein gels; sedimentation is suppressed. The effect of gellan on the structure and stability of a yogurt-based Iranian drink was investigated (Kiani et al. 2010). Incorporation of low concentration of gellan (0.01, 0.03, and 0.05 wt.%) reduced serum phase generated by sedimentation and inhibited further separation at longer times

(up to ~1 month). Low concentration of gellan was thought to form "weak gel" and gellan–casein associations (Kiani et al. 2010).

In beverages and pourable dressings, a "fluid gel" shown in the section 3.2.1 "Rheology of Gellan Solutions and Gels" is used to give a suspension at a low viscosity. Gellan can form a heat-resistant "fluid gel" so that it can be subjected to heating for pasteurization, while carrageenan and agar form only a non-heat-resistant "fluid gel" (Oomoto et al. 1999). Gellan gum is also advantageous because it is acid-resistant which is often required for drinks and beverages.

5.2 Drug Controlled Release

Natural polymers are preferred over synthetic polymers in controlled drug delivery systems because of their biodegradability, low cost, easy availability, and nontoxicity (Bhardwaj et al. 2000). However, they also possess certain drawbacks like uncontrolled hydration, microbial contamination, drop in viscosity during storage, etc. These limitations can be reduced following modification by cross-linking, blending, interpenetrating polymer network formation, etc.

The investigation of the material science of polymeric encapsulation systems has been a focused subject recently in interdisciplinary fields, such as food, drug, pharmaceutical, and environmental science (Vandegaer 1974). In particular, composite capsules are very promising and functional devices, in which the polymer matrices have been designed for protection and sustained release of the encapsulated substances (Kondo et al. 1991).

Methods to prepare the capsule include (a) complex coacervation (Das and Palchowdhury 1989; Iso et al. 1985), (b) phase separation (Iso et al. 1985; Hildebrand and Tack 2000), and (c) in situ polymerization (El-Samaligy et al. 1986; Wood and Whateley 1982). The preparative method via (a) is based on the polyionic complexation through the electrostatic interactions between cationic and anionic polymers, resulting in the formulation of insoluble spherical beads or capsules.

The advantage of this method in material science is its simple procedure, mixing a polyelectrolyte aqueous solution with a countercharged polyelectrolyte solution. In many cases the complexation of polyelectrolytes is performed in an aqueous solution, allowing the encapsulation of biological components, including enzymes or peptides, as their biological activities can be retained (Kabanov 1973).

True spherical capsules are formed by electrostatic polysaccharide interaction between chitosan and gellan gum via polyion complex (PIC) formation in aqueous solutions (Fig. 22). Dropwise addition of a chitosan solution into the gellan solution gave spherical capsules whose outside surface was gellan and whose inside was chitosan (chitosan^{in}–gellan^{out} capsule). Conversely, the addition of gellan into chitosan yields chitosan^{out}–gellan^{in} capsules. The capsules thus obtained were mechanically and chemically stable under given physiological conditions. The mechanical stability of the capsules is probably due to the fibrous network spread along the capsule membrane (Ohkawa et al. 2004).

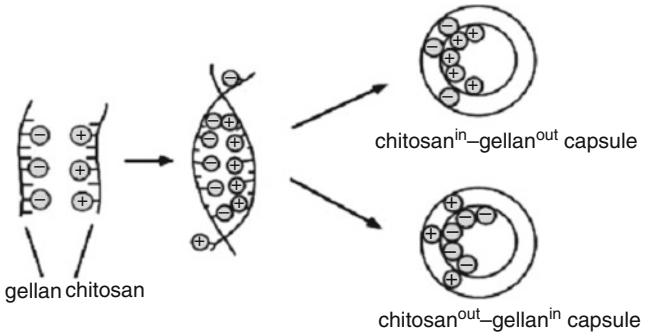

Fig. 22 Illustrative drawing of PIC capsule formation (Ohkawa et al. 2004)

Table 3 Molar mass dependence of releasing behavior of substances from chitosan–gellan capsules (Ohkawa et al. 2004)

		Release	
		%	
Substances	$\overline{M}_W$	Chitosan^{in}–gellan^{out}	Chitosan^{out}–gellan^{in}
Acetylsalicylic acid	180	29.0	48.4
Penicillin G potassium	372	25.7	45.9
Gramicidin D	1,880	16.9	34.0
Insulin	5,700	3.8	30.8
Trypsin	24,000	2.6	13.7
α-Chymotrypsin	25,000	2.4	14.0
Bovine serum albumin	57,000	1.7	12.4
Lactoferrin	86,000	1.1	12.0

Drugs and proteins could be easily loaded into the capsule by mixing the substances with the inside component then by forming the capsule. Comparison of the releasing characteristics of the two kinds of PIC capsule, i.e., chitosan^{in}–gellan^{out} and chitosan^{out}–gellan^{in} capsules, afforded several insights for controlling the release kinetics of small substances. The charge-dependent release control could be achieved by the inverse of the inside and outside composition of the PIC capsule. The M_w-dependent releasing properties of the chitosan^{in}–gellan^{out} and chitosan^{out}–gellan^{in} capsules were also examined (Table 3). The selectivity of permeation was rather steep for the chitosan^{in}–gellan^{out} capsule as compared to that of the chitosan^{out}–gellan^{in} capsule. The results described here, proved the usefulness of the chitosan–gellan capsule as a drug-carrier material having the property of a controlled-release mechanism (Ohkawa et al. 2004).

A polymer drug system based on gellan and PVA interpenetrated network (IPN) was prepared (Dumitriu et al. 2004). The drug (cephotaxime, CEF) has been included through a diffusion process, from an aqueous solution into a high swelling degree hydrogel. The amount of included drug, as well as the rate of its inclusion, depends on the network cross-linking degree and its water swelling characteristics,

respectively. The kinetics of CEF release from the hydrogels used is typical to diffusional processes, a maximum rate being recorded in the first moments, followed by its stabilization at a practically constant value, over a wide time interval. The release rate of CEF became slower with increasing cross-linking degree of the interpenetrated network (Dumitriu et al. 2004).

Novel interpenetrating polymeric network microspheres of gellan gum and PVA were prepared by the emulsion cross-linking method. The prepared IPNs demonstrated a better mechanical property as compared to pure gellan gum, indicating the suitability of the IPNs for microsphere preparation. The cross-link density was significantly affected by the content of glutaraldehyde and gellan gum in the formulations. Carvedilol was successfully entrapped into the IPN matrix. Microspheres were spherical with smooth surfaces. The release of carvedilol was found to depend upon the extent of cross-linking of the matrix as well as the amount of gellan gum present in the matrix. Higher release rates were observed for microspheres with lower cross-link density and lower amounts of gellan gum in the matrix. No significant difference was observed in the diffusion coefficients in the simulated gastric and intestinal fluids (Agnihotri and Aminabhavi 2005).

Considering relatively fast drug release rate of Ca^{2+}/gellan beads in phosphate buffer solution, a novel glipizide-loaded bead system was developed through ionotropic gelation of gellan with trivalent Al^{3+} ions and covalent cross-linking with glutaraldehyde (GA) (Maiti et al. 2011). Following GA treatment, spherical Al^{3+}/gellan beads contracted leaving wrinkles on bead surface. A maximum of 97.67 % drug entrapment efficiency was achieved; however, GA treatment reduced the efficiency by 11.89 %. All the beads released only 10 % drug in acidic medium in 2 h; however, it was found to be 38–47 % for Al^{3+}/gellan beads and only 15 % for GA-treated beads in weakly alkaline medium. The drug release did correlate well with their swelling behaviors. An exponent value of n greater than 0.85 in Korsmeyer–Peppas equation signifies super case II transport mechanism (Ritger and Peppas 1987). The anomalous drug transport mechanism for GA-treated beads shifted to super case II transport since the value of diffusion exponent n was 1.27, where the polymer relaxation phenomenon was dominant. The drug was relatively stable, amorphous in the beads. Thus, both GA-treated and -untreated Al^{3+}/gellan beads could be useful carriers for the controlled oral delivery of glipizide.

In recent years, controlled drug delivery formulations and the polymers used in controlled drug delivery systems have become much more sophisticated, with the ability to do more than simply extend the effective release period for a particular drug. For example, intelligent or smart polymers play an important role in drug delivery since they may dictate not only where a drug is delivered but also when and with which interval it is released (Soppimath et al. 2002). So, a novel class of unsaturated gellan derivatives/*N*-isopropylacrylamide stimuli-responsive hydrogels was synthesized by free radical polymerization. Gellan gum was partially functionalized by esterification with maleic anhydride under various conditions. By copolymerization of this maleate polysaccharide with *N*-isopropylacrylamide, a known temperature-sensitive precursor, water-swollen hydrogel with interpenetrating polymer networks was obtained. Depending upon composition

and the nature of the base polysaccharide, the hydrogels showed different response rates to the external changes of temperature as well as pH. By changing the feed composition ratio of precursors and cross-linking agent (β-cyclodextrin acrylate or *N*,*N*′-methylenebisacrylamide, respectively), the phase-transition temperature (lower critical solution temperature) could also be adjusted near to the body temperature for biomedical and biotechnological applications (Hamcerencu et al. 2008).

Polymeric implants are one of the attractive devices for targeted drug delivery (Dash and Cudworth 1998). The polymeric matrix can protect drugs from conditions that could degrade or render the drug in the body inactive. Therefore, various polymers have been investigated in order to obtain an ideal drug delivery system that would allow ease of incorporation of drugs without affecting their bioactivity and delivery to the target site at a desired rate and exhibit biocompatibility when in contact with the tissue. An implant controlled-release system for methotrexate (MTX) delivery based on a polyion complex composed of chitosan and gellan was investigated (Kumar et al. 2008). Multilayered implant was prepared by using PVA, gellan, and chitosan. Two chitosan layers sandwiched the PVA–gellan layer, which acted as a methotrexate reservoir. Both in vitro and in vivo results indicate that MTX release is slow from implants. The results of the in vitro release of MTX from the implants showed that percent release rate decreased with increasing $CaCl_2$ concentration, which was attributed to the increase in cross-link density in the network. Chitosan coated PVA–gellan multilayered implants can represent an effective delivery system for the sustained release of MTX. Moreover, the potential for toxicity is low because of the extended period over which the release occurs. Also the implants showed good biocompatibility, which is essential for implant-based sustained delivery systems (Kumar et al. 2008).

5.3 Tissue Engineering

Modified gellan gum can be of potential of a suitable material for tissue engineering applications though some challenges still remain in the aspects of toughness, extensibility, and appropriate mechanical characteristics. A lot of work has been done taking advantage of the excellent characteristics of gellan gum in tissue engineering (Ferris et al. 2013a).

5.3.1 The Advantage of Gellan Gum for Tissue Engineering Applications

Gelation of GG, as described previously, is preceded by a conformational transition from coil to double helix, and association of these helices in junction zones is facilitated through either monovalent or divalent cations. Consequently, GG hydrogels may be formed at low concentrations of divalent cations or even in the presence of monovalent cations alone (Morris et al. 2012). This could be advantageous in tissue engineering applications, and it has been shown that GG can be cross-linked to form self-supporting hydrogel structures simply by the addition of

standard cell culture media with no added ions (Miyamoto et al. 1996). In addition, GG formed a gel on contact with tear fluid (Rupenthal et al. 2011), which is advantageous for ophthalmic drug delivery. GG in combination with hyaluronan was reported to be a candidate for short-term vitreous substitutes because of its transparency and similar wetting properties to that of vitreous (Suri and Banerjee 2006).

GG hydrogels are also stable during long-term culture in standard media and do not suffer from unwanted dissolution due to ionic exchange (De Silva et al. 2013). De Silva et al. (2013) found a steady mass loss during soaking GG gels for a much longer time of 28 days than 7 h; after that Hossain and Nishinari (2009) found a much greater chain release and erosion of GG gels at 10 °C although De Silva et al. examined the mass loss at the higher temperature (37 °C) of the surrounding medium. The difference in the period of the steady mass loss was due to the difference in cations: Hossain et al. used the potassium-type GG without further addition of cations, while De Silva et al. added calcium in the gel preparation. Taking into account the previous results reported by Hossain et al., De Silva et al. interpreted that there was a smaller amount of unassociated GG chains in their gels compared to that of the K–GG gels without added cations. Using murine dermal fibroblasts (L929), De Silva et al. examined the cell growth inhibition (CGI) of hydrogels. The percentage CGI was determined by the following equation:

$\mathrm{CGI} = (n_c - n_s)/n_c$, where n_s and n_c are the number of cells in the sample and media control dishes, respectively. Cell growth inhibition of hydrogels was found to be proportional to mass loss, that is, CGI values increased with increasing GG concentration in the degradation medium (De Silva et al. 2013).

In addition to these gelation properties, GG's excellent optical clarity could prove advantageous in analysis of encapsulated cells (Giavasis et al. 2000). It has been shown that GG scaffolds can be made porous using straightforward fabrication methods (Peña et al. 2010). Furthermore, GG appears not to inhibit polymerase chain reaction (PCR) analysis (Rath and Schmidt 2001) and is suitable as an injectable material (Du et al. 2012; Ferris and in het Panhuis 2009; Oliveira et al. 2010b).

A further attractive characteristic of GG for tissue engineering is the mechanical similarity to the elastic moduli of common tissue. The mechanical characteristics of GG depend on type (low acyl GG (LAGG) or high acyl GG (HAGG)) and concentration as well as the type and amount of physical cross-linker. Other strategies involve methacrylation of the GG chain followed by physical and/or chemical cross-linking (Shivkumar et al. 2006). These approaches can be used to tune the elastic modulus of GG hydrogels to that comparable with a wide range of human soft tissues such as the muscle, liver, and cartilage (Discher et al. 2005).

Finally the degradation behavior of GG can be controlled. There are a number of human enzymes such as lysozyme, amylase, and trypsin which are known to degrade common polysaccharides (Garrett and Grisham 2007). These enzymes are commonly found in tears, mucus, milk, and the stomach and degrade polysaccharides through hydrolysis. It has been reported that the enzymatic degradation of GG containing hydrogels resulted in a mass loss of 20 % and 30 % over 7 days with lysozyme and trypsin, respectively (Suri and Banerjee 2006).

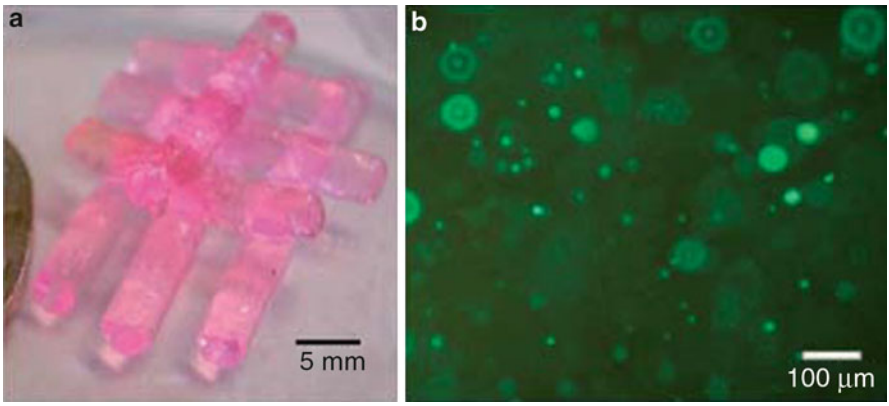

Fig. 23 (**a**) Gellan hydrogel cylinders produced by extruding 1 % w/v gellan solution into culture medium. (**b**) Calcein-stained rat bone marrow cells in gellan hydrogel after 10 days in culture (Smith et al. 2007)

5.3.2 Gellan Gum as Tissue Engineering Material

GG hydrogels could be used to encapsulate viable mammalian cells (Smith et al. 2007). GG could be cross-linked by the addition of cell culture media alone, owing to the gelation of GG at millimolar concentrations of divalent cations which are present in most media formulations, to form self-supporting hydrogels (Fig. 23a). This enabled a mild encapsulation process for rat bone marrow cells (Fig. 23b), which remained viable in the GG hydrogels for 21 days in culture.

Chondrocytes remain viable when encapsulated in GG hydrogels (Oliveira et al. 2010a) and exhibited extracellular matrix (ECM) production when implanted subcutaneously in nude mice (Oliveira et al. 2009a). Injectable delivery of these chondrocyte-laden gels was also investigated, taking advantage of the ability of GG to form a gel under physiological conditions (Oliveira et al. 2009b). GG hydrogels were also used to encapsulate oligodendrocyte-like cells within the center of a tubular structure fabricated by 3D extrusion printing of starch (Silva et al. 2010). GG can be methacrylated to introduce the possibility of photo-initiated cross-linking (Coutinho et al. 2010), thus enhancing the range of mechanical and degradation properties that can be tailored in GG hydrogels (Fig. 24). These materials have been studied for application as cellular or acellular artificial nucleus pulposus implants in the treatment of intervertebral disk degeneration (Silva-Correia et al. 2011, 2012; Pereira et al. 2011).

Physical parameters of GG hydrogels for cartilage applications can be optimized by blending low acyl and high acyl GG (Lee et al. 2011). Increasing the HAGG/LAGG ratio resulted in a decrease in the gel's stiffness, and that gels of 2 % (w/v) LAGG were most suitable for fibrocartilage applications. Blending GG with other types of biomolecules (e.g., polysaccharides and enzymes) for tissue engineering applications has also been considered (Ciardelli 2005; Bertoni et al. 2006; Cascone et al. 2001b; Patil et al. 2011; Coutinho et al. 2012; Barbani et al. 2012).

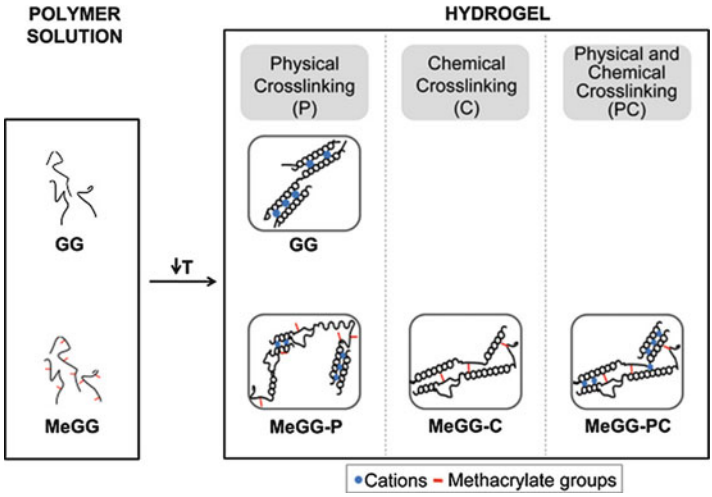

Fig. 24 Possible cross-linking mechanisms for GG, low-MeGG, and high-MeGG hydrogels (Coutinho et al. 2010)

GG is a relatively bio-inert material. This has been demonstrated through the lack of cell infiltration and angiogenesis observed when implanting GG hydrogels in vivo (Silva-Correia et al. 2012) and through evaluation of the behavior/response of anchorage-dependent cells encapsulated in GG hydrogels (Coutinho et al. 2010; Silva et al. 2010). Thus, application has so far been largely limited to anchorage-independent cells like chondrocytes (Gong et al. 2009; Oliveira et al. 2010a). Therefore, in order to function as a useful artificial ECM for anchorage-dependent cell types, GG must be modified. Previously, GG microspheres produced by a water-in-oil emulsion process have been covalently functionalized with gelatin through redox-mediated cross-linking to encourage the attachment of human dermal fibroblasts and human fetal osteoblasts (Fig. 25) (Wang et al. 2008). Photocrosslinkable variants of both GG and gelatin have also been combined in a novel double-network hydrogel with enhanced mechanical properties (Shin et al. 2012). More recently, GG hydrogels were modified with RGD-containing peptides to enhance interaction with encapsulated neural stem/progenitor cells (Fig. 26) (Silva et al. 2012). Another interesting development is the modification of GG with surfactants to function as a bio-ink for cell printing applications (Ferris et al. 2013b).

Although it is straightforward to prepare GG hydrogels with elastic moduli similar to that of tissue, matching the toughness and load tolerance of mammalian tissue is not. For example, LAGG and HAGG gels can be prepared with elastic moduli (kPa range) similar to that of the liver, fat, muscle, or cartilage (Coutinho et al. 2010; Discher et al. 2009). But the compressive stress at failure of these gels (kPa range) is orders of magnitude lower than tissues such as the cartilage (MPa range) (Coutinho et al. 2010; Kerin et al. 1998). In other words GG hydrogels are mechanically weak, which is a generally recognized drawback of hydrogel materials under consideration for tissue engineering.

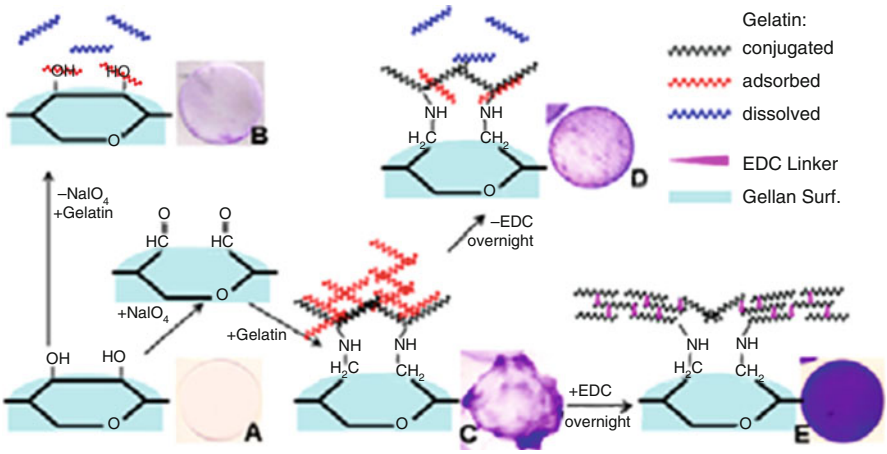

Fig. 25 Schematic diagrams of fabrication of gelatin-grafted-gellan (TriG) microspheres (Wang et al. 2008)

A number of strategies have been adopted to address the mechanical weakness and/or load intolerance. Hydrogels based on chemically/physically cross-linked methacrylated GG resulted in improvements in the magnitude of compressive stress at failure (up to 0.9 MPa) (Coutinho et al. 2010). It is not known if these gels would be able to recover from damage (load tolerance). Progress toward the latter has been made by building on the pioneering research on toughening gels by Gong et al. (Gong 2010; Gong et al. 2003; Haque et al. 2012). These gels exhibit excellent mechanical performance, for example, compressive stress at failure values of up to 60 MPa (Haque et al. 2012). The toughening of hydrogels is achieved using an interpenetrating polymer network approach which results in the so-called "double-network" (DN) hydrogels with mechanical properties that are significantly improved compared with either one of the parent networks (Gong 2010; Gong et al. 2003; Haque et al. 2012). The two polymer networks in the DN approach are chemically (covalently) cross-linked, and the toughening mechanism arises from efficient energy dissipation due to fragmentation of the first (brittle) network, thereby allowing the second (ductile) network to facilitate large deformations (Gong 2010; Haque et al. 2012). The DN approach has also been adopted for methacrylated GG in combination with methacrylated gelatin (Shin et al. 2012). The resulting DN gels exhibited compressive stress at failure values of close to 7 MPa. DN gels are extremely tough, but due to the irreversible, permanent fracture of the chemical cross-links (Gong 2010; Haque et al. 2012), DN gels are not able to recover from significant loading and have poor fatigue resistance.

Recently, it has been demonstrated that preparing IPN gels combining one network with reversible physical (non-covalent) bonds and one network with irreversible covalent networks results in gels that are tough but can recover from damage (Haque et al. 2011; Bakarich et al. 2012; Sun et al. 2012). For example, it was demonstrated that hydrogels consisting of ionically cross-linked LAGG and

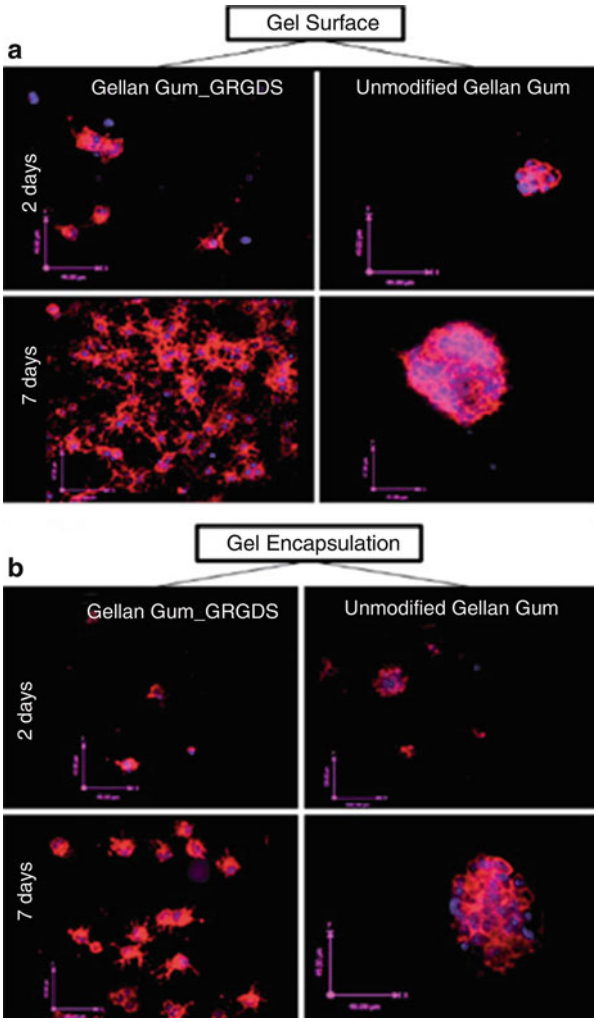

Fig. 26 Morphology and dispersion of neural stem/progenitor cells (NSPCs) on the gellan gum hydrogel modified with the cell-adhesive peptide (GG–GRGDS). Confocal analyses revealed substantial differences in NSPC morphology when cultured either (**a**) on the surface or (**b**) encapsulated within the GG–GRGDS versus unmodified GG gel. Cell spreading and visible cytoplasmatic extensions were only observed in the GG–GRGDS. In the unmodified GG, NSPCs proliferated as neurospheres. The cytoplasm was stained with the anti-F-actin/phalloidin (*red*) and nuclei counterstained with DAPI (*blue*) (Silva et al. 2012)

covalently cross-linked poly(acrylamide) exhibited double-network behavior, i.e., improved mechanical properties compared to their respective single-network hydrogels (Bakarich et al. 2012). These so-called ionic–covalent entanglement hydrogels exhibited self-recovery of 53 ± 4 % within 80 min from the first compressive cycle.

5.4 Other Applications in Biology and Environment

The dispersibility of carbon nanotubes (CNTs) in most common solvents is rather limited, but it is well known that this can be improved through the use of dispersants

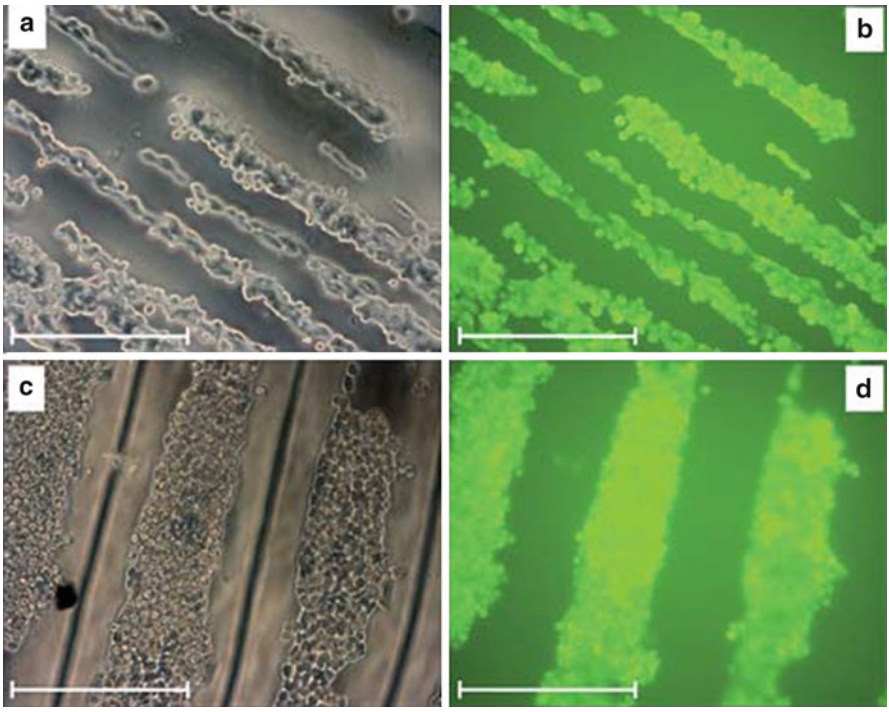

Fig. 27 Microscopy images of cells growing on optimal hydrogels (Ferris and in het Panhuis 2009). (**a**) and (**c**) Bright field microscopy images of adherent L-929 cells after 3 days of culture growing on hydrogels molded by VR1 and VR2 substrates, respectively; (**b**) and (**d**) fluorescent microscopy images of cells growing on hydrogels molded by VR1 and VR2 substrates, respectively, after 3 days of culture

such as surfactants and polymers (in het Panhuis 2006). Gellan gum is an extremely good dispersant for carbon nanotubes (CNTs) in aqueous solutions, able to disperse CNTs at concentrations as low as 0.0001 % w/v of gellan gum (in het Panhuis et al. 2007). Gellan gum hydrogels containing carbon nanotubes have been prepared. They are a promising candidate for biomaterials which are able to stimulate incorporated cells toward functional tissue formation. The ability to tailor the gelation temperature to be physiologically relevant suggests the possibility of cell-encapsulating or injectable scaffold systems. By altering hydrogel composition or incorporating topographical surface features, it demonstrated the ability to modify cell responses (Fig. 27). This could be implemented in the design of scaffolds for specific cell types. Furthermore, it demonstrated percolation of a CNT network in a gellan gum hydrogel, and it is hoped these composite systems will be developed further into a means by which electrical signals may be propagated through biomaterials (Ferris and in het Panhuis 2009).

It was demonstrated that these gellan gum/carbon nanotubes dispersions could be inkjet-printed onto flexible substrates to create transparent, conducting, thin films.

The resistance of the composite films under ambient conditions (12 MΩ) was found to be only one order of magnitude lower than that of gellan films (350 MΩ). Interestingly and contrary to most other water-soluble polymer composite materials, the resistance of these inkjet-printed gellan and gellan–CNT films decreased significantly (to 0.850 MΩ) in the presence of water vapor. In other recent works, the gel and carbon nanotube gel fibers prepared by polyelectrolyte complexation of gellan gum and chitosan exhibited similar behavior (Granero et al. 2008a, b). It can be explained as follows. Under ambient conditions only transport pathways through inter-nanotube junctions contribute to the current. Exposure to humid conditions enables transport through the additional polymer-dominated pathways resulting in the observed increased current. It was shown that cation mobility and polymer conformation play an important role in this water-sensitive behavior. In particular, it was suggested that the current contains an electrical contribution from electron transport through the nanotubes and an ionic contribution due to cations. It was shown that increasing the nanotube mass fraction increases the relative contribution to the current of the electron transport over ion mobility. Moreover, it was observed that there was a variable ionic contribution to the current rather than the expected ionic contribution being a constant value. The ionic contribution was found to scale exponentially with increasing nanotube mass fraction (in het Panhuis et al. 2007).

Printing is the deposition of a material (ink) onto a substrate in order to produce a desired structure. Specialist technologies are increasingly requiring advanced material properties from the printed structures, such as flexible, stretchable conductors and sensors (Siegel et al. 2010; Rogers et al. 2010; Yamada et al. 2011). There is a drive to develop new printing processes to further extend the sophistication and the capabilities of the printed structures. Extrusion printing (also known as direct writing and solid free-form fabrication) is a process that involves the pressurized delivery of an ink through a capillary onto a moving substrate (Lewis 2004; Calvert and Crockett 1997). Relative to other printing processes, extrusion printing offers greater flexibility in the ink materials and a large range in the printed structure's minimum feature sizes (or resolution), from the micro- to the macroscale (Calvert et al. 1997). Extrusion printing can also manufacture three-dimensional, structurally robust structures and embed material into substrates (Mire et al. 2011). This functionality makes up for some of the drawbacks (e.g., resolution) compared to other methods such as inkjet printing (Mire et al. 2011; Calvert 2001; Singh et al. 2010). Carbon nanotube networks in biopolymer solutions are explored as potential ink systems for the extrusion printing of conducting structures. The biopolymer gellan gum is found to act as an excellent dispersant of multiwalled carbon nanotubes and has the appropriate flow properties to act as a thickener for the controlled dispensing of carbon nanotube networks. Absorbing substrates are found to improve the resolution and the flexibility of the printed structures. These printed conducting carbon nanotube networks exhibit interesting mechanical and electrical characteristics, which are applied to demonstrate their actuating and strain gauging capabilities (Pidcock and in het Panhuis 2012).

Currently gold and silver nanoparticles are being explored for drug delivery and other biomedical applications; therefore, it is necessary to develop a novel and

green synthesis process for these nanoparticles. Recently, gellan gum has been employed as a reducing and stabilizing agent for the synthesis of gold and silver nanoparticles (Dhar et al. 2008, 2011, 2012). These nanoparticles display greater stability to electrolyte addition and pH changes relative to the traditional citrate and borohydride-reduced nanoparticles. Furthermore, these gellan gum capped/reduced gold nanoparticles were further conjugated with sophorolipids which again were accessed through a biochemical transformation of a fatty acid. These sophorolipid-conjugated gellan gum reduced/capped gold nanoparticles showed greater efficacy in killing the glioma cell lines and more prominently glioma stem cell lines. The cytotoxic effects became more prominent once the doxorubicin hydrochloride was also conjugated to these gold nanoparticles (Dhar et al. 2011).

Hazardous waste compounds such as gasoline cause a serious pollution of the aquifer, and bioaugmentation, the introduction of microorganism which can degrade these harmful compounds, has been expected to be a promising solution to solve the problem of contamination of groundwater. To ensure the viability of microorganism and transport to a wide area, the microencapsulation method is used. Moslemy et al. (2002) encapsulated an enriched bacterial consortium in gellan gum microbeads (16–53 μm) and dispersed encapsulated cells within the porous soil matrix of saturated soil microcosmos and found that gasoline hydrocarbons were degraded effectively.

Heavy metals released into the environment have posed a significant threat to the environment and public health because of their toxicity and persistence in environment and, therefore, must be removed from water. Various conventional processes (precipitation, electrochemical processes, and/or membrane processes) have been employed to treat industrial effluents (Gavrilescu 2004). However, these applications are often limited by technical and economical issues.

The integrated process, which couples magnetic separation with surface complexation adsorption and ionic exchange, is especially effective in the remediation of heavy metals (Ngomsik et al. 2006; Yantasee et al. 2007). This system has several advantages that the process does not generate secondary waste and the materials involved can be recycled and facilely used on an industrial scale, and furthermore that the magnetic particles can be tailored to fix specific metal species in water, waste, or slurries (Ngomsik et al. 2006; Li et al. 2008). So, a composition of gellan gum and Fe_3O_4 nanoparticles was employed as a unique adsorbent for heavy metal removal in aqueous solutions. Adsorption kinetics analysis showed that the adsorption capacities were in an order of $Pb^{2+} > Cr^{3+} > Mn^{2+}$. Different experimental parameter studies indicated that adsorbent dosage, initial metal concentration, temperature, and initial pH played important roles in adsorption process (Wang et al. 2009).

6 Conclusions

Gellan gum has been one of main bacterial polysaccharides with various applications such as additives in food and cosmetic industry. According to current reports, chemically modified gellan gum offers great opportunities as a material for tissue

engineering though its toughness and extensibility, appropriate mechanical characteristics, suitable degradation behaviour should be further improved. Many further advances will be made before gellan gum comes close to realising its full potential. These will undoubtedly include identification of new areas of application, and formulation of novel or improved products. An additional approach, however, might be informed manipulation of acyl content, by variant cultures or controlled deacylation, to tailor the properties of gellan to the requirements of specific applications. Although the feasibility of this approach has already been demonstrated, it has not yet been exploited on a commercial scale.

Contents

Abstract

Marine microorganisms have been under research for the last decades, as sources of different biocompounds, each with various applications. Polysaccharides (**PSs**) are among these chemicals being produced and released by marine microalgae. These are very heterogeneous, including cyanobacteria and eukaryotic microalgae from several divisions/phyla, each of which with different characteristics. The **PSs**, sulfated or not, that they produce have already proved to be promising agents in various fields, such as food, feed, pharmaceutical, and biomedical. They can also be applied in wastewater and/or soil treatment and in some engineering areas, as naval engineering.

After a brief introduction on the general types of biopolymers produced by marine microalgae and cyanobacteria, this chapter starts by presenting the species of these microorganisms and the types of **PSs** they produce, as well as

the respective chemical composition; goes into the production of **PSs** and the effect of specific compounds; and focuses on the physicochemical properties of these **PSs** and their composition and structure, approaching the rheological properties relevant for their functions and behavior. The bioactivity of **PSs** and their applications are, next, presented, including therapeutic applications based on their antiviral and antibacterial activities, antioxidant properties, anti-inflammatory and immunomodulatory characteristics, antitumoral activity, and antilipidemic and antiglycemic properties, among others. The potential use of **PSs** from marine microalgae as it is or incorporated in health foods is also considered. The mechanisms behind their antiviral and antibacterial activities are explained. Toxicological and safety issues are also disclosed, and there is a brief mention of the bioavailability of **PSs** from microalgae. The chapter ends by listing some preclinical studies with this type of polymers.

Keywords

Abbreviations

arab	Arabinose
CaSp	Calcium spirulan
CB	Cyanobacterium(a)
EC_{50}	The molar concentration of a drug that produces 50 % of the maximum possible response for that drug
ED_{50}	In vitro or in vivo dose of drug that produces 50 % of its maximum response or effect
fru	Fructose
fuc	Fucose
GAG	Glycosaminoglycan
gal	Galactose
galAc	Galacturonic acid
glcAc	Glucuronic acid
glc	Glucose
IC_{50}	The molar concentration of a drug which produces 50 % of its maximum possible inhibition
ID_{50}	In vitro or in vivo dose of a drug that causes 50 % of the maximum possible inhibition for that drug
man	Mannose
MW	Molecular weight
NaSp	Sodium spirulan
NO	Nitric oxide
PS	Polysaccharide
rham	Rhamnose

sEPS	Sulfated exopolysaccharide
sPS	Sulfated polysaccharide
xyl	xylose

1 Introduction

Polysaccharides (**PSs**) and oligosaccharides can be synthesized by microorganisms; some of them are even secreted out into the environment (or culture medium), from which they are easily extracted. **PSs** have been studied for a long time due to their characteristics, especially their conformation, which is reflected in their chemical behavior and, therefore, in their wide range of applications. However, the knowledge on their complete composition and structure is still taking the first steps, and despite the applications that might appear after a solid understanding of their structure and conformation, these applications could even be extended to the medicine field. As a matter of fact, there is some difficulty on studying these polymer chains because of the diversity and distribution of simple sugars (mono-, di-, and oligosaccharides) along the **PSs** chains and whether these chains are linear or ramified. Therefore, the analysis of the **PSs** structures and, consequently, their applications is a real challenging task. Thus, the analysis of these polymer chains has been limited to oligosaccharides obtained by hydrolysis of high molecular polymers and to *X-ray* diffraction studies of **PSs** gels (Eteshola et al. 1998).

Among the **PSs** produced by microalgae and cyanobacteria (thereafter referred to as microalgae), especially marine species, only the **sPS** from *Gyrodinium impudicum* is a homopolymer of **gal** (Yim et al. 2007) and perhaps a cell wall **PS** from *Chlorella vulgaris*, a β-(1,3)-glucan (Nomoto et al. 1983), composed of D-**glc**; the **PSs** from all the other marine unicellular algae are heteropolymers, mostly constituted of **xyl**, **gal**, and **glc** in different proportions, but some other neutral sugars can also be constituents of the **PS**, as it is the case of **rham**, **man,** or **fuc**, and also some methyl sugars (Table 1). But in spite of this similarity in monosaccharide composition, the types of sugar themselves and the glycosidic bonds between each molecule are two of the characteristics that establish all the differences between the properties of **PSs** found in microalgae. Either the composition of monosaccharides and their distribution or the percentage in sulfate and uronic acids greatly determines the rheological behavior of the **PSs**, whose aqueous solutions can be highly viscous, as it happens with the **EPSs** from the marine red microalgae, or they may not present any apparent viscosity, as it is the case of the glucuronorhamnan from *C. vulgaris*.

2 Marine Sources

In the last decades the interest in products that have a marine origin, mainly seaweeds and microalgae, and also in the compounds they produce is growing rapidly. Nevertheless, microalgae have an advantage over macroalgae: they are easy to grow and manipulate, and harvesting does not depend on the climate or

season. Marine microalgae do not need much for culturing: a simple medium of seawater, with a source of nitrogen, phosphate, iron, magnesium, and some minor salts, is the only requirement to produce them. Their culture can be easily controlled and, hence, the properties and physicochemical characteristics of the biocompounds they produce, such as the polysaccharides, can be maintained all over different cultures.

2.1 Marine Unicellular Algae Producing PSs

Some marine/brackish species are already produced commercially, as it is the case of *Arthrospira* (*Spirulina*) *platensis*, *Dunaliella salina*, *Isochrysis galbana*, *Nannochloropsis salina*, *Phaeodactylum tricornutum*, and *Porphyridium cruentum* (Fig. 1), either for their biomass and/or extracts or the compounds they produce. In addition, many other species are known to produce and secrete out **PSs** into the culture medium (Table 1), **EPSs**, which can be, or not, sulfated polysaccharides (**sPSs**) these **EPSs** show properties that go from application as antiviral agents to inclusion in health foods. But these marine microalgae are so diverse (Table 1) that it seems useful to locate their taxonomic positions and present some of their characteristics.

All diatoms belong to the class Bacillariophyceae, which includes organisms with round cells (Centrophycidae) and organisms with elongated cells (Pennatophycidae). *Chaetoceros* and *Skeletonema* belong to the first group; *Amphora*, *Cylindrotheca*, *Haslea*, *Navicula*, *Nitzschia,* and *Phaeodactylum* (Fig. 1-V) are included in the second group. The main characteristic of these unicellular organisms is the presence of a silicate ornamented two-piece frustule surrounding the protoplast. Their brownish color comes from the large quantities of xanthophylls (fucoxanthin, diatoxanthin, diadinoxanthin, neoxanthin), but they also possess chlorophylls a and c and α- and β-carotenes. Their main reserves are lipids, leucosin (or chrysolaminarin, a β-(1,3)-linked and β-(1,6)-linked glucose polymer) being the second main reserve.

Isochrysis (Fig. 1-IV) is a flagellated organism belonging to the class Prymnesiophyceae (or Haptophyceae). These golden-colored unicellular algae also have chlorophylls a and c, β-carotene, and xantophylls fucoxanthin, diatoxanthin, diadinoxanthin, and echinenone. They usually present two flagella and one smooth haptonema (hence the name of the class). Their main reserve compound is leucosin. Prymnesiophyceae and Bacillariophyceae are two classes of the phylum Chromophyta.

Another diverse group of algae is phylum Chlorophyta. As it happens with the plants, the microalgae members of Chlorophyta are green in color due to the high quantities of chlorophylls a and b. But α- and β-carotene and xantophylls (neoxanthin, lutein, violaxanthin, and zeaxanthin) are also present. Their reserve is mainly starch. This is a very diverse group, including macro- and microalgae. Only two classes are referred to in this chapter: Prasinophyceae, to which *Tetraselmis* belongs, and Chlorophyceae, the latter includes *Chlorella* (Fig. 1-II), *Ankistrodesmus*, and *Botryococcus braunii* (Fig. 1-I), all of them being Chlorococcales.

Porphyridium and *Rhodella* are two genera from the phylum Rhodophyta. This is the group that includes red macro- and microalgae. The main photosynthetic pigments are chlorophylls a and d, but their red color is associated mostly to the phycobiliproteins phycocyanin, allophycocyanin, and phycoerythrin. Lutein is the main xanthophyll. *Porphyridium* belongs to the class Porphyridiophyceae, order Porphyridiales, and family Porphyridiaceae; *Rhodella* is included in the class Rhodellophyceae, order Rhodellales, and family *Rhodellaceae*. However, there are still some organisms with different scientific names, such as *Dixionella grisea*, *Rhodella reticulata*, and *Porphyridium purpureum* and *P. cruentum* (Fig. 1-VI).

Both *Cochlodinium* and *Gyrodinium* are dinoflagellates that belong to the phylum Pyrrophyta, class Dinophyceae, and order Gymnodiniales. The pigments that characterize dinoflagellates are chlorophylls a and c2, β-carotene, and xantophylls piridinine, dinoxanthin, diadinoxanthin, diatoxanthin, and neodinoxanthin; fucocyanin is the main pigment responsible for the brownish color of pyrrophytes; starch and lipidic droplets are the main reserve substances. Dinoflagellates are very particular organisms, many of them produce highly toxic compounds (dinotoxins), the most known being saxitoxins and gonyautoxins (paralytic shellfish toxins or PST), two groups of carbamate alkaloid neurotoxins, brevetoxins (another group of neurotoxic shellfish toxins or NST), and the diarrheic shellfish toxin okadaic acid (Camacho et al. 2007; Wang 2008). These toxins affect all marine organisms' and also humans' lifes as

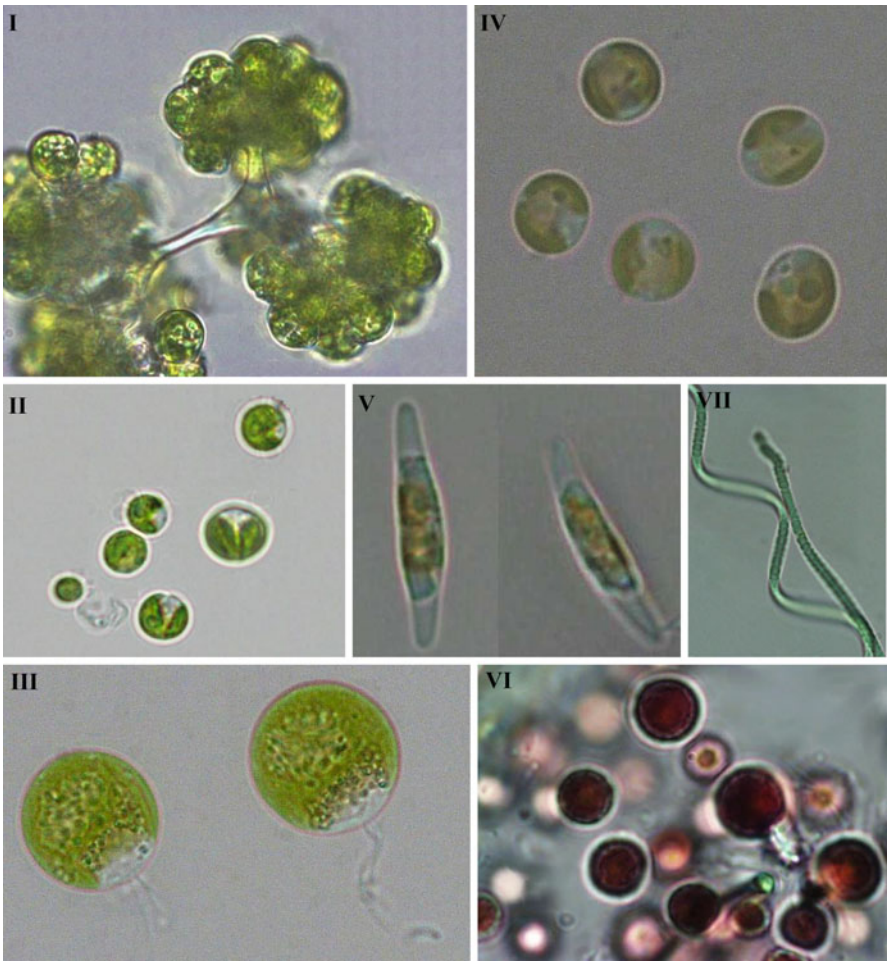

Fig. 1 Some of the microalgae cited in this chapter: **I**, *Botryococcus braunii*; **II**, *Chlorella vulgaris*; **III**, *Dunaliella salina*; **IV**, *Isochrysis galbana*; **V**, *Phaeodactylum tricornutum*; **VI**, *Porphyridium cruentum*; **VII**, *Arthrospira platensis*

seafood consumers. The red toxic tides are due to a high accumulation (or bloom) of flagellated dinophyceae, the red color coming from the remarkable accumulation of carotene.

Cyanophyta is a group of prokaryotic organisms that is most of the times studied along with microalgae (eukaryotic organisms). Cyanophytes are unicellular, solitary, or colonial organisms. This phylum includes a class, Cyanophyceae, with either filamentous or nonfilamentous structures, distinction of subclasses being based on hormogonia formation. *Aphanocapsa*, *Aphanothece*, *Cyanothece*, *Gloeothece*, and *Synechocystis* do not form hormogonia and, therefore, they are included in the subclass Coccogonophycidae, order Chroococcales; *Anabaena*,

Arthrospira (Fig. 1-VII), *Nostoc*, and *Phormidium* belong to the subclass Hormogonophycidae, order Nostocales/Oscillatoriales, whose filaments are not ramified or, if they present branches, these are false. Only one chlorophyll (chlorophyll a) and phycocyanin are their main pigments, but they also contain carotenes and phycoerythrin (Table 2).

2.2 Production of the Polysaccharides: Influence of Specific Compounds

The production of **EPSs** and their composition depend on the algal species; on the strain; on the composition and nutrient status of the culture medium, namely, the N source (Banerjee et al. 2002), the N/P ratio, and the deficiency in silicon (for diatoms); and on the culture growth phase. Some microalgae produce large amounts of **EPSs** during the stationary phase, but some others increase the yield and continue to release even during the exponential phase of growth (Ramus and Robins 1975), when synthesis of biocompounds is more active, or even during both the growth phases, depending on the culture conditions (Penna et al. 1999).

Glyoxylate is one of the compounds that can positively influence the production of **EPSs** (Bergman 1986). In *A. cylindrica*, *C. capsulata*, and *Scenedesmus obliquus*, the addition of glyoxylate to the culture medium enhanced the yield of **EPSs**. One explanation could be the metabolization of glyoxylate into serine via glycine, a process associated to photorespiration. Glyoxylate, thus, induced some changes in the metabolism of carbon, increasing its relative yield and, therefore, increasing intracellular **PSs** and the release of soluble **EPSs** (Bergman 1986; De Philippis et al. 1996; Liu et al. 2010). However, in some microalgae, the **PS** is secreted out into the culture medium only when N metabolism is not affected. As a matter of fact, after being exposed for a short period to glyoxylate, the concentration of **EPSs** produced by *C. capsulata* increased by 43 % (De Pilippis et al. 1996). Nevertheless, nitrogen starvation had also proved to induce an overproduction of carbohydrates, via an alternative pathway, with the consequent release of **PSs**, not only in other cyanobacteria but also in microalgae (de Phillipis et al. 1993; Arad et al. 1992). In addition to glyoxylate, some other substances can interfere with the production and release of **PSs**. For example, an increase of **EPS** can be induced by a magnesium shortage (de Phillipis et al. 1991; Raposo et al. 2014) or by higher ion concentrations (Raposo et al. 2014), depending on the culture medium and species of microalga. The ratio N/P and a deficiency in silicon also influence the production and release of **PSs** – while a high ratio N/P induces an increase in the **EPS** from *N. closterium*, *S. costatum* and *Chaetoceros* produce high quantities of **EPS** under low N/P ratios (Penna et al. 1999).

3 Biochemical Composition and Physical Properties

Carbohydrates represent the major group of compounds synthesized by microalgae and include some of the substances under research for the last decades because of their physicochemical and biological properties and promising applications, even in medicine. But it is well known that the biological activities of **PSs** are closely related to the chemical composition and structure of the polymers, these factors being also the reason for their physicochemical behavior. Some of the characteristics that must be taken into account are their molecular weight, as large molecules are difficult to transfer across membranes in order to carry out their specific functions, and their sulfate and uronic acid content (or other constituents that can give the polymers their anionic and acidic properties), as these components seem to have great influence on their biological activity and applications. The number of monosaccharides, the type of linkages and distribution in the molecule, the conformation and type of chains (linear or ramified), and the existence of some other chemical groups (such as amino acids, proteins, or nucleic acids) that can be (non)covalently linked to the **PS** chains are other features that are worthy to be evaluated, along with the rheological properties and resistance to digestion, either acidic or enzymatic.

The composition of the **PSs** may differ due to the method used for the extraction and hydrolysis. Sometimes a single strong step of acidic hydrolysis is used; some other times the sugar profile is obtained by means of a multistep hydrolysis

associated to an ion exchange fractionation (Dubinsky et al. 1992). The fractionation and centrifugation can help to obtain different polymers, which can be separated from the initial **PS**, as they have different sedimentation coefficients (Kieras and Chapman 1976). In *Porphyridium*, for example, one of the fractions obtained by the elution with urea showed to be xylan, **xyl** and **glcAc** being the main constituents (75 % and 13 %, respectively) (Geresh et al. 1992). In *R. reticulata*, a similar fraction was obtained by the same technique, **xyl** and **glcAc** also being the predominant constituents (Dubinsky et al. 1992). Cleavage of the **PS** molecule can also be attained by enzymatic action by **PS**-lyases (EC4.2.2.-) and **PS**-hydrolases (EC3.2.1.-), endo-and exoenzymes, but the process can be time-consuming (Badel et al. 2011b) due to all the techniques that have to be employed. These researchers, however, developed a new promising method by adapting the Biofilm Ring Test® (or BRT®) technique used to degrade the **PS**. They applied the BRT in microplate assays and associated the BRT® to the biofilm index (BFI), which corrects some of the discrepancies between images of the former technique, before and after the magnetic treatment of particles (Badel et al. 2011b).

3.1 Structure

Within the group of **PSs**, not only the intracellular and the cell wall **PSs** but also and mainly the exo- or extracellular polysaccharides (**EPS**) will be focused in this work. Among all these polymers, only the **sPS** of *G. impudicum* is a homopolymer of **gal** (Yim et al. 2007), a galactan, and perhaps the cell wall **PS** of *C. vulgaris*, a *β*-(1,3)-glucan, composed of **glc**; the **EPSs** from all the other marine microalgae are heteropolymers of **gal**, **xyl**, and **glc** in different proportions. Other sugars can also be constituents of the **PSs**, such as **rham**, **fuc**, **fru**, and some unusual methyl sugars. The types of glycosidic linkages are described only for some of the **PSs** produced by microalgae. This is the case of the **EPS** from *A. halophytica* – most of the linkages are 1,3-type (1,3-linked **glc**, 1,3-linked **fuc**, 1,3-linked **arab**, 1,3-linked **glcAc**), but 1-linked **glc** and 1-linked **glcAc** (Fig. 2a) can also be found, as well as 1,2,4-linked **man** and 1,3,6-linked **man** (Li et al. 2001). In the **CaSp** of *A. platensis*, the linkages and monosaccharides of the backbone structure are usually 1,3-linked **rham** and 1,2-linked 3-*O*-methyl-**rham** (acofriose) (Lee et al. 1998). 2,3-di-*O*-methyl-**rham** and 3-*O*-methyl-**xyl** are the monosaccharides in the nonreducing end. Besides D-**xyl**, D-**glc,** and L- and D-**gal**, the main neutral sugars, the **EPS** from *P. cruentum* has also small amounts of 3-*O*-methyl-**xyl**, 3-*O*- and 4-*O*-methyl-**gal**, and 2-*O*-methyl-**glcAc** (Percival and Foyle 1979). This type of monosaccharide is also part of the glucuronorhamnoglycan, or glucuronorhamnan (White and Barber 1972; Ogawa et al. 1999) of *Chlorella*, as 2-*O*-methyl-L-**rham** and 3-*O*-methyl-L-**rham** (or acofriose) (Ogawa et al. 1997); these methylated **rham** sugars seem to appear only in some green algae. 2-*O*-methyl-L-**rham** was firstly reported by Ogawa et al. (1997) to be part of the **PS** of *Chlorella*, but, in fact, it was also identified in *A. platensis* (Collins and Munasinghe 1987). Despite seeming to be a characteristic of *Chlorella* (Ogawa et al. 1997), 3-*O*-methyl-L-**rham** was also identified in *B. braunii* and *A. platensis* (Lee et al. 1998;

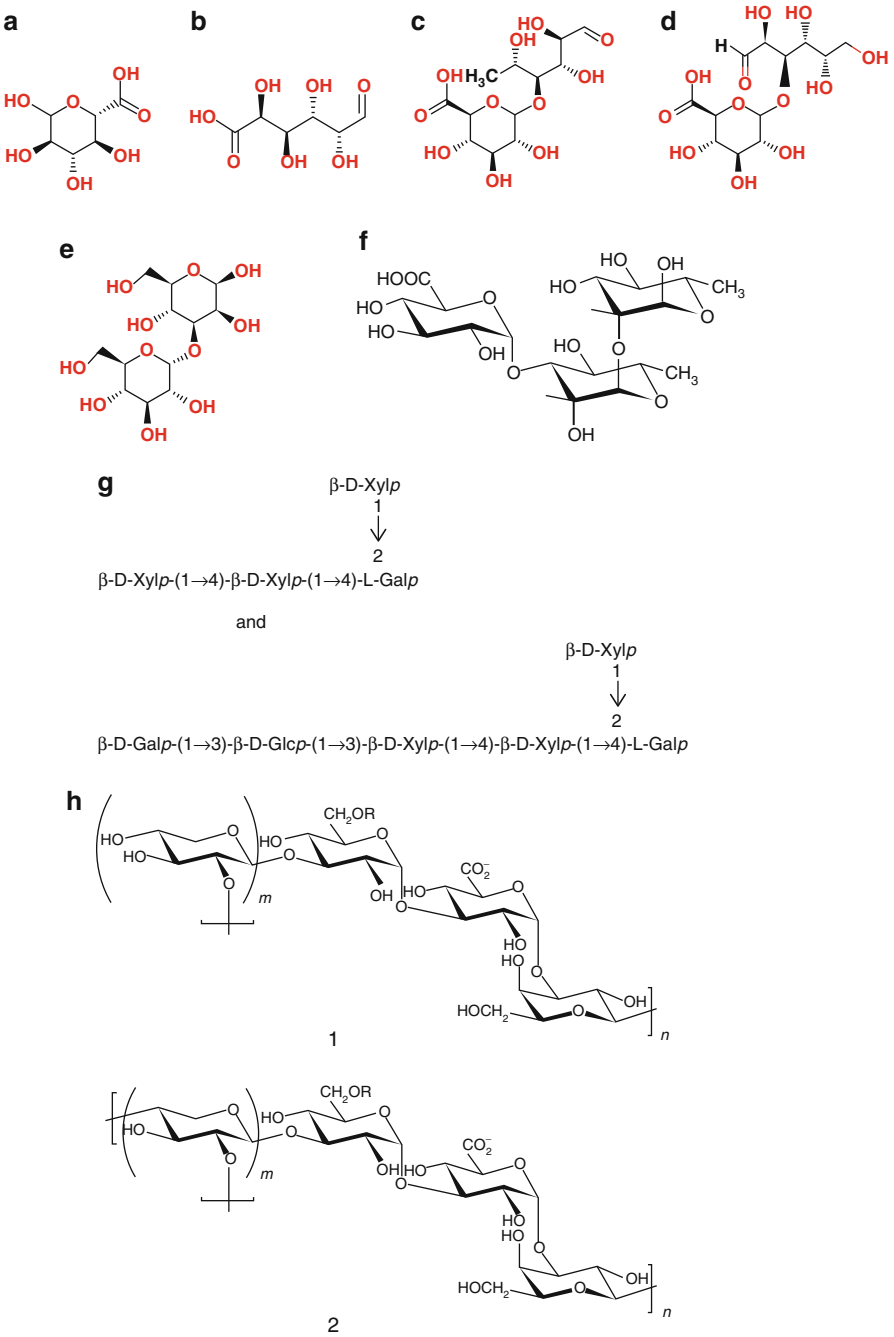

Fig. 2 Some of the components already identified for the **PSs** produced by marine microalgae: (**a**) D-glucuronic acid; (**b**) D-galacturonic acid (http://www.chemspider.com; accessed on 07-04-14);

Collins and Munasinghe 1987). *B. braunii* also present other less common methyl sugars: 3-*O*-methyl-**fuc** and 6-*O*-methyl-hexose besides **fuc** (Banerjee et al. 2002). Besides **rham** (52.3 %), the main neutral sugar, and other minor monosaccharides (**fuc**, **glc**, **arab**), **CaSp**, another **PS** of *A. platensis*, presents small amounts of 2,3-di-*O*-methyl-**rham** and 3-*O*-methyl-**xyl** (Lee et al. 1998). The positions of sulfate in the exocellular glycan of *P. cruentum* were identified (Archibald et al. 1981) in the **glc** and **gal** residues, as D-galactopyranose 6-sulfate, D-glucopyranose 6-sulfate, and D-galactopyranose 3-sulfate.

If the composition of monosaccharides is indicated for most of the **PSs** by several researchers, further information for higher levels of organization of the polymers is scarce and only for a couple of microalgae. Only some di- and oligosaccharides are described, some of them are characteristic for the microalgae from which the **PS** was obtained. White and Barber (1972) and Ogawa et al. (1998, 1999) advanced in the structure of the glucuronorhamnan of *Chlorella* with the identification of the disaccharide 3-*O*-*α*-D-glucopyranuronosyl-L-rhamnopyranose (or glucoronosyl-**rham**) (Ogawa et al. 1998) (Fig. 2c) and the acidic trisaccharide *α*-D-glucopyranuronosyl-(1→3)-*α*-L-rhamnopyranosyl-(1→2)-*α*-L-rhamnopyranose (or glucoronosyl-rhamnosyl-**rham**, $C_{18}H_{30}O_{15}$, Ogawa et al. 1999) (Fig. 2f), whose molecular weight was found to be 73 kDa, and with the determination of the respective structures. Besides the aldobiuronic acid 3-*O*-(*α*-D-glucopyranosyluronic acid)-L-galactopyranose (Fig. 2d), two different heterosaccharides were found to be part of the structure of the **EPS** from *P. cruentum*. These two oligosaccharides were identified after digestion of the **EPS** (Pignolet et al. 2013), whose complete structure was established by Gloaguen et al. (2004) (Fig. 2g, h), who also found the monosaccharide composition and distribution, their absolute configuration in the molecules, and that the oligosaccharide 1 was part of the oligosaccharide 2. Hence, they found the unusual presence of both L- and D-**gal** isomers in the **EPS** from *P. cruentum*, a common characteristic of the red algae **PS**, besides having confirmed the presence of the aldobiuronic acid. **EPS** from *P. cruentum* can, eventually, present two other aldobiuronic acids (3-*O*-(2-*O*-methyl-*α*-D-glucopyranosyluronic acid)-D-galactopyranose and (3-*O*-(2-*O*-methyl-*α*-D-glucopyranosyluronic acid)-D-glucopyranose) (Heany-Kieras and Chapman 1976), but signals of OMe groups should be confirmed (Geresh et al. 1990). This acid-type was also found in other species of *Porphyridium* and in *Rhodella reticulata* (Geresh et al. 1990). However, a lot of work is still necessary in order to determine whether these oligosaccharides are repeating building blocks of the **EPS** and whether there is

Fig. 2 (continued) (**c**) glucuronyl-**rham** (or glucuronosyl-(1,4)-L-**rham**), (**d**) 3-*O*-*α*-D-glucopyranuronosyl-L-**gal,** and (**e**) *O*-D-glucopyranosyl-(1,3)-*O*-D-mannopyranose are aldobiuronic acids found in the acidic **PSs** produced by microalgae (**c** and **e** http://www.chemspider.com; **d** adapted from http://www.chemspider.com and http://www.ebi.ac.uk; accessed on 07-04-14); (**f**) *α*-D-glucuronosyl-*α*-L-rhamnosyl-*α*-L-**rham**, an acidic trisaccharide found in *Chlorella* (Ogawa et al. 1999); (**g**) oligosaccharides I and II from *Porphyridium* (Gloaguen et al. 2004); (**h**) models 1 or 2 for the possible acidic repeating unit in polysaccharide II, from *Porphyridium* sp., according to Geresh et al. (2009); R = H, SO_2O, terminal **gal** or terminal **xyl**, m = 2 or 3

any kind of alternate distribution. Another microalga, whose **sPSs** (**CaSp** and **NaSp**) have an aldobiuronic acid-type disaccharide, the *O*-hexunorosyl-**rham**, and *O*-rhamnosyl-acofriose, another disaccharide, is *A. platensis*. But as far as we know, the "hexose" is still waiting to be identified. Further, Lee et al. (2000) referred the structure as consisting alternately of a uronic acid and a **rham**. The *O*-rhamnosyl-acofriose, *O*-rhamnosyl-(3-*O*-methyl-**rham**), is the other repeating di-unit identified as being part of **CaSp** and **NaSp** (Lee et al. 2000; Kaji et al. 2004) constituted by alternating molecules of **rham** and acofriose (Lee et al. 2000). Besides these disaccharide units, an oligosaccharide is also part of the **CaSp** – the trisaccharide *O*-rhamnosyl-acofriosyl-**rham** (Lee et al. 2000). A tetrasaccharide was also identified: it is composed of two units of an aldobiuronic acid; in other words, two uronic acids alternating with two **rham** monosaccharides make up that tetrasaccharide. The di-unit uronic acid-**rham** can eventually be repeated some more times along the **CaSp** glycan, forming some more repeated units of the aldobiuronic acid-type disaccharide (Lee et al. 2000).

Despite being almost "forgotten," some knowledge on the structure of the **PS** produced by *P. tricornutum* came into light some decades ago (Ford and Percival 1965a, b). At that time, these researchers found that the **PS** from this diatom is a hetero-, ramified polymer, one of the products obtained by acid hydrolysis being a sulfated glucuronomannan, composed of β-(1,3)-linked **man**. The aldotriuronic acid *O*-D-glucopyranosyluronic acid-(1,3)-*O*-D-mannopyranosyl-(1,2)-*O*-D-mannopyranose (Fig. 2e) was found to be a constituent of the side chains. As a matter of fact, an aldobiuronic acid was also identified as being *O*-D-glucopyranosyluronic acid-(1,3)-D-mannopyranose. Another derived product, a glucan, seems to be the other constituent of the crude **PS**, comprising of β-(1,3)-linked **glc** units.

3.2 Rheology

In order to fully understand the several uses and applications of (**E**)**PSs**, the physicochemical characteristics must be taken into account. Rheological properties and the molecular weight are some of the most important parameters as they seem to be relevant to their functions and behavior.

Most **PSs**, especially **EPSs**, are polymers of high molecular weight (220–2.9 × 10^3 kDa; Kaji et al. 2004; Hayashi et al. 1996b; Hasui et al. 1995; Li et al. 2001; Pignolet et al. 2013; Mishra et al. 2011), negatively charged (anionic) and sulfated. Sulfated half-ester groups and uronic acids (mostly **glcAc** and **galAc**), along with the carboxyl groups, are responsible for the acidic and anionic characteristic of **PSs**.

Unfortunately, information on the rheological properties and behavior is scarce and described only for *A. platensis* and a couple of red marine unicellular algae.

Qualitatively, solutions of **sPSs** from red microalgae, such as *Porphyridium* and *Rhodella*, are characterized by their pseudoplastic properties (Sun 2010; Geresh and Arad 1991) and thixotropic characteristics (i.e., exhibit a stable form at rest but become more fluid when under some agitation) (Eteshola et al. 1998) these characteristics can be evaluated quantitatively by their viscosity, elasticity, shear rate, shear strain, and shear stress (www.vilastic.com). It is well known that hydrocolloid

solutions of **sPSs** produced by red microalgae and the cyanobacterium *A. platensis* present a non-Newtonian behavior, as their viscosity depends negatively on the shear strain rate, i.e., decreases with the increase of this last parameter (Raposo et al. 2014; Geresh et al. 2000, 2002a; Eteshola et al. 1998; Badel et al. 2011a; Ginzberg et al. 2008), thus showing to be a pseudoplastic compound (Geresh and Arad 1991) with a strong shear-thinning behavior (Eteshola et al. 1998). However, Sun et al. (2009b) showed that fragments of **EPSs** from *Porphyridium* have a different rheological behavior, depending on the degree of degradation, sometimes exhibiting even the typical characteristics of Newtonian fluids. In addition, elasticity, viscosity, and intrinsic viscosity decrease when high temperatures (>90 °C) are applied in the drying process of the **EPS**, as these high temperatures cause significant modifications in the conformation of the polymer chains (Ginzberg et al. 2008). Another reason supporting the idea of **EPS** from *Porphyridium* having weak-gel characteristics is the fact that the elasticity (G') values are higher than the viscosity (G") ones (Raposo et al. 2014) after small deforming oscillatory forces are applied to the **EPS**, which was previously dried at temperatures below 140 °C (Geresh et al. 2002a; Ginzberg et al. 2008). These properties prevailed also when the polysaccharide was obtained from cultures grown under different concentrations of sulfate (Raposo et al. 2014). The decrease in viscosity with the application of higher shear rates was suggested to be related to the dissociation of the strong hydrogen bonds that exist between polymer chains (Ginzberg et al. 2008). In this study, Ginzberg and coworkers described well the influence of several factors on conformational modifications and also highlighted the effects caused by drying on the interactions between the polymer and its non-covalently linked glycoprotein. Raposo et al. (2014) also found that the viscosity of the **EPS** from *P. cruentum* decreases with the increase of $MgSO_4$ concentration in the culture medium. The reason for this behavior can be associated with the decrease in the dimensions of the chains as a result of the intrachain electrostatic repulsions. An explanation of the similar behavior of the **EPS** was given by Eteshola et al. (1998) when NaCl, at different concentrations, was added to the aqueous solutions of **EPSs**. Another mechanism that can explain the gel-forming characteristic of polymers might be associated with hydrophobic and ionic forces, as it was referred for the anionic colloids of *Amphora*, *P. tricornutum* (diatoms), and *Ankistrodesmus* (chlorophyte) (Chen et al. 2011). Hence, some of these extracellular polymers behave as fluid-dynamic polymers, as it is the case of the **EPS** from *Porphyridium*, giving place to highly viscous solutions at very low concentrations, in a wide range of pH and temperatures, showing rheological properties similar to the ones of industrial **PSs** (Arad and Levy-Ontman 2010; Patel et al. 2013). Viscosity indexes, or the degree of polymerization, also seem to be closely associated with the culture growth temperature, since solutions with similar concentrations of the polymer presented higher viscosities when the cultures had been grown at the optimum temperature (Lupi et al. 1991). Therefore, growth of the culture at the optimum temperature might induce polymers with a higher polymerization degree.

Further, Eteshola and coworkers (1998) presented a fairly complete study on the rheology of the **EPS** produced by the red microalgae, including X-ray diffraction

techniques, referring as well the viscoelastic properties of the **EPS** by using dynamic mechanical spectra. They observed, as well, an increase in the G' modulus for temperatures above 60 °C, suggesting that heat promoted polymer self-association in an aqueous solution.

However, as far as we know, some **PSs** only jellify when dropped into $FeCl_3$ solutions, and some others are not viscous at all. In fact, the somewhat turbid solutions of the glucuronorhamnan produced by *C. vulgaris* do not have the ability to form gels, and hence the solutions do not show any viscosity (Ogawa et al. 1999), and the calcium-rich **PS** produced by *A. halophytica* has the capacity to jellify when some drops of the **EPS** aqueous solution (1 % w/v) are put in contact with $FeCl_3$ solutions (0.05 M), the jellified beads formed being stable for over 1 month (Li et al. 2001).

Furthermore, the rheological behavior of the **EPS** released by both *C. capsulata* and *P. cruentum* seems to be similar, the viscosity decreasing with the increase of the shear rate. Also, there were no significant differences between the **EPS** behaviors when the microalgae were subjected to different culture media (De Philippis et al. 1996; Raposo et al. 2014). This might indicate that the molecular weights of **EPSs** are stable, showing no major differences no matter the changes to the growth media and conditions, even under nutrient starvation (Gasljevic et al. 2008; Geresh and Arad 1991).

The high molecular weight is also an important requirement for the **PSs** to be good drag-reducing polymers, as polymers with higher molecular weights are usually more efficient as drag-reducing agents (Gasljevic et al. 2008). Therefore, **EPSs** from microalgae are promising candidates, as their **PSs** have similar, if not higher, molecular weights than industrial polymers, as xanthan gum, for example.

4 Bioactivity and Applications

Below is a list of some potential applications of the polysaccharides produced by microalgae:

- Drugs or nutraceutical carriers in the pharmaceutical industry, to slow and control the release of the substances; for bacterial vaccines, to improve nonspecific immunity (Mishra et al. 2011);
- Thickeners and gelling agents in food industries, to improve quality and texture (Mishra et al. 2011);
- In soils and water treatment, to act as nutrient carriers to fertilize soils (Raposo and Morais 2011); to improve the aggregation of soils and sand particles (Paterson 1989; Sutherland et al. 1998), influencing the stability and cohesiveness of sediments and improving water holding capacity of soils (Mishra et al. 2011); to act as soil conditioners (Kroen and Rayburn 1984; Metting and Rayburn 1983) and to improve sludge settling and dewatering (Subramanian et al. 2010); to be used in wastewater treatment (Raposo et al. 2010), in detoxification acting as metal chelators due to the presence of uronic acids (Kaplan et al. 1987), and in bioremediation to remove toxic metals from polluted waters (Otero and Vincenzini, 2003); and to act as growth promoters for crops (Pignolet et al. 2013).

4.1 Therapeutical Applications

Antiviral, antibacterial, anti-inflammatory, immunomodulatory, antilipidemic, antiglycemic, anti-adhesive, antioxidant and free radical scavenging, and prevention and treatment of tumors are some of the therapeutical applications of **PSs**.

4.1.1 Antiviral Activity

Many studies have already highlighted that the polysaccharides released (or not) into the culture medium by some marine microalgae present antiviral bioactivity against different kinds of viruses, either mammalian or otherwise (Table 3); the interest increased after some experiments were conducted on HIV (Hayashi et al. 1996a; Hasui et al. 1995). Radonic et al. (2010) and Chen et al. (2010) have recently reviewed the antiviral effects of several **sPS** on different host cell lines. To date, **PSs** from *Arthrospira* and *Porphyridium* were the most studied anionic sulfonated polymers, exhibiting antiviral activity against a wide range of viruses, including *Herpes simplex* and *Varicella zoster* viruses (HSV AND VZV), human cytomegalovirus (HCMV), measles, mumps and Flu-A viruses, and *vaccinia virus*, a variola-related virus. In fact, the **PS** TK-V3 from *A. platensis* and **EPS** from *P. purpureum* proved to be active against *Vaccinia* and *Ectromelia orthopoxvirus* infection; in studies conducted with HEp-2 and Vero C1008 cells, the $\mathbf{IC}_{50}$ is significantly lower (0.78 and 0.65 μg/ml, respectively) than the response to dextran sulfate (1.24 μg/ml). Despite being slightly toxic, **PSs** can be safely applied for in vivo experiments, as they were also effective *in ovo*, by decreasing the VACV replication (Radonic et al. 2010). Besides, the **EPS** from *P. cruentum* has also demonstrated a significant inhibition against *Vesicular stomatitis* virus proliferation on HEL cells (Raposo et al. 2014), the response being higher for the **EPS** isolated from the culture medium enriched with 104 mM in sulfate. As a matter of fact, the antiviral activity of the **EPS** from *P. cruentum* depends not only on the culture medium, algal strains, and cell lines used for testing but also on the methodology and the degree of sulfation and uronic acid content of the **EPS** (Raposo et al. 2014; Huleihel et al. 2001, 2002). These acidic compounds, along with the half-ester sulfate groups and the carboxyl groups of the polymer, contribute to their anionic characteristics, making the **EPS** of *Porphyridium* a good agent to be used against viruses (Raposo et al. 2014). **CaSp**, an intracellular polysaccharide produced by *A. platensis*, inhibited the replication of several viruses in vitro by inhibiting the penetration of the virus into the different host cells used (Hayashi et al. 1996a, b). The experiments conducted by Hayashi and coworkers (1996b) also confirmed the importance of sulfate groups on the antiviral activity of **CaSp** from *A. platensis*, activity proved by studying the effect of calcium-free-Spirulan and another compound derived from **CaSp**, without sulfate, on the replication of HSV-1 and on the cytotoxicity in HeLa cells, the latter compounds showing a higher toxicity and a significantly lower antiviral capacity. However, the molecular configuration due to the chelation of the calcium ion with the sulfate groups might have a crucial role in the antiviral properties, as no antiviral effect was verified when the calcium-free compound was used despite the presence of sulfate groups (Hayashi et al. 1996b).

Table 3 Antiviral applications of **EPS** from marine microalgae (*in* Raposo et al. 2013)

EC_{50}/ED_{50} is the concentration/dose at which 50 % of the population exhibit a response after being exposed to a certain compound

Other factors that are correlated to the inhibition of viral infection are the size of the molecules and the degree of sulfation (Ghosh et al. 2009); the composition of monosaccharides and the diversity of the linkage types also determine the specificity of **sPSs** and influence their functional properties. That is why tests for antiviral capacity should be carried out with a variety of virus and isolates, as wide as possible.

Unlike what happens with most of **sPSs**, the **PS** from *C. polykrikoides* showed to be effective against influenza virus type B (Flu-B), among other different viruses, including that of HIV-1. This sulfated polymer that does not contain proteins, aminoacids, or nucleic acids showed an inhibitory effect higher than that of dextran sulfate on Flu-B and MSLV, with no cytotoxic effects against the different cell lines used for testing concentrations up to 100 μg/ml (Hasui et al. 1995).

The antiviral activity is probably the most studied quality exhibited by sulfated polysaccharides of marine microalgae, especially the one produced by *Porphyridium*. The mechanisms for this activity are not yet completely understood. As happens with heparin, the anionic nature of **sPS** makes it a good candidate to protect against viruses. Several mechanisms have been proposed. Hayashi and colleagues (1996a, b) noted that **sPS** inhibited infection by different viruses through inhibiting the penetration of viral particles into host cells. But other mechanisms can also be involved, such as the inhibition of attachment/adsorption, or even replication during the early phases of the virus cycle (Martinez et al. 2005; Kim et al. 2012), without any toxicity to the host cells (Hasui et al. 1995).

4.1.2 Antibacterial Activity

The **PS** from *A. platensis* has antibacterial properties, the activity depending on the solvent used to extract the polymer. While water and methanolic extracts showed antimicrobial properties on both Gram-positive and Gram-negative bacteria, methanolic **EPS** extracts show a wider capacity to inhibit the growth of bacteria than aqueous extracts. However, methanolic extracts presented only a bacteriostatic effect against the strain NCIMB8166 of *Micrococcus luteus*, needing an MBC/MIC ratio >4, i.e., the minimum inhibitory concentrations (MIC) of **EPS** is considerably lower than the concentration needed to kill the organisms (MBC, minimum bactericidal concentrations) (Challouf et al. 2011). Ethanolic and some other solvent extracts did not show any antimicrobial activity. In fact, the **EPS** did not exhibit any activity against *E. coli* (strain ATCC25922) and *S. aureus* (ATCC25923). A similar explanation can be applied to the results obtained by Raposo et al. (2014), who tested the antimicrobial activity of the **EPS** from *P. cruentum* and reported that their ethanolic extracts did not show a significant inhibition on the growth of bacteria *E. coli* and *S. aureus*. Perhaps the bioactive portions of the molecules have different affinities to the solvents used, being highly influenced by mutual interactions (Basedow et al. 1980), and ethanol might not be adequate for the extracts to maintain the antibacterial active principle/ingredient of the **EPS**. Nevertheless, the ethanolic extract of the **EPS** from *P. cruentum* showed some activity against *S. enteritidis* (Raposo et al. 2014).

4.1.3 Antioxidant Activity and Free Radical Scavenging

As photoautotrophs, microalgae are highly exposed to oxidative and radical stresses, therefore accumulating effective antioxidative scavenger complexes to protect their own cells from free radicals (Pulz and Gross 2004). Oxidation of lipids by reactive oxygen species (ROS), like hydroxyl radicals, hydrogen peroxide, and superoxide anion, can affect the safety of pharmaceuticals and also decrease the nutritional quality of foods. Sulfated **PSs** produced and secreted out by marine microalgae may act not only as dietary fiber (Dvir et al. 2009), but have also showed the capacity to prevent the accumulation and the activity of free radicals and reactive chemical species, therefore acting as a protective system against these oxidative and radical stress agents (Table 4).

It was already demonstrated that the **sPS** from *Porphyridium* exhibited antioxidant activity against the autoxidation of linoleic acid and inhibited oxidative damage to 3T3 cells that might be caused by $FeSO_4$ (Tannin-Spitz et al. 2005). These researchers also proved that the bioactivity was dose dependent, correlating positively with the sulfate content of the **sPS**, and mentioned the possibility of the glycoprotein to contribute to the antioxidant properties. They even suggested that the antioxidant activity of this polymer relied on its ability to act as a free radical scavenger. Despite the various applications suggested for the **EPSs** from different species/strains of marine microalgae, when the biological activity involves crossing the cellular membrane of cells, the high molecular weight of the polymers can be a drawback to pursue their properties. This feature was confirmed by Sun et al. (2009b). These researchers submitted the **EPS** from *P. cruentum* to microwave, and the **EPS**-derived products (6.55, 60.66, and 256.2 kDa) showed different levels of antioxidant activity, a lower molecular weight (6.55 kDa) being a requisite for a stronger activity either by scavenging hydroxyl, superoxide anion, and $DPPH^{\bullet}$ (1,1-diphenyl-2-picrylhydrazyl radical) free radicals or by inhibiting the (per)oxidation of lipids induced by $FeSO_4$ and ascorbic acid, thus giving better protection to mouse cells and tissues against oxidative damage. They found that the antioxidant ability is dose dependent; the same is true in relation to the inhibition of oxidation damage of both liver cells and tissue. The free radical scavenging of some of the **EPS** fragments was significantly higher at the same, or even lower, concentration than that reported for vitamin C (Xing et al. 2005). But strangely, they found no scavenging activity and no inhibition of oxidative damage in cells and tissues for the crude high molecular **sPS** from *Porphyridium cruentum* (Sun et al. 2009b).

The sulfated exopolysaccharide from *Rhodella reticulata* also has antioxidant activity, the effects being dose dependent (Chen et al. 2010). Unlike what happened with the **sPS** from *Porphyridium* (Sun et al. 2009b), crude **sPS** from *Rhodella* exhibited higher antioxidant properties than the polysaccharide-modified samples, these demonstrating lower radical scavenging activity (Chen et al. 2010). These researchers found that all the different samples of **sPS** from *R. reticulata* had a stronger ability than α-tocopherol against superoxide anion radical scavenging, the crude polysaccharide being twice as strong as α-tocopherol.

Besides the antibacterial properties, the methanolic extracts of **EPS** from *A. platensis* also exhibit a moderate antioxidant capacity (TEAC=0.27 mg/mL)

Table 4 Applications, other than antiviral uses, of **EPS** from marine microalgae (*in* Raposo et al. 2013)

Microalgae/ cyanobacteria	Applications	Cells/animals used for in vitro/in vivo studies	References

using Trolox, a common antioxidant substance, while the ethanolic extracts presented lower antioxidant activity (Challouf et al. 2011). According to Mendiola et al. (2007) and Sun et al. (2009b), uronic acid contents are directly related to the radical scavenging properties of **PSs**, but other factors also seem to have influence on the antioxidant capacity, namely, low molecular weights (Chen et al. 2008; Sun et al. 2009a), and the structure and conformation of the polymer (Tao et al. 2007). The antioxidant properties of these **PSs** might be exerted by improving the activity of antioxidant enzymes, scavenging free radicals, and/or inhibiting lipid (per) oxidation (Sun et al. 2009a).

4.1.4 Anti-inflammatory and Immunomodulatory Properties

Polysaccharides from marine microalgae, like *Porphyridium*, *Phaeodactylum*, and *C. stigmatophora*, had already demonstrated to have pharmacological properties, such as anti-inflammatory activity and as immunomodulatory agents (Table 4). The **sPS** from both *C. stigmatophora* and *P. tricornutum* demonstrated a significant anti-inflammatory activity against paw edema induced by carrageenan injected as a sterile saline solution (0.9 %), with $\mathbf{IC}_{50}$ values of 2.25 and 2.92 mg/kg for *C. stigmatophora* and *P. tricornutum*, respectively, compared to the anti-inflammatory indomethacin, with an $\mathbf{IC}_{50}$ of 8.50 mg/kg. The anti-inflammatory efficacy was tested in vivo, by intraperitoneally injecting the crude **PS** in female rats and mice, and in vitro, the phagocytic activity being evaluated in macrophages from mice (Guzman et al. 2003). The direct stimulatory effect of *P. tricornutum* on immune cells was evidenced by the positive phagocytic activity tested either in vitro or in vivo, and the activity of the extract of **sPS** from *C. stigmatophora* showed immunosuppressant effects (Guzman et al. 2003). As reported for the polysaccharide from *Ulva rigida*, a green seaweed (Leiro et al. 2007), the **sPS** p-KG03 from the marine dinoflagellate *G. impudicum* also activates the production of nitric oxide and immunostimulates the production of cytokines in macrophages (Bae et al. 2006). On the other hand, inhibition of leukocyte migration seems to be related to the anti-inflammatory activity of the polysaccharides (Matsui et al. 2003). As leukocyte movement to the site of injury contributes to additional cytokine release and to the production of nitric oxide, therapeutics has to be effective against this over-inflammation. In fact, the **sPS** from *Porphyridium* seems to be a good candidate for this role as it inhibited the movement and adhesion of polymorphonuclear leukocytes in vitro and inhibited the development of erythema in vivo as well (Matsui et al. 2003).

Besides inhibiting tissue oxidative damage, **EPS** from *P. cruentum* can be used to inhibit the biomembrane peroxidation as well (Sun et al. 2009b) and to enhance in vitro immunomodulatory activity (Sun et al. 2012). These researchers have also explained the mechanism/pathway that is most probably involved in the immune response enhancement by **EPS** from *P. cruentum* – the stimulation of macrophages. They found that low molecular fractions of **EPS** can stimulate the proliferation of macrophages and the production of NO (nitric oxide). NO is a signaling free radical gas molecule that can be synthesized by phagocytes (monocytes, macrophages, and neutrophils) and is involved in the human immune system response. When studying the effects of **EPS**-derived products, Sun (2010) showed that **EPS** from *Porphyridium* presented immunostimulating activity in mice with S180 tumors by increasing both spleen and thymus index and also spleen lymphocyte index. Sulfated **PS**-derived products, with lower molecular weight, can also improve the production of NO in mouse macrophages. In his Ph.D. Thesis, Sun referred to the fact that sulfate content has a positive correlation with the immunomodulatory system. Furthermore, Namikoshi (1996) noted that **sPS** can stimulate the immune system by triggering cells and humor stimulation. This shows the capacity of marine unicellular algae **sPS** to directly stimulate the immune system.

Spirulan is a **GAG**-like **PS** (Senni et al. 2011). This means that spirulan from *A. platensis*, for example, is recognized as having similar properties as glycosaminoglycans (GAG), present in all animals. **GAG**s are sulfated (or not)

PSs composed of disaccharide repeating units, a uronic acid or a neutral monosaccharide, and an amino sugar (Senni et al. 2011) with anticoagulant properties, such as heparin and hyaluronic acid. By interacting with a vast range of proteins involved in many human body physiological and pathological responses, GAGs show several bioactivities associated either to inflammatory processes or to tissue repair (Gandhi and Mancera 2008; Mulloy and Linhardt 2001). Some sulfated **GAG**s can be covalently linked to proteins (proteoglycans); this is the case of the **sPS** from red marine unicellular algae *Porphyridium*, which has also some protein moieties non-covalently linked, but shows anti-inflammatory properties.

On the other hand, immunomodulators are response modifier biocompounds that present an enhancement or suppression of the immune responses, depending on a wide range of factors, such as dose, way, and time of administration, but also on the site of activity and the respective mechanism of action (Tzianabos 2000). β-(1,3)-Glucans, such as that of *C. vulgaris* (Nomoto et al. 1983), have already proved to exhibit several biological properties, including prevention of some infections and antitumor activity (Bleicher and Mackin 1995; Nomoto et al. 1983). These polymers stimulate the functional activity of macrophages (Burgaleta et al. 1978) and the proliferation of monocytes and macrophages, presenting also potent hematopoietic properties (Patchen and Lotzova 1980; Riggi and DiLuzio 1961).

4.1.5 Activity Against Tumors and Vascular Muscle Cell Proliferation

Sometimes, after suffering some kind of damage, vascular endothelial cells are not sufficiently repaired by their own cell type; there can be an invasion of platelets and/or macrophages or other blood cell types, which secrete cytokines and growth factors that can increase the proliferation of vascular smooth muscle cells, causing a hyperplasia of the arterial *intimae*. This atherosclerosis is one of the main causes of myocardium and cerebral infarction.

Some **PSs** that are used as anticoagulants have also some inhibitory activity against the proliferation of vascular smooth muscle cells. This is the case of heparin (Clowes and Clowes, 1987) and heparin sulfate (Kaji et al. 2004) and the sulfated fucoidan from some seaweeds (Vischer and Buddecke 1991). Nevertheless, spirulan (either Na- or Ca-) from *A. platensis* is a more potent inhibitor of cell proliferation, as it was demonstrated by Kaji and coworkers (2004) on bovine arterial smooth muscle cells. These researchers also demonstrated that it is not enough to be composed of sulfate for the **PSs** to show inhibitory activity against cell growth: while both **NaSp** and **CaSp** inhibited the proliferation of vascular smooth muscle cells, as it happened with heparin and heparin sulfate, the desulfated equivalent compounds did not show this effect. And, as depolymerized compounds (**PS**-derived products with lower molecular weights) of **NaSp** and **CaSp** maintained the inhibitory capacity against the proliferation of arterial smooth muscle cells, with MW $\geq$14,700, this suggests that spirulan (especially **NaSp**) is a particular polymer with a specific structural sequence and conformation maintained by the linkage of Na^+ to the sulfate groups, keeping, therefore, that strong inhibitory activity (Kaji et al. 2004); the effect is dose and time dependent. Furthermore, depolymerized **NaSp** inhibited the growth of vascular smooth muscle cells without inhibiting the growth of vascular endothelial cells (Kaji et al. 2002, 2004).

Spirulan is also capable of inhibiting pulmonary metastasis in humans and to prevent the adhesion and proliferation of tumor cells (Senni et al. 2011).

Other **sPSs** have also antiproliferative activity in cancer cell lines (in vitro) and inhibitory activity against tumor growth (in vivo). The **sPS** p-KG03 from *G. impudicum* is one of these polymers that prevents and suppresses tumor cell growth either in vitro or in vivo by activating NO production and by stimulating the innate immune system, increasing the production of cytokines interleukin-1 (or IL-1), IL-6, and THF-α in macrophages (Bae et al. 2006; Namikoshi 1996; Yim et al. 2005). This **PS** has immunostimulating properties in vivo as well (Yim et al. 2005).

Another candidate with potential to be used as an antitumor agent is the *β*-(1,3)-glucan from *C. vulgaris*, besides being considered an active immunostimulator (Laroche and Michaud 2007). Low molecular weight fragments (6.53–1,002 kDa) of the **sPS** from *P. cruentum* are also good immunostimulators as they all inhibited in vivo S180 tumors implanted in the peritoneal cavity of mice models by inhibiting the tumor cell proliferation and the growth of the tumor, increasing the spleen and thymus indexes and the number of spleen lymphocytes as well, enhancing the immune system in this way (Sun et al. 2012). However, nonmodified or higher molecular weight fragments of the same **sPS** showed no inhibition of tumor cell growth (Geresh et al. 2002b; Sun 2010). Nonetheless, in a recent study, Gardeva et al. (2009) reported the strong antitumor activity exhibited by the polysaccharide of *P. cruentum*. This sulfated polymer strongly inhibited Graffi myeloid tumor proliferation in vitro and in vivo, the activity being dose dependent, and the survival time of hamsters was increased by 10–16 days. Gardeva and coworkers (2009) also suggested that the antitumor activity could be related to the immunostimulating properties of the polymer. Therefore, it can be concluded that the reinforcement of the immune system induced by the **sPSs** is probably the main mechanism against tumor growth and respective effects (Sun et al. 2012; Zhou et al. 2004). However, other mechanisms, such as changes in the biochemical characteristics of the cell membrane, inducing tumor cell differentiation and apoptosis, and regulation of the cell signaling pathways, can also be involved (Zhou et al. 2004). Besides these mechanisms, the antimetastatic properties may be associated to the capacity of blocking the interactions between cancer cells and the basement membrane or inhibiting the adhesion of tumor cells to the substrates.

In addition, some years ago, it has already been demonstrated that high molecular weight oversulfated **EPSs** from *Porphyridium* inhibited neoplastic mammalian cell growth and that the biomass of this marine microalga could prevent the proliferation of colon cancer in rats (Geresh et al. 2002b; Shopen-Katz et al. 2000).

4.1.6 Antilipidemic and Antiglycemic Properties

Sulfated **PSs** from seaweeds and marine animal origin are potent inhibitors of human pancreatic cholesterol esterase, an enzyme that promotes its absorption at the intestinal level (Laurienzo 2010). These inhibitory effects are enhanced by higher molecular weights and degree of sulfation, as well as by the presence of 3-sulfate in the monosugar molecule (Laurienzo 2010). And most of the **PSs** from marine microalgae are naturally and highly sulfated with high molecular weights, making them non-readily absorbable and thus enabling them to be used as anticholesterolemic agents.

However, this area of research has not been sufficiently explored in what concerns microalgae (Table 4). When Ginzberg and coworkers (2000) fed chickens with biomass containing **EPS** from *Porphyridium*, they verified that cholesterol decreased either in serum or egg yolk of chickens, the fatty acid profile was modified, and the carotenoid content in the egg yolk was improved as well. Furthermore, in rats fed with *Porphyridium* and *R. reticulata* biomass, which **PSs** contain dietary fibers, there was a decrease in serum cholesterol and triglycerides; hepatic cholesterol levels were also improved and the levels of VLDL considerably lowered with no toxic effects noticed in the animals (Dvir et al. 1995, 2000, 2009). Also, either the biomass of *Rhodella* or the **sPSs** from *Porphyridium* were able to lower the levels of insulin and/or glucose in diabetic rodents (Dvir et al. 1995; Huang et al. 2006), causing no modifications in the pancreatic island cells and no fibrosis or hemorrhagic necrosis in cells (Huang et al. 2006).

These experiments suggest the strong potential of sulfated polysaccharides from unicellular algae to be used as hypolipidemic and hypoglycemic agents, but they are also promising substances in reducing coronary heart disease due to their hypocholesterolemic effects (Dvir et al. 2000, 2009).

Mechanisms focusing on the role of dietary fibers in lowering cholesterol are not yet completely understood, but Oakenfull (2001) proposed that it could be related to the increase in the viscosity of intestinal contents, which have influence on nutrient absorption, micelle formation, and decreasing of lipid absorption. The decrease in serum cholesterol levels and the increase in bile excretion, caused by the disruption of the enteropathic circulation of bile acids, were suggested as another possible explanation (Glore et al. 1994; Marlett 2001).

4.2 Other Biological Activities

4.2.1 Anticoagulant and Antithrombotic

There are several studies on the anticoagulant properties of the **PSs** isolated from seaweeds, presented in a recent review by Wijesekara and coworkers (2011). Carrageenans, for example, are **sPSs** that show potent anticoagulant activity, inhibiting platelet aggregation as well, probably due to the antithrombotic capacity, which, in turn, is associated to a high sulfate content (Prajapati et al. 2014). However, there are only a few references to microalgae. On one hand, it was stated that the anticoagulant activity is associated to the high sulfate content of the **PS**, which is a characteristic of most of the **PSs** with marine microalgae origin. But, this feature could be an inconvenience when considering their use for the treatment of virus-induced diseases, for example, as an anti-inflammatory. On the other hand, Hasui and colleagues (1995) found no anticoagulant activity in the **sPS** of *C. polykrikoides* in spite of the high contents in sulfate of this **PS**. This suggests that the anticoagulant properties of polysaccharides may not only depend on the percentage of sulfate residues but rather on the distribution/position of sulfate groups and, probably, on the configuration of the polymer chains

(Ginzberg et al. 2008; Pereira et al. (2002). Spirulan from *A. platensis* is one of the marine microalgae **PS** that strongly interferes with blood coagulation-fibrinolytic system and exhibits antithrombogenic properties (Hayakawa et al. 1996, 2000). Both **NaSp** and **CaSp** enhance the antithrombin activity of heparin cofactor II and the production of the tissue-type plasminogen activator in human fetal lung fibroblasts (Hayakawa et al. 1997), and, in addition, **NaSp** still enhances the secretion of urokinase-type plasminogen activator and inhibits the secretion of the plasminogen activator inhibitor type 1, sulfate being essential for these properties (Yamamoto et al. 2003). Therefore, spirulan is a promising antithrombotic agent in clot breakdown, but some care should be taken in relation to hemorrhagic strokes.

4.2.2 Biolubricant

This is one of the lesser known applications for **sPSs**, and very little has been published on this issue (Table 4). Nevertheless, the **sEPS** of *Porphyridium* has already shown good lubrication capacity due to its rheological properties (Arad and Weinstein 2003). Arad and coworkers (2006) have compared the lubricating properties of **sPSs** to the most used hydrogel lubricant, hyaluronic acid. They simulated efforts of joints, during both walking and running, and found a better quality of the **EPS** from *Porphyridium*. The explanation for these properties is associated to **EPS** rheological characteristics as they showed to be stable than most lubricants at higher temperatures, the viscosity of the latter decreasing along with a decrease of lubricity. A 1 % **PS** solution presented the best friction properties under high loads, and its viscosity did not suffer any significant change when incubated with hyaluronidase, with standing degradation by this enzyme (Arad et al. 2006). This experiment shows the potential of the **sPS** from *Porphyridium* to be an excellent candidate to substitute hyaluronic acid as a biolubricant. Another promising application could be as a substance to be part of a joint-lubricating solution, as it was demonstrated by injecting the **EPS** from *Porphyridium* into the joints of rabbits' knees (Arad and Atar 2007), thus mitigating degenerative joint disorders caused by arthritis.

4.2.3 Anti-adhesive

Sulfated **PSs** from marine microalgae revealed the ability to block the adhesion of pathogenic microorganisms, suggesting the hypothesis to be used in anti-adhesive therapeutics. In fact, several **sPSs** presented a higher inhibition of the adherence of both *Helicobacter pylori* to HeLa S3 cell line and three fish pathogens to spotted sand bass gills, gut, and skin cultured cells (Guzmán-Murillo and Ascencio 2000) (Table 4).

Infection by microorganisms appears usually after binding to the cell membrane. Carbohydrates were already demonstrated as recognition sites for decades (Ofek et al. 1978), heparan sulfate glycosaminoglycan being one of those receptors in the host cells (Ascencio et al. 1993). These researchers suggested that this interaction could be associated to the net charge and molecular stereochemistry of the polymer.

4.3 Health Foods, Nutraceuticals, Functional Foods

Nowadays, the implications of specific diets on health assume a relevant role in developed countries, and the pursuit for equilibrated diets, supported by considerable epidemiological evidences, is a major issue for the scientific community and consumer in general, who more and more look for natural food products. In this context, microalgae have great potential to be used in food and feed preparation due to their rich composition, including high protein content with balanced amino acid pattern, carotenoids, fatty acids, vitamins, polysaccharides, sterols, phycobilins, and other biologically active compounds (Gouveia et al. 2008). The commercial production of microalgae for human nutrition is already in practice, and they find many applications either as nutritional supplements, for instance, in the form of tablets and pills, or as functional foods, incorporated in food products, such as pastas and cookies. The health-promoting effects associated with microalgal biomass are probably related to several effects due to their phytochemical constituents.

Some **PSs** from microalgae may by themselves be of interest for industrial and commercial applications. **PSs** can find applications in the food industry as emulsifying and gelling agents and as flocculant and hydrating agents, emulsifiers, stabilizers, and thickening agents, i.e., food additives (Bernal and Llamas 2012), like agar E406, alginates E400-404, and carrageenan E407. Because of the presence of peptide/protein moieties and deoxysugars, such as rhamnose and fucose, some **PSs** from marine cyanobacteria and unicellular algae show a significant hydrophobic behavior, conferring them emulsifying characteristics (Flaibani et al. 1989; Shepherd et al. 1995). In addition, some **PSs** include fucose as a constituent, this deoxysugar being of high value in the chemical synthesis of flavoring agents (Lupi et al. 1991). The **sPS** from marine microalgae could also be used as nutraceuticals due to their fiber content, their ability of acid binding and cation exchange, and their property of fecal bulking, and they are also good candidates as prebiotics (Ciferri 1983) and in some cases with a strong bioactive potential as hypolipidemic and hypoglycemic agents (Gonzalez de Rivera et al. 1993; Dvir et al. 2000, 2009) similar to polysaccharides from seaweeds (O'Sullivan et al. 2010). The **PSs** from microalgae alone or in combination with other compounds have also great potential to be used in edible films and coatings of foods other than carriers of flavors, colorants, spices, and nutraceuticals (Marceliano 2009). **PSs** from microalgae also have the potential to be used in low-fat or fat-free food products, as fat replacers in mayonnaises (Franco et al. 1998; Raymundo et al. 1998), and salad dressings and other food emulsions (Raymundo et al. 2005).

4.4 Other Applications

Another little known field of application is as drag reducers. Only a few studies were conducted in order to determine whether polysaccharides had the potential of drag-reducing ability (Ramus et al. 1989; Gasljevic et al. 2008), in order to extend

their functionalities to engineering applications (Table 4), namely, naval engineering. It is known for some years that the efficiency of **PSs** drag-reducing properties is improved by the high molecular and linear structure of the polymers, associated with a strong resistance to mechanical degradation (Gasljevic et al. 2008). In fact, these researchers have already studied the potential of several marine microalgal **PSs** as drag reducers. *P. cruentum* and *R. maculata* were the ones whose polysaccharides showed the higher drag-reducing power at lower concentrations, followed by *Schizochlamydella* (former *Chlorella*) *capsulata*. However, the **PSs** of some of these microalgae proved to be more powerful than others. As a matter of fact, to have the same level of drag-reduction effectiveness, 25 % more **PS** of *R. maculata* is required in relation to *P. cruentum* and almost three times more than the polysaccharide of *S. capsulata* (Gasljevic et al. 2008). Thus, if applied to the hulls of the vessels, these high-molecular **EPSs** could reduce friction losses by reducing flow turbulence due to the elasticity of the polymers. Therefore, there could be a reduction in the fuel consumption and in the propelling power for a ship to achieve a certain velocity (Gasljevic et al. 2008).

Another promising and emerging application of microalgae might be associated to the production of nanofibers from the biomass of *A. platensis* to be used as extracellular matrices for the culture of stem cells in order to treat spinal cord injuries (Raposo et al. 2010).

Their gluing and adhesive capacities and also their strong cohesive and binding strength, allied to their nontoxic and nonirritating properties, make these bioadhesive **PSs** produced by marine microalgae good candidates as mucobioadhesives or glues for bone gluing and soft tissue closure after surgery, promising to be, in the near future, the substituents of metallic screws and traditional wound closure methods, respectively (Laurienzo 2010).

Other areas of application of the marine microalgal **sPSs** could be as diverse as cosmetics or as ion exchangers, due to their chemical composition, rheological characteristics, and ion affinity.

Finally, besides all these applications, the adhesion properties of the **sPSs** produced by microalgae seem to play an important role in either the locomotion of some algae (Wetherbee et al. 1998) or in the aggregation of soil and sand particles (Paterson 1989; Sutherland et al. 1998), influencing stability and cohesiveness of sediments.

5 Mechanisms of Action

5.1 Antibacterial Activity

Some researchers have found that some **PSs** have an inhibitory effect on some bacteria: the extract from *Chaetomorpha aerea* inhibited the growth of *S. aureus* (Pierre et al. 2011); **EPS** from *P. cruentum* inhibited the growth of *S. enteritidis* (Raposo et al. 2013); fucoidan from the brown seaweed *Laminaria japonica* inhibited *E. coli* (Li et al. 2010). This inhibitory effect might be explained by the

anti-adhesive properties of sulfated exopolysaccharides of some microalgae against the adherence of microorganisms. Several **sPSs** inhibited the adherence of both *Helicobacter pylori* to HeLa S3 cell line and three fish pathogens to spotted sand bass gills, gut, and skin cultured cells (Guzman-Murillo and Ascensio 2000). **PSs** may compete with carbohydrates as recognition sites to which microorganisms can attach to, this mechanism having already been evidenced for other carbohydrates in cell surfaces (Ofek et al. 1978). Heparan sulfate glycosaminoglycan was identified as a receptor in host cells, this interaction having been associated with the net charge and molecular stereochemistry of the polymer (Ascencio et al. 1993).

However, the same **PS** may also not show activity against other bacteria (*C. aerea* extract against *S. enteritidis*, Pierre et al. 2011; *P. cruentum* extract against *S. aureus*, Raposo et al. 2014). The different reactions of various bacteria to the biological extracts of **PSs** could be due to the composition of the bacterial cell wall, to the absence of a specific structure in the bacteria, or also to the ability of the bacteria to change the chemical structure of the extract (Michael et al. 2002). The antibacterial activity may also be related to the antibiofilm formation ability of the **EPS** (Bernal and Llamas 2012) and, therefore, with the anti-adhesive properties. Most evidence suggests that these molecules act by modifying the physical properties of biotic surfaces (Rendueles and Ghigo 2012). Gram-negative *E. coli* and Gram-negative *S. enteritidis* present different cell surfaces that might explain the differences found between the correspondent inhibitions by the **EPS** (Raposo et al. 2014).

Rendueles and Ghigo (2012) suggest that **PSs**, as surfactant molecules, may modify the physical properties of the bacterial cell surfaces. **PSs** from microalgae might act in a similar way as *E. coli* exopolysaccharides, which can inhibit the autoaggregation via adhesins of bacterial cells (Valle et al. 2006; Rendueles et al. 2011). Polysaccharides, as sugar polymers, have also the capacity to act as inhibitors of lectin, which, being mainly located on the surface of bacteria cells, facilitate the attachment or adherence of bacteria to host cells by binding to the glycan substrates present on the surface of those host cells (Esko and Sharon 2009). **PSs** compete with the sugar-binding domain of lectins and inhibit the lectin-dependent adhesion of pathogens and biofilm formation, therefore reducing the occurrence of infection.

5.2 Antiviral Activity

Several mechanisms have already been proposed to explain the antiviral activity of **EPSs**, either involving the inhibition of the virus penetration into the host cells (Hayashi et al. 1996b), by competing with the glycoprotein attachment sites of the membrane/envelope of the viruses (Damonte et al. 2004; Radonic et al. 2010; Rashid et al. 2009), or relating to the replication during the early phases of the virus cycle (Martinez et al. 2005; Kim et al. 2012).

The general mechanism of the antiviral activity of most **PS** against enveloped viruses could be based on shielding off the positively charged sites in the viral

envelope glycoprotein through ionic interactions between the anionic (mainly sulfate) groups in the polysaccharide and the basic amino acids of the glycoprotein (Damonte et al. 2004; Radonic et al. 2010; Rashid et al. 2009), in a similar way to what happens when a virus attaches to a cell through the cell surface heparan sulfate receptor (Witvrouw and De Clercq 1997). Therefore, the **EPS** could compete with the amino acids of the virus glycoprotein, blocking the viral adsorption process, in an identical way to what happens in relation to bacteria, already mentioned. There is evidence that carrageenan, a sulfated polysaccharide from a macroalgae, could directly bind to human papillomavirus capsid (Buck et al. 2006). The **EPS** from *P. cruentum* is a good candidate to protect against viruses (Raposo et al. 2013), since uronic acids, along with the half-ester sulfate groups and the carboxyl groups of the **EPS**, contribute to its anionic properties. Raposo et al. (2014) found that the **EPS** from a Spanish strain of *P. cruentum* revealed, in general, greater antiviral activity than the **EPS** from an Israeli strain, and this fact might be related to the higher degree of sulfation of the former, although they did not discard other factors.

6 Safety and Regulatory Aspects

The safety hazards of a **PS** as food or food ingredient is directly or indirectly associated to the microalgae which it was extracted or secreted from, respectively.

Some microalgae have been widely commercialized and used, mainly as nutritional supplements for humans and as animal feed additives, and some have the GRAS status being attributed by the FDA (Food and Drug Administration) of the USA (Table 5).

In the EU, several *Chlorella* species and *A. platensis* were on the market as food or food ingredient, and consumed to a significant degree, before 15 May 1997. Thus, in general, they are not subject to the Novel Food Regulation EC No. 258/97. However, in some EU Member States, specific legislation may restrict the placing of these products in the market, and it is recommended to check this issue with the national competent authorities.

Safety hazards related to algae may include allergens and toxins, heavy metals and pesticides, and pathogens (van der Spiegel et al. 2013). Allergenicity has been reported for the cyanobacteria *Phormidium fragile* and *Nostoc muscorum* (Sharma and Rai 2008) and the green algal genus *Chlorella* (Tiberg and Einarsson 1989). No toxins have been found in *Arthrospira* and *Chlorella*, but toxic microcystines were detected in other cyanobacteria (Kerkvliet 2001; Heussner et al. 2012). Extracts from *Aphanizomenon flos-aquae*, *Spirulina*, and *Chlorella*, or mixtures thereof, were cytotoxic (Heussner et al. 2012). Pheophorbides may be formed in *Chlorella*, which give rise to photosensitization in some humans (Kerkvliet 2001). *A. platensis* remarkably reduced the incidence of liver tumors and prevented DBN-induced hepatotoxicity in rats without causing any side effects or organ toxicity (Ismael et al. 2009). Microalgae may also accumulate heavy metals, depending on the conditions under which they are grown (Hung et al. 1996; Wong et al. 1996). The presence of pathogenic microorganisms is another crucial safety aspect that must be considered. If microalgae are cultivated in open tanks, this may result in

Table 5 Some food and feed applications of microalgae and safety aspects

Microalgae/cyanobacteria	Species	Safety aspect	Microalgae/cyanobacteria	Species	Safety aspect
Cyanophytes	*Arthrospira/spirulina*	GRAS	Diatoms	*Navicula*	NT
	Synechococcus	NT		*Nitzschia dissipata*	NT
Prasinophyte	*Tetraselmis*	NT		*P. tricornutum*	NT
Chlorophytes	*Chlamydomonas reinhardtii*	NT		*Thalassiosira pseudonana*	NT
	H. pluvialis	NT		*Odontella aurita*	NT
	Dunaliella	NT		*Skeletonema*	NT
	Chlorococcum	NT	Eustigmatophytes	*Monodus subterraneus*	NT
	Scenedesmus	NT		*Nannochloropsis*	NT
	Desmodesmus	NT	Haptophytes	*Isochrysis*	NT
	Parietochloris incisa	NT		*Pavlova*	NT
	Chlorella	GRAS	Dinoflagellate	*Crypthecodinium cohnii*	GRAS
Rhodophyta	*P. cruentum*	GRAS			

Adapted from Enzing et al. (2014)
NT no toxins known, *GRAS* generally recognized as safe

microbiological contamination from birds, insects, or rodents (Kerkvliet 2001). These safety problems might be eliminated by growing the microalgae in closed bioreactors (Amara and Steinbuchel 2013).

PSs from microalgae might be a valuable material for a wide potential range of uses, including food, feed, and biomedical applications due, in general, to the absence of or to no known toxicity problems. Most toxicological data from the **PSs** from microalgae are driven from in vitro tests. Raposo et al. (2014) found no cytotoxic effects of the **EPS** from *P. cruentum* for the concentration (100 μg/mL) and cell lines tested. Other studies with Vero cells indicated that the cytotoxic effect only occurred for concentrations higher than 250 μg/mL, and some other in vivo assays indicated that this type of polysaccharide does not show any cytotoxic effect at 2 mg/mL (Huleihel et al. 2001).

The treatment of aortic endothelial smooth muscle cultured cells with depolymerized sodium spirulan (NaSP), an **sPS** obtained from a hot water extract of *A. platensis*, resulted in a significant inhibition of the proliferation of the arterial smooth muscle cells, therefore preventing atherosclerosis without exhibiting any toxic effects on the integrity of the vascular endothelial cell layers (Yamamoto et al. 2006). Some **sPSs** may interfere with blood coagulation and, therefore, have the potential to be used in some biomedical applications and not in another (Raposo et al. 2013).

It should be remarked that any **PS** extracted from microalgae/cyanobacteria and refined to be used as food is considered a new product and, thus, falls under the Novel Food Law of EU. For biomedical applications the novel biological products, in the USA, must comply with FDA Biologics Control Act (21 CFR 600 Biological Products General, Subpart A – General Provisions, Sec.600.3 Definitions) (Whiteside 2011). In the EU the term "biological product" was first published in the Directive 2003/63/EC, amending Annex I of the Directive 2001/83/EC (Noffz 2011). This implies that companies have to provide information on the safety of the food product (including results of animal testing) to the EFSA or FDA, before commercialization is authorized. For instance, carrageenans, which are polysaccharides from seaweeds, not from microalgae, are used as a food additive (E-407), have very low toxicity, and have been shown not to be teratogenic (Necas and Bartosikova 2013). However, the poligeenan, formerly referred to as degraded carrageenan, is not a food additive, exhibiting toxicological properties at high doses (Cohen and Ito 2002). Nilson and Wagner (1959) found no adverse effects on rats lifelong fed with kappa-/lambda-carrageenan from *C. crispus* or *G. mamillosa* at concentrations up to 25 %, while in two other unidentified strains of carrageenan, they found evidence of hepatic cirrhosis, but only at a concentration of 25 % and with no effect on mortality. Therefore, any **PS** from a novel source must be tested prior to be used in human applications.

7 Bioavailability and Metabolism

To our knowledge, there are no known bioavailability studies on the **PSs** from marine microalgae, the bioavailability of **PSs** from microalgae being yet to be studied on humans (Raposo et al. 2013). The **EPS** from *P. cruentum* is not

hydrolyzed in the gastrointestinal tract; therefore, its bioavailability is null or very reduced (Arad et al. 1993). However, some knowledge may be withdrawn from studies carried out with polysaccharides from macroalgae, plants, or microorganisms of structures similar to the **PSs** from microalgae.

Sulfated **PSs** from seaweeds, such as fucoidan from brown seaweeds (Senthilkumar et al. 2013) and carrageenans, alginates, and porphyrans from red seaweeds, are known to have biological effects that could be useful in the prevention or reversal of metabolic syndrome (Holdt and Kraan 2011).

As discussed previously in point 4.3, **PSs** could act as prebiotics. In fact, these **PSs** cannot be digested by human endogeneous enzymes, belonging, therefore, to the dietary fibers (Baird et al. 1977). They are able to modify gastrointestinal hormone secretion, glycemia regulation, and lipid metabolism, preventing, in this way, obesity (Parnell and Reimer 2012). One of the physicochemical properties of **PSs** is the ability to be fermented by the human colonic microbiota, resulting in beneficial health effects (Mišurcová et al. 2012). Also, in vitro and in vivo animal studies highlighted anti-hyperlipidemic and anti-hyperglycemic activities of **PSs** from microalgae (Raposo et al. 2013).

8 Clinical Trials

Reporting to what was already mentioned in Sect. 4 on bioactivity and applications, **PSs** constitute a good source for potential development of novel food ingredients and biomaterials. However, the exploitation of the biomedical potential of these **PSs** will be a long and challenging road, as the regulatory context of medical devices and, in this case, advanced therapy medicinal products are very demanding. Also, the lack of industrial-scale extraction and purification of many of these molecules is an obstacle for their application development. In fact, any clinical application will demand for the implementation and validation of industrial manufacturing methods. Besides this issue, the natural provenience of **PSs** imposes a strict control of their purity, stability, and safety, which imply extensive and, above all, expensive studies (Silva et al. 2012).

In spite of all these considerations, a large number of preclinical essays have already been conducted with microalgae. Recently, extensive studies have been performed to evaluate the therapeutic benefits of microalgae on several disease conditions including hypercholesterolemia, hyperglycerolemia, cardiovascular diseases, inflammatory diseases, cancer, and viral infections. Some studies reported the antioxidant and/or anti-inflammatory activities of *Spirulina* or its extracts, containing **PSs**, in vitro and in vivo, suggesting that *Spirulina* may provide a beneficial effect in managing cardiovascular conditions (Deng and Chow 2010). Some of the preclinical trials of polysaccharides from marine microalgae that have been carried out are listed in Table 6.

With respect to clinical essays and applications in the market, the area of cosmetics is one of the few known. An **EPS** from a cyanobacterium was reported to be effective in skin aging (Loing et al. 2011). There is a recent US patent defending the use of **sPSs**

Table 6 Preclinical trials of polysaccharides from marine microalgae (see also Table 4)

Microalgae species	Compound	Experimental model	Effects	References
Arthrospira sp.	Biomass	Several models	Hypolipidemic, antioxidant, and anti-inflammatory activities	Deng and Chow 2010
A. platensis	CaSp	Raw macrophages	Synthesis of TNF-α	Parages et al. 2012
Spirulina sp.	Spirulan-like substance	Several types of cell cultures	Antiviral activity against human cytomegalovirus (HCMV), herpes simplex virus (HSV-1), human herpes virus type 6 (HHV-6), human immunodeficiency virus type 1 (HIV-1), non-susceptibility of Epstein-Barr virus (EBV), and human influenza A virus (A/WSN/33)	Rechter et al. 2006
N. flagelliforme	Nostoflan	Vero, HEL, MDCK, and HeLa cells	Antiviral activity against HSV-1 (HF), HSV-2 (UW-268), HCMV (Towne), influenza (NWS)	Kenji et al. 2005
C. pyrenoidosa; *C. ellipsoidea*	Polysaccharide complex	Natural killer cells	Immunostimulating properties, inhibition of the proliferation of *Listeria monocytogenes* and *Candida albicans*	Barrow and Shahidi 2008
C. ellipsoidea	Chlorellan	Reticuloendothelial system in rats	Stimulate phagocytic activity of the reticuloendothelial system	Kojima et al. 1974
P. cruentum	(**EPSs**) degraded by Hermetic microwave and H2O2 under ultrasonic waves	Mouse tumor model, peritoneal macrophage activation, splenocyte proliferation assay	Antitumor and immunomodulatory activities of different molecular weight	Sun et al. 2012
Porphyridium sp.	Polysaccharide	NIH/3T3 cells	Antiviral activity against retrovirus MuSV-124 and MuSV/MuLV	Talyshinsky et al. 2002
P. aerugineum				
P. cruentum	**EPS**	Confluent cultures of human erythroleukemia cell line (HEL)	Antiviral activity against HSV type 1 (HSV-1; strain KOS), HSV type 1 (HSV-1; strain TK-KOS ACVr) and type 2 (HSV-2; strain G), vaccinia virus, and vesicular stomatitis virus	Raposo et al. 2014

in cosmetics. Indeed, microalgae extracts, mainly from *Arthrospira* and *Chlorella* (Stolz and Obermayer 2005; Spolaore et al. 2006), are incorporated in many face and skin care products (e.g., antiaging cream, refreshing or regenerating care products, emollient, and anti-irritant in peelers), sun protection, and hair care products (Martins et al. 2014). Alguard™ is a purified **sPS** from *P. cruentum* that is used in cosmetics worldwide as antiaging, anti-inflammatory, anti-irritant, skin maintenance, UVB damage prevention, soothing and healing creams, and lip balms. Also a mixture of **PSs** from microalgae makes part of the composition of a commercial product called Algenist™ antiaging skin care formulas in the form of alguronic acid.

There is a patent (WO 2007066340 A1, Arad and Atar 2007) defending the use of a material composed of algal polysaccharides for viscosupplementation in the treatment of degenerative joint disorders related to joint lubrication, preferably osteoarthritis, rheumatoid arthritis, gout, trauma, and age-related degeneration.

9 Conclusion

Microalgae are easy to grow organisms, and, in comparison with seaweeds, their culture conditions are easily controlled in closed systems, thus avoiding safety hazards. The chemical composition and structure and the rheological behavior of the polysaccharides they produce are relatively stable no matter the period/phase of harvest. However, the polysaccharides synthetized and/or released by marine microalgae can be so heterogeneous and structurally different that research on these compounds can be a very challenging task.

Polysaccharides may be regarded as key ingredients for the production of bio-based materials in life sciences (e.g., food, cosmetics, medical devices, pharmaceutics). The biological source and biodegradability of these biopolymers, coupled to the large variety of chemical functionalities they encompass, make them promising compounds. Despite having showed several interesting properties, including for human nutrition and health, their use in humans and clinical trials and bioapplications are yet to be explored, one of the reasons being the high molecular weights of the polymers. It would be an interesting issue to explore its use orally and therapeutically in human subjects, considering their anti-inflammatory, hypoglycemic, and anticoagulant/antithrombotic activities. However, the toxicity and bioavailability of such compounds are yet to be studied on humans. Although there are a large number of products on the market with biomass or extracts from microalgae, there are very few commercial products from polysaccharides isolated and purified on the market, but the outlook for such products is considered of major importance. Only a few patent applications on microalgae polysaccharides exist. However, the properties of polysaccharide-based products indicate great potential in the food and biomedical sectors.

Other areas of interest, due to their biochemical characteristics and rheological behavior, could be in engineering fields, such as naval (as drag-reducing agents), in food science/engineering, or in biomedical applications, as joint biolubricants and in arthritis treatment.

The extensive use of marine microalgae polysaccharides in these fields, however, would require a reliable supply of raw materials to guarantee the affordable price, sufficient purity, and constant high quality of these bioproducts. In addition, the possibility of obtaining polysaccharides in high quantities from modern microalgae biorefineries might be a competitive advantage with other sources.

Pectic Polysaccharides and Their Functional Properties

55

Beda M. Yapo and Dago Gnakri

Contents

Abstract

Since their first discovery in 1790–1825, pectins are still fascinating plant and food scientists who continue to carry out numerous structural as well as functional studies on them. This great interest of scientists for pectins is accounted for by their large spectrum of (bio)functionalities, starting from their natural location in plant cell walls as bioactive components for cell growth, defense, and protection via diverse manufactured food and nonfood products as techno-functional (gelling, emulsifying, film-forming, etc.) agents to terminate in human welfare as health-benefit (prebiotic, anticomplementary, antioxidant, anticancer, etc.) agents. The extraordinary functional versatility of pectins is thought to be intimately related to fine structure. Unfortunately, structurally, pectins are extremely diversified that establishment of structure-function relationship appeared so far a difficult task to go through. On the other hand, the extended structural variability of pectins presages for the finding of new functions hitherto unknown. Nevertheless, for some structurally well-known pectic cobiopolymers such as homogalacturonan, solid evidence for

structure-related functions, especially gelling properties, has been provided, including new insights very recently.

After a brief introduction on the "pectin structural repertoire," the main sources of industrial pectins will be exposed, followed by a succinct structural description of the different pectic block cobiopolymers, commonly referred to as "pectic polysaccharides." Finally, some remarkable structure-related functions, namely, gelling, emulsifying/emulsion-stabilizing, and antitumor properties of pectins will be revisited in the light of the latest work.

Keywords
Pectins • Sources • Production • Structures • Properties

1 Introduction

Pectic substances (or merely pectins) are a group of extremely diversified polysaccharides from plant cell walls, mucilages, and exudates. No less than 17 different glycosyl residues (Vincken et al. 2003), such as α-D-galactopyranosyluronic acid (α-D-Gal*p*A), α-L-rhamnopyranose (α-L-Rha*p*), β-D-galactopyranose (β-D-Gal*p*), α-L-arabinofuranose (α-L-Ara*f*), β-D-xylopyranose (β-D-Xyl*p*), and β-D-apiofuranose (β-D-Api*f*), to name a few, are believed to be sugar constituents of pectins. Several structural studies using combinatory approaches including enzymatic and chemical fingerprints have revealed, in heterogeneously complex pectic macromolecules, that these glycosyl residues are not randomly distributed, but rather concentrated in different regions, giving rise to various block cobiopolymers. To date, the pectin group may encompass at least eight distinct block cobiopolymers (often referred to as "pectic polysaccharides"), namely, unbranched (or linear) homogalacturonan (HG), rhamnogalacturonan-I (RG-I), rhamnogalacturonan-II (RG-II), xylogalacturonan (XGA), apiogalacturonan (A_pGA), galacturonogalacturonan (GaGA), galactogalacturonan (GGA), and arabinogalacturonan (A_rGA) (Schols and Voragen 1996; Caffall and Mohnen 2009; Ridley et al. 2001; Yapo 2011a). The latter six are sometimes gathered under the generic terms of "substituted galacturonans." This striking structural diversity renders pectins functionally versatile with multiple biological (plant cell growth, defense, protection against harmful hosts, etc.), techno-functional (gelling, emulsifying/emulsion-stabilizing, thickening, film-forming, etc.), and health-benefit (immunological, prebiotic, anticomplementary, antioxidant, antitumor, etc.) properties. Pectin functionality is, indeed, intimately related to fine structure (Sørensen et al. 2009; Sila et al. 2009).

2 Marketable Pectins: Sources and Production

Most commercial (or industrial) pectins, mainly intended for the preparation of gelling food products, are produced from citrus (lemon, lime, orange, and grapefruit) peel and apple pomace (May 1990; Voragen et al. 1995; Sriamornsak 2003; Srivastava and Malviya 2011), two raw materials from the western juice industry,

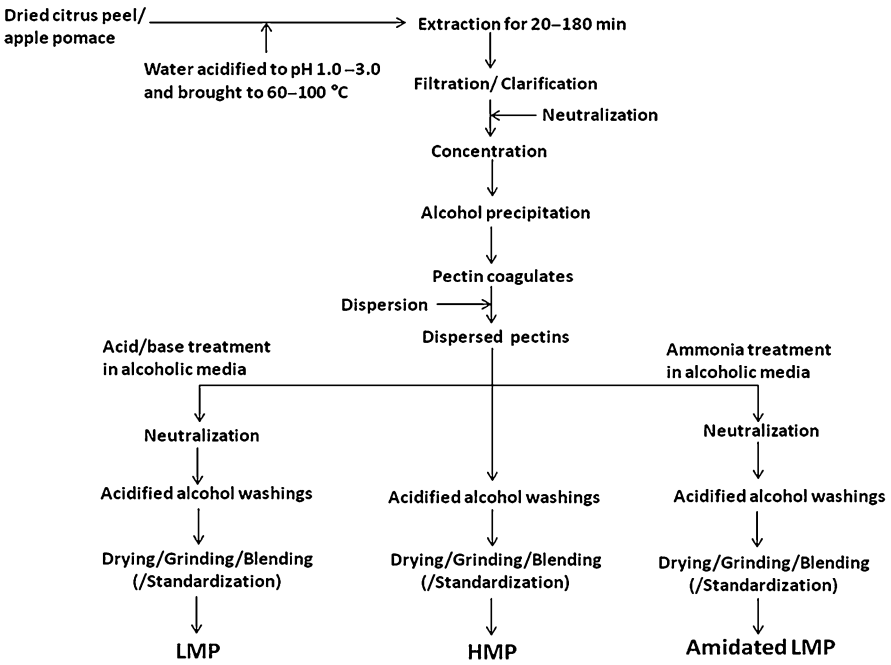

Fig. 1 Simplified scheme for the production of marketable HMP, LMP, and amidated LMP (LMP = low methoxy pectins; HMP = high methoxy pectins)

available in large quantities. The two industrial by-products are pectin-rich sources, with a pectin content of 15–30 % (for citrus peel) and 10–15 % (for apple pomace) on a dry weight basis. Moreover, acid-extracted citrus and apple pectins are usually high methoxy pectins (HMP) with high viscosity-average molecular weight ($\overline{Mv}$ ~100–300 kDa) and galacturonic acid content no less than 65 % on a dry weight basis as required by the international market. These features enable one to prepare good sugar-acid-mediated high methoxy pectin gels (HMP-SAG). In addition (amidated) low methoxy pectins (LMP) with good gelling properties can be produced from initially extracted citrus or apple HMP by partial de-esterification with acid (commonly)/base or with ammonia in alcoholic media (Fig. 1).

It is worth underlining that other commercially viable sources of pectins are sugar beet pulp (for producing pectin emulsifiers), sunflower head residues (for naturally (nonchemically tailored) LMP), and some tropical fruit by-products such as mango peel (for HMP), yellow passion fruit rind (for naturally HMP and LMP), and cashew apple pomace (for naturally LMP) (Schieber et al. 2001; Yapo and Koffi 2014). Passion fruit rind, for example, is used in some emerging countries such as Brazil for manufacturing marketable pectins.

Commercial pectins are usually extracted by acidified hot water under specified extraction conditions kept secret by producers but generally thought to be as follows: dry raw material to solvent ratio 1:35–1:15 (w/v), water acidified with

HNO_3 (or HCl) to pH 1.0–3.0, temperature 60–100 °C, and duration 20–180 min (Fig. 1). The pectin slurry is then filtered, concentrated, and precipitated with alcohol, usually isopropanol. The gelatinous pectin material is then extensively purified by acidified alcohol washings to remove various impurities including pigments and free saccharides of small sizes and salts, thereby converting pectin galacturonates into pectin galacturonic acid residues (the acid form of the pectin product). During this treatment, neutral sugar chains of solubilized pectin polymers are further hydrolyzed, which results in increase of the pectin galacturonic acid content. As pectins are extracted from natural plant materials in a practically unchanged form, they demonstrate different properties depending on the quality of the raw material (Herbstreith 2014a, b). Therefore, quality control and standardization of the pectins are very important criteria. The yield, sugar composition, esterification degree, and functional properties of pectins are influenced by extraction conditions, and therefore optimization is always a prerequisite for every new pectin source that is being investigated for marketing purposes.

To manufacture low-calorie gelling products, LMP which form Ca^{2+}-induced gels are needed. This compels producers to add a demethylesterification step to the production process yielding HMP. Usually, commercial LMP are produced by acid demethylation from primarily extracted citrus or apple HMP. In this case, initially methylesterified pectin GalA residues are randomly demethylated, which gives LMP products with randomly distributed unesterified GalA residues in the pectin chains. Ammonia treatment can also be applied, in which case methyl groups are partially replaced by amide groups, thereby yielding amidated LMP with randomly distributed unesterified GalA residues in the pectin chains. As required by the market, the pectin degree of amidation (DAm) should not exceed 25 %.

"Nonchemical" demethylation may also be performed by using demethylating enzymes, viz., fungal (f-PME) or plant (p-PME) pectin methylesterases. This produces LMP with non-blockwise (by f-PME) or blockwise (by p-PME) distribution of unesterified GalA residues within the pectin chains. More than acid demethylation, enzymatic demethylation is kinetically precisely controlled to produce LMP with the exactly desired degree of methylesterification (or degree of methoxylation, DM) without significant modification of the pectin molecular weight. However, this requires the use of highly purified PME preparations and will obviously add to the cost of production. For all these reasons, no commercial LMP have so far been enzymatically tailored.

Various extraction methods, which are relatively new, such as microwave-assisted extraction (MAE) and ultrasound-assisted (UAE) extraction, have been compared with the conventional acid extraction on a laboratory scale. Most studies showed that MAE or UAE gives higher amount of pectins with often higher viscosity-average molecular weight for considerably shorter extraction duration (Fishman et al. 2003; Wang et al. 2007; Bagherian et al. 2011). In addition, an environmentally friendly aspect of MAE and UAE methods using water solvent instead of dilute acid has also been put forward by some workers (Maran et al. 2013) with respect to generated effluents. On an industrial scale, however, the practicability of these "new methods" remains to be proven.

3 Structural Characteristics of the Different Pectic Cobiopolymers

3.1 Homogalacturonan

Homogalacturonan (HG) is generally the most abundant pectic polysaccharide, accounting for more than 50 % of complex pectins from various sources and up to 90 % of citrus pectins (Ridley et al. 2001; Voragen et al. 2009; Yapo 2011b). HG is an unbranched polymer of 1,4-linked α-D-Gal*p*A residues (Fig. 2), partially methylesterified at *C*-6 position and sometimes acetylesterified at *O*-2 and/or *O*-3 positions. The degree of methylesterification (DM) is the number of α-D-Gal*p*A residues, out of 100, esterified with methyl alcohol groups, and the degree of acetylesterification (DAc) corresponds to the number of α-D-Gal*p*A residues, out of 100, esterified with acetyl groups, assuming one acetylation per α-D-Gal*p*A residue. Depending on the value for DM of pectin HG, low methoxy pectins (LMP, DM <50 %) can be distinguished from high methoxy pectins (HMP, DM ≥50 %). Native HG may be (almost) fully methylesterified and only later partially de-esterified to about 70–80 % by plant PME. HG is renowned for its ability to form gels, a property widely utilized in the food industry and in all likelihood a property that determines some of the functions of (HG-containing complex) pectins in primary cell walls (Albersheim et al. 1996). Both DM and DAc of pectin HG influence its functional properties. The average degree of polymerization ($\overline{DP}$) of individual native HG is not known with certainty, but may be approximately of 50 in cell walls of commelinoid-related monocot species and a twofold higher in cell walls of dicotyledonous species at maturation stage (Voragen et al. 2009; Yapo 2009). The amount and $\overline{DP}$ of pectin HG also affect the pectin functional (especially gelling) properties (Yapo 2009).

3.2 Rhamnogalacturonan-I

Rhamnogalacturonan-I (RG-I) is generally quantitatively the second pectic cobiopolymer, which may represent 10–25 % of complex pectins and up to 45 % of sugar beet pulp, potato tuber, and tobacco leaf pectins (Ridley et al. 2001; Voragen et al. 2009; Yapo 2011a). RG-I is a structurally complex polysaccharide with a [→2)-α-L-Rha*p*-(1 → 4)-α-D-Gal*p*A-(1→]$_{n\geq 1}$ backbone partly branched, at *O*-4 (mainly) and/or *O*-3 positions of α-L-Rha*p* residues, with neutral sugar side chains of various types and sizes, viz., (1 → 5)-α-L-arabinan, (1 → 4)-β-D-galactan, arabinogalactan-I, and galactoarabinan (Fig. 3), and probably also by arabinogalactans-II.

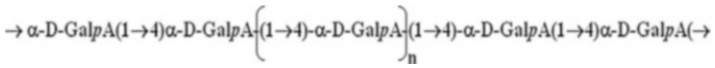

Fig. 2 Schematic representation of homogalacturonan

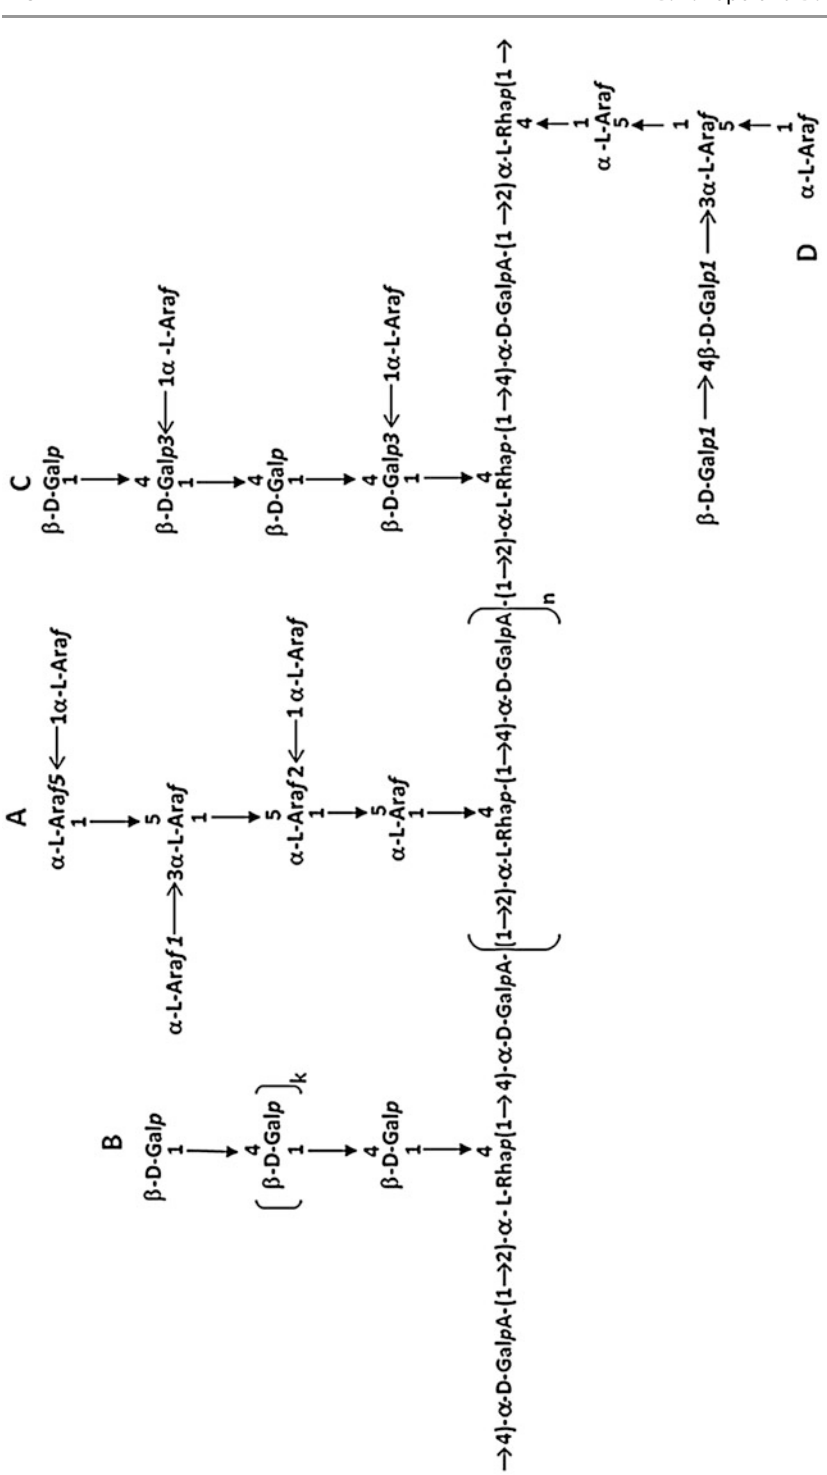

Fig. 3 Schematic representation of rhamnogalacturonan-I (With permission from Yapo (2011a). Copyright Taylor & Francis Group)

The $\overline{DP}$ of the backbone of individual native RG-I is not known with certainty and may be dependent on the polysaccharide origin; for example, ~30–40 diglycosyl repeats for citrus RG-I, 80 repeats for beet RG-I, and as many as 100–200 diglycosyl repeats for RG-I from suspension-cultured sycamore cells (Albersheim et al. 1996; Yapo 2011a). RG-I is structurally extremely varied, depending on plant source, organ, and even on location within the same cell tissue that it is nowadays viewed as a family of molecularly diversified polysaccharides with the same diglycosyl repeating backbone carrying side chains of different types and sizes.

3.3 Rhamnogalacturonan-II

Rhamnogalacturonan-II (RG-II) is undoubtedly the most ubiquitous of substituted galacturonans, being purified from primary cell walls of seedless plants such as ferns (e.g., *Ceratopteris thalictroides*), horsetails (e.g., *Equisetum hyemale*), and lycopods (e.g., *Lycopodium nummularifolium*) and all higher plants hitherto examined for. RG-II is, however, a quantitatively minor block cobiopolymer of complex pectins, accounting hardly for 0.1 % of the pectin-poor primary cell wall of commelinoid-related monocotyledonous species and for 0.5–8.0 % of the pectin-rich primary cell wall of non-commelinoid monocotyledonous and dicotyledonous species (O'Neill et al. 2004; Yapo 2011c). It is also remarkably structurally conserved throughout vascular plants and is believed to exist in the primary cell wall, predominantly as a borate diester cross-linked dimer (dRG-II) rather than as a monomer (mRG-II) (O'Neill et al. 2004). In vitro interconversion of dRG-II into mRG-II or vice versa is now well demonstrated. This pectic cobiopolymer, with an average molecular weight of 5.0–10.0 kDa, has an oligogalacturonan backbone ($\overline{DP}$ 11–15), which is branched with four well-defined side chains (A, B, C, and D) containing six unusual and specific (or diagnostic) sugars, namely, apiose (Api; 3-*C*-(hydroxymethyl)-*β*-D-erythrose), 2-*O*-methyl-fucose (2-*O*-Me-Fuc), 2-*O*-methyl-xylose (2-*O*-Me-Xyl), aceric acid (AceA; 3-*C*-carboxy-5-deoxy-L-xylose), 2-keto-3-deoxy-D-*manno*-octulosonic acid (KdoA), and 3-deoxy-D-*lyxo*-heptulosaric acid (DhaA) (Fig. 4). RG-II is, therefore, structurally different from RG-I in that rhamnose is not present in its backbone, but rather in three (A, B, and C) out of the four authenticated side chains and has only been named so for distinction sake.

3.4 Xylogalacturonan

Xylogalacturonan (XGA) is the second known substituted galacturonan. This pectic cobiopolymer has an (1 → 4)-linked α-D-galacturonan backbone, which is partially substituted at *O*-3 (mainly)/*O*-2 position by single nonreducing β-D-Xyl*p* residues and/or by relatively short side chains ($\overline{DP}$ 2–8) of 1 → 2/1 → 3/1 → 4/1 → 2,3/1 → 2,4/1 → 3,4-linked β-D-xylans (Fig. 5). The degree of substitution by β-D-Xyl*p* residues of the galacturonan backbone can range from approximately 20 % to

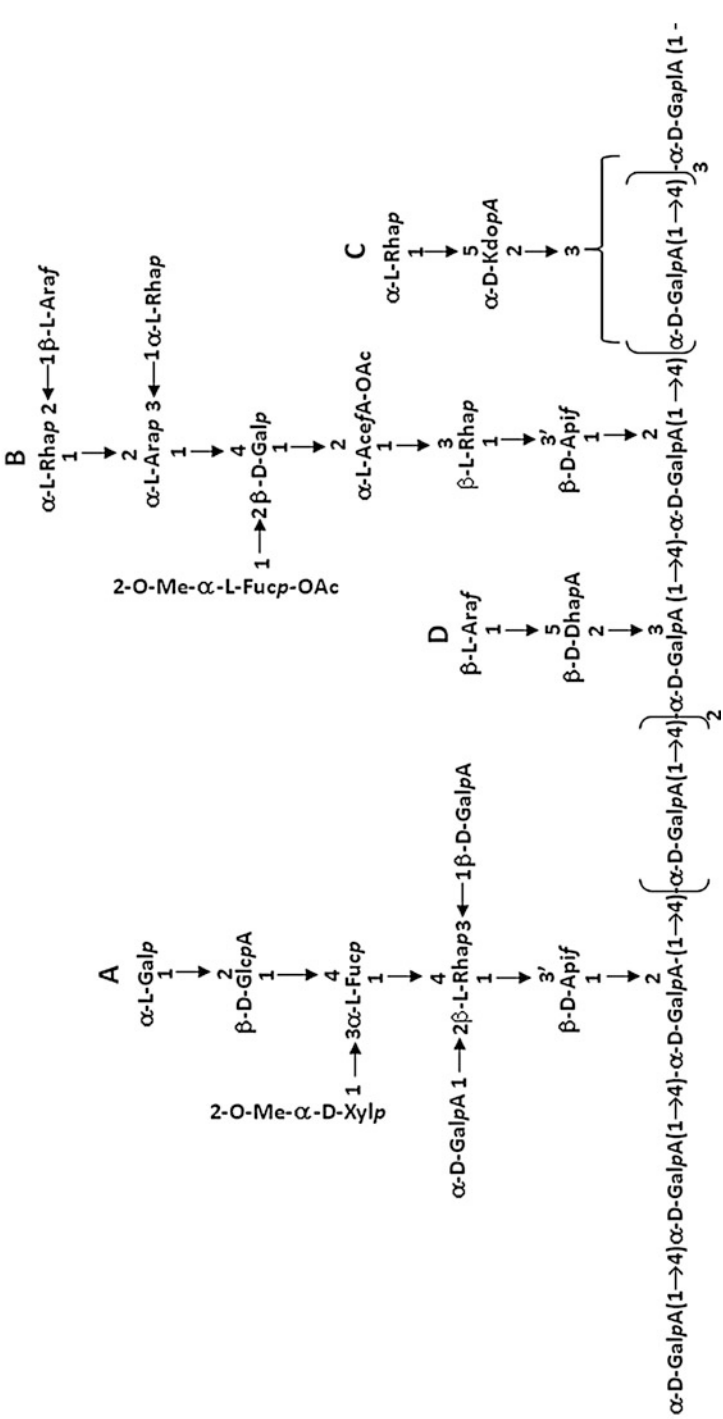

Fig. 4 Schematic representation of rhamnogalacturonan-II (With permission from Yapo (2011c). Copyright Hindawi Publishing Corporation)

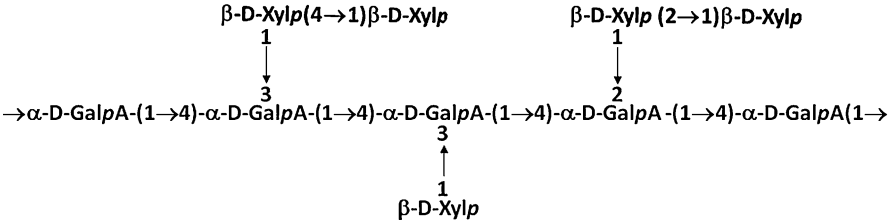

Fig. 5 Schematic representation of xylogalacturonan

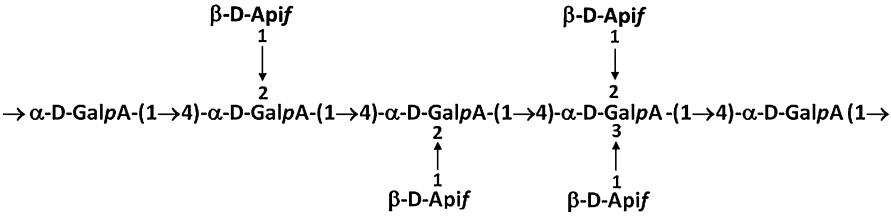

Fig. 6 Schematic representation of apiogalacturonan

100 %, depending on the polysaccharide origin. The $\overline{DP}$ of the galacturonan backbone of XGA is not known with certainty, but may be comparable to that of HG. Furthermore, the β-D-xylan side chains of XGA may be substituted with α-L-Ara*f*, α-L-Fuc*p*, and/or β-D-Gal*p* units. The DM of XGA is dependent on the polysaccharide source and may vary from about 40 to 90 %. In complex apple pectins, XGA is present in the vicinity of RG-I and is therefore an integral part of the so-called pectic hairy regions (Schols and Voragen 1996; Coenen et al. 2007).

3.5 Apiogalacturonan

Apiogalacturonan (A_pGA), an apiose-substituted galacturonan, is a relatively low molecular weight (20–25 kDa) pectic cobiopolymer from the primary cell wall of certain aquatic monocotyledonous species such as the duckweed *Lemna minor* (Lemnoideae) and eelgrasses of the Zosteraceae family (*Zostera marina*, *Z. pacifica*, and *Phyllospadix*). A_pGA has a (1 → 4)-linked α-D-galacturonan backbone, partly substituted at *O*-3 (mainly)/*O*-2 position by single nonreducing β-D-Api*f* (Fig. 6), (1 → 5)-linked β-D-Api*f* residues and/or by "apiobioside" (β-D-Api*f*-(1 → 3′)-β-D-Api*f*-(1→).

The degree of substitution of the galacturonan core may vary from about 5 to 90 %. Moreover, the galacturonan core of A_pGA is partially methylesterified to a usually low DM (15–30 %). The $\overline{DP}$ of the galacturonan backbone of A_pGA is not clearly known, but may be in the order of 65. A_pGA is likely an integral part of

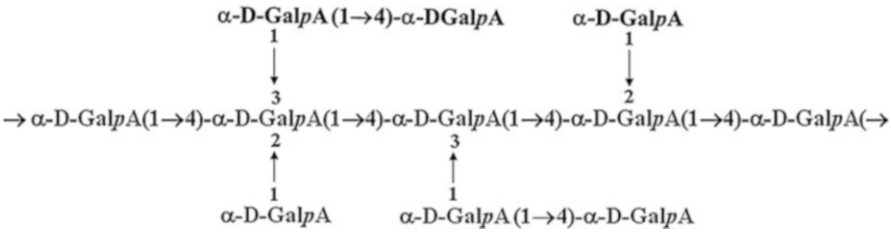

Fig. 7 Schematic representation of galacturonogalacturonan

complex pectins called lemnan and zosteran encompassing additionally blocks of HG and RG-I (Golovchenko et al. 2002). Unlike lemnan and zosteran, A_pGA is soluble in highly salted waters (containing up to 2 M NaCl). This property may be promoted by a high degree of apiosylation of the pectic polysaccharide and is likely related to the ability of these species (Lemnoideae and Zosteraceae) to grow and proliferate in aquatic and marine media. Contrary to zosteran, A_pGA is a rather poor-gelling agent for preparing sugar-acid-mediated gels. It is, however, not known if A_pGA may be a good gelling agent in calcium-mediated gels, considering its rather low DM.

3.6 Other Quantitatively Minor Substituted Galacturonans

Galacturonogalacturonan (GaGA), a galacturonic acid-substituted galacturonan, is a block cobiopolymer of complex pectins isolated from cell wall materials of plant species such as the marsh cinquefoil *Comarum palustre* and *Solanum licopersicum* (tomato) (Ovodova et al. 2006; Round et al. 2010). GaGA has a (1 → 4)-linked α-D-galacturonan backbone, partially substituted at *O*-2 and/or *O*-3 positions by single nonreducing α-D-Gal*p*A residues (Fig. 7) and/or by relatively long side chains of 1 → 3/1 → 4/1 → 3,4-linked α-D-Gal*p*A residues.

Galactogalacturonan (GGA), a galactose-substituted galacturonan, is a block cobiopolymer of various complex pectins such as gum karaya (from *Sterculia* species), zosteran (from *Z. marina*), panaxan (from *Panax ginseng* C. A. Meyer), and soya sauce acidic polysaccharide. GGA has a (1 → 4)-linked α-D-galacturonan backbone, partly substituted by single β-D-Gal*p* residues and/or 1 → 3/1 → 4/1 → 6/1 → 3,6-linked β-D-Gal*p* residues (Fig. 8). The galacturonan backbone of GGA can be highly methylesterified.

Arabinogalacturonan (A_rGA), an arabinose-substituted galacturonan, has a (1 → 4)-linked α-D-galacturonan core branched, via *O*-3 position and/or terminal reducing point, by single (nonreducing) or multiple side-stubs of α-L-Ara*f* residues (Fig. 9). This cobiopolymer has been isolated from complex pectins extracted from miscellaneous plant materials such as apple fruits, field-bean hulls, *Plantago psyllium* seeds, *Plantago major* leaves, *Amabilis* fir bark, alfalfa leaves and stems, and carnation (*Dianthus caryophyllus*) roots.

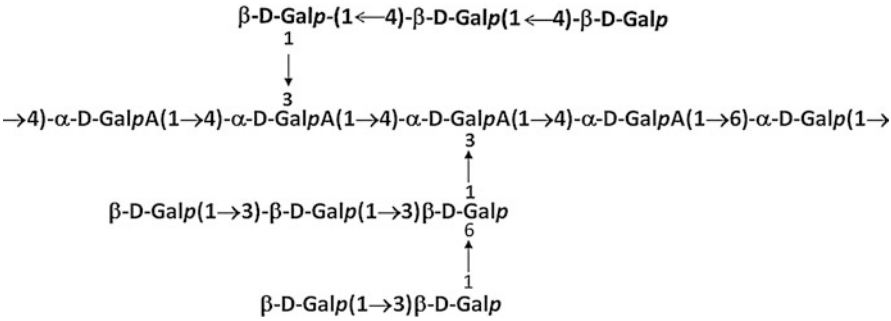

Fig. 8 Schematic representation of galactogalacturonan

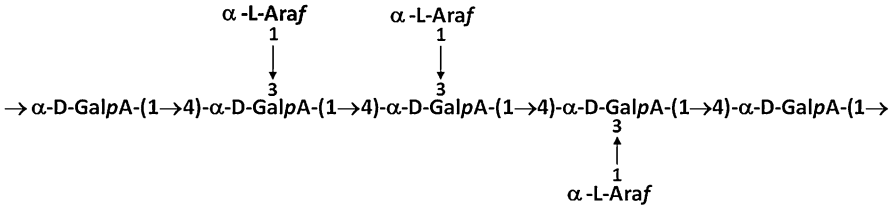

Fig. 9 Schematic representation of arabinogalacturonan

4 Structural Aspect of Complex Pectins

Native pectins in plant cell walls may generally be viewed as multi-polymer complexes which are formed by interconnections of various "pectic polysaccharide" elements, including block cobiopolymers of HG (predominantly), RG-I, and substituted galacturonans such as RG-II and to a lesser extent XGA (Albersheim et al. 1996; Schols and Voragen 1996; O'Neill and York 2003; Ovodov 2009; Voragen et al. 2009; Yapo 2011a). However, the type(s) of substituted galacturonans present in complex pectins may be dependent on the source. For example, in complex pectin fractions from cell wall materials of the marsh cinquefoil *Comarum palustre* and tomato, GaGA and/or RG-II appeared to be attached to HG and RG-I. In complex apple pectins, RG-II and XGA are associated to HG and RG-I. Zosteran and lemnan from *Z. marina* and *L. minor* (respectively) are composed of blocks of A_pGA, HG, and RG-I. In all cases, HG and RG-I elements appeared to be the most widespread in complex pectins, and therefore, most general schemes proposed for (complex) pectin structure included at least the two types of pectic polysaccharides, often referred to as pectin "smooth" (HG) and "hairy" (RG-I) regions. To date, three key hypothetical models exist in the literature. These are (i) the alternating "smooth" and "hairy" regions model (Schols and Voragen 1996; Fig. 10a), (ii) the "RG-I backbone" model (Vincken et al. 2003; Fig. 10b), and (iii) "the living thing-like" model (Yapo 2011b; Fig. 10c).

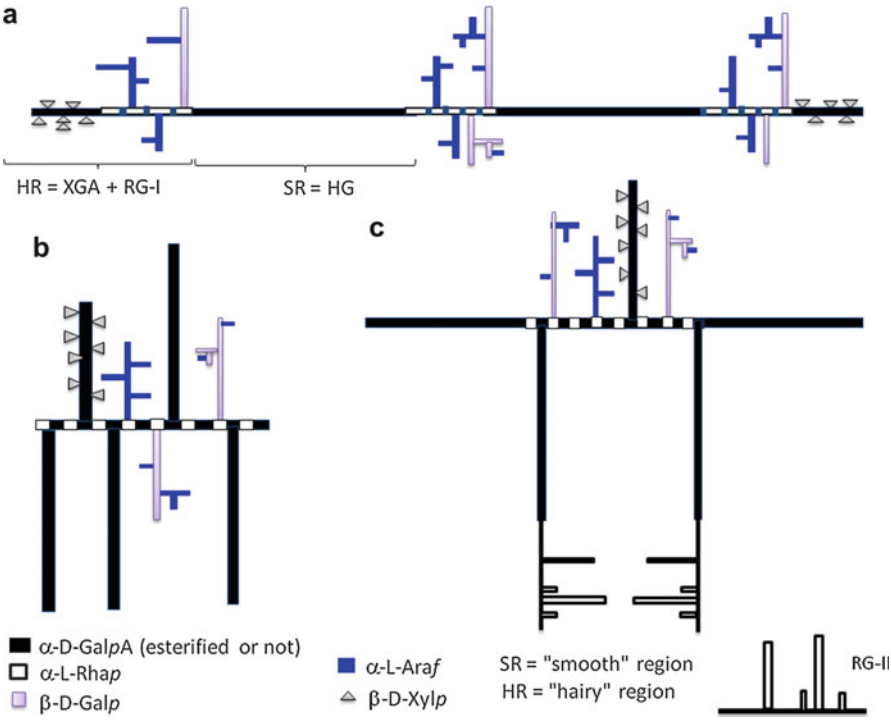

Fig. 10 The key hypothetical models proposed for pectins as multi-block cobiopolymer complexes of HG, RG-I, XGA, and/or RG-II (With permission from Yapo (2011b). Copyright www.Elsevier.com)

5 Functional Properties of Pectins

Pectins are undoubtedly the most functionally versatile biopolymers, with a large spectrum of biological (plant cell growth, defense, protection against harmful hosts, etc.), techno-functional (gelling, emulsifying/emulsion-stabilizing, thickening, film-forming, etc.), and health-benefit (biosorbent, immunomodulating, prebiotic, anticomplementary, antitumor, antioxidant, antimicrobial, etc.) properties. The extraordinary functional versatility of pectins may be related to their high structural variability. The impressive range of activities of pectins has remarkably been reviewed for years by several (groups of) workers (Voragen et al. 1995; Thakur et al. 1997; Sriamornsak 2003; Willats et al. 2006; Ovodov 2009; Sila et al. 2009; Yapo 2011a; Gullón et al. 2013; Espitia et al. 2014). However, new insights into the different mechanisms of action of pectin cobiopolymers are continuously provided for a better understanding of their structure-related properties. Will be dealt with here are the gelling, emulsifying/emulsion-stabilizing, and antitumor properties of pectin multi-block cobiopolymers.

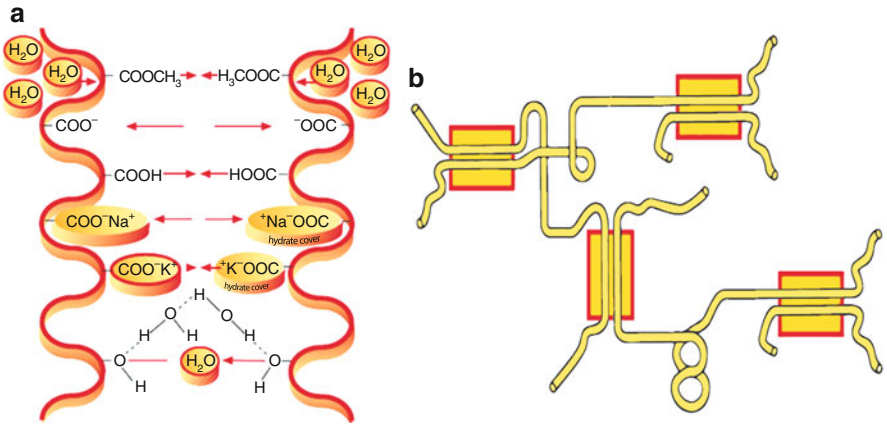

Fig. 11 Schematic representations: (**a**) Gelling mechanisms of high methylester pectins; (**b**) Bonding zones in the gel network. (With permission from Herbstreith and Fox Corporate Group. Copyright www.herbstreith-fox.de)

5.1 Gelling Properties of Pectins

As conveyed by the name per se, "pectin" (*in reference to the Greek word* "*pektikos*," *which means to* "*congeal*, *solidify or curdle*") is a naturally gelling polysaccharide. This oldest functionality of pectins is mainly exploited for manufacturing diverse gelling food products such as marmalades, jams, preserves (for HMP), and low-calorie jellies (for LMP). However, the mechanism of gelation of HMP is different from that of LMP.

HMP form sugar-acid-mediated gels (HMP-SAG). Gelation of HMP requires the presence of 55–65 % soluble sugar (generally sucrose) and acidic conditions (pH 2.0–3.5). Gelation occurs by formation of junction zones between the pectin HG chains, promoted by added cosolutes (sucrose). The soluble sugar added to the dispersed pectin system (intended for gelation), indeed, reduces the water activity and thus fosters pectin chain-to-chain interactions at the expense of pectin-solvent interactions. It may also function as a "coating agent" that aids in strengthening branch points, possibly through cooperative interactions and may influence self-association of pectin chains by "condensing" around them or binding to them (Fishman and Cooke 2009; O'Brien et al. 2009). Acid (low pH condition) prevents deprotonation of unesterified GalA residues of the pectin HG chains, thereby annealing (or at least minimizing) intermolecular electrostatic repulsions. The junction zones formed are then stabilized by interchain hydrogen bonds between protonated carboxyl groups and secondary alcohol groups of the pectin HG chains and by interchain hydrophobic interactions between pectin HG methylester groups (Fig. 11a). Gelation results in formation of vast tridimensional networks in which solvent and cosolutes are all immobilized (Fig. 11b). The gel formed is a thermo-irreversible cohesive system, resisting deformation and showing a stress/strain relationship for small deformation. Studies using atomic force microscopy (AFM)

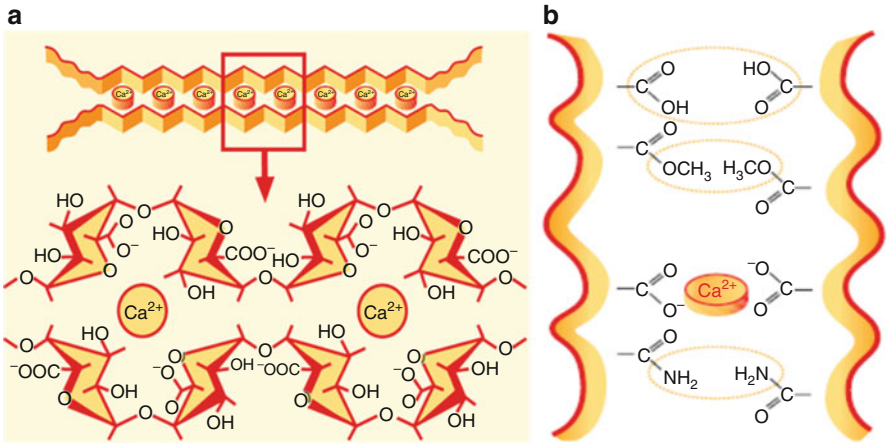

Fig. 12 Schematic representations: (**a**) Gelling mechanism after the "egg-box model" of (non-amidated) low methylester pectins; (**b**) amidated low methylester pectins. (With permission from Herbstreith and Fox KG. Copyright www.herbstreith-fox.de)

have, however, revealed that HMP-SAG comprise partially cross-linked networks, quite deformable in that they are held together by relatively easily disrupted secondary interactions such as hydrogen bonds and van der Waals forces, and this could actually be the basis of the unique ability of pectins to form spreadable gels (Fishman and Cooke 2009). Furthermore, the strength of the gels formed appeared to be correlated to the density of pectin strands and uniformity of pectin (chain) distribution within the gels (Fishman and Cooke 2009).

LMP solutions require, for gel formation, the presence of multivalent cations, especially Ca^{2+}, but not necessarily sugar (sucrose) and low pH conditions. Gelation can indeed occur within a larger pH range (3.0–7.0) whether soluble solids are added or not to the calcium-containing pectin system. This property allows LMP, unlike HMP, to be used in various food systems, such as low-calorie jellies, acidic milk products, yogurts, and desserts. Gelation is believed to result from formation of intermolecular junction zones, via Ca^{2+}-bridges, between unesterified GalA residues of the pectin HG chains, according to the so-called egg-box junction model (Fig. 12a), first posited for polyguluronate-rich alginates (Grant et al. 1973), since (1 → 4)-linked α-L-guluronate is a mirror image of (1 → 4)-linked α-D-galacturonate. The minimum length of sequences of unesterified GalA residues required for formation of stable egg-box junction structures may vary from approximately 6 to 20 residues, corresponding to a minimum array of approximately 3–10 site-bound Ca^{2+} between chains of twofold symmetry (O'Brien et al. 2009; Fraeye et al. 2010; Morris et al. 2011). Once formed, the junction zones are stabilized by van der Waals interactions and hydrogen bonds between protonated carboxyl groups and by electrostatic interactions. Cohesive LMP gels are thermo-reversible, with sometimes appearance of structural changes-related thermal hysteresis after a relatively long period of ageing.

It should be underlined that the ability of LMP to form egg-box-type junction zones does not only depend on its degree of demethylation (100 – DM) but also on intermolecular and intramolecular distribution patterns of unesterified GalA residues of the individual polyelectrolyte chains (Kohn and Luknar 1977; Taylor 1982; Voragen et al. 1995; Fraeye et al. 2010). Thus, the de-esterification pattern, according to the "blocky parameter" known as the absolute degree of blockiness, which represents the ratio of the amount of unesterified (mono, di-, and tri-) GalA residues, liberated by homogenous endopolygalacturonases, to the total amount of (esterified and unesterified) GalA residues within pectin chains, has been found to play a crucial role in the gelling behavior of LMP (Fraeye et al. 2010). In addition, the block size and the block size frequency may actually be the two key factors that govern calcium-mediated gelation of LMP, while stabilization of the gel formed requires junction-zone-terminating structures evolved from pectin RG-I block cobiopolymers (Yapo and Koffi 2013a).

The presence of amide groups improves, under low pH conditions, the gelling ability of LMP (Alonso-Mougan et al. 2002) and the elasticity and stability of the gel formed and decreases its tendency to syneresis by promoting additional hydrogen bonds (Fig. 12b). Thus, amidated LMP are able to form homogenous gels which are less sensitive to calcium ion concentration over a wide range. The presence of acetylester groups in polygalacturonate chains, by contrast, would hinder formation of junction zones, by decreasing the polyelectrolyte affinity for Ca^{2+} ions. This would mainly account for the rather poor gelling ability of amply acetylated pectins from, for example, cauliflower, chicory, cacao pod husk, endive, pumpkin, and sugar beet by-products. Nevertheless, good gelation has been reported for enzymatically deacetylated beet pectins (Oosterveld et al. 2000).

5.2 Emulsifying Properties of Acetylated Pectins

While high acetylation is likely to impair the gelling capability of certain HG-rich pectins, it may, due to the hydrophobic character, at least be partly accountable for the oil-in-water (O/W) emulsifying/emulsion-stabilizing activities of some amply acetylated pectins from various plant by-products such as sugar beet pulp, cacao pod husks, pumpkin pulp, and cauliflower leaves (Dea and Madden 1986; Yapo and Koffi 2013b). On the other hand (almost unacetylated) depolymerized pectins, from citrus, apple, or apricot by-products, containing 1–4 % proteinaceous compounds also appeared able to emulsify O/W systems (Akhtar et al. 2002; Baississe et al. 2010), suggesting that hydrophobic compounds other than acetyl groups might be involved in the pectin-emulsifying activity. Among acetylated pectins, much intention has been focused on (acid-extracted) sugar beet pectin (BP). It is posited that a hydrophobic protein moiety, relatively strongly associated to BP, is responsible for its emulsifying activity, while the hydrophilic polysaccharide part stabilizes the emulsion droplets formed by providing a protective thick layer, which bestows an effective steric stabilization during extended storage (Akhtar et al. 2002). AFM has enabled a group of workers (Kirby et al. 2008) to show

that BP is mainly composed of un-aggregated linear protein-polysaccharide complexes in which a single protein strand is attached to one end of the polysaccharide chains, thereby forming the so-called tadpoles that contribute to its unusually interesting emulsifying properties. However, other studies showed that the freak emulsifying activity of BP cannot only be explained by the presence of tadpole structures but could result from combination of several emulsion-promoting factors, viz., a high acetylation level, medium-sized polymer chains, and high amount neutral sugars that might constitute the interacting zones with protein which confers this activity without the need for pre-depolymerization (Yapo et al. 2007a). It has subsequently been found, in corroboration, that protein is predominantly bound to the neutral side chains of BP (Funami et al. 2011), which shows involvement of branched polysaccharide structures in the emulsifying/emulsion-stabilizing properties of BP. According to the same authors, contribution of BP ferulation might be little to null, in contrast to previous reports (Williams et al. 2005). Furthermore, BP has been found to exhibit, under acidic conditions (pH ~3), a higher emulsifying ability than gum arabic (the hydrocolloid emulsifier so far unequalled), at an approximately sevenfold lower polymer concentration (Nakauma et al. 2008). Because gum arabic is expensive to use in practice and that a rather high gum/oil ratio (~1:1) is required for producing fine stable emulsion droplets (Dickinson 2009), naturally acetylated pectins with demonstrated emulsifying properties may appear to be good alternative to gum arabic, the benchmark hydrocolloid emulsifier.

5.3 Anticancer Properties of Pectins

Among the miscellaneous potential health-benefit effects of pectic polysaccharides, special attention has recently been focused on their antitumor properties. In this connection, the so-called modified citrus pectin (MCP) has gained interest as the (pharmacological) product of choice for investigation. Most studies on the anticancer properties of pectic polysaccharides have indeed been carried out on MCP. Interestingly, the bulk of the studies (Platt and Raz 1992; Eliaz 2002; Nangia-Makker et al. 2002; Glinsky and Raz 2009) showed that MCP could be effective against any of the main four stages (cell adhesion, cell aggregation, angiogenesis, and metastasis) of development of galectin-3-meditated malign tumors (Fig. 13). Nevertheless, the molecular origin of MCP bioactivity has remained unknown hitherto, probably because MCP is in fact a heterogeneous mixture of pectic oligosaccharides (POS) and polysaccharides (PPS), produced by depolymerization of commercial citrus HMP ($\overline{Mv}$ ~100–300 kDa), based on modification of the reaction medium pH and temperature. In addition, preparation methods of MCP products varied widely from workers to workers to such a point that final products appeared considerably different from a molecular point of view.

Depending on the method of preparation, three molecularly different MCP products can be distinguished: polygalacturonan-rich MCP ($\overline{Mw}$ 10–20 kDa), commercially known as PectaSol (MCP_1); galactose-enriched RG-I-like MCP (MCP_2);

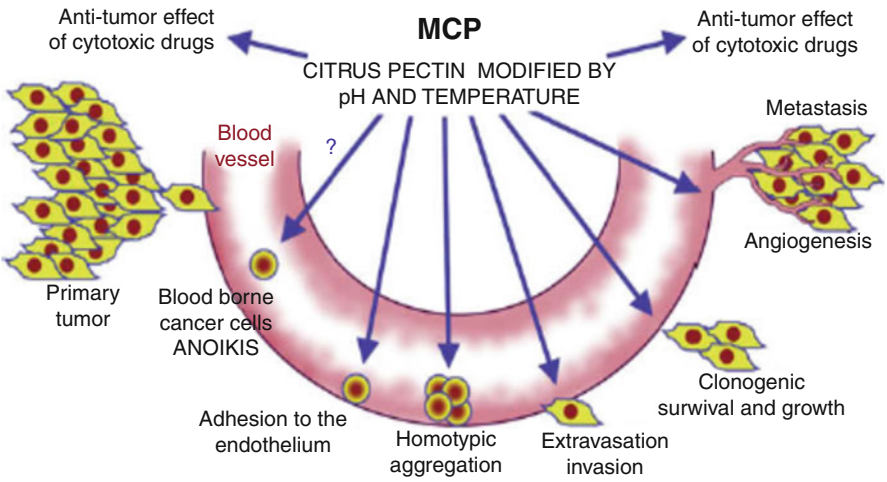

Fig. 13 Schematic representation of critical rate-limiting steps in cancer metastasis, which could be efficiently targeted by MCP. (With permission from Glinsky and Raz (2009). Copyright www.Elsevier.com)

and fractionated citrus pectin powder (MCP_3). The preparation method of PectaSol is not known, for obvious commercial purposes; however, according to the producer, this product belongs to a special class of polysaccharides known as polyuronides with low DM ($\leq$10) and $\overline{Mw}$ (~10–20 kDa). Therefore, MCP_1 is likely produced on the principle of difference in resistance of pectin glycosyl residue linkages to acid agents (Ara*f*-Ara*f* < Ara*f*-Gal*p* $\leq$ Gal*p*-Ara*f* < Gal*p*-Gal*p* < Rha*p*-Gal*p*A $\leq$ Gal*p*A-Rha*p* << Gal*p*A-Gal*p*A) and sounds like a relatively homogenous HG product, as judged from similar data in the literature (Yapo et al. 2007b; Yapo 2009). MCP_2 is obtained by hot alkaline treatment (β-elimination) of commercial citrus pectin followed by mild acid hydrolysis (Platt and Raz 1992; Nangia-Makker et al. 2002) and is classified as a nondigestible galactose-rich polysaccharide fiber of shorter size, readily soluble in water, and better absorbed and utilized by the human body than ordinary high molecular weight citrus HMP. MCP_3 is obtained by treating commercial citrus pectin under neutral pH and high-temperature conditions (Jackson et al. 2007), which causes β-elimination of the pectin HG regions, and is a mixed product of oligogalacturonans and galactose- and/or arabinose-rich-RG-I oligomers of various types. The discrepancy in the three methods adds to the complexity of the problem to solve, thereby reducing chances to unravel, in the short run, the molecular origin of the antitumor properties of MCP.

Furthermore, enzymatically purified okra pod RG-I, carrying short galactan side chains, also exhibited antiproliferative and proapoptotic activities (Vayssade et al. 2010), and hot water-extracted galactan-rich RG-I fractions from various plant materials such as yellow passion fruit rind, banana peel, and tobacco leaf showed efficacious antiproliferative activities in vitro

(Yapo 2011a; Silva et al. 2012). Moreover, specific binding of pectin galactans to galectin-3 has been reported (Gunning et al. 2009). All these recent reports strongly suggest that "modified pectins" may principally exert their antitumor activity, hitherto not clearly understood, at least by binding (via not yet identified linkages) to galectin-3 on the surface on malign cells. Elucidation of this extremely important "pharmacological" of pectins may lie in the use of enzymatically and/or chemically tailored model pectin products that are homogenous in size, in composition, and if possible in charge density.

6 Concluding Remarks

Since their first discovery in 1790–1825 and the correct prediction of Sir Henri Braconnot that pectins would have important functions in all plants and many applications in the art of the "confiseur," these naturally occurring polysaccharides continue to fascinate plant and food scientists who carry out numerous studies on them. However, It is a quite difficult task to deal with the impressive structural diversity and functional versatility of pectins, starting from their natural location within plant cell walls, as bioactive agents for growth, defense, protection of the cells, etc., via their technological properties as gelling, emulsifying/emulsion-stabilizing, film-forming, etc., agents in miscellaneous manufactured food and nonfood products to their physiological and pharmacological effects as health-benefit (biosorbent, immunomodulating, prebiotic, anticomplementary, antitumor, antioxidant, antimicrobial, etc.) agents for the human body. Pectins then represent an outstanding group of heterogeneously complex biopolymers with extraordinary functions, some of which remain to be understood in relation to their fine structure. This fully accounts for the particularly remarkable attention that multidisciplinary scientists should continue to pay to them by developing powerful techniques with the aim of unraveling the intriguing and so far puzzling structures of some pectic cobiopolymers (especially RG-I) and complex native pectins *in muro*, a result of which will surely be a great step toward a full understanding of structure-related functions and improvement of their known properties and finding of new area of applications.

Chitosan, Cellulose, and Starch

Véronique Coma, Carmen S. R. Freire, and Armando J. D. Silvestre

Contents

Abstract

This chapter aims at presenting a comprehensive overview of the latest advances in the development of antibacterial materials based on chitosan, cellulose, and starch, which being the most abundant polysaccharides have a high potential to be explored in large variety of applications (e.g., food or biomedical fields).

Owing to its intrinsic antibacterial and film-forming properties, chitosan can be directly used to create antibacterial materials. Thus, the first part of this chapter focuses mainly on the factors affecting its inherent bioactivity and the strategies potentially used to enhance it, in order to broaden chitosan-based materials applicability. Then the strategies developed to impart antibacterial properties to cellulose and starch, mainly through chemical modification or combination with bioactive natural and synthetic components and polymers as

1 Introduction

Microbial contamination in food and medical fields can cause serious problems to human's health and safety.

In food preservation field, despite increased awareness of the importance of high-level hygiene in food supply chain, foodborne illnesses caused by microorganisms including *Salmonella* spp., *Staphylococcus aureus*, *Campylobacter jejuni*, *Listeria monocytogenes*, and *Escherichia coli* are still a large public health problem (De Moura et al. 2012; Coma 2008).

The European Food Safety Authority and the European Centre for Disease Prevention and Control reported, after analyzing information submitted by 27 European Union members, that campylobacteriosis was the most commonly reported zoonosis. The decreasing trend in confirmed salmonellosis and listeriosis cases in humans continued but not sufficiently (95,548 salmonellosis cases in 2011). One of the last reports available from the European Union (2006) showed that *Listeria* was the most severe pathogen on average. In addition, substantial increases have been observed, over the past few decades, in the incidence of diseases caused by pathogens *E. coli* 0157 (VTEC) and *Yersinia enterocolitica*, among others (EFSA 2011). It seems that the growing demand for prepared or minimally processed foods has contributed significantly to the increased number of outbreaks of foodborne illnesses (Lagaron et al. 2012).

In the biomedical field, despite the dramatic change in chemotherapeutic approaches, widespread antibiotic resistance and dissemination of communicable diseases remain as the leading causes of morbidity, mortality, and rising health costs. As specified by Harding and Reynolds (2014), infections arising from bacterial adhesion and colonization on medical device surfaces are a significant healthcare problem. The increasing use of invasive medical procedures for the implantation of devices leads to an increased risk for the development of device-associated infections. Estimates place the occurrence of bacterial-related infections for humans at 65 %, and are associated with the growth of bacterial biofilms on device surfaces (Harding and Reynolds 2014); once a suitable environment for attachment is established, bacterial species are capable of adhering to the surface and proliferating into microcolonies, eventually forming biofilms. Increased dependence on artificial implant replacement technology has contributed as new attachment opportunities to opportunistic, as well as to previously nonpathogenic resident flora. As mentioned by Ahmed (2012) as an example, *Staphylococcus epidermidis*

is primarily a human commensal bacterium of skin and mucosal surfaces with low pathogenic potential. With the introduction of implants, *S. epidermidis* became one of the most significant pathogens in biomaterial-associated infections (Schierholz and Beuth 2001). Moreover, there is a specific problem related to the use of nanofibers in medical applications. Nanofibers have shown to be particularly promising in fibrous scaffolds for tissue engineering, drug release, wound dressings, etc. Unfortunately, due to the high affinity for cellular attachment to such kind of scaffolds, many potential applications of nanofibers are limited by the possibility of bacterial adhesion and resulting infections (Coneski et al. 2014).

In this context, the development of antibacterial materials for food and biomedical applications, among others, can be one attractive solution. In addition, the generation of large amounts of wastes and the use of nonrenewable materials along with an increase in consumer environmental awareness led to the use of more eco-friendly materials. As mentioned by Cheng and Gross (2010), interest in biobased materials appears to be increasing proportionally to increased crude oil prices (Cheng and Gross 2010). Biobased materials available for films and coatings generally fall into the categories of polysaccharides, proteins, and lipids. Biopolymer-based materials may possess inherent antimicrobial activity, but usually, in order to exhibit specific functionality, bioactive compounds must be immobilized or incorporated into the polymer matrix. Among polysaccharides potentially used in active biomaterials, we can find:

- Chitosan, as an intrinsic antimicrobial aminopolysaccharide
- Cellulose, starch, hyaluronan, chondroitin sulfate, alginates, heparin, curdlan, pullulan, gellan as polysaccharides with induced bioactivity

The present chapter focuses on antibacterial polysaccharide-based materials, concerning antibacterial properties for active packaging for food preservation or biomedical applications (such as active medical device surfaces, active nanofibers, and wound dressing among other applications). The specific properties of chitosan and the easy accessibility and high production of cellulose and starch led to a very significant research interest and high scientific productions in terms of publications and industrial developments. As a result, in this chapter, we attempt to categorize the approaches that were commonly described from 2005 to date in the design of **antibacterial chitosan-**, **cellulose-**, and **starch**-based materials.

2 General Considerations on Antimicrobial Materials

2.1 Definitions

In food preservation and biomedical domains, different definitions associated with bioactive materials are found in the literature. To avoid misunderstandings, some terms frequently used in this chapter are defined in Table 1.

Table 1 Definition of some specific active materials adapted from Niu et al. (2014)

Bioactive materials	Materials which may include those that:
	Possess antimicrobial activities
	Exhibit immunoregulatory properties
	Promote tissue regeneration
	Possess cell-instructive and molecular signalling properties (i.e., regulating cell proliferation, migration, differentiation, protein expression, etc.)
	Are designed for biosensing
	Contain recognition sites for cleavage of enzymes involved in cell functions
	Incorporate bioactive molecules with specific properties such as antithrombotic, antihypertensive, antioxidative properties, etc.
Antibacterial materials	Materials capable of reducing the proliferation of bacteria
	Medical applications: antifouling, bactericidal and/or materials exhibiting a bacteriostatic effect
	Food packaging applications: bactericidal and/or materials exhibiting a bacteriostatic effect against bacterial strains encountered in foodstuffs
Antifouling materials	Materials able to decrease or avoid bacterial cells attachment (i.e., decrease the colonization of specific medical devices or food systems)
	Some of the low-adhesive, superhydrophobic and self- cleaning surfaces
Bactericidal materials	Materials that kill the live bacteria or some fraction therein
Materials exhibiting a bacteriostatic effect	Materials that hinder the growth of bacteria but do not imply whether or not bacteria are killed
	Inactivation action on the growth of bacterial strains

A few different approaches for imparting antibacterial functionalities have been attempted including the use of naturally antibacterial materials, the chemical modification of the polymer matrix itself, or the physical entrapment of bioactives.

2.2 Approaches for Imparting Antimicrobial Functionalities

Different classifications can be found for antimicrobial materials potentially used in biomedical or food applications. One of them is based on the antibacterial functional role that could be achieved through migratory or non-migratrory systems (Fig. 1). Briefly, materials can be distinguished, depending on whether the active agent is temporarily trapped within the biopolymer-based material or permanently attached to the chains (Lecomte et al. 2012).

The migratory systems can be used to deliver antibacterial agents to the food or the body target. This release can occur by different modalities such as simple

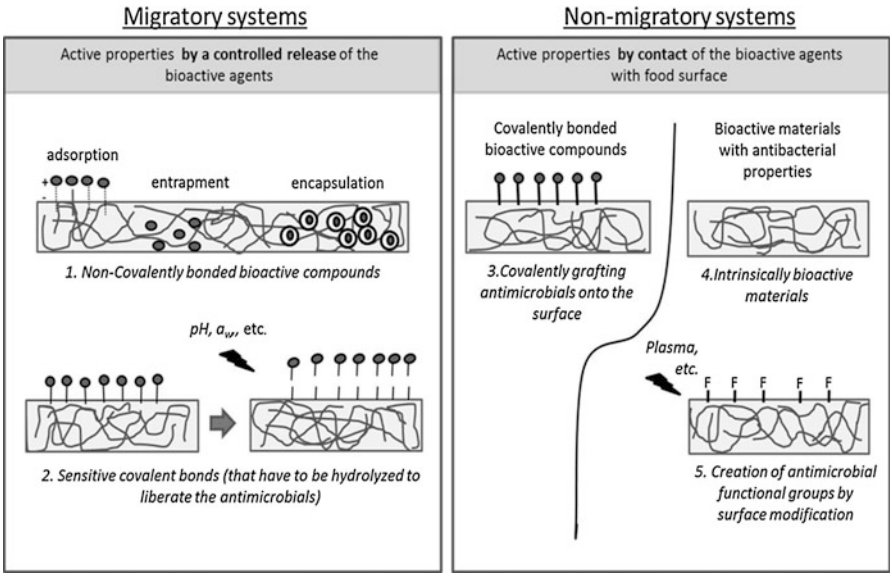

Fig. 1 The different approaches for imparting antimicrobial functionalities leading to migratory or non-migratory materials (Reproduced with permission from Coma and Olabarrieta 2014)

diffusion, degradation of loaded matrices, or hydrolysis of sensitive covalent bonds. In some cases, e.g., pH-sensitive bond, chemical bonds are created to allow an active agent slow-release system. In non-migratory systems the release of the antimicrobial agent is not required and even prohibited.

As another classification, we can propose three categories of antimicrobial materials. These are based on the following processes:

1. Direct utilization of active polymers exhibiting film-forming properties: active polymers created by chemical modification leading to bioactive properties or use of inherently antimicrobial polymers exhibiting film-forming properties
2. Incorporation of antimicrobial agents into the matrix
3. Coating of the matrix with a film-forming solution that acts as a carrier for the antimicrobial agents

An illustration of these categories is presented in Fig. 2.

Matrices with bioactive agents chemically bound to the polymer are included in the first category, and the immobilization of the antimicrobial onto the material can be used for drugs that have not yet obtained authorization for release. The other two categories can generally release the antimicrobials onto the surface where antimicrobial action is predominantly needed.

The potential use of chitosan, cellulose, and starch to develop antibacterial material following different strategies is then discussed below.

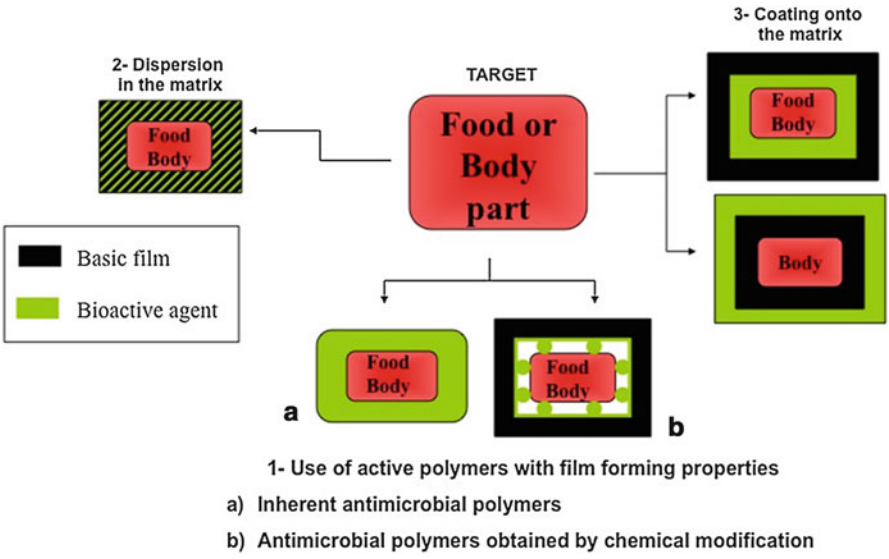

Fig. 2 The three categories of antimicrobial matrices (Adapted and reproduced with permission from Coma and Verestiuc 2012)

3 Polysaccharide-Based Materials with Antibacterial Properties

3.1 Antibacterial Chitosan-Based Materials: Use of an Inherently Active Polysaccharide

In the specific case of chitosan, a point of its antibacterial activity and factors affecting its ability is firstly proposed, due to its very particular properties in terms of bioactivity and to its film-forming ability. Because of the high scientific production regarding antibacterial activity of chitosan-based materials, the discussion was oriented to the strategies potentially used to enhance antibacterial activity in order to create highly active biobased materials.

3.1.1 General Considerations on Chitosan and Chitosan-Based Material Processing

Chitosan is a pseudonatural cationic polysaccharide, which is edible, nontoxic, biodegradable, and commercially available and that has been employed in a variety of applications. This linear copolymer of β-(1–4)-linked 2-acetamido-2-deoxy-β-D-glucopyranose and 2-amino-2-deoxy-β-D-glycopyranose is the *N*-deacetylated form of chitin (Fig. 3). Chitin is widely distributed in nature, such as in crustaceans, currently the main source, insects, fungi, yeasts, and algae. In the case of fungal source, chitin is the characteristic component of the taxonomical groups zygo-,

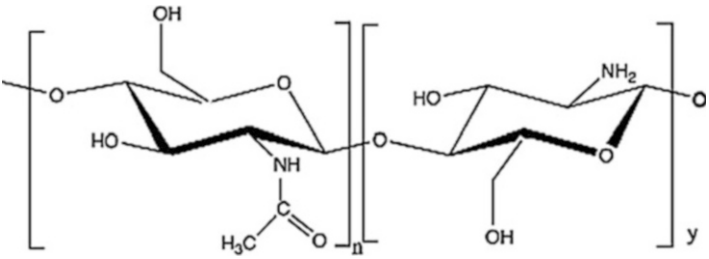

Fig. 3 Repeating unit of partially acetylated chitosan characterized by an average degree of acetylation

asco-, basidio-, and deuteromycetes. Yeasts and filamentous fungi contain glucan complexes with chitin or chitosan in their cell walls and septa (Muzzarelli et al. 2012). According to Shchipunov et al. (2009), as estimated, as much as 100 billion tons of chitin are produced annually in living nature. It constitutes a huge renewal resource of biomass that is still almost unutilized. Therefore, chitin and more precisely its derivative chitosan is believed to have a great potential for applications in many fields, being an extraordinary underexploited biopolymer of significant versatility (Muzzarelli 2010).

Most of the naturally occurring polysaccharides, e.g., cellulose, starch, alginate, dextran, pectin, agar, agarose, and carrageenans, are neutral or anionic in nature, whereas deacetylated chitin and chitosan are examples of cationic polysaccharides (Muzzarelli et al. 2012, Table 2). As already discussed above, since biocide-resistant bacteria and fungi, growing public health awareness of pathogenic micro-organism raised demands for safe, effective, and possibly biobased agents that were less prone to stimulating development of resistance (Kong et al. 2010). In this point of view, due to its broad antibacterial activity spectrum, effectiveness with high killing rate against Gram-positive and Gram-negative bacteria, and nontoxicity, chitosan, a GRAS polymer, is possibly one of the most studied as non-migratory antibacterial biomaterial (Anklam and Battaglia 2001; Kong et al. 2010; Coma and Verestiuc 2012; Coma 2012; Meng et al. 2014).

Chitosan can be used as an inherent bioactive material or as an antibacterial additive in synthetic or natural polymers (see the examples below with cellulose and starch) to prepare antibacterial materials.

Solutions of chitosan are prepared in acidic conditions and processed to the needed conformation (cast for a film, spun for fibers, freeze-dried for sponges) and sometimes immersed in a precipitation alkaline solution before washing and drying steps (Rinaudo 2013). Properties of chitosan materials depend on acid type and preparation procedure (Park et al. 2002; Lupei et al. 2013). With results in terms of basic film properties, acetic acid resulted in the toughest films followed by malic, lactic, and citric acid. Films prepared with citric acid had the highest elongation values (Park et al. 2002). Chitosan films prepared with malic acid showed the lowest oxygen permeability, followed by acetic, lactic, and citric acid. To summarize, the films elaborated with chitosan in lactic acid solution are more hygroscopic,

Table 2 Expected antibacterial properties of chitosan in food preservation or some biomedical applications according to Muzzarelli (2009) and Piozzi and Francolini (2013)

Chitosan in food preservation	
Packaging – coating	**Surfaces**
Decrease the risk of food spoilage and food-borne illnesses by reducing microbial contamination of food products during storage or distribution	Prevention of biofilm formation during food processing
	Biopesticide – Plant elicitor
	Controlling plant-diseases by displaying toxicity and inhibiting fungal growth. High interest for some mycotoxinogen fungal strains
	Eliciting activities of some coatings which lead to a variety of defense responses in host plants in response to microbial infections
Chitosan in biomedical applications (notably regenerative medicine)	
Wound healing	**Implantable medical devices**
Release of glucosamine and *N*-acetylglucosamine oligomers exhibiting antibacterial activities and stimulation of cellular activities	Decrease biofilm formation at the surface of medical devices, such as catheters, orthopedic implants, which is associated with the development of antibiotic-resistant, often life threatening, infections
Intrinsic antibacterial activity and controlled release of exogenous bioactive agents to prevent infection	
Tissue engineering	
Suitable for controlled release of antibiotics or other antibacterial agents	

permeable, and elastic and show a higher transparency. The films made from acetic acid solutions are generally less hygroscopic, show lower water vapor permeability, and are more resistant to traction but less elastic. As a result, chitosan film-forming solutions are more frequently elaborated using acetic acid. Because chitosan films are rigid and brittle in nature, plasticizers (i.e., glycerol, xylitol, and sorbitol) are generally used during solution casting to improve their flexibility and processability. As opposed to the usual casting–evaporation procedure, which requires the evaporation of a large quantity of solvent, plasticized chitosan with hierarchical structure, including multiple length scale structural units, can be prepared by a "melt"-based method. Chitosan was plasticized by thermomechanical mixing in the presence of concentrated lactic acid and glycerol (Meng et al. 2014).

3.1.2 Chitosan's Antibacterial Ability

Inherent Activity

Chitosan applications in advanced materials are mainly justified by their antibacterial activity against pathogenic and spoilage microorganisms. Chitosan has wide spectrum of activity and high killing rate against Gram-positive and Gram-negative bacterial strains.

The degree of deacetylation is one of the parameters, which allow to control some of the physical characteristics of films but also their antibacterial activity (Muzzarelli et al. 2012; Kong et al. 2010). Although the exact mechanism by which chitosan exerts its bioactivity is currently unclear, its polycationic nature is a crucial factor. Several mechanisms have been proposed such as:

- Interaction between positively charged chitosan molecules and negatively charged microbial cell membranes which may cause:
  - The leaching out of intracellular constituents such as low molecular weight materials, nucleic acid, proteins, and so on (Raafat et al. 2008; Li et al. 2010)
  - The decreases of membrane permeability, preventing nutrient transport (Eaton et al. 2008)
- Binding of chitosan to DNA triggers inhibition of mRNA synthesis through penetration of the microbial nuclei by chitosan and interfering with the synthesis of mRNA and proteins.
- Chelation of metals, spore elements, and essential nutrients (Cuero et al. 1991).

Factors Influencing Antibacterial Activity

Antibacterial activity of chitosan and its derivatives relied on numerous intrinsic and extrinsic factors that include pH, temperature, salinity, microorganism species, presence or absence of metal cations, suspending medium, molecular weight (Mw), and degree of deacetylation (DD) (Kong et al. 2010). Because chitosans have been tested under widely varied conditions, it is hard to compare chitosan's antibacterial effect among results obtained by different researchers. However, some general factors influencing antibacterial activity have been identified and would be very useful to elaborate chitosan-based material with high efficiency.

Generally, the cytotoxic effect of chitosan and chitosan derivatives is dependent upon: (1) inherent properties of chitosan, (2) microbial factors, and (3) environmental factors, such as medium pH, temperature, and ionic strength. Only points 1 and 2 are discussed thereafter.

Factors Related to Inherent Properties of Chitosan and Chitosan-Based Matrices

One of the main factors influencing the antibacterial properties of chitosan materials is the deacetylation degree (DD) (Takahashia et al. 2008; Coma and Verestiuc 2012). As already mentioned, it is generally assumed that the cationic nature of chitosan, conveyed by the positively charged NH_3^+ groups of glucosamine, might be a fundamental factor contributing to its interaction with the negatively charged microbial cell surface, ultimately resulting in impairment of vital bacterial activities. Because the positive charge is associated with DD and pH values, a higher DD with more positive charge is especially successful in inhibiting the microbial growth. In other words, antibacterial activity of chitosan enhances with increasing DD.

The molecular weight (Mw) is the other parameter frequently identified as a factor affecting antibacterial properties. No et al. (2002) observed a minimum

inhibitory concentration (MIC) of chitosans ranged from 0.05 % to more than 0.1 % (w/v) depending on the bacteria and Mw of chitosan. They reported that chitosans (Mw > 28 kDa) showed higher antibacterial activities than chitosan oligomers (<22 kDa). However, numerous research works on bactericidal activity of chitosan have generated equivocal results concerning correlation between bactericidal activity and chitosan Mw. Some studies reported that increasing chitosan Mw leads to decreasing chitosan antibacterial activity. As an example, Gerasimenko et al. (2004) examined chitosan with Mw from 5 to 27 kDa and reported that antibacterial activity against *E. coli* increases as Mw decreased. The relationship between Mw and antibacterial is not cut and dry (Jung et al. 2014).

The physical state of chitosan seems to have also a decisive role in its antibacterial activity. As reported by Kong et al. (2010), soluble chitosan is generally more effective in inhibiting bacterial growth, due to the fact that the dissociating form in solution has an extending conformation, which enables a reaction with the counterparts to a sufficient degree. However, it tends to be difficult to know if the improvement of antibacterial activity is only due to an increase of water solubility or to the chemical modification conducted on the polymer structure. For example, reducing the Mw of chitosan markedly heightens solubility but not necessarily antibacterial activity. In the case of chitosan-based material, chitosan can be considered as a solid and generally leads to a lower antibacterial action than soluble chitosan (film-forming solution). Thus, because molecules of solid chitosan tightly contact with each other, the Mw of chitosan is of negligible concern. More generally, different physical states of chitosan (water solutions, beads, films, fibers, and hydrogels), as a crucial factor influencing antibacterial activity, are supposed to have been strongly considered but always being underestimated (Kong et al. 2010).

Antibacterial properties also depend upon the casting temperature of the films. Fernandez-Saiz et al. (2009) found that this capacity significantly decreased for higher temperatures. These authors have demonstrated that just-formed low Mw chitosonium acetate films present significant biocide properties against *S. aureus* and *Salmonella* spp. when cast at 37 °C or 80 °C, whereas this capacity is reduced when films are cast at 120 °C.

To conclude, the storage temperature could also be a key factor. Films should be stored at low temperature under dry conditions. Mayachiew et al. (2010) reported that ambient drying, low-temperature hot air-drying led to films with higher antibacterial activity and higher degree of swelling due to lower intermolecular interaction. If chitosan-based materials were maintained at high relative humidity conditions (i.e., 75 %) or relatively high temperatures (i.e., 37 °C), the samples presented a gradual loss of their antibacterial capacity, compared to lower temperatures and dry conditions (23 °C, 0 % RH) during the storage periods (Fernandez-Saiz et al. 2009). These results could be related to a substantial loss in the release of antibacterial protonated species as a result of cross-linking and/or other molecular entanglement process and/or chemical alterations of a more hydrophobic nature in the biomaterial.

Factors Related to Microorganisms

Chitosan is well known for its broad spectrum of activity. However, its antibacterial action is dependent on the bacterial genus, species, and Gram-stain group. The NH_3^+ groups of chitosan can alter bacterial surface morphology, which either increase membrane permeability in some bacteria or decrease membrane permeability in other bacteria (Tang et al. 2010; Wang et al. 2012). For example, Kumar et al. (2005) reported that chitooligomers caused pore formation and permeabilization of the cell wall of *Bacillus cereus*, whereas blockage of nutrient flow due to aggregation of chitooligomers was responsible for the growth inhibition and lysis of *E. coli*. According to Kong et al. (2010), based on the available evidences, bacteria appear to be generally less sensitive to the antibacterial action of chitosan than fungi. The bacterial effectiveness on Gram-positive or Gram-negative bacteria, due to different cell surface characteristics, is however somewhat controversial. However, as specified by Tang et al. (2010), the MICs reported to range from 100 to 10,000 mg L^{-1} against Gram-negative bacteria and from 100 to 1,250 mg L^{-1} against Gram-positive bacteria.

Finally, the age or the bacterial growth phase of the cell can also influence the antibacterial efficiency of chitosan (Jiang et al. 2013; Lahmer et al. 2014).

The phenomena involved in the antibacterial activity of both films and solutions were quite complex and depended not only on a series of factors but also upon the interactions between them (Jung et al. 2014). As a result, the sometimes conflicting results in literature, along with the differing effects of the various factors, highlight the need for additional research in order to elaborate chitosan-based material with optimum antibacterial ability.

3.1.3 Chitosan-Based Material: Strategies to Enhance the Antibacterial Ability of Chitosan-Based Materials

In the last decade many researchers attempted to modulate or increase this biopolymer activity, which will broaden its applications in active material field. This part of the chapter provides an overview of strategies used to enhance chitosan antibacterial activity, focusing on two specific topics: (i) strategies based on non-covalent grafting or simple combination with other compounds that also exhibit activity against bacteria and (ii) strategies based on permanent chemical grafting/modifications of chitosan.

Via Non-covalent Grafting Techniques or Simple Combination with Bioactives

Chitosan can be used as scaffold for controlled release of antibacterial agent. Chitosan films, porous chitosan, chitosan hydrogels, chitosan microspheres, and chitosan nanofibers were reported for the delivery of bioactives.

Positively charged groups make chitosan very sensitive to the presence of anionic substances in its solutions. This phenomenon can be useful to non-covalently immobilize antibacterial agents onto chitosan-based matrix. Moreover, a simple physical entrapment of antibacterial agent molecules in a chitosan matrix can also be envisaged to enhance antibacterial ability.

As a result, the antibacterial effect of chitosan can be improved by binding active **metal ions** such as Zn(II), Cu(II), Fe(II), Mn(II), or Ag(I) through different mechanisms such as ion exchange, chelation, or formation of ternary complexes. The minimum bactericidal concentration strongly decreased by one or two orders of magnitude for composite materials (metal-complexed chitosan) compared to chitosan or metal ions alone (Guibal et al. 2014). Hybrid materials with improved antibacterial ability can then be produced. Silver is the most widely used in biomedical fields due to its strong antibacterial activity at low concentrations. Ag^{+}-chitosan complex showed a wide antibacterial spectrum, with minimum inhibition concentrations 20 times lower than those of the initial chitosan. Material based on chitosan containing silver ions was found to decrease the amount of bacteria present by 98 % (No et al. 2002). Another example is the loading of silver nanoparticles in a chitosan matrix as recently studied by Ravindra et al. (2010). Vimala et al. (2010) fabricated a porous chitosan film impregnated with silver nanoparticles with potential applications in wound dressing. The antibacterial activity results revealed that these porous chitosan–silver nanocomposite films exhibited superior inhibition against bacterial strains such as *E. coli*, *Bacillus*, and *Klebsiella pneumoniae*.

Chitosan material may be also enriched by active molecules such as **protein**, **peptides**, or **antibiotics**. Enzymes or active peptides can be entrapped into the polysaccharide network and maintained by hydrogen bonds and/or electrostatic interactions. As mentioned by Macquarrie and Bacheva (2008), a simple process can be used to perform antibacterial protein– or peptide–chitosan interaction. The dissolution of chitosan in dilute acid and addition of an antibacterial protein-based solution before film formation can be sufficient. For pH-sensitive water-soluble antibacterials, this process could also be carried out at a pH closer to neutral by preparing chitosan acetate first of all from dilute acetic acid solutions of chitosan and then redissolving the salt in water. Arancibia et al. (2014) studied different blend coatings prepared by solubilizing chitosan in lactic acid and blending it with several shrimp active wastes including proteins. The incorporation of an astaxanthin-rich protein concentrate had increased the antibacterial capacity of the blend solution. Tin et al. (2009) combined ten **antibiotics** with different degrees of deacetylated chitosans and chitosan oligosaccharides. All the chitosans show synergistic activity with sulfamethoxazole, a sulfonamide antibacterial agent, against *Pseudomonas aeruginosa*. Another example is given by the study of Wu et al. (2014a). They prepared gentamicin sulfate-loaded carboxymethyl-chitosan hydrogel cross-linked by genipin and achieved a very high inhibition of *S. aureus* growth and biofilm formation. At the same time, Ordikhania et al. (2014) showed that the physical encapsulation of vancomycin in a chitosan hydrogel network allows the antibiotic controlled release. Antibacterial tests against *S. aureus* demonstrated that the infection risk of titanium foils used as orthopedic implant models was significantly reduced.

Antibacterial chitosan films and coatings have also been created by combination with a number of other active compounds, such as **essential oils**. The potential applications are generally for interactive food packaging. Due to the very large

amount of papers regarding this specific field, only some examples are given below. Azevedo et al. (2014) created efficient antibacterial edible coating using chitosan combined with *Lippia gracilis* extracts, which consists mainly in thymol and carvacrol. Sun et al. (2014) showed that chitosan coatings incorporated with certain essential oils (carvacrol, cinnamaldehyde, and *trans*-cinnamaldehyde) may be an effective alternative for fresh blueberry preservation. It has been observed that carvacrol at $\geq$0.1 % or *trans*-cinnamaldehyde at $\geq$0.2 % incorporated in chitosan coatings improved the inhibition of the *E. coli* growth. Iturriaga et al. (2014) prepared bioactive citrus extract–chitosan films through solvent casting–evaporation method, and the antilisterial activity of the material was clearly improved by the enrichment in essential oil.

Via Permanent Chemical Modifications of Chitosan

Because chitosan exhibits antibacterial functionalities based on the existence of amino groups, bioactive properties are related to a high degree of deacetylation. To potentially enhance bioactivity, efficient deacetylation methods have been proposed. In addition, chitosan being a multifunctional polymer containing both hydroxyl and amino groups, covalent or non-covalent graftings have been widely investigated to improve antibacterial properties.

Enhancement of the Deacetylation Degree

Conventional deacetylation of chitosan has been performed, by hydrolyzing acetamido groups by using highly concentrated aqueous alkaline solutions, such as caustic soda (Focher et al. 1990). Because the traditional method can cause degradation of chitosan backbones resulting in a lower molecular weight, Ishii et al. (2014) proposed a very interesting new method using 1-butyl-3-methylimidazolium acetate (BMIMOAc) as the reaction medium and catalyst. An imidazolium IL containing the acetate anion was used as a basic catalyst promoting the hydrolysis of remnant acetamido groups in chitosan. An enhancement from 77 % close to 87 % was attained by simple hydrothermal treatment (100 °C for 2 h), larger than the conventional method, which enhanced the DD to 79 %. The control of the amount of water added contributed to the improved homogeneity of the reaction, which is another key point for developing highly active deacetylated chitosans.

N and *O* Covalent Grafting

According to Kong et al. (2010), irrespective of their form or quantity, antibacterial agents typically require water for activity. The creation of water-soluble chitosan and its derivatives has been a central goal of investigations of antibacterial activity, which have included saccharization, alkylation, acylation, and quaternization. Furthermore, the grafting of antibacterials within the chitosan structure can also be a strategy to globally enhance bioactive properties. Various antibacterial substances, such as antibiotics, antiseptics, and enzymes, have been grafted on the surfaces of chitosan-based matrices (Yuan et al. 2013). The different strategies associated to a few examples are given below.

N-grafting: The easiest way to chemically modify chitosan is to produce *N*-chitosan derivatives.

For a polymeric quaternary ammonium biocide, the hydrophilic–lipophilic balance influences antibacterial properties by affecting the mode of interaction with the cytoplasmic membrane. Grafting **alkyl chains** on chitosan generally leads to higher antibacterial activity, and quaternization is one of the most studied chitosan modifications. Rationalization of the parabolic relationship between antibacterial properties and alkyl chain lengths has been debated. It has been attributed to (a) dual binding sites on the surface for which the relative binding affinities at each site differ for long and short alkyl substituents or (b) different aggregational behaviors for long and short hydrophobes (Kenawy et al. 2007). *N*-Alkyl chitosan derivatives were prepared by introducing alkyl groups into the amine groups of chitosan via a Schiff base intermediate. For quaternized derivatives, one direct effect is an enhancement of water solubility over a broad pH range (Mourya and Inamdar 2009). Quaternized chitosans generally lead to materials with stronger antibacterial activity, broader spectrum, and higher killing rates compared to unmodified chitosan materials (Belalia et al. 2008; Xu et al. 2011; Vallapa et al. 2011; Wiarachai et al. 2012).

Ma et al. (2008) synthesized an *N*-alkylated chitosan derivative by Michael addition reaction of chitosan and hydroxyethylacrylate in moderate conditions. Even if the chitosan derivatives exhibited an excellent solubility in distilled water, its antibacterial activity against *E. coli* was decreased compared with that of chitosan. But other bacterial strains have to be tested.

Peng et al. (2010) demonstrated that water-soluble quaternary ammonium salts, which are produced by the reaction of chitosan with glycidyl trimethylammonium chloride, provide chitosan derivatives with enhanced antibacterial ability. Hydroxypropyltrimethyl ammonium chloride chitosans with 18 % or 44 % substitution were significantly more effective than those with 0 % or 6 % substitution against *S. aureus*, methicillin-resistant *S. aureus*, and *Staphylococcus epidermidis*.

Water solubility of chitosans at neutral or basic pH was largely improved by specific attachment of **carbohydrates** to the 2-amino functions achieved by Maillard's reaction or further reductive alkylation of Schiff bases (Ying et al. 2011). These authors prepared chitosan derivatives with different degrees of substitution of various saccharides. The most potentially water-soluble chitosan was the Schiff base-typed chitosan–fructose derivative. No specific information about antibacterial activity was given but this derivative exhibited higher antioxidant activity. Unfortunately, even if the Maillard's reaction is promising and easy for commercial manufacturing of water-soluble chitosans, we could expect a decrease in terms of antibacterial activity due to the resulting non- or less-protonated chitosan derivative. However, Chung et al. (2011) showed high antibacterial activity of water-soluble chitosan derivatives prepared by Maillard's reactions against various Gram-positive and Gram-negative bacterial strains.

Another approach could be the functionalization of chitosan with **amino/peptide acid** moieties, containing potentially bioactive free amino groups. Many bioactive peptides are featured by their unique amino acid compositions

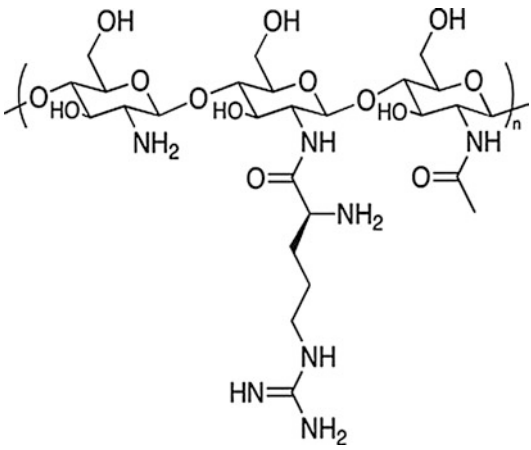

Fig. 4 Schematic representation of the chitosan-arginine derivative according to Lahmer et al. (2012)

such as arginine/lysine-rich biomolecules. Water-soluble arginine-functionalized chitosans (Fig. 4), obtained by the addition of a single arginine residue, via the formation of a stable peptide bond of the arginine carboxylic acid with the amine on the glucosamine unit, were studied by Tang et al. (2010) and Lahmer et al. (2012). The resulting cationic arginine-functionalized chitosans were soluble and polycationic at neutral pH, due to the higher p*K*a (12.48) of the guanidinium side chain relative to that of the amine of the chitosan. They strongly inhibited *P. fluorescens* and *E. coli* growth.

Another example included materials made from other basic amino acids, such as histidine-grafted chitosan. The imidazole ring present in the side chain of histidine has a pKa of approximately 6.0. At pH below 6, the imidazole ring is mostly protonated and carries two -NH bonds, with a positive charge. Even if no information was found about the antibacterial properties of histidine-grafted chitosan, histidine-containing peptides have demonstrated pH-dependent antibacterial activity (Tu et al. 2009), leading to a potential increase regarding the antibacterial ability. The functionalization of chitosan glucosamine moieties with histidine amino acid was found to enhance the buffering capacity over the parent chitosan polymer (Casettari et al. 2012).

Following the same idea, instead of amino acids, covalent fixation of active peptides, poly(peptides), or enzymes could be used to create new active chitosan-based matrices. Indeed, highly antibacterial active peptides can be potentially grafted onto the chitosan backbone; arginine- and tryptophan-rich peptides are very promising short peptides from this point of view. Tryptophan has a distinct preference for the interfacial region of lipid bilayers, while arginine residues endow the peptides with cationic charges and hydrogen-bonding properties necessary for interaction with the abundant anionic components of bacterial membranes (Chan et al. 2006). Poly(peptide)-grafted chitosan copolymer showed, in addition to being good candidates for developing a biomaterial with a better solubility in neutral conditions, a real potential to develop highly antibacterial biomaterials.

Poly(L-arginine)-grafted chitosan and poly(L-lysine)-grafted chitosan are generally good candidates notably in the biomedical applications (Zhou et al. 2013). Another approach is to covalently graft the enzyme on the biopolymer. Natural defense substances secreted by living organisms, such as hydrolytic enzymes, have recently emerged as a particularly attractive class of biocidal agents (Krajewska 2004). However, as mentioned by Yuan et al. (2013), only a few studies have been devoted to the immobilization of antibacterial enzymes on chitosan for improved antibacterial activity. Hen egg-white lysozyme, or 1,4-β-*N*-acetylmuramidase, a natural defensive and bacteriolytic enzyme, displays antibacterial activity especially for Gram-positive bacteria, such as *S. aureus* and *S. epidermidis*. It can be conjugated to chitosan, via the 1,1′-carbonyldiimidazole (CDI) as a bifunctional linker, to enhance biocidal functionality (Yuan et al. 2013; Duan et al. 2007).

Covalent immobilization of **phenolic** compounds on chitosan could also be used to create new antibacterial materials. Because these compounds can possess antibacterial properties in addition to antioxidant activities, the grafting can result in derivatives with unique antibacterial ability (Liu et al. 2014). In this specific approach, the use of enzyme-catalyzed reaction is currently one of the most popular, naturally connected to green chemistry development. There are few enzymes known that might react with chitosan to build macromolecular structure and confer material function. Examples are the grafting of phenolic compounds using laccase or tyrosinase. Bozic et al. (2012) functionalized chitosan with quercetin or tannic acid using the laccase from *Trametes versicolor*, leading to a biobased product with synergistic antioxidant and antibacterial properties. Tyrosinase enzymes can also effectively graft phenolic compounds onto chitosan through their conversion into reactive *o*-quinone intermediates, which subsequently undergo nonenzymatic reactions with the nucleophilic amino groups of chitosan (Govar et al. 2003; Puskas et al. 2009). By using tyrosinase, Vartiainen et al. (2008) grafted octyl gallate and dodecyl gallate onto chitosan, resulting in coatings with strong antibacterial activity against *S. aureus* and *L. innocua*.

N,O-derivatization: To increase the water solubility and cationic charges at pH 7 and then maintaining or improving antibacterial properties, cationic moieties can be introduced onto both C_6–OH and C_2–NH_2 groups in the chitosan backbone. Even if the aim of the study was not to improve antibacterial activity but to synthesize a flocculant water-soluble cationic chitosan derivative, Jiang et al. (2011) prepared glycidyl methacrylate (GMA)-modified chitosan bearing double vinyl groups, through ring-opening reaction of GMA with the C_6–OH of chitosan (chitosan–GMA). Then, the flocculant was synthesized by means of radical copolymerization between chitosan–GMA and a cationic vinyl monomer. Strong antibacterial activity of this derivative can be expected, due to the presence of numerous cationic charges, but unfortunately they were not studied here.

In order to increase the number of free amino groups on chitosan chains, Xie et al. (2007) prepared an ethylamine hydroxyethyl chitosan (Fig. 5). A good water solubility of this derivative was observed in a relatively wide range of molecular weights, and antibacterial activity results ($M_n = 1.9 \times 10^5$) against *E. coli*, explored

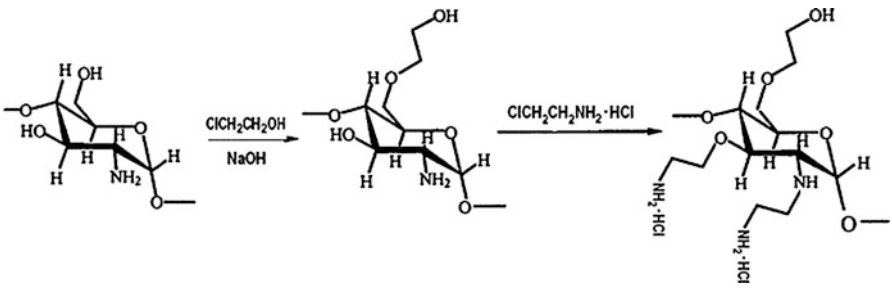

Fig. 5 Ethylamine hydroxyethyl chitosan synthesis according to Xie et al. (2007)

by using an optical density method, showed good inhibition effects but without a clear comparison with the unmodified chitosan.

O-Derivatization: Chemoselective substitution provides a way of developing novel chitosan derivative-based materials with really enhanced bioactive activity. *O*-Selectivity is still a challenge on chitosan because of the difference in reactivity between amino and hydroxyl groups of chitosan. An approach based on the selective protection of the amino group followed by a deprotection step can be useful. Interestingly, Ifuke et al. (2011) proposed a highly chemoselective *N*-phthaloylation of chitosan by performing a reaction in aqueous acetic acid media. The degree of substitution values of phthaloyl groups was approximately 1. These authors mentioned that phthaloyl group is most useful for amino group protection from the point of easy deprotection and chemoselectivity in mild conditions. With recent interest in green chemistry, the use of water as solvent for protection process on chitosan could be a key point in the future. *N*-Phthaloyl chitosan could act as a precursor to allow further modifications of hydroxyl groups at C_3 and C_6 positions. That could be a solution to prepare new antibacterial chitosan derivatives with free amino groups.

Another approach to proceed to the selective *O*-modification of chitosan is to conduct derivatization in the presence of H_2SO_4 as a catalyst. Even if the protecting effect of H_2SO_4 on the amino group was not yet clear, it seems that it can be related to the salt formation of the primary amino group. A water-soluble chitosan derivative, *O*-fumaryl-chitosan (Fig. 6), was prepared by Feng and Xia (2011), using the selective partial acylation of chitosan and fumaric acid in the presence of H_2SO_4. Fumaric acid is a food-grade acidulant with strong bactericidal activity. The prepared derivatives had good solubility over a wide pH range, and the antibacterial activity, investigated against *E. coli* and *S. aureus*, was much stronger than that of chitosan. At pH 7.0, chitosan was not antibacterially active since it was not soluble and therefore the amino groups were not positively charged. Interestingly, the *O*-fumaryl chitosan was completely soluble at pH 7.0 and was very effective in decreasing the viable cell population of both strains. Bioactivity increased with increasing DS and the *O*-fumaryl chitosan with a DS of 0.48 appeared as the best one to be used as a food preservative. Unfortunately, the authors did not specify if

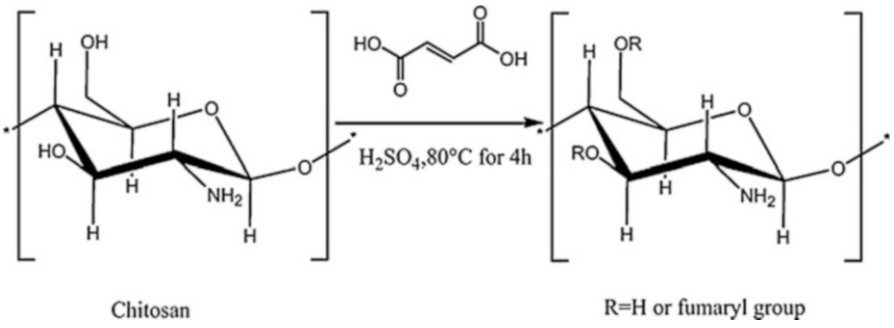

Fig. 6 *O*-fumaryl chitosan according to Feng and Xia (2011)

the chitosan derivative has maintained its polymerization degree and, in other words, its film-forming properties to be used directly as a bioactive material.

3.2 Antibacterial Cellulose- and Starch-Based Materials

3.2.1 Cellulose

Cellulose, the main component of plant cell walls, is by far the most abundant natural polymer and has been explored for a long time in the paper and textile industries. The production of a wide range of cellulose derivatives, as well as the emerging of nanocellulose forms (as nanofibrillated cellulose (NFC), obtained by mechanical disintegration of plant fibers, and bacterial cellulose (BC) produced by several nonpathogenic bacteria), opened the chance of using this biopolymer in other technological fields, including packaging and coatings, films, nanocomposites, and biomedical materials and devices, among many others.

In most of these areas and singularly in food packaging, textiles, and biomedical products, the control and/or prevention of contaminations by microorganisms constitutes a key issue because of their straight relation with human's health and life quality. Therefore, antibacterial materials and in particular antibacterial cellulose-based materials have attracted a great deal of attention in the latter decades as a sustainable alternative for the traditional materials used in many fields. Antibacterial cellulose-based materials are obtained primarily by the simple combination of cellulose (or cellulose derivatives) with distinct biocides (including metal and metal oxide nanoparticles and salts, polymers, and organic molecules) or by chemical grafting/modification with antibacterial moieties or groups.

Antibacterial Cellulose/Metal (Metal Oxide) Nanoparticle Composites

In the last decade, the combination of different forms of cellulose, like plant fibers (Csóka et al. 2012; Raghavendra et al. 2013; Simonc et al. 2008; Teli and Sheikh. 2012; Wang et al. 2011, 2013b; Zhu et al. 2009), cotton fabrics (Kim et al. 2010; Park et al. 2012), filter paper (Imani et al. 2011; Tang et al. 2009; Tankhiwale and Bajpai 2009), microcrystalline cellulose (Dong et al. 2014; Huang et al. 2013;

Jankauskaitė et al. 2014; Li et al. 2011, 2012a), bacterial cellulose (Barud et al. 2011; Dobre and Stoica-Guzun 2013; Jung et al. 2009; Liu et al. 2012a; Maneerung et al. 2008; Maria et al. 2010; Sureshkumar et al. 2010; Wu et al. 2014b; Yang et al. 2012a, b, 2013; Zhang et al. 2013), nanofibrillated cellulose (Díez et al. 2011; Martins et al. 2012; Xiong et al. 2013), as well as cellulose derivatives (e.g., cellulose acetate (Hyuk Jang et al. 2014; Perera et al. 2014; Scheeren et al. 2011; Son et al. 2006), hydroxypropyl cellulose (Angelova et al. 2012), and cellulose acetate phthalate (Necula et al. 2010)), with silver nanoparticles (Ag NPs), following diverse methods, is definitely the most extensively studied strategy for the design of antibacterial cellulose-based materials because of the recognized strong activity of Ag NPs.

For example, Wang et al. (2013b) reported the preparation of cellulose fiber/TiO_2 nanobelt-Ag NP hierarchically structured paper with photocatalytic and antibacterial properties. The characterization results showed that the Ag/TiO_2 nanobelt cellulose composite paper holds a typical hierarchical structure; specifically the TiO_2 nanobelt-based nanomaterials adsorb on the cellulose fiber surface forming an organic/inorganic hybrid paper, whereas Ag NPs are assembled on TiO_2 nanobelt surface creating metal oxide composite nanobelts. The photocatalytic activity and cycle stability of the hybrid paper in degrading methyl orange solution were enhanced by increasing the fraction of TiO_2 nanobelts. The papers with 40 wt% of TiO_2 nanobelt exhibit high photocatalytic activity even after three photocatalysis cycles. Paper with Ag-loaded TiO_2 nanobelts displayed also good antibacterial effect against *E. coli* due to the release of silver ion from the paper. In a distinct line, Tankhiwale and Bajpai (Tankhiwale and Bajpai 2009) described a cerium ammonium nitrate-initiated graft copolymerization of acrylamide onto cellulose filter paper followed by entrapment of Ag NPs (12–42 nm) by in situ reduction of Ag^+ ions with sodium citrate. It was suggested that the cross-linked polyacrylamide network formed onto the cellulose fibers stabilizes the Ag NPs avoiding their agglomeration, as observed when using plain paper filter. This material demonstrated fair biocidal activity against *E. coli* and it was proposed as a potential candidate for use as antibacterial food packaging material. In a different work, antibacterial active metal–cellulose hybrids were produced by covalent assembly of Ag or Pd NPs on cellulose fabric via impregnation of thiol-modified cellulose in colloidal Ag or Pd nanoparticle solutions (Park et al. 2012). The robust linkage between the NPs and the cellulose fabric, as confirmed by X-ray photoelectron spectroscopy, leads to the suppression of the release of metal NPs from the fabric. Therefore, these hybrids may avoid cell damage caused by diffusion and fixation of metal NPs into the cells but also act as a bioactive textile.

In another study, a simple microwave-assisted approach to produce microcrystalline cellulose/Ag NP composites by reducing silver nitrate in ethylene glycol was developed (Li et al. 2011). Ethylene glycol acts as the solvent, reduction agent, and microwave observer in the system. Thermogravimetric analysis showed that the temperature and heating time in the preparation stage had minor effect on the thermal stability of the ensuing nanocomposite. In addition, these materials exhibited strong antibacterial activity against *E. coli* and *S. aureus*. A comparable

methodology was also used to prepare cellulose/AgCl nanocomposites (Li et al. 2012a); however, in this case the formation of the nanocomposites was based on the simultaneous formation of AgCl nanoparticles and cellulose precipitation. More recently, antibacterial cellulose/Ag/AgCl hybrids against *E. coli* and *S. aureus* were also fabricated by means of an environmentally friendly and rapid methodology using a cellulose solution in NaOH/urea, $AgNO_3$, and $AlCl_3$ with ultrasound agitation (Dong et al. 2014). In a distinct manner, new antibacterial nanocomposite films against *E. coli* and *S. aureus* were also prepared by employing amino acids (phenylalanine or tryptophan) functionalized TEMPO-oxidized microcrystalline cellulose with Ag NPs prepared by in situ reduction via homogeneous (in an ionic liquid solution) and heterogeneous (in a aqueous dispersion) methods (Huang et al. 2013).

Bacterial cellulose has received particular attention on the design of novel hybrid materials due to its tridimensional porous structures that allow the entrapment of several molecules and nanoentities, such as Ag NPs. For instance, Sureshskumar et al. (2010) developed innovative magnetic antibacterial nanocomposites based on BC and Ag NPs (Fig. 7). Precisely, the nanofibrous network of BC was homogenized with a ferric and ferrous mixture, and magnetite nanoparticles were incorporated into BC structure by adjusting the alkaline pH. The magnetic BC membrane was then coated with a polydopamine layer, and finally Ag NPs were incorporated by soaking with a silver nitrate solution that reduced spontaneously. The obtained BC–Ag nanocomposite membranes own superparamagnetic properties and antibacterial action against both *E. coli* and *B. subtilis* bacteria and were found to be effective on the sterilization of fermentation culture mediua. More recently, Yang et al. (2012a) described a hydrothermal synthesis of a BC–Ag NP composite using BC as both reducing and stabilizing agent. Under optimum conditions, small-size Ag NPs (17.1 + −5 nm) were formed on the BC

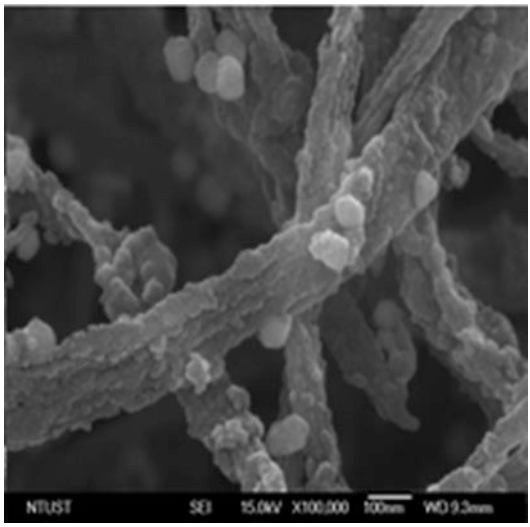

Fig. 7 Scanning electron microscopy (SEM) image of magnetic antibacterial nanocomposites based on BC and Ag NPs (Adapted and reproduced with permission from Sureshkumar et al. 2010)

matrix, with an Ag content of 1.78 % (%w/w) and an MIC (*S. aureus*) value of 1.30×10^{-4} mug/CFU. In another study, *Gluconacetobacter xylinus* bacteria were utilized as versatile factories that produce bacterial cellulose and induced the formation of Ag/AgCl nanoparticles, yielding BC/Ag–AgCl nanocomposites with Ag contents of 0.05 % (Liu et al. 2012a). The obtained nanocomposites showed required activity against *S. aureus* and *E. coli* demonstrating enormous potentialities as antibacterial wound dressing materials.

Nanofibrillated cellulose has also been explored for the preparation of cellulose/Ag nanocomposites materials. For instance, the functionalization of nanofibrillated cellulose using silver nanoclusters as a way to prepare novel functional nanocellulose/nanocluster composites was recently reported by Diez et al. (2011). This functionalization was mediated by poly(methacrylic acid) that simultaneously protected the silver nanoclusters and allowed hydrogen bonding with cellulose, as tentatively suggested by the authors. The ensuing composites retained the attractive properties of silver nanoclusters, namely, fluorescence, and antibacterial activity against *E. coli*. Xiong et al. (2013) developed novel catalytic and antibacterial (against *S. aureus*) Fe_3O_4/Ag@NFC nanocomposites which enable tunability from highly porous aerogels to stiff films. In a quite different strain, antibacterial composites of nanofibrillated cellulose and Ag NPs were prepared by means of electrostatic assembly, using distinct electrolytes as macromolecular linkers, of Ag NPs onto NFC (Martins et al. 2012). These NFC/Ag nanocomposites were further used as fillers in starch-based paper sheet coating formulations for the development of antibacterial paper products against *S. aureus* and *K. pneumoniae*.

Cellulose derivatives, e.g., cellulose acetate (Hyuk Jang et al. 2014; Perera et al. 2014; Scheeren et al. 2011; Son et al. 2006), hydroxypropyl cellulose (Angelova et al. 2012), and cellulose acetate phthalate (Necula et al. 2010), due to their film-forming ability and other specific properties have been also used for the design of innovative antibacterial films by combination with Ag NPs. For instance, metal (Ag, Au, and Pt) NPs containing membrane cellulose films were obtained by combining NPs of monomodal size distributions in the ionic liquid 1-*n*-butyl-3-methylimidazolium bis(trifluoromethane sulfonyl)imide with a syrup of cellulose acetate in acetone (Scheeren et al. 2011). The addition of the ionic liquid to the membrane increased its elasticity and toughness. High antibacterial activity against *E. coli* and *S. aureus* was perceived in membranes with metal NP concentrations as low as 0.2 mg/g of cellulose acetate.

In addition to the well-documented Ag NPs, other metal (e.g., Cu NPs; Grace et al. 2009; Jia et al. 2012; Mary et al. 2009; Oporto et al. 2013; Pinto et al. 2013) and metal oxide (e.g., ZnO NPs; Chaurasia et al. 2010; Martins et al. 2013; Wang et al. 2014) NPs have also been suggested as antibacterial agents to fabricate bioactive cellulose-based materials.

For instance, Pinto et al. described novel nanocomposites containing copper NPs and nanowires in both plant and bacterial cellulose matrices prepared by in situ and ex situ approaches (Pinto et al. 2013) (Fig. 8). The results showed that the chemical and morphological nature of the copper nanostructures and of the cellulose substrates have a great influence on the antibacterial activity of the nanocomposites

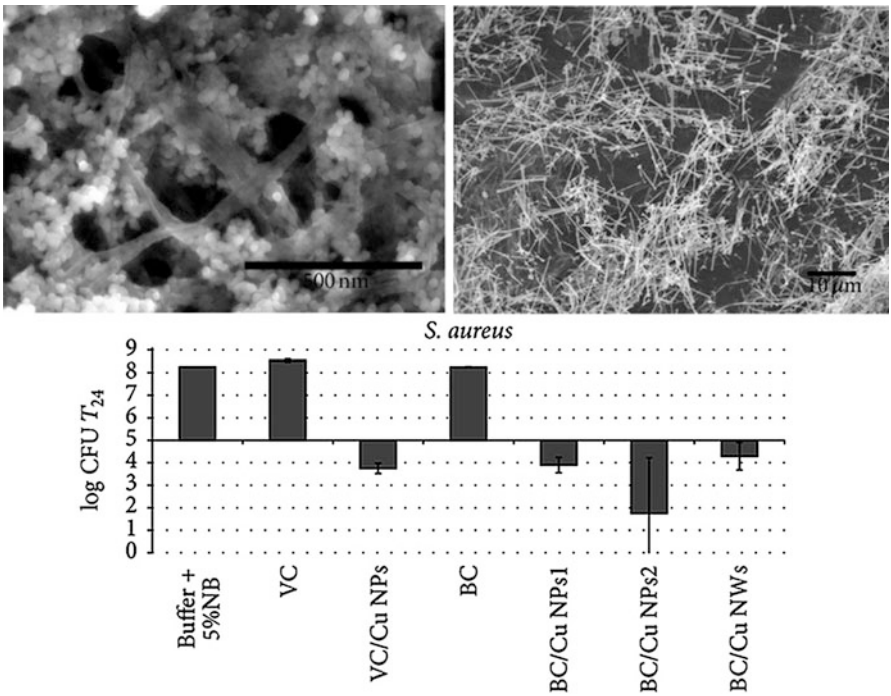

Fig. 8 SEM images of BC-Cu NPs and BC-Cu nanowires and antibacterial activity of cellulose/Cu nanocomposites with variable Cu content against *S. aureus* (Adapted and reproduced with permission from Pinto et al. 2013)

against *S. aureus* and *K. pneumoniae*, with plant fibers and Cu NPs being the most effective substrate and nanofiller, respectively. Zong et al. reported a simple method to prepare cellulose-based nanocomposites with antibacterial properties by introducing Cu NPs (10–20 nm) on carboxymethyl cellulose using sodium borohydride as the copper-reducing agent (Oporto et al. 2013). In a different study, regenerated cellulose films coated with Cu NPs were fabricated from cellulose–cuprammonium solution through coagulation in aqueous NaOH followed by reduction with sodium borohydride (Jia et al. 2012). Cu NPs were found to be definitely embedded on the surface of the cellulose films that showed effective antibacterial activity against *S. aureus* and *E. coli*. Indeed, the reduction of viable bacteria could be observed within 0.5 h of exposure, and all bacteria were killed within 1 h.

Antibacterial composites of NFC and ZnO NPs have been prepared by electrostatic assembly in aqueous medium and using polyelectrolytes as macrolinkers (Martins et al. 2013). These ZnO/NFC systems were further tested as fillers in starch coating formulations for paper sheets. Antibacterial paper sheets (against Gram-positive and Gram-negative bacteria and at both light exposure and dark conditions) with low ZnO content (<0.03 %) and slight enhancements in air

permeability and mechanical performance were obtained. The results obtained seem to suggest that the mechanism for the ZnO antibacterial activity is not mediated merely by the photoactivity of this semiconductor but likewise by the presence of oxidized species formed at the NP surface. Recently, Wang et al. (2014) reported the development of monolithic, flexible, and porous ZnO biocomposite foams (with 70 % ZnO load and a BET (Brunauer–Emmett–Teller) surface area of 92 $m^2\ g^{-1}$) with a hierarchical architecture assembled by controlled hydrolysis and solvothermal crystallization using a BC aerogel as a pattern in ethanol. This ZnO/BC nanofoam revealed outstanding antibacterial activity toward *E. coli* under both daylight and UV light that could be a result of the efficient integration of the porous structures and small ZnO nanocrystals and which give them prospective as bioactive wound healing dressings and water sterilization materials.

Finally, the use of metal salts (e.g., AgCl (Kim et al. 2009), $AgNO_3$ (Ng and Jumaat 2014), and silver sulfadiazine (Luan et al. 2012)) as antibacterial agents, particularly explored in the past, was only marginally reported in the last decade mainly due to the emerging of the nanotechnology domain associated with this field, as described in the latter paragraphs. Though gallium has emerged as a new therapeutic agent, in a quite recent study (Valappil et al. 2013), a novel antibacterial gallium exchanged carboxymethyl cellulose was developed and tested for the vulnerability on *P. aeruginosa*. The results indicate that an increase in average molecular weight (from 90,250 to 700 kDa of Ga–carboxymethyl cellulose) triggered a decrease in antibacterial activity. The sample with MW 250 kDa and DS 0.9 showed the most promising activity against planktonic *P. aeruginosa* (0.85 log (10) CFU reduction compared to sodium-carboxymethyl cellulose after 24 h).

Antibacterial Cellulose-Based Materials with Bioactive Polymers and Organic Molecules

The development of antibacterial cellulose-based materials through the combination with bioactive polymers and organic molecules has also been extensively investigated in the latter years, with particular emphasis for the use of biopolymers as chitosan, proteins, and peptides.

Chitosan, the deacetylation product of chitin, is well documented by its film-forming ability and antibacterial properties and due to its polysaccharide-based structure has been extensively explored for the development of bioactive cellulose-based materials (Abou-Zeid et al. 2011; Bu et al. 2012; Fras et al. 2012; Liu et al. 2012c, 2013; Ren et al. 2012; Zemljic et al. 2012) for several applications.

For example, water-soluble *N*-(2-hydroxy)propyl-3-trimethylammonium chitosan chloride, prepared by reaction of chitosan with glycidyltrimethyl ammonium chloride, was used to modify cotton fabrics for improving aqueous pigment-based inkjet printing and antibacterial properties (Bu et al. 2012). Scanning electron microscopy images showed that water-soluble chitosan derivative was obeyed onto the cotton fabrics surface and formed a film structure. Modified cotton samples showed good antibacterial activity, with an inhibitory rate for both *S. aureus* and *E. coli* higher than 95 % when the concentration of the chitosan derivative used in the pretreatment solution was 0.8 %. Moreover, the antibacterial effect was found to be

long lasting for 20 laundering cycles. However, the hand feeling of modified cotton fabrics presented a slight decrease. Mututuvari et al. developed a green methodology to prepare multifunctional composites for bone tissue regeneration containing cellulose (to impart mechanical strength), chitosan (to induce antibacterial activity), and hydroxyapatite (to impart osteoconductivity). Chitosan and cellulose were co-dissolved in an ionic liquid and then regenerated from water. Hydroxyapatite was then formed in situ by alternately soaking chitosan/cellulose composites in aqueous solutions of $CaCl_2$ and Na_2HPO_4. These hybrid composites retained the desirable properties of their constituents. For instance, the tensile strength of the composites was improved 1.9 times by increasing cellulose content from 20 % to 80 %. Integrating chitosan in the composite materials resulted in antibacterial activity against Gram-positive (methicillin-resistant *S. aureus*, *S. aureus*, and vancomycin-resistant *Enterococci*) and Gram-negative (*E. coli* and *P. aeruginosa*) bacteria. In another study, aiming to enhance the antibacterial and mechanical properties of agar films (Liu et al. 2013), a chitosan–methylisothiazolinone complex was first prepared, by an ionic gelation method, adsorbed onto microfibrillated cellulose (MFC), and then the obtained composite was incorporated into the agar films. In comparison with the pure agar films, the tensile strength of the agar composite films was increased by about 19 % for 10 wt% of chitosan–MFC composite. The antibacterial tests revealed that the agar composite films showed notable antibacterial activities against both *E. coli* and *S. aureus* and therefore are suitable to be used as multifunctional agar films in the medical domain. In a recent study, He et al. (2014) reported the development of functional chitosan-coated oxidized regenerated cellulose gauze for biomedical applications. Oxidized regenerated cellulose gauze, prepared by oxidation of regenerated cellulose using NO_2/CCl_4, was treated with dissolved chitosan in aqueous acetic acid and finally neutralized with NaOH/ethanol. The results of the hemostatic test on rabbit liver and ear-artery injuries showed that the adsorption of high molecular weight chitosan to the surface of regenerated cellulose gauze significantly improved the hemostatic effect of the material without compromising its antibacterial activity against *E. coli* and *S. aureus* and degradability.

Quaternary ammonium salts or polymers containing quaternary ammonium groups are also well recognized for their high antibacterial activity. Zhao and Sun (2007) employed three quaternary ammonium salts, namely, 4-aminolaurylpyridinium chloride, 4-benzoylamino-1-dodecylpyridinium bromide, and 4-(1-naphthoyl)amino-1-dodecylpyridinium bromide, in the antibacterial finishing of undyed and dyed cotton cellulose fabrics. These quaternary ammonium salts could establish ionic interactions with sulfonate groups on the dyed cotton fibers, which contributed to higher exhaustion uptakes of the salts and better antibacterial activities against *E. coli*. In another study, antibacterial BC films for potential application as functional wound dressing for acute trauma treatment were produced by immersion of freeze-dried BC membranes in a benzalkonium chloride solution (a cationic surfactant type antibacterial agent) followed by an additional freeze-drying stage. Some physical and antibacterial properties of the ensuing BC films were inspected, and the results indicated that the loading capacity of the BC dry film was about 0.116 mg/cm^2 when soaked in 0.102 % benzalkonium chloride

solution. With respect to the antibacterial activity, a stable and prolonged antibacterial effect for at least 24 h was achieved against *S. aureus* and *B. subtilis*, Gram-positive bacteria commonly found on the contaminated wounds. Chen et al. (2013) reported a simple method to produce durable antibacterial activity on cellulose by deposition of a CO_2-philic silicone with pendant quaternary ammonium groups, synthesized through hydrosilylation reaction of poly(methylhydrosiloxane) (PMHS) and 2-(dimethylamino)ethyl acrylate in the presence of platinum-based catalyst and subsequent quaternization with 1-bromohexane, onto cellulose by adsorption from supercritical CO_2. Offered data revealed that the antibacterial layer, against *S. aureus* and *E. coli*, was very stable toward washing and UV irradiation due to the low surface tension and relatively high bond energy of the backbone of silicone.

Westman et al. (2009) developed a polyelectrolyte multilayer film with antibacterial properties prepared by the layer-by-layer assembly of hydrophobically modified polyvinylamine and polyacrylic acid on porous cellulose membranes. The methodology included the preliminary introduction of negative charges onto cellulose membranes by NaBr and TEMPO-catalyzed oxidation which generated anchoring sites for the positively charged polyvinylamine. A substantial decrease in bacterial (*E. coli*) growth, ascribed to the modified polyvinylamine, was observed with increasing number of polymeric bilayers (between three and six layers of cationic polymer) on the cellulose membranes.

The use of carboxymethyl cellulose to form polyelectrolyte polymer complexes with cationic antibacterial-wet-strength polymers with guanidine residues in an effort to further increase wet strength and dry strength of paper was also investigated (Qian et al. 2008a) as well as its antibacterial efficiency (Qian et al. 2013). In a different work, Liu et al. (2012b) prepared a series of antibacterial nanofibrous membranes against *E. coli* from cellulose acetate and polyester urethane and using polyhexamethylene biguanide as the antibacterial agent by coelectrospinning or blend electrospinning. The presence of cellulose acetate in the nanofiber membrane improved its hydrophilicity and permeability to air and moisture. Drug release dynamics of the membranes was controlled by its structure and component ratios. The controlled-diffusion membranes exerted long-term antibacterial effect for wound healing.

Antibacterial proteins, specifically lysozyme and lactoferrin, were also incorporated into a matrix of cellulose and carboxymethyl cellulose fibers during the preparation of conventional paper sheets (Barbiroli et al. 2012). More than 60 % of the proteins added (alone or in combination) to the slurry used in the paper preparation were released in buffered saline solutions. The released proteins retained their structural and functional features, indicating that the papermaking process did not affect their structure. The antibacterial activity on common food contaminants was also preserved in the released protein, and a synergic effect between the two proteins was clear in tests carried out with paper sheets containing both proteins against *L. innocua*. Additional tests on thin meat slices placed on these paper sheets indicated that lysozyme was most active in preventing growth of this particular microbiota. In another study (Gemili et al. 2009), antibacterial

packaging materials were obtained by incorporating lysozyme into cellulose acetate films. The maximum release rate, soluble lysozyme activity, and antibacterial activity were achieved with the film prepared with 5 % cellulose acetate solution and 1.5 % lysozyme. Increasing cellulose content decreased the porosity of the films and therefore the release rate and the antibacterial activities of the films. In general, the incorporation of lysozyme did not cause significant reductions in tensile strength and elongation at break values of the films. In a quite distinct vein, Basmaji et al. (2014) reported novel antibacterial bacterial cellulose/polyhexanide biguanide composites produced by symbioses culture between polyhexanide biguanide and green tea culture medium resulting in a 3-D structure consisting of an ultrafine network of biocellulose/PHMB nanofibers matrix (2–8 nm), highly hydrated (99 % in weight), with higher molecular weight, and biocompatible.

In a different study, cellulose fibers were rendered antibacterial against *E. coli* by using cationic beta-cyclodextrin polymer host–guest complexes with antibiotics (butylparaben and triclosan) (Qian et al. 2008b) (Fig. 9). Results of inhibition zones and shaking flask methods of antibacterial-modified cellulose fibers showed that both antibiotics/cationic β-cyclodextrin complexes had exceptional antibacterial activities when spread over on the cellulose fibers; however, triclosan appeared to be more effective. Morphology investigations by atomic force microscopy (AFM) suggested that these complexes inhibited bacteria through disturbing their

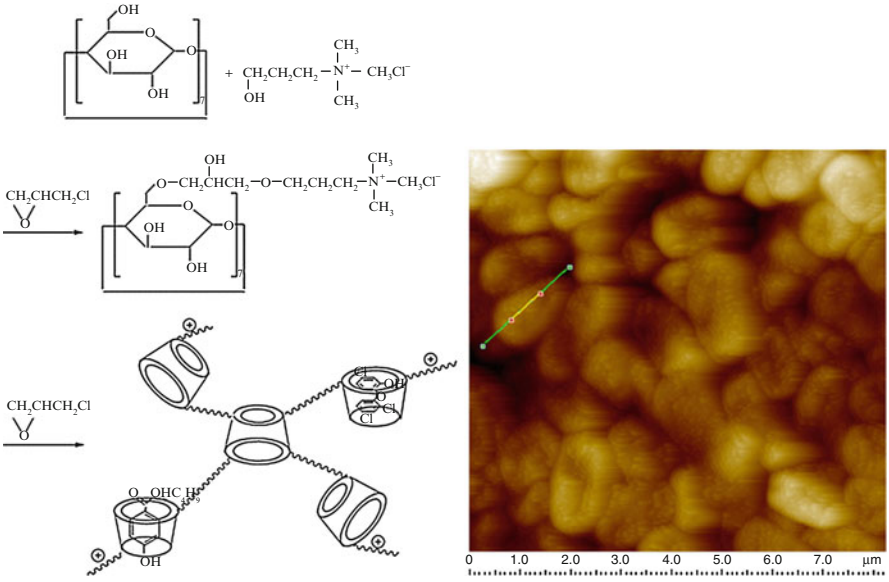

Fig. 9 Schematic representation of the synthesis of cationic β-cyclodextrin polymers and its inclusion with antibiotics. And morphology of *E. coli* treated by butylparaben/ cationic β-cyclodextrin polymer complex (Adapted and reproduced with permission from Qian et al. 2008b)

metabolism instead of damaging the cell membrane (Fig. 9). In a more recent study, Peila et al. (2013) compared two different production ways of obtaining antibacterial cotton fabrics against *E. coli* and *S. aureus* by triclosan inclusion into a beta-cyclodextrin cavity, namely, before or after grafting of beta-cyclodextrin on the cotton fabric. It has been revealed that the stability of the antibacterial finishing depends on the production method, attaining a more durable antibacterial action in case of previous triclosan inclusion followed by grafting. This result proposes that the immobilization onto the fiber has affected the cyclodextrin cavity accessibility. Imra et al. (2010) described novel bioactive composite coatings based on hydroxypropyl methylcellulose and the broad-spectrum food preservative nisin. Glycerol was used as plasticizer. The tensile strength of composite films decreased and the elongation at break increased significantly. Moreover, the transparency and water permeability of the hydroxypropyl methylcellulose films were undesirably affected by the additives. Finally, film bioactivity revealed efficacy against *Listeria* > *Enterococcus* > *Staphylococcus* > *Bacillus* species.

Several other organic biocides, including triazine derivatives (Hou et al. 2009), oregano and sage essential oils (Royo et al. 2010), potassium sorbate (Jipa et al. 2012a; Sayanjali et al. 2011), phenolic compounds (cinnamaldehyde (Nutcha et al. 2012; Rosa et al. 2013), eugenol (Nutcha et al. 2012), thymol (Rodríguez et al. 2014), carvacrol (Rosa et al. 2013; Tunç and Duman 2011), anthraquinones (Zhuo and Sun 2013), and benzoic acid (Dobre et al. 2012)), sorbic acid (Jipa et al. 2012a), dyes (Decraene et al. 2006; Farouk and Gaffer 2013), and streptomycin sulfate (Rajan et al. 2014), have also been used to impart antibacterial properties to cellulose-based materials.

For instance, biodegradable bacterial cellulose-based films, incorporating sorbic acid as antibacterial agent, have been obtained (Jipa et al. 2012b). Monolayer films, prepared using powdered BC and poly(vinyl) alcohol, were coated with BC membranes to obtain multilayer films. Results indicated that both sorbic acid and powdered BC concentration influenced the water sensitivity, release rate, and antibacterial ability of mono- and multilayer films. The release of sorbic acid was faster when powdered BC concentration was higher but significantly slower, as a consequence of formed crystal dissolution, when sorbic acid concentration was increased. The antibacterial activity was tested against *E. coli*, and the results achieved indicated that it was mainly influenced by the sorbic acid concentration and water solubility of the films. These biocomposite films could be used as antibacterial food packaging materials. In a recent study (Zhuo and Sun 2013), two anthraquinone derivatives were incorporated onto cotton fabrics by a vat dyeing process. The dyed cotton fabrics revealed durable light-induced biocidal activity against washing and long-term light exposure but dependent on the anthraquinone compounds used. In a very recent report (Rajan et al. 2014), antibacterial electrospun nanofibrous scaffolds (diameters 400–700 nm) were prepared by physically blending polyurethane, cellulose acetate, and zein. To prevent common clinical infections, streptomycin sulfate, an established antibacterial agent, was integrated into the electrospun fibers. These novel composite nanoscaffolds showed

enhanced blood clotting ability in comparison with original polyurethane nanofibers. The existence of cellulose acetate and zein in the nanofiber composite membrane enhanced its hydrophilicity and bioactivity (against *E. coli*, *S. typhimurium*, *V. vulnificus*, *S. aureus*, and *B. subtilis*) and created a moist environment for the wound, which can accelerate wound recovery.

Antibacterial Cellulose-Based Materials Obtained by Chemical Modification

The development of antibacterial cellulose-based materials by simple blending with antibacterial agents constitutes an up-front strategy; however, it is normally accompanying by the leaching of the antibacterial agents during usage and consequent decrease of the bioactivity. The introduction of permanent antibacterial activity is normally accomplished by chemical grafting of different antibacterial moieties onto the cellulose backbone, though this field is still less explored.

One of the first studies on this domain reported the covalent bond of a reactive melamine derivative, 2-amino-4-chloro-6-hydroxy-*s*-triazine, onto cotton cellulose through nucleophilic substitution (Sun et al. 2005). Upon chlorine bleaching treatment, the covalently bound melamine derivative moieties could be transformed into chloromelamine derivatives, affording strong, long-lasting, and rechargeable antibacterial activity against 10^6–10^7 CFU/mL of drug-resistant Gram-negative (*S. aureus* spp.) and Gram-positive (*E. coli* spp.) bacteria under both waterborne and airborne conditions. However, the inclusion of chlorine bleaching in the process is not very motivating considering its negative environmental impact. In a very attractive work, microfibrillated cellulose was grafted with a quaternary ammonium compound (octadecyldimethyl(3-trimethoxysilylpropyl)ammonium chloride) by an adsorption-curing process (Andresen et al. 2007). Films obtained from the modified MFC showed substantial antibacterial capacity against *S. aureus*, *E. coli*, and *P. aeruginosa* even at very low concentrations of antibacterial agent immobilized on the surface (0.14 % of atomic nitrogen from the quaternary ammonium compound). The zone of inhibition test demonstrated that no quaternary ammonium compound diffused into the surrounds, corroborating that the films were definitely of non-leaching type. These films could be suitable for application as antibacterial separation filters.

More recently, a similar approach was applied to bacterial cellulose aiming to design functional nanostructured membranes for biomedical applications (Fernandes et al. 2013). Precisely, aiming to mimic the natural antibacterial activity of chitosan macromolecules, antibacterial nanostructured bacterial cellulose membranes were obtained by chemical grafting of aminoalkyl groups onto the surface of its nanofibrillar network (Fig. 10). Interestingly, these novel grafted bacterial cellulose membranes are simultaneously lethal against *S. aureus* and *E. coli* and nontoxic to human adipose-derived mesenchymal stem cells (ADSCs). In addition to these motivating biological properties, the bioactive nanostructured membranes also showed enhanced mechanical and thermal properties. In a more complex way, Rouabhia et al. (2014) reported novel gentamicin-activated BC membranes obtained by chemically grafting RGDC peptides (R, arginine; G, glycine; D, aspartic acid; C, cysteine) using the coupling agent 3-aminopropyltriethoxysilane

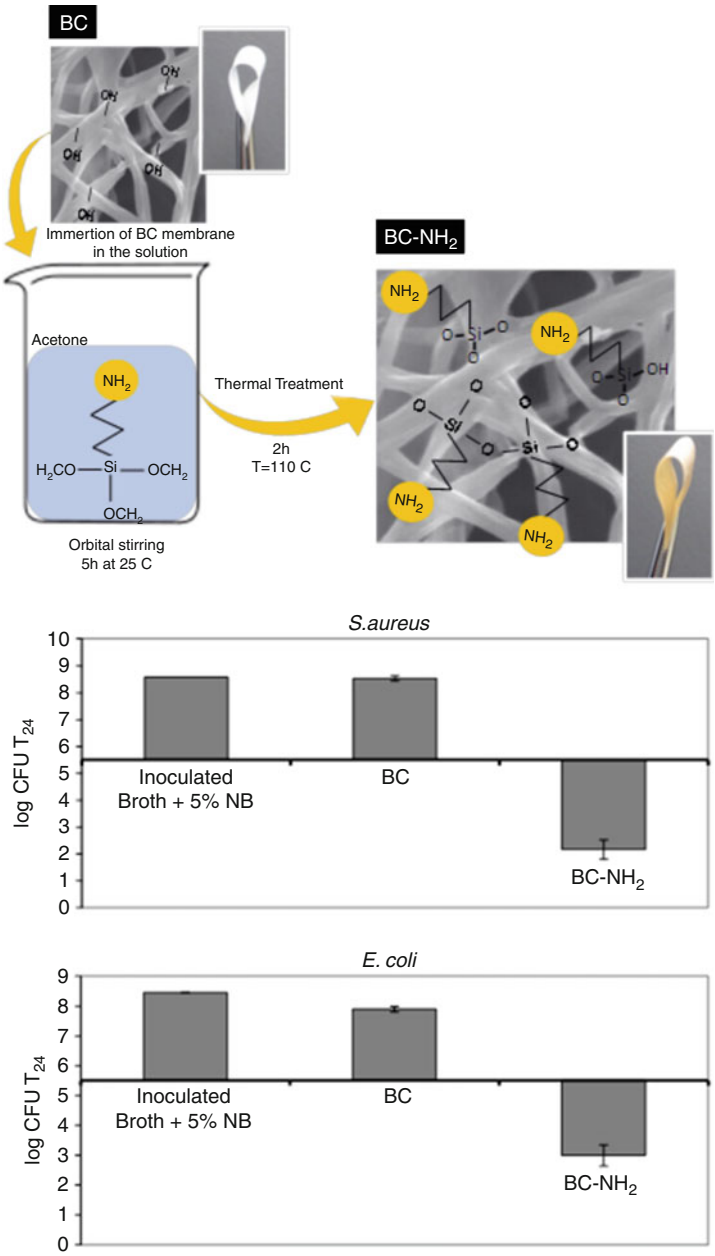

Fig. 10 Mechanism of silane-bacterial cellulose chemical grafting using APS as active reagent to prepare BC membranes with antibacterial properties. And antibacterial activity of blank BC and BC-NH2 mats respect to *S. aureus* and *E. coli* of. The obtained results are compared with reference sample (unmodified BC mat) as well as inoculated broth added with 5% of Nutrient Broth (NB) (Adapted and reproduced with permission from Fernandes et al. 2013)

followed by covalent linkage of gentamicin onto the surface of the BC. As well as in the preceding example, the gentamicin–RGDC-grafted BC membranes are bactericidal against *S. mutans* but nontoxic to human dermal fibroblasts and thus may be advantageous for multiple applications such as functional wound healing and drug delivery systems. In a previous study (Lochman et al. 2010), the effect of topically applied gentamicin attached to a new biodegradable carrier formed by microdispersed oxidized cellulose in microfiber and nanofiber form for treatment of acute wound infection was also investigated. However, in this case gentamicin was not chemically attached to cellulose.

In another pioneering work, 2-(dimethylamino)ethyl methacrylate (DMAEMA) was polymerized from cellulosic filter paper via reversible addition–fragmentation chain transfer (RAFT) polymerization (Roy et al. 2008). The tertiary amino groups of the grafted polymeric chains were subsequently quaternized with alkyl bromides of different chain lengths (C8–C16) to afford a large concentration of quaternary ammonium groups on the cellulose surface. The antibacterial activity of the obtained materials against *E. coli* was found to be reliant on the alkyl chain length and on the degree of quaternization, with the PDMAEMA-grafted cellulose fiber with the highest degree of quaternization and quaternized with the shortest alkyl chains showing the highest activity. In a different line, Elegir et al. (2008) developed antibacterial cellulose packaging via laccase-mediated grafting of phenolic compounds (*p*-hydroxybenzoic acid, caffeic acid, gallic acid, dopamine, eugenol, isoeugenol, and thymol). The handsheet papers obtained by laccase antibacterial surface treatment exhibited a greater efficiency against Gram-positive (*B. subtilis*, *E. hirae*, *S. epidermidis*, *S. aureus*) and Gram-negative (*E. coli*, *P. aeruginosa*, and *K. pneumonia*) bacteria than those treated only with monomeric phenolic compounds. Antibacterial effect was dependent on the grafted structure, time of the reaction, and concentration of phenolic derivatives. For example, the laccase antibacterial surface obtained in the presence of caffeic acid or *p*-hydroxybenzoic acid produced paper handsheets with strong bactericidal effect on *S. aureus* even at low phenol monomer concentration (4 mM). Feese et al. (2011) and carpenter et al. (2012) described the synthesis and characterization of groundbreaking cellulose nanocrystals surface-modified with a cationic porphyrin. The porphyrin moiety was appended onto the cellulose surface via the Cu(I)-catalyzed Huisgen–Meldal–Sharpless 1,3-dipolar cycloaddition. The obtained materials showed outstanding efficiency toward the photodynamic inactivation of *M. smegmatis* and *S. aureus*, although only slight activity against *E. coli*, and therefore could have potential utilization in the health care and food preparation industries. In a different study, the antibacterial properties of oxidized cellulose (commercial oxidized cellulose sample for biomedical applications with different carboxylic acid %, up to 20.6 %) and its salts (with Ag^{+}, Mg^{2+}, Na^{+} or Zn^{2+}) in linters, microsphere, and textile form were tested by a dilution method against a range of several microbial strains, namely, *E. coli*, *P. aeruginosa*, *S. epidermidis*, *B. licheniformis*, *A. niger*, *P. chrysogenum*, *R. oryzae*, *S. brevicaulis*, *C. albicans*, and *C. tropicalis* (Vytrasova et al. 2008). The results of this study showed that the acidic form of the oxidized cellulose with zinc has a pronounced potential to be

explored in biomedical applications, e.g., as dressing material, against bacteria as well as against fungal *Candida* species.

Chitosan cross-linked cellulose fibers were obtained by means of a benign process aiming to confer antibacterial properties to cellulose fibers (Alonso et al. 2009). Citric acid was used as the cross-linker agent and NaH_2PO_4 as catalyst in formerly UV-irradiated cellulose fibers. Further heat dried-cure process and washing with detergent, water, and acetic acid (0.1 M) yielded a maximum incorporation of 27 mg of chitosan/gram of functionalized cellulose. The material with the highest chitosan content displayed augmented thermal stability compared to the initial cellulose and chitosan samples. The colony-forming units/mL for *E. coli* and the biomass and spore germination fraction of *P. chrysogenum* decreased significantly on the cross-linked materials as compared to native cellulose fibers. For illustration, the sample with the highest chitosan content incorporated inhibited the fungal growth with 66 % less biomass amount than that obtained with raw cellulose. In a different study, the flocculation and antibacterial properties of water-soluble quaternized cellulose derivatives synthesized by reaction with 3-chloro-2-hydroxypropyltrimethylammonium chloride in NaOH/urea aqueous solutions (degree of substitution (DS) of 0.38, 0.50, and 0.74) were investigated (Song et al. 2010). The results showed that the obtained quaternized cellulose derivatives were effective flocculating agents for montmorillonite over a wide range of pH values and that powerfully inhibit the growth of *E. coli* and *S. aureus*, being potentially applicable as an original wastewater treatment agent with high flocculation efficacy as well as effective antibacterial effect. Bieser et al. (2011) reported the synthesis of contact-active antibacterial coating that only degraded in the presence of cellulase. Specifically, 2′,3′-dideoxyadenosine (DDA) function was grafted to a cellulose backbone via a poly(2-ethyloxazoline) spacer. It was found that all coatings were effective active against *S. aureus* and those with high DS and long polymeric spacers degraded in water. This constitutes an interesting strategy for the development of new antifouling paints useful for marine fouling prevention. In another study (Salimpour Abkenar and Mohammad Ali Malek 2012), two generations of poly(propylene imine) dendrimers with amino-terminated groups were successfully grafted on cotton fabric using citric or glutaric acids as cross-linking agents, as confirmed by FTIR analysis. Moreover, nitrogen content determination revealed the presence of the dendrimers on the cotton fabric even after five washing cycles. The dendrimer grafted cotton fabric showed a 99 % reduction in microbial counts against *S. aureus*, *E. coli*, and *C. albicans*. Kang et al. (2012) synthesized a novel quaternized *N*-halamine precursor (3-chloro-2-hydroxypropyl)-(5, 5-dimethylhydantoinyl-1-ylmethyl)-dimethylammonium chloride by a two-step reaction that was then efficiently grafted onto the surface of cellulose by a dehydrochlorination reaction. The quaternized precursor grafted on cellulose was finally converted to an *N*-halamine structure by a chlorination reaction with a diluted NaClO solution. The antibacterial experiments revealed that the chlorinated grafted cellulose fabric was capable of 5-log inactivation of *S. aureus* and *E. coli* within 5 min. This methodology could be used in the antibacterial finishing

of textiles. In another recent study, a "clickable" quaternary ammonium compound, specifically *N*-(2-ethoxy-2-oxoethyl)-*N*,*N*-dimethylprop-2yn-1-aminium bromide, was synthesized through an artless reaction and covalently bonded to a cellulose derivative containing an azido group (3-*O*-azidopropoxypoly(ethylene glycol)-2,6-di-*O*-thexyldimethylsilyl cellulose, DS 0.54 at C3) to form non-leaching antibacterial cellulose-based material via the simple Cu(I)-catalyzed alkyne-azide [2 + 3] cycloaddition reaction. Noteworthy antibacterial activity of the obtained cellulose derivative (DS = 0.30 at C3) was established by testing against *E. coli* (about 50 % of the bacteria were killed when 0.4 mg of the compound were added to a solution containing 2,700,000 CFU of live cells). This investigation offers a simple and robust route toward the development of permanent antibacterial materials and biomedical devices.

3.2.2 Starch

In recent decades starch has attracted an enormous interest as a source of new renewable materials, due to its low cost, biocompatibility, nontoxicity, and simplicity to convert into a thermoplastic material, referred to as thermoplastic starch (TPS), through the breaking of the hydrogen bond interactions between polymeric chains by a plasticizer at specific temperature and/or mechanical energy conditions (Carvalho 2008; Chivrac et al. 2009). The preparation of TPS-based materials is often preceded by the treatment of starch in water at specific temperatures leading to the dissolution of starch granules due to the disruption of the hydrogen bonds between the polysaccharide chains, leading to the so-called gelatinized starch solutions, that can be used to coat materials (e.g., food products and nanoparticles, among others) or to produce TPS-based films or membranes by casting. However, starch-based materials present several limitations such as poor mechanical performance and water resistance and, particularly relevant in the present context, the intrinsic lack of biological activity. To overcome such limitations, the most common approach involves the combination of starch with other chemicals or polymeric materials in gelatinized solutions used to produce coatings or blended/composite films where the specific target properties are imparted by those additives (bioactive polymers, natural compounds, or metal nanoparticles among others), while preserving most of the connotations associated with the starch matrix, such as its biodegradability, biocompatibility, renewable character, and in a large number of cases edibility.

Here an overview of the most common strategies, reported in the last decade, to impart antibacterial activity to starch containing materials will be comprehensively explored. The major strategy used to produce starch-based materials with antibacterial properties (mainly edible coatings, films, and membranes, aimed at reducing fresh food contamination and extending shelf life) involved its combination with bioactive plant extracts (with special emphasis in essential oils and phenolic extracts, or corresponding pure compounds), followed by the blending with chitosan and several other bioactive materials. Another approach pursued was the combination with metal nanoparticles (especially silver); however, in most of these studies, starch was used to coat/stabilize the metal nanoparticles which might

find uses in active packaging and biomedical applications rather than to produce edible films and coatings.

Antibacterial Starch-Based Materials with Plant Extracts

One of the simplest examples regarding the preparation of starch-based antibacterial materials involves the use of gelatinized starch solutions with bioactive plant extracts and their direct use in food coatings. As an illustrative example, Goswami et al. (2009) spread pre-gelatinized pea starch with 0.5 % thyme essential oil over chicken breast meat after inoculation with several bacteria (from the genera *Salmonella*, *Listeria*, *Campylobacter*, and *Pseudomonas*), followed by packing in plastic bags and storage at 4 °C. It was shown that the starch/thyme oil coating effectively reduced the viability of *Salmonella*, as well as the growth of *Listeria* and *Pseudomonas*, and eliminated *Campylobacter* during storage.

Edible coatings combining tapioca starch with decolorized hsian-tsao leaf gum matrix and glycerol and with various green tea extracts, obtained under different extraction conditions, were also evaluated for their antibacterial activity (Chiu and Lai 2010). All the green tea extracts showed a pronounced inhibition of Gram-positive bacteria, including *Staphylococcus aureus*, *Bacillus cereus*, and *Listeria monocytogenes*, increasing with the extract content, but not of Gram-negative bacteria, such as *Escherichia coli* and *Salmonella enterica*. When the various green tea extracts were added to the edible coating formulations, a strong antibacterial activity on Gram-positive bacteria was also observed as evaluated by using cylinder diffusion and antibacterial migration tests. It is proposed that the green tea extract active components leave the coating matrix and migrate to the surface of the substrate to increase the nongrowth area. These edible coatings with green tea extracts were sprayed over several food components (fruit-based salads, romaine hearts, and pork slices), demonstrating a pronounced antibacterial activity against Gram-positive bacteria, during refrigerated storage of romaine hearts and pork slices for 48 h. These coatings also showed that they could successfully reduce the aerobic counting and growth of yeasts/molds in fruit-based salads, as compared to the control samples. These two studies (Chiu and Lai 2010; Goswami et al. 2009) clearly demonstrate the potential of the addition of bioactive extracts to starch-based edible coating formulations to prevent food products spoilage and contamination and therefore improve their safety and shelf life.

Distinct plant extracts and selected bioactive compounds were also included in starch films leading to antibacterial materials. One of the first approaches comprises the use of phenolic-rich plant extracts as will be highlighted by the following examples (Corrales et al. 2009; Kuorwel et al. 2014; Li et al. 2013; Nouri and Mohammadi Nafchi 2014; Pyla et al. 2010).

As an illustrative example, Corrales et al. (2009) used grape seed extracts, with high total phenolic content and antioxidant activity (mostly attributed to their flavonoid and phenolic acid composition), to prepare antibacterial starch-based films. The extracts were tested against several bacteria showing that they inhibited the growth of Gram-positive foodborne pathogens but not Gram-negative ones. These extracts were incorporated into pea gelatinized starch solutions, followed by

solvent casting. The films containing 1 % of grape seed extracts revealed an increment in thickness and decrease in the puncture and tensile strength compared to control ones. Furthermore, the in vitro tests of the films containing the grape seed extracts with pork loins infected with *Brochothrix thermosphacta* showed a bacterial growth reduction in 1.3 log CFU mL^{-1} after 4 days of incubation at 4 °C, demonstrating that these films can be used to inhibit the growth of pathogens in meat products, improving meat quality and shelf life.

Tannic acid (a commercially available complex mixture of polyphenolic structures which can be obtained from several plants), known as a food additive with antibacterial activity against common food pathogens, was also used as such or after an hydrothermal treatment, to produce starch-based films by casting (Pyla et al. 2010). The resulting films were then tested against *E. coli* and *L. monocytogenes*. It was demonstrated that the bacterial inactivation curves correlated well with the kinetics of release of tannic acid from the starch films.

Li et al. (2013) studied the antibacterial activity against *E. coli* of cornstarch films incorporating extracts of several Chinese medicinal herbs, evaluating also the mechanical properties and moisture resistance of the resulting films. The authors highlighted the effect of the addition of *Scutellaria baicalensis* and *Schisandra chinensis* extracts, which, despite some decrease in mechanical properties (e.g., extensibility) and water resistance, induced strong antibacterial properties on the films.

Nouri et al. (2014) studied the biological activity of sago starch films incorporating different contents of betel leaf ethanolic extract, showing a decrease in tensile strength with increasing elongation with growing extracts content, whereas the water and oxygen permeability increased. These films were claimed to show a good inhibitory activity against nonspecified Gram-positive and Gram-negative bacteria with the exception of *P. aeruginosa*.

The incorporation of essential oils or some pure monoterpenic compounds into starch edible films has also been considered in several studies (Ehivet et al. 2011; Kuorwel et al. 2011, 2013, 2014). For example, Ehivet et al. (2011) prepared sweet potato starch-based edible films by casting, containing origanum (*Thymus capitatus*) oil and different plasticizers (propylene glycol, sucrose, sorbitol, and glycerol), and evaluated their antibacterial properties against *S. enteritidis*, *E. coli*, and *L. monocytogenes* as well as their mechanical properties and water vapor permeability. The films produced with 2.5 % (w/v) starch and 40 % (w/v) sorbitol demonstrated the best mechanical and barrier performance, and their antibacterial activity was shown to be directly related with the content of origanum oil, in the range of 0.5–2 % (v/v).

In a study with pure essential oil components, namely, linalool, carvacrol, and thymol incorporated in starch-based films, Kuorwel et al. (2011) demonstrated their antibacterial activity against *S. aureus* both in vitro and inoculated in cheddar cheese. In vitro, using the agar diffusion method, it was demonstrated that the antibacterial activity increased significantly with the concentrations of the antibacterial agents. Furthermore, all the starch films containing the bioactive agents inhibited the bacterial growth in inoculated cheddar cheese, with the highest

activity being reported for thymol, followed by carvacrol and linalool. However, as in most studies mentioned above, it was shown (Kuorwel et al. 2014) that the increasing amounts of the antibacterial agents decreased the tensile strength of the films and increased the elongation at break. However, at low contents these three components did not drastically affect the transparency or the water vapor permeability and the morphology of the films.

In addition to the straightforward combination with bioactive extracts (again mainly phenolic-rich extracts and essential oils) with starch, several studies additionally involved the blending with other polymeric materials to improve the properties of the ensuing starch-based materials (Chiu and Lai 2010; Jagannath et al. 2006; Maizura et al. 2007; Wu et al. 2010).

Jagannath et al. (2006) prepared starch–casein-based edible films by casting, followed by heat pressing, with the incorporation of neem (*Melia azardirachta*) water extract. The films showed suitable water vapor and oxygen permeability, as well as thermal and mechanical properties, which were in general enhanced with the hot pressing operation. The addition of the neem extract did not affected these properties and imparted the films with antibacterial properties against *E. coli*, *S. aureus*, *B. cereus*, *L. monocytogenes*, *Pseudomonas* spp., and *S. typhimurium*.

Wu et al. (2010) studied the production of starch–polyvinyl alcohol films impregnated with catechin-rich green tea extracts. Although the mechanical properties (tensile strength and elongation) decreased with increasing amounts of incorporated extract, the inclusion of 1000 ppm of catechins in the films resulted in a considerable antioxidant capacity and antibacterial activity against *E. coli*, as well as some yeasts in raw beef at refrigeration temperature, although a slightly negative effect over meat color was observed.

The combination of tapioca starch with decolorized hsian-tsao leaf gum used above to produce antibacterial coatings (Chiu and Lai 2010) has been also used in the preparation of films incorporating potassium sorbate and an ethanolic thyme extract, which have been tested against *L. monocytogenes*. The inclusion of the thyme extract contributed to a smoother microstructure of the films, as evidenced by SEM analysis, but in general their mechanical performance (tensile strength and modulus) decreased with the increasing content of the antibacterial extract. The antibacterial properties of the films were lower than those of the isolated extracts which was attributed to limited migration of the extract from the film. These films were also tested in fresh beef demonstrating to inhibit the growth of the tested bacteria.

Edible films of partially hydrolyzed sago starch (*Metroxylon sagu*) and alginate, with glycerol as plasticizer and lemongrass oil as bioactive component, were tested for their antibacterial activity against *E. coli* based on the zone inhibition assay and proved to be active in all lemongrass oil concentration levels (Maizura et al. 2007). It was also noticed that the antibacterial activity of these films against *E. coli* was substantially enhanced by the addition of the plasticizer (20 % glycerol). Furthermore, although the addition of lemongrass oil did not have any interaction with the functional groups of film components, as measured by FTIR, the elongation at break and water vapor permeation of the plasticized materials were found to

increase significantly with increasing lemongrass oil content. In another study, starch and alginate films incorporating sodium dehydroacetate or a rosemary extract have been studied for their antibacterial activity against *E. coli* (Yan et al. 2013). Both additives reduced starch crystallinity, as well as the mechanical properties of the films (tensile strength and elongation at break), and increased both the surface roughness and the water vapor permeability, as well as the color of the films. Films with either sodium dehydroacetate or rosemary extract showed a strong anti-*E. coli* effect.

In a distinct application Arfa et al. (2007) used octenyl-succinate-modified starch (and soy protein isolates for comparative purposes) as paper coatings and inclusion matrices for antibacterial cinnamaldehyde and carvacrol and tested for their antibacterial activity against *E. coli*. Both modified starch and soy protein isolates demonstrated good retention ability of the bioactive compounds during paper coating and drying. The ability of coated papers to release these compounds over storage time was assessed and demonstrated that both compounds are gradually released from the coating; furthermore, the favorable antibacterial properties are related with the total release of the bioactive agents.

Antibacterial Starch-Based Materials with Chitosan

The combination of starch and chitosan to produce edible films and membranes has also been investigated with some detail. Here chitosan brings both its filmogenic and antibacterial properties to the resulting materials arising from the presence of amino groups of the glucosamine unit and its ability (in the cationic form) to disrupt bacterial membranes.

Most starch/chitosan films were prepared using gelatinized starch and chitosan (and cationized water-soluble chitosan; Tome et al. 2012) solutions with a plasticizer (most often glycerol) by casting (Durango et al. 2006; Liu et al. 2009; Mei et al. 2013; Tomé et al. 2013; Vásconez et al. 2009; Yoksan and Chirachanchai 2010; Zhong et al. 2011) or by extrusion (Bie et al. 2013; Pelissari et al. 2009; Tome et al. 2012).

In general, the obtained starch/chitosan edible films/membranes are thermally stable with a good flexibility (Durango et al. 2006) and with elongation at break and water vapor permeability considerably improved when compared to the single components films, mainly due to the interaction between the hydroxyl groups of starch and the amino groups of chitosan (Liu et al. 2009); additionally, some additives, such as oregano essential oil (Pelissari et al. 2009) or potassium sorbate (Shen et al. 2010), also improved film properties such as elongation and water vapor permeability. Furthermore, it was also demonstrated that the mechanical properties and water vapor permeability of starch/chitosan films might also be affected by the nature of the acid used to dissolve chitosan, with the best results in terms of mechanical properties being obtained with acetic and lactic acid, respectively (Zhong et al. 2011).

Apart from the combination of starch/chitosan with other bioactive additives, the combination with polylactic acid (Bie et al. 2013) and bacterial cellulose (Tomé et al. 2013) has also been reported. In the case of the combination

with polylactic acid (Bie et al. 2013), the resulting material acted as a slow chitosan release system whose rate depended on the hydrophilicity of the blend, which in turn was mainly determined by its starch content. The combination of starch/chitosan with bacterial cellulose (Tomé et al. 2013) was aimed at improving the mechanical properties of the materials, without affecting its transparency, taking advantage of the unique features of the bacterial cellulose nanofibrillar structure.

Another distinct approach involved the preparation of antibacterial starch/chitosan nanocomposite films loaded with spherically shaped (20–25 nm) silver nanoparticles by casting (Yoksan and Chirachanchai 2010). The incorporation of Ag NPs leads to a slight improvement in tensile strength and oxygen barrier properties and to a decrease in water barrier properties.

The starch/chitosan films showed excellent antibacterial properties against *S. enteritidis* (Durango et al. 2006; Pelissari et al. 2009), *E. coli* (Bie et al. 2013; Liu et al. 2009; Mei et al. 2013; Pelissari et al. 2009; Shen et al. 2010; Yoksan and Chirachanchai 2010; Zhong et al. 2011), *S. aureus* (Bie et al. 2013; Mei et al. 2013; Pelissari et al. 2009; Shen et al. 2010; Tome et al. 2012, 2013; Yoksan and Chirachanchai 2010; Zhong et al. 2011), *B. cereus* (Pelissari et al. 2009; Yoksan and Chirachanchai 2010), and *L. monocytogenes* (Mei et al. 2013) but not against *Lactobacillus* spp. (Vásconez et al. 2009). In specific cases, it was suggested that the antibacterial activity of the films was not only due to chitosan but also to the addition of other bioactive agents such as oregano essential oil (Pelissari et al. 2009), potassium sorbate (Shen et al. 2010), *Cornus officinalis* fruit extract, and pine needle essential oil and nisin (both isolated or combined with each other) (Mei et al. 2013). The antibacterial properties of the starch/chitosan films are also affected by the acid used to dissolve chitosan, with the best results against *S. aureus* and *E. coli* being reported with malic acid (Zhong et al. 2011).

Antibacterial Starch-Based Materials with Metal Nanoparticles

The use of metal nanoparticles as antibacterial agents found a tremendous boost in recent years, with particular emphasis in silver nanoparticles. In this context, there are also a considerable number of studies dealing with metal nanoparticles (again mainly silver) and starch; however, as will be highlighted in the key examples put forward below, instead of being used to produce edible coatings or films, starch is being used as a stabilizing agent for silver nanoparticles (Ag NPs). Nevertheless in most cases these stabilized Ag NPs have been successfully tested for their antibacterial activity.

Ag NPs stabilized with starch are normally produced from $AgNO_3$ aqueous solutions in the presence of solubilized starch, followed by reduction either by γ-irradiation (Kassaee et al. 2008), by hydrothermal treatment (Mohanty et al. 2012), or by reduction with sodium borohydride (Raji et al. 2012), glucose (Gao Xianghua et al. 2013), and other monosaccharides (Kahrilas et al. 2014) or even by starch itself (Ayala Valencia et al. 2013; Taheri et al. 2014) or starch dialdehyde (Wang et al. 2013a) acting as the reducing agent, resulting in starch coated Ag NPs.

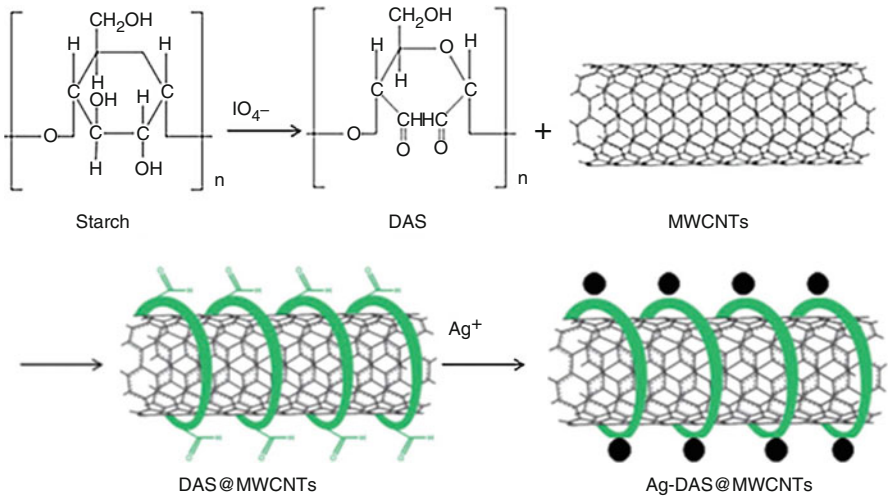

Fig. 11 Schematic description of the process of production of multiwalled carbon nanotubes decorated with silver nanoparticles using starch dialdehyde (Reproduced with permission from Wang et al. 2013a)

Ag NPs coated with starch are most commonly spherical with average size distributions in the range of 10–30 nm (Ayala Valencia et al. 2013; Gao Xianghua et al. 2013; Kahrilas et al. 2014; Mohanty et al. 2012; Raji et al. 2012), although cubic shape NPs with average sizes of 14 nm have also been reported (Kassaee et al. 2008),

In general, it was demonstrated that Ag NPs are embedded in starch macromolecules (Kassaee et al. 2008) and tested as such against distinct bacterial strains. In a more sophisticated approach, Wang et al. (2013a) have bound starch dialdehyde (obtained by partial oxidation of starch with sodium periodate) to multiwalled carbon nanotubes. In a second step the starch dialdehyde was used as the reducing as well as a complexing agent to deposit Ag NPs onto the surface of starch modified multiwalled carbon nanotubes (Fig. 11), which demonstrated to have superior antibacterial activity against several bacteria as enumerated below.

Ag NPs have also been prepared in situ and incorporated into starch base nanocapsules by a miniemulsion/polyaddition polymerization of 2,4-toluene diisocyanate using polyglycerin-polyricinoleate as surfactant (Taheri et al. 2014). The resulting round-shaped nanocapsules were then carboxymethylated with monochloroacetic acid under alkaline conditions. The nanocapsules' shell thickness could be tuned from 13 to 29 nm by varying the amount of cross-linker.

Starch materials with Ag NPs were shown to have a broad range of antibacterial activity against Gram-positive and Gram-negative pathogens, and at the same time to be nontoxic to macrophages at the bactericidal concentrations, and can even augment their intracellular killing potential (Mohanty et al. 2012). In detail, the antibacterial activity of Ag NPs has been demonstrated against *E. coli*

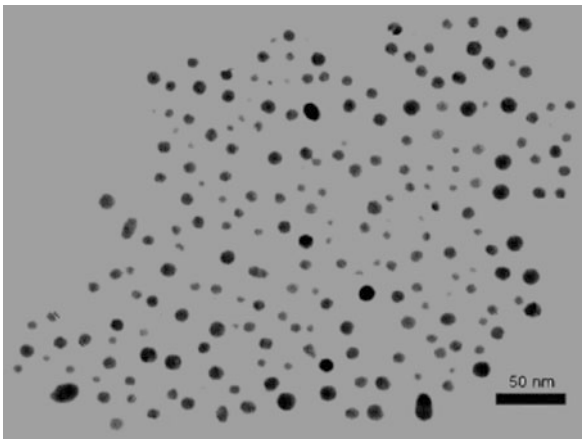

Fig. 12 TEM images of starch capped copper nanoparticles (Reproduced with permission from Valodkar et al. 2012)

(Gao Xianghua et al. 2013; Kahrilas et al. 2014; Kassaee et al. 2008; Raji et al. 2012; Taheri et al. 2014; Wang et al. 2013a), *S. typhi* (Mohanty et al. 2012), *P. aeruginosa* (Kahrilas et al. 2014; Mohanty et al. 2012; Raji et al. 2012), *S. aureus* (Ayala Valencia et al. 2013; Gao Xianghua et al. 2013; Kahrilas et al. 2014; Mohanty et al. 2012; Raji et al. 2012), *S. flexneri* (Mohanty et al. 2012), *S. epidermidis* (Raji et al. 2012; Taheri et al. 2014), *M. smegmatis* (Mohanty et al. 2012), *Bacillus megaterium* (Wang et al. 2013a), *Bacillus subtilis* (Kahrilas et al. 2014; Wang et al. 2013a), *Klebsiella pneumonia* (Kahrilas et al. 2014), and *Janthinobacterium lividum* (Kahrilas et al. 2014).

Apart from Ag NPs coated with starch, a few other examples of conjugations of starch with NPs include copper nanoparticles (Valodkar et al. 2012) and zinc oxide nanorods (Nafchi et al. 2012).

As in the case of Ag NPs, monodisperse copper NPs, with average size of 10 nm (Fig. 12), were prepared by microwave irradiation using starch as green capping agent; the ensuing solutions were shown to exhibit excellent bactericidal action against *S. aureus*, *E. coli*, and *S. typhi* (Valodkar et al. 2012). It was also demonstrated that copper nanoparticles capped with starch are not cytotoxic against 3T3L1 cells at the concentrations required for antibacterial activity, opening the perspective of application of these NPs in biomedical field.

Finally, zinc oxide nanorods were incorporated into sago starch solutions at different concentrations and nanocomposite films were obtained by casting (Nafchi et al. 2012). These films showed excellent antibacterial properties against *S. aureus* directly related with the nanorod content. Additionally, the inclusion of the zinc oxide nanorods substantially decreased the water permeability and increased the hydrophobicity of the film surface and low light transmittance in the UV-Vis.

Antibacterial Starch-Based Materials with Miscellaneous Components

Apart from bioactive plant extracts and chitosan, several other components have been used to prepare antibacterial starch-based material, namely, lysozyme (Basch et al. 2012; Dawson et al. 2005; Li et al. 2012b), nisin (Basch et al. 2012;

Dawson et al. 2005), and the combination with other antibacterial cationic polymers as polyhexamethylene guanidine (Guan et al. 2008a, b; Ziaee et al. 2010), among others discussed below.

Pea starch-based materials with lysozyme were prepared by Nam et al. (2007) under different extrusion conditions aiming to obtain extrudates with strong mechanical properties able to be used in biodegradable rigid containers, with antibacterial activity against *B. thermosphacta* due to the gradual release of lysozyme. The release of lysozyme from microgels of oxidized starch was also evaluated (Li et al. 2012b). Here starch was oxidized with 2,2,6,6-tetramethyl-1-piperidinyloxy (TEMPO) and chemically cross-linked with sodium trimetaphosphate (STMP), yielding a gel that could be converted into a finely powdered material. The dry gel particles were then suspended in water to which a solution of lysozyme was added. The microgel is negatively charged and interacts with positively charged lysozyme by electrostatic attraction. Application of the lysozyme-containing starch particles to environments contaminated with amylase producing microbes may lead to the hydrolysis of starch. As a result, lysozyme is released and will inhibit the growth of lysozyme-sensitive bacteria. The potential application of this material was demonstrated against *B. licheniformis* and *B. subtilis*. Due to the frequent presence of amylase-producing bacteria in food products, this material might find application in food protection systems. Finally, lysozyme was also incorporated in pea protein-/corn starch-based films, and its release into a food simulant (agar gel) was evaluated (Fabra et al. 2014) showing that the protein diffuses from the film at increasing rate with increasing temperature and concentrated mainly on the surface of the simulant where most of its antibacterial activity against *L. monocytogenes* was observed, being therefore able to preserve the surface of food products from microorganisms.

Another bioactive proteic material, the antibacterial peptide nisin has been incorporated in starch powders and films (Basch et al. 2012; Dawson et al. 2005). Nisin has been adsorbed into cornstarch powder (among other food-grade powders), by placing them in agitated nisin solutions, followed by dehydration and testing against *L. plantarum* or *L. monocytogenes* (Dawson et al. 2005). Nisin adsorbed into starch preserved 54 % of its original activity, and between 45 % and 61 % of the peptide was released over time (depending on the initial load). The starch-based powder showed an intense antibacterial activity against *L. monocytogenes*. Nisin and potassium sorbate have also been incorporated into tapioca starch edible films plasticized with glycerol (Basch et al. 2012), which demonstrated that the combination of both bioactive agents resulted in an enhanced activity against *L. innocua* as well as some yeast, when compared with films with a single compound. The addition of the bioactive agents led to some reduction in the mechanical properties of the films, when compared to pure starch, but they were still suitable for packaging applications.

In another approach, antibacterial starch materials were prepared by coupling starch with polyhexamethylene guanidine via a reaction with a diepoxide (Guan et al. 2008a), and their adsorption onto cellulose fibers was studied in detail (Guan et al. 2008b). These modified starch materials showed a high antibacterial activity

against both *E. coli* (Guan et al. 2008a; Ziaee et al. 2010) and *S. aureus* (Guan et al. 2008a), due to the disruption of cell membranes, which as in the case of chitosan is attributed to the cationic nature of the material, both when adsorbed onto cellulose fibers in paper sheets (Guan et al. 2008a) and recycled fibers (Ziaee et al. 2010). In adequate doses, these modified starches promoted a 100 % growth inhibition of the studied bacteria.

In another study implying the cationization of starch-based materials, quaternary phosphonium starch has been grafted with acrylamide and allyl triphenyl phosphonium bromide at different ratios by simultaneous gamma irradiation, and the resulting copolymers were tested against *S. aureus* (Song et al. 2013). The key factor influencing the antibacterial activity of the material was the degree of cationization, which demonstrated that the grafted starch derivatives with higher cationic degree were able to kill >99.75 % of the bacteria within 30–60 min.

Bursali et al. studied the preparation and antibacterial activity of casted films based on boron/starch/polyvinyl alcohol hydrogels by blending gelatinized starch with polyvinyl alcohol and boric acid with or without the addition of glutaraldehyde as cross-linking agent (Bursali et al. 2011). The best film formulations, incorporating boron complexes and glutaraldehyde, showed an antibacterial activity against *E. coli* comparable to that of the standard antibiotic erythromycin, whereas cross-linked films without boron complexes were not active. Starch/poly(vinyl alcohol) blends prepared by using citric acid as plasticizer and glutaraldehyde as the cross-linker have also been used to prepare composite films with cellulose as reinforcing agent (Priya et al. 2014). The good adhesion of the starch/poly(vinyl alcohol) blends to the fibers resulted in a composite with improved mechanical properties when compared to isolated starch/poly(vinyl alcohol) films. The composite films showed a good antibacterial activity against *S. aureus* and *E. coli*.

In another study, Mehyar et al. (2007) investigated the use of pea starch and calcium alginate incorporating trisodium phosphate and sodium chlorite as antibacterial coatings on chicken skin and demonstrated its effectiveness against *Salmonella* spp. It was verified that the antibacterial activity of the films was significantly higher than that of trisodium phosphate and sodium chlorite applied alone, which might be related with the high adhesion of the starch-based formulation, when compared to the isolated compounds that rapidly dripped from the skin.

4 Conclusion: Future Trends

The possibility of incorporating antibacterial agents either in surface coatings or within material matrices has attracted considerable global attention in recent years. For example, in the food preservation fields, antibacterial materials have been identified as one of the most promising forms of active packaging technologies. Also, in a context of fatal nosocomial and community-acquired infections, the development of antibacterial materials has opened novel opportunities to inhibit microbial adhesion and limit transmission. In addition, it would be highly desirable to really develop biodegradable (or even edible in case of food preservation fields)

and sustainable matrices capable of safe and long shelf-life integration of bioactive substances.

In this perspective, it is clear that biobased materials will act as an "added value" argument for the upward use of sustainable biomass-derived material components. The present appraisal clearly demonstrates that abundant polysaccharides can be used to effectively prepare antibacterial materials either by improving/modulating the properties of naturally antibacterial chitosan or by de novo conferring these properties to cellulose or starch. The combination of antibacterial activity with other well-known properties of these polysaccharides opens wide perspectives for the future development of innovative functional materials. In this context, nanomaterials and nanotechnology in general are emerging as powerful tools for the design of new materials with unique functional properties among which antibacterial activity will certainly be targeted with increased efficiency and specificity (Lagaron et al. 2012).

However, most of the research studies mentioned in this chapter have been carried out often in vitro and at a laboratory scale. Because antibacterial material efficiency may be influenced by interfering substances that inhibit the antibacterial action, it is thus necessary to conduct in vivo studies more frequently. Furthermore, the scale-up of the production of those materials that prove to be successful in vivo is also a big challenge to address in the coming years to allow them to be turned into marketable products.

To conclude, the development of bioactive materials based on a release-on-demand of antibacterials is a real new challenge. The release of antibacterial agents from materials in response to an increase in microbial population is still in the research phase, especially in the case of food preservation, and far from a final optimized commercial process. That is to say, the development of stimuli-responsive materials could be a very good opportunity for new preservation trends.

Modified Polysaccharides for Drug Delivery 57

Eleni K. Efthimiadou, Aikaterini-Foteini Metaxa, and George Kordas

Contents

Abstract

In recent decades, polysaccharides have come to play an important role in pharmaceutical science, among them in the domain of nanotechnology. As a result, there is an increased interest in their isolation, synthesis, modification, characterization, and application in this relevant new topic in nanotechnology. This has led to the use of modified polysaccharides in changing nanocomposite morphology and properties. Delivery of hydrophobic molecules, drugs, and proteins is difficult due to poor bioavailability following administration. Thus, modifications to natural polymeric carrier systems are being investigated to

improve drug solubility, stability, and induced toxicity. Due to problems of toxicity and immunogenicity, natural modified polysaccharides are being explored as substitutes for synthetic polymers in the development of new drug-delivery systems, such as coating or copolymer material. By conjugating different entities to the polysaccharide backbone, resultant materials can be used for preparing self-assembled micelles, coating polymeric microspheres, and self-reorganized nanostructures, improving drug release in tumoral areas.

Keywords

Drug delivery • Cytotoxicity • Polysaccharides • In-vitro and in vivo toxicity • Natural products • Bioactivity • Mechanism of action

1 Introduction

Many polysaccharides possess inherent bioactivity that can facilitate mucoadhesion, enhanced targeting of specific tissues, and reduced inflammatory response. Furthermore, the hydrophilic nature of a great number of polysaccharides can be exploited to enhance circulatory stability. This chapter describes the advantages of polysaccharide use in the development of drug-delivery systems and provides an overview of the polysaccharide-based micelles developed to date. Smart pH and thermonanocontainers modified by succinate cellulose (Metaxa et al. 2012) and dextran xerogel (Angelopoulou et al. 2012) were reported by Metaxa et al. and Angelopoulou et al., respectively. Despite these properties and advantages, some problems can occur. For example, chitosan is soluble in acidic media and therefore cannot be used as an insoluble sorbent under these conditions, except after physical and chemical modifications (Shahidi et al. 1999). To avoid this problem, different polysaccharide derivatives have been developed. Cyclodextrins, water-soluble in their native form, are often modified to prepare new insoluble derivatives. The hydrophilic nature of starch is also known to be a major constraint that seriously limits the development of starch-based materials. Chemical derivatization has been proposed as a way to solve this problem and to produce water-resistant materials. However, the strategy for modification depends on the proposed final purpose for the material. If a water-soluble starch derivative is desired for application in wastewater flocculation or as an additive in paper manufacturing, then a random conversion of hydroxyl groups to aminopropyl (Gonera et al. 2002), hydroxyalkyl (Wesslén and Wesslén 2002), or betaine (Auzély-Velty and Rinaudo 2003) is necessary. The use of nanotechnology not only changes the structures of polysaccharides but also changes functionality of the materials and their properties.

Many polysaccharide properties are yet to be discovered, and the application of nanotechnology may open up new horizons that can noticeably change every aspect of human life, and this includes use for polysaccharides found in the exoskeleton of crab, shrimp, prawn, lobster, squid pen, and other marine products. Despite the abundant availability in nature of polysaccharides, they have not yet been

completely accepted by the scientific community. This chapter deals with various polysaccharides and discusses their physical, chemical, and biological properties; characterization; synthesis of polysaccharide-based nanoparticles, nanospheres, and nanogels; and biomedical applications.

The idea of targeting drugs in the pathogen area is quite old and was first proposed by Paul Ehrlich (1854–1915) in the early twentieth century (Torchilin 2010; Park et al. 2010). Ehrlich was awarded the Nobel Prize in Medicine (1908) for his work in the field of immunization and his ideas for specific targeting of drugs, the inspiration for the 1940 film script "Dr. Ehrlich's Magic Bullet" (Arruebo et al. 2007). There are now several different approaches to specific targeting of therapeutic and diagnostic agents that permit direct drug transfer to the affected area (organ or tissue) (Torchilin 2010).

A drug delivery system allows the introduction of a therapeutic substance or diagnostic agent to the body and improves drug efficacy and safety, controlling pace, timing, and mode of delivery. Such systems are used to transfer diagnostic and therapeutic agents either on the experimental or clinical level (Torchilin 2009, 2006). In recent years, research has focused primarily on developing drug delivery systems with sizes in the range of nanometers (10^{-9} m) (Arruebo et al. 2007). Such systems are called nanoparticles and solid, colloidal, bodies, which are composed of macromolecules and range in size from 10 to 1,000 nm (Singh and Lillard 2009). The diameter of human cells ranges between 10 and 20 microns, while various structural units of the cell range from a few to several hundred nanometers. Therefore, nanoparticles carrying the drug may interact with biomolecules on the surface and inside the cell without causing irreversible damage to that (Kim 2005). Nanoparticles are able to offer a variety of useful properties:

1. Long life to the body, high stability of the systemic circulatory system, and improve drug solubility and biocompatibility
2. Targeting of pathogenic tissue and organs
3. Sensitivity to external stimuli (e.g., external heating effect of magnetic field or ultrasound), or to the pathogen stimuli area (e.g., changes in temperature, redox environment, or pH)
4. Transfer of a reporter that provides information on metabolism and with the ability to specifically target a system (Torchilin 2009, 2006; Singh and Lillard 2009; Torchilin 2007a, b)

Nanotechnology therefore may provide a solution to problems faced by conventional therapy, offering an effective alternative treatment and better patient quality of life (Kim 2005).

Nanoparticles for transport of drugs consist of a variety of materials. Natural and synthetic polymers have been used extensively (polymeric nanoparticles, micelles, dendrimers), inorganic materials such as oxides of gold, iron, and silicon (inorganic nanoparticles), lipids (liposomes), organometallic compounds (nanotubes), and even viruses (viral nanoparticles). The material that makes up nanospheres, can be synthetic or natural polymers, which must meet certain criteria. Initially, they

should be biodegradable or biocompatible to be excreted from the body in a short time and without the risk of uncontrolled accumulation. Furthermore, these polymers, and products of their metabolism, should not be toxic and or cause an immune response (Vauthier and Bouchemal 2009).

Among others, polymers primarily used for nanoparticle synthesis in drug delivery are (Edlund and Albertsson 2002):

1. Physical origin:
   - Polysaccharides
   - Proteins (e.g., collagen, gelatin, albumin)
2. Synthetic co-polymers (Vauthier and Bouchemal 2009)
   Aliphatic polyesters:
   - Polyglycolic acid poly(glycolide), PGA
   - Polylactide poly(lactide), PLA
   - Polylactide-polyglycolide copolymer oxeosPoly (glycolideco-lactide), PLGA
   - Polycaprolactone poly(e-caprolactone), PCL
   - Polyanhydride
   - Polyaminoacids

The pharmaceutical compound is dissolved and then trapped either within the sphere, in the polymer network, or linked to the polymer by chemical modification. Drug entrapment – ideally by a nanoparticulate drug system – must have high drug-retention capacity, which depends on a drug's material composition. Drug entrapment can be done in two ways: either by incorporation during nanosphere production (incorporation method), or adsorption during incubation with isotonic solution of the pharmaceutical compound (adsorption/absorption technique).

Drug encapsulation depends upon polymer network solubility, polymer molecular weight, and interactions between polymer and drug. For small molecules, investigations show a significant role in maximizing the amount that can be trapped is played by ionic interactions between the drug and the network hardware (Mohanraj and Chen 2006).

2 Bioactivity

Polysaccharides have several advantages over synthetic biopolymers for use as a basis for synthesis of new drug-delivery systems. They are nontoxic, have good biocompatibility, and low production costs (Doshi and Mitragotri 2009). It is a fact that a combination of polysaccharides with synthetic water-soluble polymers leads to production of materials with improved biochemical and mechanical properties (Nurkeeva et al. 2003). They can extend lifespan in the body, which increases absorption of the entrapped drug. For all the above reasons, polysaccharides

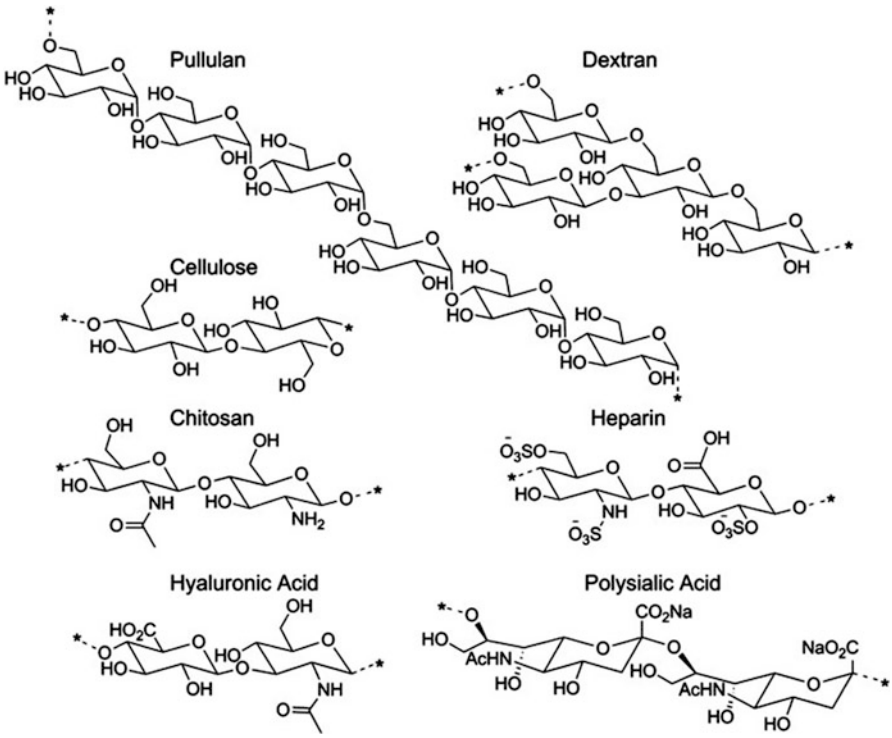

Fig. 1 Structures of polysaccharides used in the development of drug-delivery systems and the possible modified site (Zhang et al. 2013)

are ideal raw materials for synthesis of promising biomaterials in the field of drug-delivery systems (Fig. 1).

3 Bioactivity Induced by Polysaccharides' Modification

The purpose of chemical modification is to improve mechanical and chemical properties, biocompatibility, improved solubility, and control of biodegradability. In particular, modifications to polysaccharides have followed different approaches:

- Combination or chemical ligation with synthetic biopolymers
- Surface coating of micro- or nanosphere polysaccharides with biocompatible synthetic polymers
- Crosslinking with different types of reagents
- Increased hydrophobicity via alkylation reactions
- Configuring of glucuronic/mannuronic ratio, or of deacetylation degree, respectively (d'Ayala et al. 2008).

4 Cellulose

In 1838, the French chemist Anselme Payen isolated for the first time a solid plant tissue by treatment with acids and ammonia and the extraction thereof using water, alcohol, and ether. This solid residue was named *keloulozi* (cellulose) in 1839. The name means sugar (ose) combined with cell (from the English language) (Klemm et al. 2005; Pérez and Samain 2010a). Cellulose is a linear polysaccharide homopolymer of β-D-glucose (anhydrous D-glucopyranose). Structural cellulose units link with beta-1, 4 glycosidic bonds, forming long chains. Each cellulose molecule has three hydroxyl groups per glucose moiety, apart from the end edges (Williamson et al. 2002; Kamel 2008). Cellulose is the most common organic polymer in nature, with ~1.5 × 1,012 t of biomass being the structural component of the cell wall of green plants, certain species of algae, and some oomycetes (Pérez and Samain 2010b). In tall plants forming cellulose, microfiber has a diameter from 2 to 10 nm. Hydrogen bonds and forces, such as van der Waals force, stabilize microfibers and make them insoluble, chemically resistant, and mechanically robust (Williamson et al. 2002). Cellulose is located also in prokaryotes (*Acetobacter xylinum*, *Agrobacterium tumefaciens*, *Rhizobium* spp., *Escherichia coli*, *Klebsiella pneumoniae*, *Salmonella typhimurium*, *Sarcina ventriculi*) and eukaryotes.

Cellulose is insoluble in water and most common solvents. The poor solubility comes from the strong intermolecular and intramolecular hydrogen bonds developed between the independent polymeric chains. Although it is almost insoluble, it is used in many applications and is an almost inexhaustible source of raw material for the increasing demand for eco- and biocompatible products. Unlike carbohydrates with a low molar mass, reactions of cellulose are characterized by intermolecular interactions, cross-linking polymer, chain elongation, and effects of side-chain functional groups. Based on the literature, several chemical modifications of cellulose (cellulosics) have been reported (Kamel 2008). Cellulose derivatives are widely used in industrial-scale coatings, by optical films, for building materials, and in food, pharmaceutical, and cosmetic formulations. Also, because of its chirality, cellulose is for immobilization of proteins, antibodies, and heparin (HP), as well as for separating enantiomeric molecules and in the development of new synthetic materials with synthetic and natural polymers.

Cellulose is insoluble in water because of its high crystallinity. However, it may be converted to water-soluble polymer with various chemical modifications. Thanks to its structure and reactivity, cellulose can be designed and synthesized into a variety of new water-soluble polymers. Such derivatives are methylcellulose (MC), hydroxyethyl cellulose (HEC), hydroxypropyl cellulose (HPC), and hydroxypropyl methylcellulose (HPMC), all of which are commercially available (Nurkeeva et al. 2003). Chemical modification of cellulose is performed to develop derivatives of cellulose (cellulosics) that are broadly reactive, low cost, reproducible, recyclable, and biocompatible; therefore, it may be used for pharmaceutical applications. Cellulose derivatives are most commonly used to modify the release of drugs in tablet and capsule formulations; as a control agent for tablet binding,

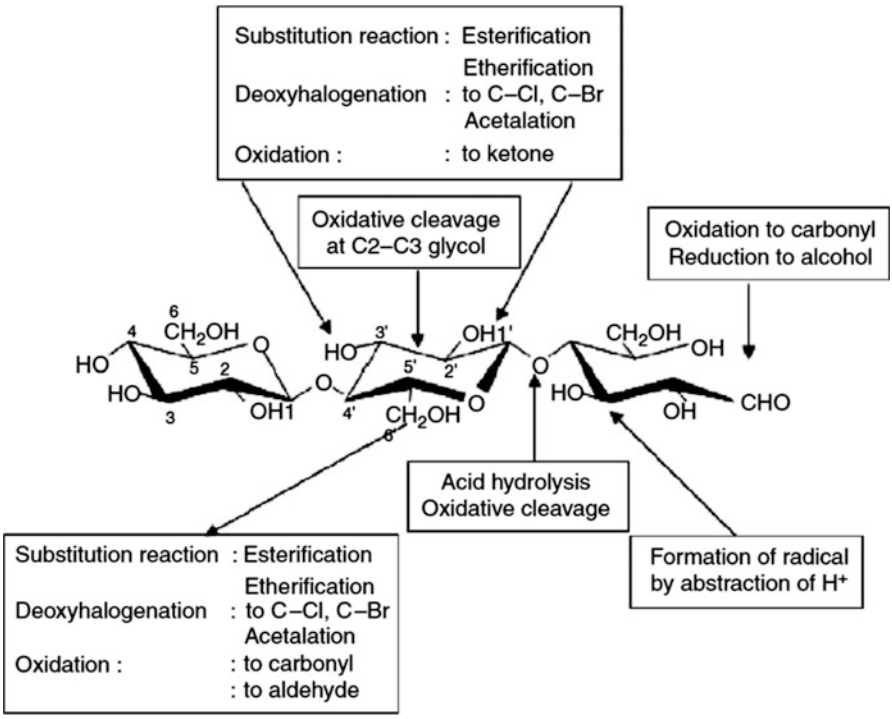

Fig. 2 Sites of cellulose modification (Pérez and Samain 2010b)

thickening, and rheology; for film formation, water retention, improving adhesive strength, and suspending and emulsifying (Kamel 2008; Fig. 2).

Hydroxypropyl cellulose (HPC) is a nonionic, biocompatible, and pH-sensitive derivative of cellulose (Kamel 2008). It is soluble in organic solvents and water but is sensitive to changes in temperature, with a minimum critical solubility temperature (LCST) in water of 41 °C (Cai et al. 2003). Hydroxypropyl cellulose used in ophthalmic formulations, mainly as a component of artificial tears.

Cellulose esters play a vital role in the development of modern drug-delivery technology. Their properties are well adapted to the needs of pharmaceutical applications and additionally permit the construction of drug-delivery systems that meet the basic needs of patients.

5 Chitin and Chitosan

Chitosan is a naturally occurring linear polysaccharide produced by alkaline deacetylation (Felt et al. 1998) of chitin, and in nature it is present only in some species of fungi (Mucoraceae) (Agnihotri et al. 2004). Chitin is the major component of the protective cuticle of crustaceans such as crab, shrimp, lobster, etc. (Felt

et al. 1998), and is a cell-wall component in certain fungi (Sinha et al. 2004; Dash et al. 2011). Nonetheless applications are minimal compared with cellulose and chitosan due to the absence of chemical activity (Agnihotri et al. 2004). Chitosan and chitin are linear polysaccharides structurally similar to cellulose, with replacement of the hydroxyl and amino groups with C6 acetyl-amido, respectively (Felt et al. 1998).

Chitin is a homopolymer of beta-(1,4)-*N*-acetyl-glucosamine, whereas chitosan is a copolymer of glucosamine and *N*-acetyl glucosamine linked by beta-1, 4 glycosidic bonds (Park et al. 2010). Generally, chitosan is provided in the form of dry flakes in solution or powder form. It has a molecular weight range between 3,800 and 20,000 Da and may have undergone deacetylation by 66–95 % (Agnihotri et al. 2004). Because amino groups can be charged positively, they can interact with negatively charged surfaces or polymers and metal ions, such as cobalt; these properties become useful in pharmaceutical applications (Agnihotri et al. 2004).

Chitosan is a cationic polysaccharide with both neutral and acidic pH. It has a weak base, is insoluble in water and organic solvents, but dissolves in a slightly acidic environment (pH <6.5). At low pH the amine is protonated and charged positively improving the chitosan solubility in aq. solutions. When the pH rises above 6.5, the amine is deprotonated, the polymer is discharged, and it becomes insoluble (Sinha et al. 2004). Therefore, chitosan precipitated in alkaline solution or polyanion solutions forms a gel at low pH. The degree of deacetylation and the molecular chitosan weight also affects the polymer solubility. After processing, chitosan becomes a stiff, crystalline structure due to the intramolecular and intermolecular hydrogen bonds.

Chitosan is a biocompatible and biodegradable polymer. It is not toxic, and has LD_{50} 16 g/kg body weight in experimental animals, and a price similar to sugar and salt. It is compatible with biological tissue and does not cause allergic reactions. Cleaved from enzymes into harmless products (amino sugars), they are absorbed fully from the human body without causing side effects (Kean and Thanou 2010). Chitosan has pharmacological properties, and its activity enhances wound healing, has an antiacid effect, and helps prevent stomach ulcers (Felt et al. 1998). It also has antimicrobial action and absorbs toxic metals, such as mercury, cadmium, and lead. Chitosan is used in dressings for protecting the injured eye, while membranes of chitosan films are used as artificial liver (Sinha et al. 2004). These properties make it ideally suited for medical and pharmaceutical purposes. For example, the properties of chitosan allow rapid blood clotting, and for this reason, it recently gained approval in the United States and Europe for use in bandages and hemostatic agents (Li et al. 2008).

A very important property of chitosan is its antimicrobial activity, which was effectively demonstrated against many bacteria, filamentous fungi, and yeasts. Chitosan has a wide spectrum of activity and high levels of Gram-positive and Gram-negative bacteria death, but exhibits low toxicity against mammalian cells. Ever since the broad-spectrum antibacterial activity of chitosan was first proposed by Allen (Allan and Hardwiger 1979), together with the significant commercial interest, the antimicrobial properties of chitosan and its derivatives have attracted great attention from researchers (Kong et al. 2010).

Although chitosan was discovered by the early nineteenth century, only in the last two decades has it been used in biological applications and drug-delivery systems, such as nanoparticle microspheres. Chitosan can be synthesized using various techniques and used to entrap drugs and release them in a controlled manner (Janes et al. 2001a). Spheres of chitosan can be synthesized by cross-linking with glutaraldehyde, formaldehyde (Jameela and Jayakrishnan 1995), and citric acid (Varshosaz and Alinagari 2005), and by the physical agent genipin extracted from the fruit of gardenia (Mi et al. 2002). Apart from the method of cross-linking, chitosan spheres are synthesized by techniques, such as multiple emulsion, solvent evaporation, coating deposition, successive bark chitosan, etc. (Lu et al. 2011; Fig. 3).

Chemical modification of chitosan is particularly interesting, as attached groups do not change the fundamental skeleton, thus maintaining the original physico-chemical and biochemical properties; while they may on the other hand lead to new and improved properties. Many modifications are reported in the literature, such as oligomerization, alkylation, acylation, hydroxy alkylation, carboxy alkylation, sulfation, phosphorylation, enzymatic modifications, copolymerizations, and many others. Chemical modification provides a wide range of derivatives with modified properties for specific applications in areas such as pharmaceutics, biomedicine, and biotechnology. A variety of modifications, including hybrids with chitosan, sugar, cyclodextrin, dendrimers, and crown ethers, have also emerged as interesting multifunctional macromolecules (Mourya and Inamdar 2008; Fig. 4).

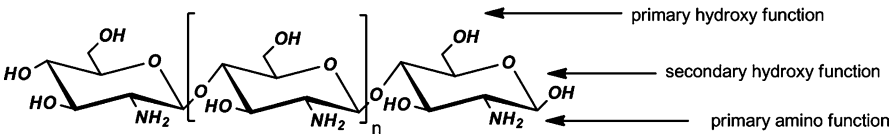

Fig. 4 Functional groups in chitosan

6 Glycosaminoglycans - Heparin

Glycosaminoglycans are a family of polysaccharides that normally cover the surface of all eukaryotic cells. Glycosaminoglycans (GAGs) are negatively charged polysaccharides composed of repeating disaccharide units. HP and heparan sulphate (HS) are related species of GAGs.

HP coupled with nanomaterials has recently been investigated for chemical and biological properties. HP improves the biocompatibility of nanoparticles and their performance in various biological applications. HP has coupled surface magnetic and metallic nanoparticles and biodegradable synthetic biopolymers. HP has also been entrapped in nanoparticles. These changes lead to the use of heparin in new applications ranging from improved anticoagulation, cancer treatment, tissue engineering, and biosensors (Kemp and Linhardt 2010).

7 Cross-Linked Polysaccharides

Polysaccharides and their derivatives can be covalently crosslinked to prepare nanoparticles for use as drug carriers. The cross-linking process involves formation of covalent bonds between function groups and functional cross-linking agents.

The free amino groups in chitosan contribute to its solubility in acidic media and in reactivity with physical and chemical cross-linkers. Glutaraldehyde cross-linked chitosan microspheres are very promising for controlled drug delivery for very long time release (Jameela and Jayakrishnan 1995), but its toxicity on cell viability limits its utility in the field of pharmaceutics (Liu et al. 2008).

Recently, other cross-linkers, such as genipin, glyoxal, and other polymers, have been examined for their possible applications in the biomedical field, but few studies are reported. Microspheres prepared with glyoxal were more hydrophobic, nonspherical, and smaller in size due to the high degree of cross-linking. These microspheres increased the controlled release period for centchroman (Ormeloxifene) in comparison with chitosan and glutaraldehyde cross-linked chitosan microspheres (Gupta and Jabrail 2006).

Chitosan has been successfully modified by condensation reaction using natural di- and tricarboxylic acids (succinic acid, malic acid, tartaric acid, and citric acid) and as cross-linking agents for intramolecular cross-linking of the chitosan linear chains, to form pH-sensitive nanoparticles (Bodnar et al. 2005). A novel

biocompatible chitosan derivative, *N*-succinyl-chitosan (NSCS), with a well-designed structure, has been successfully synthesized by Aiping et al. NSCS can self-assemble regular nanosphere morphology in distilled water, are nontoxic, and have cell-compatible properties (Aiping et al. 2006).

8 Polysaccharide Modification with Small Molecules

Generally, small molecules such as ligands on the surface of nanoparticles can be easily fitted and low cost. Their small size allows for the attachment of several molecules on a nanoparticle. Thus, while the online pharmaceutical compound with a ligand was limited to only a few ligand-binding properties, in contrast, connection of nanoparticles with linkers allows the introduction of thousands of such small molecules.

In the study of Zhang et al. 2007, chitosan was modified with oleoyl to prepare self-assembled nanoparticles with a diameter of ~250 nm and an almost spherical shape as carriers for hydrophobic antitumor agents. The antitumor drug doxorubicin was efficiently loaded into nanoparticles, and in vitro studies were subsequently performed (Aiping et al. 2006).

Choochottiros et al. studied the modification of the chitosan amine with phthalic anhydride and primary hydroxyl with polyethylene glycol and carbolytic acid (PEG-COOH) in order to synthesize amphiphilic-chitosan-monodispersed nanospheres (range 100–300 nm) with pH sensitivity. Incorporation of the model drug lidocaine into modified chitosan nanospheres was successful (Choochottiros et al. 2009).

Thiolated chitosan was synthesized by covalent attachment of glutathione (GSH) to chitosan by forming amide bonds between amine groups of chitosan and carboxylic acid of GSH. Poly(methyl methacrylate) nanoparticles coated with chitosan–glutathione, and the insoluble anticancer drug paclitaxel (PTX), was encapsulated in the nanoparticles (Akhlaghi et al. 2010).

In this context, molecules such as folic acid (Torchilin 2006, 2007b; Alexis et al. 2008) and various sugars are used extensively. The vitamin folic acid is essential for cell survival of these cells; for this reason, folate receptors are overexpressed in many types of cancer cells. The folate receptor (FR) interacts with folic acid on the surface of nanoparticles, resulting in endocytosis. This produces some problems for the potential clinical use of folic acid. Generally though, folic acid ligands are inexpensive, do not generate an immune response, are nontoxic, and easy to attach to the nanoparticles and is very stable in the bloodstream (Byrne et al. 2008). Nevertheless, immunochemical studies show that there is overexpression of folate receptors in normal tissue, such as liver and placenta (Sudimack and Lee 2000).

Mansouri et al. synthesized and characterized nanoparticles folate (FA)-chitosan-DNA and evaluated their cytotoxicity in vitro. Chitosan-DNA nanoparticles and FA-chitosan-DNA are prepared using reductive amidation and a complex process of aggregation. The authors concluded that FA-chitosan nanoparticles are promising candidates as nonviral gene vectors (Mansouri et al. 2006).

Some long-chain fatty acids, such as hexanoic acid, decanoic acid, linoleic acid, linolenic acid, palmitic acid, stearic acid, and oleic acid, have been used for modifying polysaccharides (Liu et al. 2008).

9 Graft Copolymerization

The ability of grafting synthetic polymers to polysaccharides has attracted attention in recent years, and useful derivatives have been developed. Graft copolymerization reactions introduce side chains and lead to the formation of novel types of hybrid materials composed of natural and synthetic polymers. HPC has been modified by attaching acrylates or degradable moieties as side groups. Through free-radical polymerization of side chains in aqueous solutions at temperatures above their LCST, the modified HPC network is cross-linked (Cai et al. 2003).

10 Composites and Hydrogels

Hydrogels are hydrophilic network structures that can absorb from 20 % to 1,000 times their weight in water. The ability of the network to maintain a large volume of water is considered one reason BC (BC) implants do not cause an immune response. BC hydrogels have great potential for biological application (e.g., cardiovascular implants, trauma, burns, and tissue-regeneration scaffolds). According to the study by Taxima et al., films of BC composite are produced by the addition of carboxymethyl (CM) cellulose, methyl cellulose, or polyethylene glycol to BC culture.

The cross-linking process of two cationic hydroxyethyl celluloses of different hydroxyethyl- and ammonium-group contents polyquaternium-4 (PQ-4) and PQ-10) with ethylene glycol diglycidyl ether (EGDE) was characterized and optimized. Hydrogels presented a significant loading capacity of diclofenac, with which they interrelate through ionic and hydrophobic interactions (Rodríguez et al. 2003).

11 Shelf Life and Stability of Nanoparticles in Systemic Circulation: Biocompatibility

Life within the organization plays an important role in drug-delivery systems. For the immune system, drug-delivery systems are "foreign," which become opsonizational before completing their function. For this and other reasons, properties of each nanoparticle are long life, stability, and – of course – biocompatibility. The longer the lifetime, the more stable and slower is drug release in the pathogen area. As well as long life in the circulation, leading to better drug targeting either passively or when using specific ligands that target receptors in the pathogen area, systems have more time available to act on the target (Torchilin 2006).

Prolongation of life nanoparticles into the organism occurs by modifying the surface with synthetic polymers, such as PEG. Coating nanoparticles with PEG results

in the formation of a polymeric layer over particle surfaces, which is impermeable to other solutes, even at relatively low polymer concentrations. "Steric stabilization" of PEG nanoparticles prevents interaction with blood components, thus preventing nanoparticle opsonization, phagocytosis, and their ability to capture reticuloendothelial system (RES). The term spatial (steric) stabilization was used to describe the protective capacity of PEG nanoparticles. As a protective polymer, PEG has a powerful combination of properties, such as excellent solubility in aqueous medium, flexible polymer chains, low toxicity, low accumulation in cells, and minimal impact on the pharmaceutical activity of the transported drug (Torchilin 2006).

Despite the fact that PEG is the most frequently used polymer for ensuring long life of drug-delivery systems, other biocompatible, soluble, and hydrophilic polymers are used to protect the nanoparticles. Other hydrophilic polymers used to protect and stabilize drug-delivery systems is the modified poly(acryl amide), poly (vinyl pyrrolidone) (PVP), poly(acryloyl morpholine) (PAM), poly(2-methyl-2-oxazoline), poly(2-ethyl-2-oxazoline), phosphatidyl polyglycerol, and polyvinyl alcohol (PVA).

A thermosensitive hydrogel was synthesized by block copolymerization of monomethoxy poly(ethylene glycol) macromere (PEG) onto a chitosan backbone using potassium persulfate as a free radical initiator. These block copolymers are promising and attractive materials for biomedical applications (Ganji and Abdekhodaie 2008).

11.1 Polysaccharides as Coating Materials

To the potential of nanoparticles in therapeutic applications, surface modification is most commonly used. Nanoparticles should ideally present a more hydrophilic surface in order to prevent macrophage capture (Cho et al. 2012), since the body recognizes hydrophobic moieties as foreign matter and quickly triggers the monocyte phagocytosis system (MPS). Therefore, covalent modification of nanoparticle surfaces with hydrophilic polymers avoids, or at least delays, the phagocytosis process (Lemarchand et al. 2004), thus improving circulation time, which increases the probability that nanoparticles will reach their target (Kumari et al. 2010). Using PEG or PEG-containing copolymers is the most common strategy to attain that objective. PEG is a hydrophilic nonionic polymer that presents high biocompatibility, biodegradability, and nontoxicity. PEGylation lowers the positive surface charge and decreases zeta potential, which increases nanoparticle physical stability and biocompatibility (Janes et al. 2001a). This methodology creates a hydrophilic layer around the nanostructure, thus avoiding protein absorption due to steric repulsive forces. However, the most important part of nanoparticle coating with PEG is increased circulation time, inducing the rate of sustained drug release.

Polysaccharide-coated nanoparticles are attractive candidates for biomedical applications due to their biocompatibility, biodegradability (Ladaviere et al. 2007), and application in drug-controlled delivery. Recognition of polysaccharide-coated nanoparticles is reduced by the MPS. As they are hydrophilic polymers,

polysaccharide coating induces stability in the blood circulation system (Ma et al. 2008). Other significant advantages of the nanoparticle coating with polysaccharides are their protection by steric forces. These forces protect nanoparticles against nonspecific interactions with proteins and against organ and tissue targeting in a specific manner due to their recognition and mucoadhesive properties (Ma et al. 2008). Polysaccharide coatings can then be considered as a promising alternative to PEG coatings, since they can be modified by specific targeting molecules (Lemarchand et al. 2004), thus improving the active targeting ability of nanoparticles. This is in contrast to pegylated nanoparticles, which require specific modification on their surface to enable molecular recognition and attain active targeting (Ma et al. 2008). Modification of such ligands to their surface is difficult due to lack of available groups. It is therefore more advantageous to use polysaccharide coatings, as they present many specific receptors in certain cells or tissues (Lemarchand et al. 2004). In addition, the polysaccharide-coated delivery system retains encapsulated drugs at the target site (Lemarchand et al. 2004). It is well known that polysaccharide-coated nanoparticles fabricate by dissolving in the aqueous phase in which they are prepared and/or by nanoprecipitation or solvent-emulsion evaporation (Lemarchand et al. 2004). It is worth noting that chitosan and its derivative, a main polysaccharide representative, are widely used by numerous scientific groups as coating agents for nanoparticles because of their high affinity for cell membranes and their positive charge, allowing strong adsorption into the nanoparticles (Janes et al. 2001a).

Dextran and heparin have been used to coat the surface of several nanoparticles for biomedical applications, such as cancer treatment, (Angelopoulou et al. 2012) having been proven to induce a decrease in protein adsorption and promote enhancement of nanocarrier blood-residence time.

In addition to the increasing new methods for cancer diagnosis and treatment, known as theranostics, advanced technologies for tumor imaging and early detection are also being explored by different groups (Metaxa et al. 2014).

11.1.1 Modification with Conjugated Drugs

Polysaccharides are extremely amenable to modification. There are many examples of modified polysaccharides used in drug-delivery systems, indicating that polysaccharides are easily modified. Among them, glucose-based polysaccharides, such as amylose, amylopectin, glycogen, and cellulose, offer an abundance of free reactive hydroxyl groups. Other polysaccharides possess both hydroxyl and carboxylic acid moieties that can be readily modified. A review recently published focused on the derivatization of alginate, a polysaccharide composed of β-D-mannuronic acid and α-L-guluronic acid with 1,4 linkages. Modification of alginate can be used to induce a variety of different physiological behaviors. For instance, oxidation of hydroxylic groups enhances their biodegradability, while sulfonation generates a heparin-like polysaccharide with increased blood flow.

Modification of chitosan has also been extensively reviewed. Specifically, modification of the primary amino segment with various alkyl groups can be used to improve solubility and bioactivity (Zhang et al. 2013). Many types of modified drug

polymers are synthesized by insoluble drugs and water-soluble polymers that are chemically conjugated to the drug via a biodegradable spacer. These spacers are selected to be stable in the bloodstream but cleaved at the target site by hydrolysis or enzymatic degradation, thus improving local drug release and avoiding serious side effects. Such drug conjugates can be selectively accumulated at the tumor site by the enhanced permeability and retention (EPR) effects, followed by the above-described mechanism. Based on this concept, several polymer–drug conjugates have recently entered into phase I/II clinical trials. The representative example is *N*-(2-hydroxypropyl) methacrylamide (HPMA) copolymer-based drug conjugates, such as HPMA copolymer–doxorubicin conjugate (PK1) and HPMA copolymer–doxorubicin conjugate containing galactosamine as a targeting moiety (PK2) developed for treating primary or secondary liver cancer. Based on this data, many types of chitosan-conjugated drugs have been investigated. A characteristic example, doxorubicin (Dox) conjugated with specific modified glycol chitosan through carbodiimide chemistry, was reported by Son (Son 2003; Table 1).

11.1.2 Mechanism of Action

Active Targeting Agents

The major problem with traditional cancer chemotherapeutics is the high toxicity due to indiscriminate distribution of drugs to disease and healthy cells alike following systemic administration. Anticancer drugs are poorly solubility in water, as described previously, and thus require organic solvents or detergents for clinical application, resulting in undesirable side effects such as venous irritation and respiratory distress (Zhang et al. 2013). Therefore, designing a distinct carrier system that encapsulates a large quantity of drugs and specifically targets tumor cells is indispensable for successful cancer therapy. Micelles of appropriate size, charge, and shape will facilitate improved delivery. However, this may not be enough due to defenses within the human body. To enhance target-site accumulation and uptake, additional targeting agents are often incorporated into micelle systems. Active targeting agents used in polysaccharide-based micelles can be divided into three categories: peptides, small molecules, and polysaccharides. Peptides include octreotide targeting for somatostatin receptors on tumor cells, the A54 hepatocarcinoma-binding peptide (Yuan et al. 2011), and arginylglycylaspartic acid [Arg-Gly-Asp (RGD)] containing peptide for $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins (Zhang et al. 2013; Du et al. 2011, 2012). Small molecules include glycyrrhetinic acid, a liver targeting ligand; vitamin E succinate-specific toxicity to tumor cells (Wydra and Rudolph 1992); and folic acid with a high affinity to the folate receptor, which is overexpressed on tumor cells (Metaxa et al. 2012).

Through peptide and small-molecule conjugation, nanostructuring systems have shown higher tumor accumulation and cellular uptake than blank nanostructures. It is worth mentioning that polysaccharides themselves can act as active targeting agents due to their bioactivity. As described in the literature, hyaluronan (HA) has a high affinity to the HA receptor on liver sinusoidal endothelial cells and the CD44 receptor that is overexpressed on tumor cells and inflamed synovial fibroblasts.

Table 1 Polysaccharides as pharmaceutical components (Maier et al. 2013)

Polysaccharide	Main chains	Side chains	Source	Comments
Amylose	α-1,4 D-glucose	–	Storage polysaccharide in plants	Unbranched; one of the constituents of starch; used in traditional pharmacy as tablet excipients, degraded by *Bacteroids*, *Bifidobacterium*
Arabinogalactan	β-1,4 and β-1,3 D-galactose	β-1, s and β-1,3 L-arabinose and D-galactose	Plant cell walls	Neutral pectin; hemicellulose; used as thickening agent in food industry, degraded by *Bifidobacterium*
Carrageenan	Galactose residues which are sulfated and alternatively linked in α-1,3 and β-1,4 linkage	The 4 linked residues can be 3,6 anhydro-D-galactose and 3-linked residues are at least partly 4 sulfated	Sea weed extract	–
Chitosan	Deacetylated β-1,4 *N*-acetyl-D-glucosamine	–	Shell of marine invertebrates	Deacetylated chitin; used in medicine as tablet component and absorption enhancing agent, degraded by *Bacteroids*
Chondroitin sulfate	β-1,3 D-glucuronic acid and *N*-acetyl- D-glucosamine	–	Epithelial cells	Mucopolysaccharide, connected to a protein core; contains various amounts of sulfate ester groups at the 4- or 6-position, degraded by *Bacteroids*
Dextran	α-1,6 D-glucose	α-1,3 D-glucose	Bacterial (*Leuconostoc* and *Streptococcus*)	Used in medicine as plasma expander, degraded by *Bacteroids*
Furcelleran	Composed of D-galactose and 3,6-anhydro-D-galactose, with sulfate ester groups on both sugar components	–	Sea weed extract (*Furcelleria fastigiata*)	–

Therefore, HA has been extensively investigated as an active targeting agent to tumor tissue and liver in many micelle systems (Crini 2005). In addition, heparin-based nanostructures have demonstrated enhanced inhibition of tumor growth and angiogenesis (Huang et al. 2012), while cellulose (Hsieh et al. 2008), chitosan (Ilium 1998), and pullulan-based systems promoted drug absorption across the small intestine due to enhanced mucoadhesion (Zhang et al. 2013).

Passive Targeting

The EPR concept dates back to the late 1970s, when Maeda et al. (see [60]) investigated the selective accumulation of macromolecular drugs in tumor tissues. The specific passive accumulation of macromolecules was attributed to defective tumor vasculature with disorganized endothelium at the tumor site and a poor lymphatic drainage system. Since then, researchers have capitalized on this concept for the delivery of various drugs by conjugating them with polymers or encapsulating them within nanoparticles. Nowadays, it is evident that long-circulating macromolecules (polymer–drug conjugates) and nano-sized particulates (such as micelles, nanospheres, and liposomes) accumulate passively in tumors due to the EPR effect (Son 2003). Hydrophilic drug-delivery systems are less readily absorbed by normal tissues. However, they can accumulate in cancerous tissues through the EPR effect. Cancerous tissues exhibit defective, leaky hypervasculature and deficient lymphatic drainage (Son 2003), which results in passive accumulation of nanometer-sized entities in these tissues. This EPR effect serves to localize drugs to cancerous tissues and decrease their toxicity on normal tissues.

Polysaccharides are promising alternatives to PEG because they contain a variety of functional groups (hydroxyl, amino, and carboxylic acid) that can be used for drug conjugation, nanostructure coating, and self-assembly. The advantage of polysaccharide use is the resultant surface charge in carriers that can be used to engineer biointeractions, such as cellular uptake or glomerular filtration. There are two types of charged polysaccharides, cationic and anionic, due to the fact that polysaccharides are polyelectrolytes (Luo and Wang 2014). Cationic polysaccharides promote endocytic uptake by cells, whereas anionic polysaccharides could increase bioavailability by reducing excretion through the glomerular capillary wall. Negatively charged species are less filterable because of the negative charge of the glomerular membrane. Some charge-reversible and pH-responsive polysaccharides (Jeanes et al. 1961) discussed in this chapter can be used to achieve both these functionalities (Fig. 5).

Toxicity of Modified Polysaccharides Used in Drug Delivery Systems

It is well known that many natural polysaccharides are considered as being nontoxic, biologically compatible, polymers (Park et al. 2003; Janes et al. 2001b; Thanou et al. 2001), which can be used broadly as drug-delivery systems. Among them are many types that are approved for dietary applications in Japan, Italy, and Finland, and it was approved by the US Food and Drug Administration (FDA) for use in wound dressings. However, certain modifications could make them more or less toxic, and any residual reactants should be removed carefully. The use of

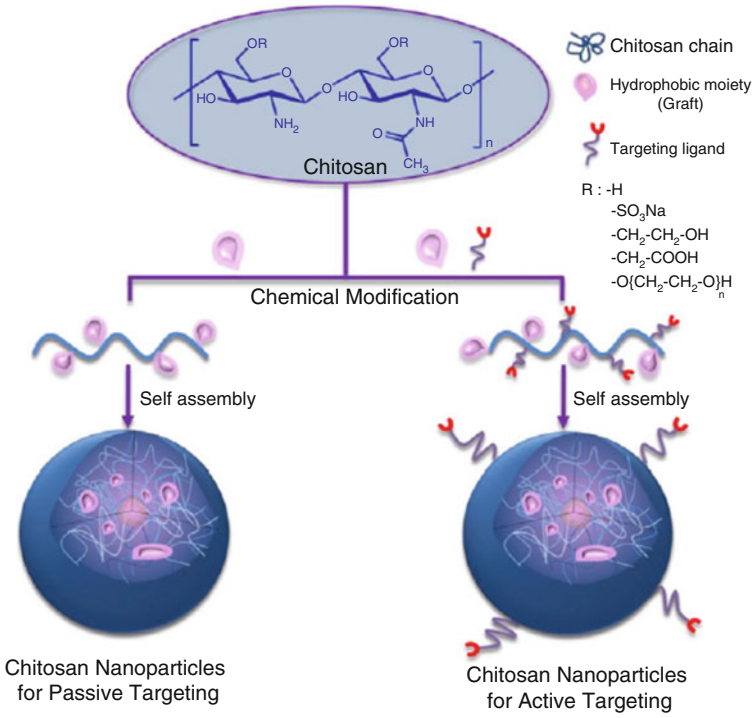

Fig. 5 Self-assembled chitosan nanoparticles for passive or active cancer targeting (Patel 2010)

hydrophilic polymers as drug carriers also helps lower drug toxicity. Zhang et al. prepared pH-responsive chitosan-based microgels (<200 nm diameter) by ionically cross-linking *N*-[(2-hydroxy-3-trimethyl ammonium)propyl chitosan chloride in the presence of tripolyphosphate (Zhang et al. 2006). These microgels were loaded with methotrexate and conjugated to apo-transferrin. The authors demonstrated that the conjugated microgels exhibited a significant increase in HeLa cell mortality compared with nonconjugated microgels. This was ascribed not only to receptor-mediated endocytosis of conjugated microgels, but also to pH-mediated release of methotrexate from microgels due to their swelling at the intracellular level. Chitosan-based micelles demonstrated to be a relatively safe carrier for oral formulation (Sonaje et al. 2011). Chitosan-based micelle systems have also been investigated for applications in antivirus (Huang et al. 2011), antithrombogenicity (Lin et al. 2011), and antiplatelet aggregation (Jiang et al. 2012; Fig. 6).

Aiming at increasing local drug release through polysaccharides, another type of modification was performed by Pankhurst et al. (2003) and Salata (2004). Magnetic targeting, an attractive physical technique, presents substantial attention for drug-delivery applications. Here, therapeutic agents to be delivered are either immobilized on the surface or encapsulated into the magnetic micro- or nanoparticulate

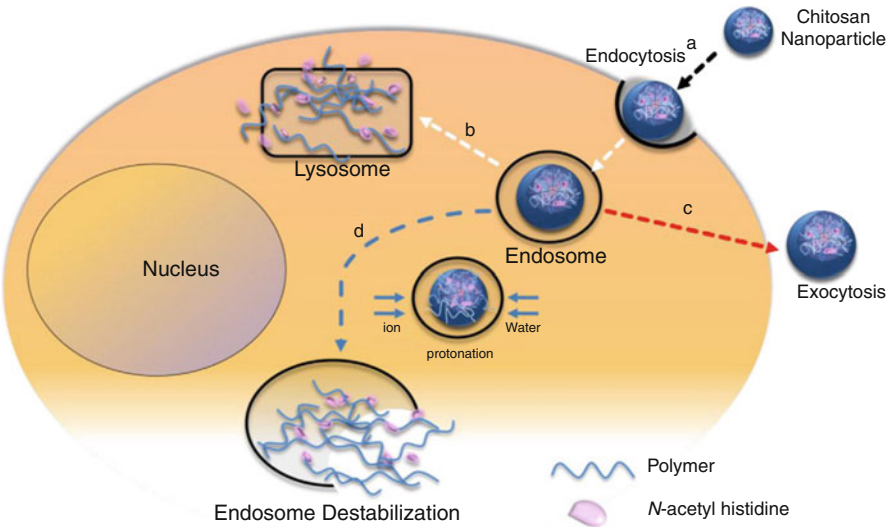

Fig. 6 A proposed model for cellular internalization and drug release of polysaccharide nanoparticles (Patel 2010)

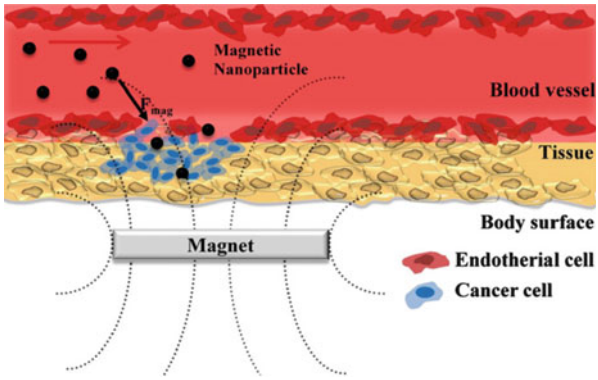

Fig. 7 Magnetic micro- or nanoparticulate polysaccharide carriers (Patel 2010)

polysaccharide carriers. These magnetic carriers, upon intravenous administration, concentrate at the specific site of interest (tumor site) using an external high-gradient magnetic field (Fig. 7). After accumulation of the magnetic carrier at the target tumor site in vivo, drugs are released from the magnetic carrier and effectively taken up by the tumor cells. A smart magnetic nanoparticle based on chitosan modification has been performed aiming at applying this type of targeting, thus increasing in vitro drug release.

In vitro Toxicity

Many groups investigated the toxicity of polysaccharides and their derivatives used in drug-delivery systems. Factors being considered are polymer molecular weight,

hydrophilicity, biocompatibility, and the conjugate system. Schipper et al. observed the effects of chitosan samples characterized by different molecular weights and drug delivery on CaCo-2 cells, HT29-H, and in situ rat jejunum. Toxicity was dependent on drug delivery and molecular weight. At high drug delivery, toxicity was related to molecular weight and concentration; at lower drug delivery, toxicity was less pronounced and less related to molecular weight. Nevertheless, most chitosans tested did not significantly increase dehydrogenase activity in the concentration range tested (1–500 g/ml) on CaCo-2 cells. The in situ rat jejunum study showed no increase in lactate dehydrogenase (LDH) activity with any chitosan sample tested (50 g/ml) (Zhang et al. 2007).

Red blood cell hemolysis assay is a study that reveals material safety. No hemolysis was observed (<10 %) over 1 h and 5 h with chitosans of <5 kDa, 5–10 kDa, or >10 kDa at concentrations up to 5 mg/ml. Furthermore, no red blood cell lysis was observed with paclitaxel–chitosan micelles at 0.025 mg/ml (Qu et al. 2009). In order to assess the intrinsic cytotoxic behavior of ulvan extracts, different standard cytotoxic strategies were followed, including evaluation of cellular viability by [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium, inner salt; MTS] (MTS) test and number, through double-stranded DNA (dsDNA), and total protein quantification. Furthermore, biological performance of ulvan was evaluated and compared to HA, a nontoxic, well-established polysaccharide, as control material due to its application in the biomedical field (Alves et al. 2013).

Polysaccharide-anchored liposomes are well documented and mostly studied as a model to for cell–cell adhesion; recently, however, they are being studied also for varied therapeutic potentials. Considering the potential of natural or hydrophobized polysaccharides, methods have been developed to link polysaccharides to liposome surfaces (Sihorkar and Vyas 2001).

Polysaccharide-anchored liposomes have been studied as stable and targetable drug carriers adaptable in effective chemotherapy, particularly for introducing chemotherapeutics into target cells or tumor cell lines. These systems possess a unique targeting ability to specific tissues, such as alveolar macrophages and other macrophages of the RES (Moreira et al. 1996). Polysaccharide-anchored liposomes could be employed as carrier constructs onto which a site-specific sensing molecule(s) like monoclonal antibodies (MAb) against tumor surface antigens could be physically or chemically attached (Sato and Sunamoto 1992). As a characteristic example, chitosan presents biological characteristics, such as low or no toxicity, biocompatibility, biodegradability, low immunogenicity, and antimicrobial properties. It can be hydrolyzed by lysozyme, and the degraded products of chitosan (amino sugars) are also nontoxic, nonimmunogenic, and noncarcinogenic, being completely absorbed by the human body (Wilson et al. 2010). Its rare positive charge converts chitosan into a special polysaccharide, as it provides strong electrostatic interaction with negatively charged mucosal surfaces and macromolecules such as DNA and RNA (Felt et al. 1998; Morille et al. 2008), which is an attractive feature for treating solid tumors (Li et al. 2009).

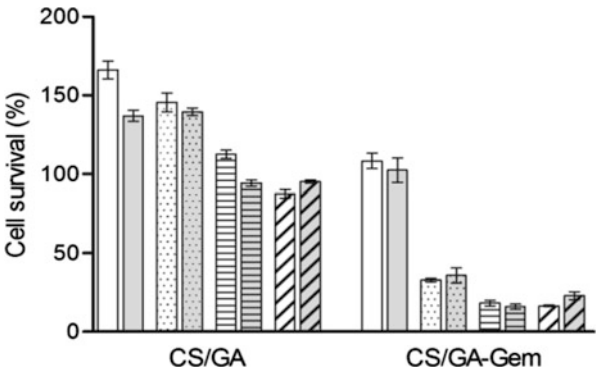

Fig. 8 Percentage of cell survival by treatment with free and chitosan-conjugated gemcitabine

The in vitro cytotoxic effects on a pancreatic-cancer cell line upon treatment with gemcitabine entrapped in prepared chitosan/glucoamylase (CS/GA) and polysorbate-80-coated CS/GA nanoparticles were assessed, comparatively to the free drug, in terms of cell survival and growth. Bare CS/GA (+p80 0.20) nanoformulations showed no deleterious effect on cell viability in this human pancreatic cell line. Moreover, paclitaxel (PTX)-loaded *N*-octyl-*N*-phthalyl-3,6-*O*-(2-hydroxypropyl) chitosan (OPHPC) micelles (PTX-OPHPC) with well-defined spherical shape and homogeneous distribution exhibited drug-loading rates ranging from 33.6 % to 45.3 % and entrapment efficiency from 50.5 % to 82.8 %. In cellular-uptake studies, PTX-OPHPC brought about a significantly higher amount of PTX accumulated in human breast adenocarcinoma cell line [Michigan Cancer Foundation-7 (MCF-7) cells] compared with Taxol®. Moreover, cellular uptake of PTX in PTX-loaded FA-OPHPC micelles (PTX-FA-OPHPC) was 3.2-fold improved in comparison with that of PTX-OPHPC. Results revealed that OPHPC micelles might be promising drug carriers for promoting PTX cellular uptake and that FA-OPHPC micelles could be used as potential tumor-targeted drug vectors (Qu et al. 2013).

The attained results (Fig. 8) showed that free gemcitabine presents the lowest IC50 and GI50 values. Nonetheless, CS/GA and p80-coated CS/GA nanoparticles loaded with gemcitabine were also effective at decreasing cell survival and inhibiting cell growth.

Microbial Toxicity

Interestingly, chitosan and its derivatives seem to be toxic to several bacteria (Miyazaki et al. 1992), fungi (Miyazaki et al. 1992), and parasites. This pathogen-related toxicity is an effect that could be beneficial in the control of infectious diseases. Bacterial inhibition took place in acidic solutions pH 5–5.3, and a 87.92 % kDa drug-distribution chitosan was more effective than a 532 kDa 73 % drug-distribution chitosan against both *Pseudomonas aeruginosa* and *Staphylococcus aureus*. Antimycotic effects against *Candida albicans* and *Aspergillus niger* was observed in a lipid emulsion of the same chitosans (Patel et al. 2010).

However, none of these studies proposed a mechanism of action for the observed inhibitory effect (Chourasia and Jain 2004).

Among the different approaches to achieve targeted drug release to the colon, the use of polymers especially biodegradable by colonic bacteria holds great promise. Polysaccharidases are bacterial enzymes that are available in sufficient quantity to be exploited in colon-targeting drugs. Based on this approach, various polysaccharides have been investigated for colon-specific drug release. These polysaccharides include pectin, guar gum, amylose, inulin, dextran, chitosan, and chondroitin sulphate. This family of natural polymers has an appeal to drug delivery, as it comprises polymers with a large number of derivatizable groups, a wide range of molecular weights, varying chemical compositions, and – for the most part – low toxicity and biodegradability and yet have high stability. The most favorable property of these materials is their approval as pharmaceutical excipients (Chourasia and Jain 2004).

11.1.3 Cancer Cell Toxicity

In vivo Toxicity

Living organisms are rich in carbohydrates. The wide chemical and functional diversity of these molecules is related to a rather large source base, which ranges from microbial to animal origin. Carbohydrates that form the structural basis of algae represent a unique group of gel-forming and viscous polymers, which are found neither in higher plants nor are digestible by nonruminant animals (Aiping et al. 2006) Industrial and technological applications of these marine carbohydrates include, among others, the food industry and aesthetics or biomedical devices. In fact, the use of natural-origin polymers on the development of novel biomaterials has already proven their feasibility and applicability, particularly in medical-related areas, including tissue-engineering applications (Dash et al. 2011).

Additionally, there are many references related to liposomes coated with various oligosaccharides and yeast-derived mannan, showing they drastically enhance induction of ovalbumin (OVA)-specific delayed-type footpad swelling response in Balb/c mice, with a peak at 24–48 host challenge. The mannan-coated liposome was included in the study as a reference to compare the effects of various neoglycolipids for their augmentation of a delayed response type. It is possible that the receptor–mannose interaction of oligomannose- or mannan-anchored liposomes might have augmented the processing of OVA reconstituted in these liposomes. In addition, mannose residues may possess some other activity, such as stimulation of IL-12 release, culminating in the activation of T lymphocytes. Only those neoglycolipids (oligosaccharides) with mannose residues at nonreducing termini were effective. However, these authors suggested that instead of using mannan, which can elicit antibody and B-cell mitosis (immunogenic) and toxic effects on i.v. administration, safer neoglycolipids – such as oligomannose – that are ubiquitously found in the body should be used as an adjuvant for the induction of cell-mediated immunity.

Recently, Venketesan and Vyas (Venketesan 2000) rationalized the role of polysaccharide-anchored liposomes in enhancing the immunogenicity of the

model antigen after oral administration. Results were compared in terms of serum immunoglobulin (Ig)G and IgA titers against bovine serum albumin (BSA) administered as control, in both plain and anchored formulations. Coating liposomes with these hydrophobized polysaccharides can be performed by incubation of aqueous solutions of polysaccharide derivatives with preformed liposomal dispersion. In some cases, cholesterol-substituted polysaccharide was used to conjugate sensory devices like sialic acid derivative or an IgM fragment. The sialic-acid-conjugated cholesterol-substituted polysaccharide or immunopolysaccharide derivatives were subsequently anchored over liposomes with the dispersion–incubation technique under optimized standard conditions. The earliest biologically active substance of marine origin was a toxin named holothurin, which was extracted by Nigrelli et al. from a marine organism, the *Actinopyga agassizi* (Nigrelli et al. 1967).

Holothurin showed some antitumor activities in mice. Since then, the search for drugs and natural products of interest from marine organisms has continued. The field of natural polysaccharides of marine origin is already large and expanding. Seaweeds are the most abundant source of polysaccharides, as are alginates, agar, agarose, and carrageenans. However, the literature lacks in vivo data in terms of drug delivery from these dosage forms, which makes it difficult to be conclusive in terms of their effectiveness as drug carriers at this stage. Since some work has been done on in vitro–in vivo correlations with chemically cross-linked chitosan hydrogels with successful and sustained drug delivery in animals, it is anticipated that optimized chitosan-based polyelectrolyte complexes may also perform up to expectation for in vivo drug delivery (Ladaviere et al. 2007; Du et al. 2011).

Bioavailability and Metabolism

In contrast to many synthetic polymers, polysaccharides have very low (if any) toxicity levels. For example, among the resorbable polymers, dextran is a natural polysaccharide that has gained interest in biomedical applications owing to its cell biocompatibility and nontoxic and antibacterial properties (Angelopoulou et al. 2012). The degradation products of polysaccharides are metabolized by human enzymes, mainly lysozyme (Angelopoulou et al. 2012). Dextrans are biopolymers composed of glucose with α-1,6 linkages, with possible branching from α-1,2, α-1,3, and α-1,4 linkages, which exhibit low toxicity and high biocompatibility. Consequently, dextrans have formed the basis of biocompatible hydrogels for controlled prolonged therapeutic release (Podder et al. 1988). Likewise, dextran has exhibited biocompatibility when formulated into microspheres, as suggested by a lack of inflammatory response following subcutaneous injection into rats (Sato and Sunamoto 1992; Saito et al. 2003; Jones 1994). Also, owing to their native presence within the body, most polysaccharides are subject to enzymatic degradation. Through enzyme catalysis, polysaccharides can be broken down to their monomer or oligomer building blocks and recycled for use as storage, structural support, or even cell-signaling applications (Nurkeeva et al. 2003). For example, glycosidases are common, constituting 1–3 % of the human genome (d'Ayala et al. 2008), and can readily catalyze the hydrolysis of many different glycosidic linkages (Nurkeeva et al. 2003). In contrast to

glycosidase, other enzymes are more polysaccharide specific. Hyaluronidase, for instance, specifically degrades the polysaccharide HA by cleaving β-1,4 linkages between D-glucuronic acid and D-*N*-acetylglucosamine, particularly in regions of high HA concentration (Necas et al. 2008). Of note, some polysaccharides are particularly susceptible to degradation by lysosomal enzymes following endocytosis, including glycosidases, esterases, and proteases (Stern 2003). For example, lysozyme, *N*-acetyl-β-D-glucosaminidase, and a range of proteases play a role in the degradation of chitosan (PÉrez and Samain 2010a; Williamson et al. 2002) Thus, enzymatic degradation provides a mechanism of release for therapeutics associated with polysaccharide-based carrier systems. Recently reported is the synthesis of a D-glucose-sensitive dextran hydrogel containing concanavalin A demonstrating that diffusion of proteins (insulin, lysozyme, and BSA) through this gel varied with D-glucose concentration (Zhang et al. 2005). Dextran-based hydrogel incorporating carboxyl groups was prepared using carbodiimide chemistry and cast into membranes. Zhang et al. presented a novel pH-responsive dextran hydrogel produced by the intermolecular cross-linking of CM dextran using carbodiimide chemistry and *N*-hydroxysuccinimide (NHS) as a biocompatible dextran drug-delivery system (Angelopoulou et al. 2012). The diffusion rate of proteins through the membranes is influenced by pH, increasing as pH increases, due to loosening of the gel structure resulting from mutual repulsion of ionized carboxyl groups. Protein diffusion rates through hydrogel membranes are also sensitive to changes in ionic strength. This response appears as a bell-shaped curve, increasing at low ionic strengths, and then decreasing as ionic effects swamp the charge-repulsion effects. The hydrogel is formed by esteric bonds between hydroxyl and carboxyl in CM-dextran in the presence of *N*′-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC) and NHS. The formed ester bonds can be frocked, and they release the desired entity (Angelopoulou et al. 2012).

Other Biological Activities

According to the literature (Zhang et al. 2013), many scientific approaches aim at achieving high therapeutic efficacy through new drug-delivery systems, which increase circulation time in the body, ensuring an effective concentration at the target site. However, results are not convincing regarding immune-system toxicity, and studies are ongoing regarding free drugs and various carrier systems for interaction with plasma proteins causing rapidly clearance. To minimize clearance and prolong drug circulation, PEG has been conjugated or coated on many drug-delivery systems. For example, studies show that PEG protected octyl-succinyl-chitosan from plasma protein (Qu et al. 2009) and that PEG modification could prolong HA-ceramide circulation (Cho et al. 2012). Moreover, PEG could inhibit liver uptake of HA-conjugated micelles, thereby increasing systemic circulation (Le Droumaguet et al. 2011). Another example of the PEG-conjugated polysaccharide system is PEGylated chitosan nanoparticles, which have been investigated as carriers for diverse, small-molecular drugs, such as paclitaxel, camptothecin, methotrexate, and all-trans retinoic acid (ATRA) (Sun et al. 2012). The effect of PEG conjugation

on PTX-loaded *N*-octyl-sulfate chitosan nanoparticles was investigated by Qu et al. (2009). Despite demonstrable improvements relative to unmodified systems, there are potential drawbacks of PEG usage, such as the nonbiodegradable PEG backbone, continuous accumulation in the body, and possible induction of an immune response In addition, the PEG coating may interfere with cellular uptake of drugs because PEG has been reported to reduce drug–cell interaction and hinder drug release from carrier systems (Luo and Wang 2014). Other hydrophilic, biodegradable, nontoxic, and nonimmunogenic molecules are being sought as an alternative. For example, polysialic acid (PSA) meets all of the latter criteria, and – of equal importance – PSA has no known receptors in the human body, suggesting the possibility for further improvement in circulatory stability. A series of PSA-protein conjugates has been investigated, which shows prolonged circulation of insulin (Zhang et al. 2013), asparaginase (Jain 2007), and catalase (Cho et al. 2012). Recently, Zhang et al. synthesized PSA-based micelle systems for future applications in drug delivery (Zhang et al. 2013).

Clinical Trials

Early results from clinical trials suggest that micelles should be designed and developed with careful attention toward material selection. Ideally, micelles developed for drug delivery should be biodegradable and have high stability, high biocompatibility, and low immunogenicity. Natural polysaccharides meet the latter requirements and can be used to develop micelles in lieu of synthetic polymers. In addition, polysaccharides can be readily modified and exist in positive-, negative-, or neutral-charge states (Zhang et al. 2013). Finally, some polysaccharides are bioactive and can be used to augment the therapeutic efficacy of an associated drug or can enhance the targeting ability of a carrier system (Joke Vandorpe et al. 1997; Gref et al. 1994). Despite these advantages, polysaccharide-based micelle systems are still under development, and outcomes have not met clinical requirements.

12 Conclusions

Nowadays, polysaccharides are the focus of attention in many areas of research. Polysaccharides of marine origin are playing a central role, as the marine environment represents an open source of attractive molecules with potential applicability in many fields of interest. Examples of these are chitin and its derivative chitosan, alginate, carrageenan, agar, and collagen, among others. Since Ehrlich suggested the concept of a “magic bullet” (Torchilin 2010; Park et al. 2010), many research scientists have attempted to develop drugs that selectively destroy disease cells but are not harmful to healthy cells. However, prior to any application development, every polysaccharide should undergo cytotoxicity screening. For the development of such targeted delivery systems, chitosan and its derivatives possess various advantages, such as biocompatibility, biodegradability, mucoadhesivity, and other

unique biological properties. Over the last decade, increasing attention has been paid to the development of systems to deliver drugs for long periods at controlled rates. Some of these systems can deliver drugs continuously for >1 year. However, little effort has been given to developing systems for the controlled release of nucleic acids. Recently, a novel gene-transfer method that allows prolonged release and expression of plasmid DNA in vivo in normal adult animals was established. In this system, a biocompatible natural polymer such as collagen or its derivatives acts as the carrier for the delivery of DNA vectors. The biomaterial carrying the plasmid DNA was administered to animals, and once introduced, gradually released plasmid DNA in vivo. A single injection of plasmid DNA biomaterial produced physiologically significant levels of gene-encoding proteins in the local and systemic circulation of animals and resulted in prolonged biological effects.

Chitosan has been the subject of interest for its use as a polymeric drug carrier material in dosage-form design due to its appealing properties, such as biocompatibility, biodegradability, low toxicity, and relatively low production cost from abundant natural sources. However, one drawback of using these natural polysaccharides in modified-release dosage forms for oral administration is its fast dissolution rate in the stomach. Since chitosan is positively charged at low pH values (below its pKa value), it spontaneously associates with negatively charged polyatomic ions in solution to form polyelectrolyte complexes.

Acknowledgments We thank the European Research Council (ERC) for financial support of this work under the IDEAs Project titled "A Novel Nano-container drug carrier for targeted treatment of prostate cancer" (NANOTHERAPY); reference number 232959.

Abstract

In recent years, significant developments have been achieved in the field of tissue engineering. Biopolymers and bioceramics are known to play major role in the construction of artificial organs. Chitosan is one of the biopolymers extensively studied for tissue engineering, drug delivery, and wound healing applications. Chitosan is biocompatible and biodegradable. Its pore-forming ability also enhances efficient cell growth and differentiation. In the present chapter, we have discussed about chitosan and its usage toward bone and skin tissue engineering, drug delivery, and wound healing applications.

1 Introduction

Chitosan is a partially deacetylated derivative of chitin, commonly found in crustaceans. It is a linear polysaccharide consisting of β-(1–4)-linked D-glucosamine residues with variable number of randomly located *N*-acetylglucosamine groups. Chitosan's molecular weight may range from 50 to 1,000 kDa depending on the source and preparation method employed (Francis Suh and Matthew 2000). Chitosan is normally insoluble in aqueous solutions above pH 7. But, it can be soluble below pH 5. Molecular structure of chitosan is shown in Fig. 1.

Artificial skin, surgical sutures, artificial blood vessels, controlled drug release, contact lens, eye humor fluid, bandages, burn dressing, blood cholesterol control, anti-inflammation, tumor inhibition, bone healing treatment, wound healing accelerator, hemostatic agent, antibacterial, antifungal, and weight loss are important biomedical applications of chitosan (Pighinelli and Kucharska 2013; Şenel and McClure 2004). Chitosan is biologically renewable, biodegradable, biocompatible, nonantigenic, nontoxic, and biofunctional material. It has a hydrophilic surface promoting cell adhesion, proliferation, and differentiation and evokes minimal foreign body reaction on implantation (Li et al. 2005).

2 Tissue Engineering

Tissue engineering is one of the interdisciplinary research fields to construct the artificial organs. Combining knowledge of living cells as well as their genetic composition to aid in the development of biologically active substitutes for the use as biomaterial implants to foster tissue growth and/or repair the damaged sites, which ensure their active biological functions in a host system (Shalumon et al. 2009). Chitosan polysaccharide is extensively used in skin, bone, cartilage, liver, nerve, and blood tissue engineering to make artificial organs. Porous chitosan scaffolds are commonly prepared by freezing and lyophilization methods. Madihally and Matthew (1999) prepared porous chitosan scaffold for bone tissue engineering (Di Martino et al. 2005; Kim et al. 2008; Madihally and Matthew 1999). Chitosan-based biocomposites with collagen were examined ultrastructurally and characterized for their ability to regulate cellular activity. Scanning electron microscopy indicated that the addition of chitosan greatly influences ultrastructure and changes the orientation of the cross-linking of collagen fibers,

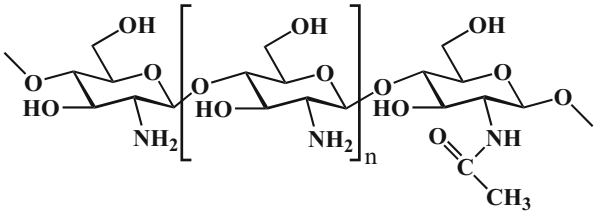

Fig. 1 Molecular structure of chitosan

thereby reinforcing the overall structure to increase pore size (Tan et al. 2001). Huang et al. (2005) prepared the chitosan-gelatin-based scaffold, which has gained much attention in tissue engineering. Degradation results from these studies showed that gelatin-containing chitosan scaffolds represent faster degradation rate and significant loss of material than chitosan. Three-dimensional chitosan and chitosan-gelatin scaffolds supported fibroblast viability equally (Huang et al. 2005).

Homogeneous blends of 25 %, 50 %, and 75 % PCL (polycaprolactone) composites were formed. Increased viability and redistribution of actin fibers was observed on blends formed with 50 % PCL and 75 % PCL relative to individual polymers. 50:50 blends when processed at 55 °C in an oven showed significant improvement in mechanical properties as well as support for cellular activity relative to chitosan (Sarasam and Madihally 2005). Chitosan-gelatin 2D as well as 3D scaffolds have exhibited greater degradation rate with minimal immunological response in the presence of lysozyme, which is an important dimension for their successful use in tissue engineering applications (Huang et al. 2005). The antimicrobial resistance of chitosan provides a stable microclimate for wound healing and repair of damaged tissue (Jayakumar et al. 2010). Chitosan has extensively studied materials for biomedical applications by Asian researchers (Khor and Lim 2003).

2.1 Skin Tissue Engineering

The skin is an important organ with wide range of cellular, molecular, physiological, as well as metabolic functions. Hence, it poses as a complex biological interface to repair and stabilize its roles (barrier formation, pigmentary defense against UV irradiation, thermoregulation, mechanical, and aesthetic functions), when it got damaged. Skin tissue engineering seeks to resolve this efficiently, by developing and functionalizing biomaterial constructs to ensure complete regeneration (Haipeng et al. 2000; Kim et al. 2008; Lee et al. 2003). Ma et al. (2003) developed a scaffold with chitosan and collagen for skin tissue engineering. In vivo animal tests revealed that the scaffold could sufficiently support and accelerate the fibroblast infiltration from the surrounding tissue. Immunohistochemistry analysis of the scaffold embedded for 28 days indicated that the biodegradation of the 0.25 % glutaraldehyde-treated scaffold is a long-term process (Ma et al. 2003). Adekogbe and Ghanem (2005) fabricated and characterized DTBP (dimethyl 3–3, dithiobis' propionimidate) cross-linked chitosan scaffolds for use in skin tissue engineering (Adekogbe and Ghanem 2005). Chitosan sugar residues have been reportedly modified to induce specific cell recognition for use in tissue engineering, such as the synthesis of sugar-bound chitosan, and present unique possibility of extracellular matrix attachment in hepatocyte (Li et al. 2000; Madihally and Matthew 1999). It is also reported elsewhere that an unwoven cloth of chitin fiber and a film of chitosan or N-carboxybutyl chitosan promote the healing of skin wound when applied in wound dressing (Ma et al. 2001). Chitosan oligosaccharide stimulatory effects on macrophages function as chemoattractants for neutrophils both in vitro and in vivo early events essential for wound healing (Shi et al. 2006; Yoshimoto et al. 2003).

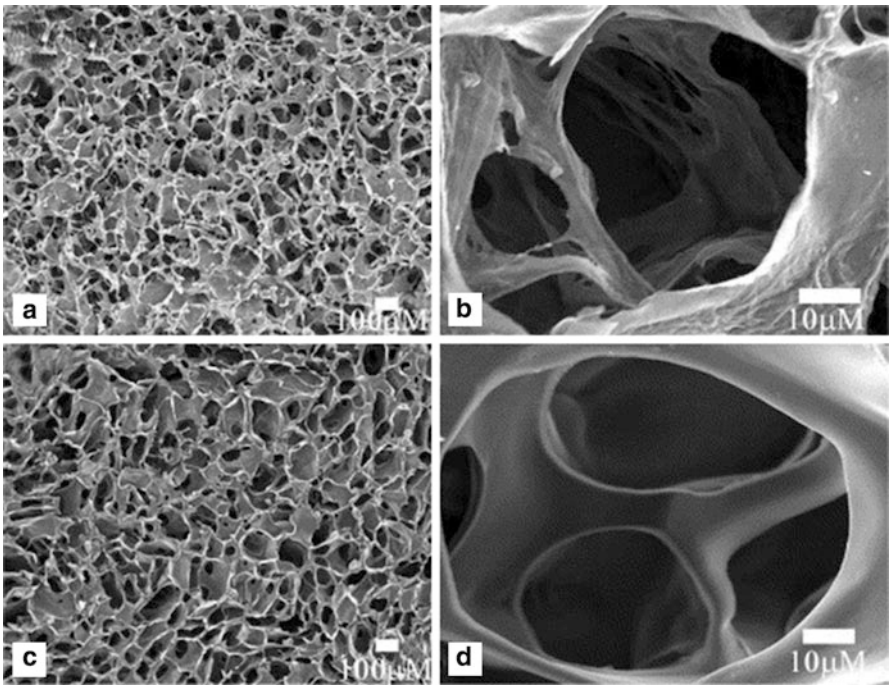

Fig. 2 Scanning electron micrographs (**a** and **b**) chitosan-alginate scaffold and (**c** and **d**) pure chitosan scaffold (Reproduced the figure from Li et al. (2005))

2.2 Bone Tissue Engineering

Scaffolds, cells, and growth factors are playing major role in the construction of bone tissue. Varieties of synthetic and natural polymers have been extensively used for the scaffold fabrication. The typical synthetic polymers are poly(glycolic acid), poly(L-lactic acid), and poly(DL-lactic-*co*-glycolic acid) and the natural polymers are chitin, chitosan, and alginate.

Chitosan is one of the extensively used natural polymers in bone tissue scaffold fabrication. Seol et al. (2004) reported that chitosan sponges can be used as tissue-engineering scaffold with a 100–200 μm pore diameter, which allowed significant cell proliferation (Seol et al. 2004). Cell density, alkaline phosphatase activity, and calcium deposition were monitored for up to 56 d culture. Histological results corroborated that bone formation within the sponges had occurred (Seol et al. 2004). Li et al. (2005) represented the biodegradable porous scaffold of chitosan and alginate polymers with significantly improved mechanical and biological properties. The porosities of pure chitosan and chitosan-alginate scaffolds in this study were determined to be 84.86 ± 2.18 % and 91.94 ± 0.90 %, respectively (Fig. 2). The compressive yield strength was determined to be 0.1257 ± 0.015 MPa and 2.567 ± 0.41 MPa, respectively, for pure chitosan and chitosan-alginate scaffolds.

Similarly, the Young's modulus is 0.467 ± 0.022 MPa and 8.167 ± 1.57 MPa for chitosan and chitosan-alginate scaffolds, respectively. Cell attachment on chitosan and chitosan-alginate scaffolds is increased with time (1, 3, and 7 days). The in vivo study showed that the hybrid scaffold had a high degree of tissue compatibility. Calcium deposition occurred as early as the fourth week after implantation (Li et al. 2005).

However, the mechanical strength of polymer-based scaffolds is often not suitable for mimicking the natural bone. Thus, a combined form of bioactive polymer, carbon materials, and bioceramic-based scaffolds is often used for bone tissue engineering (Lee et al. 2014; Sowmya et al. 2013; Venkatesan and Kim 2010, 2012, 2014; Venkatesan et al. 2012a, b, 2014a, b, c). Zhang and Zhang (2001) prepared chitosan-calcium phosphate composite scaffold for bone tissue engineering (Zhang and Zhang 2001).

Zhang et al. (2008) reported chitosan-hydroxyapatite nanocomposite, which was prepared by in situ coprecipitation with electrospinning process. Poly(ethylene oxide) (PEO) was used as a fiber-forming additive to develop a chitosan-hydroxyapatite nanofiber with a diameter 214 ± 25 nm (Fig. 3). Significant bone formation was observed on chitosan-hydroxyapatite then compared to electrospun chitosan scaffold with human fetal osteoblast (hFOB) (Zhang et al. 2008).

Thein-Han and Misra (2009) reported chitosan-nanohydroxyapatite (chitosan-nHA) in the form of porous scaffold which was prepared by freeze-dry method with pore size ~50–120 μm. The compression modulus of hydrated chitosan scaffolds was increased on the addition of 1 wt.% nanohydroxyapatite from 6.0 to 9.2 kPa in high-molecular weight scaffold. Higher cell proliferation (1.5 times) was observed in the chitosan-nanohydroxyapatite composite scaffold than compared to chitosan scaffold alone (Fig. 4) (Thein-Han and Misra 2009).

Chitosan has been combined with various polymers (Jiang et al. 2006, 2010; Kim et al. 2008; Liuyun et al. 2009; Rezwan et al. 2006; Tan et al. 2001; Wang and Stegemann 2010) and ceramics (Cai et al. 2009; Katti et al. 2008; Kong et al. 2006; Lee et al. 2000; Muzzarelli 2009; Oliveira et al. 2006; Peter et al. 2010; Swetha et al. 2010; Venkatesan et al. 2011; Yin et al. 2003; Zhang et al. 2003, 2008; Zhang and Zhang 2001) and used for bone tissue construction. γ-PGA/chitosan (gamma-poly(glutamic acid)/chitosan) composites showed enhanced serum adsorption, cell attachment, and proliferation in matrix surfaces becoming an important milestone in tissue engineering (Hsieh et al. 2005). Chitosan materials are found to evoke a minimal foreign body reaction as well as fibrous encapsulation with accelerated angiogenesis effectively contributing to the healing process. Chitosan and chitosan fragments on stimulatory immune response are reported to induce local cell proliferation and integration of the material implant (Drury and Mooney 2003; Francis Suh and Matthew 2000). Lysozyme is responsible for the primary degradation of chitosan in vivo and targets acetylated residues (Hirano et al. 1989). Chitosan with hydroxyapatite is one of the better materials to mimic the natural function of bone. Phosphorylated chitosan to calcium-phosphated cement through a creeping substitution process is reportedly used to fill bony defects of tibia and radius in vivo, showing a higher modulus, osteoconductivity,

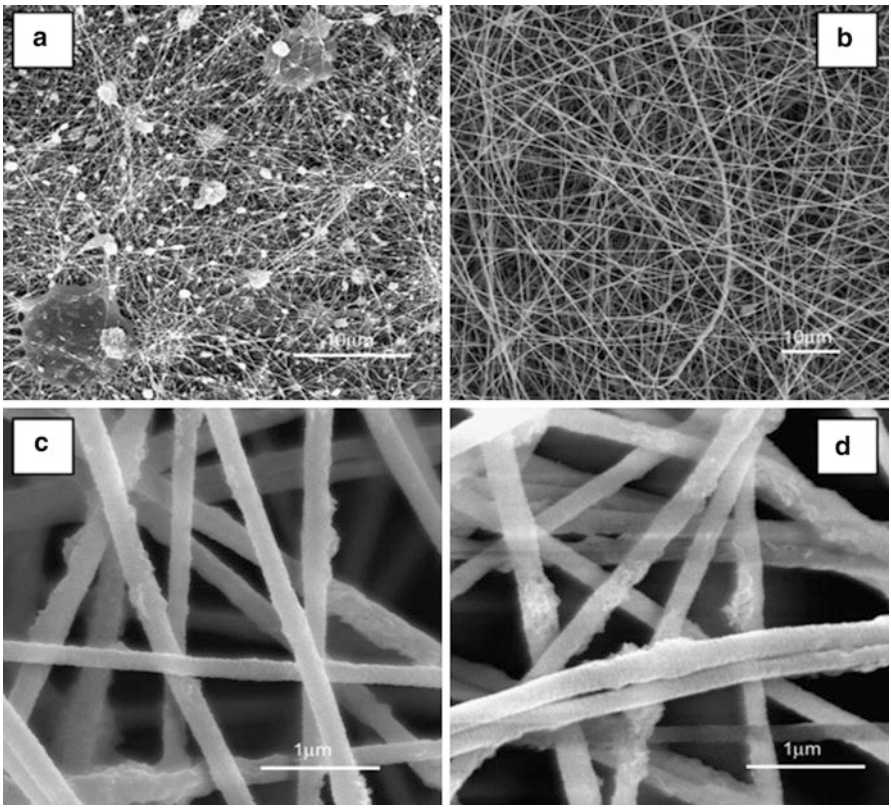

Fig. 3 Field emission scanning electron microscopy images of electrospun chitosan-hydroxyapatite nanocomposite nanofibers: doped with 20 wt% conventional PEO with a moderate molecular weight (**a**), doped with 10 wt% ultrahigh-molecular weight poly(ethylene oxide) at low magnification (**b**), at higher magnification (**c**), and after alkali treatment (**d**) (Reproduced the figure from Zhang et al. (2008))

bioresorbability, and biocompatibility (Di Martino et al. 2005; Rezwan et al. 2006). However, much research has is needed to further develop and functionalize chitosan for clinical trials.

3 Drug Delivery

Significant amount of research has been conducted on chitosan biomaterial for drug delivery. Chitosan can be used to deliver drugs into various administration routes such as oral, buccal, nasal, transdermal, parenteral, vaginal, cervical, intrauterine, and rectal (Felt et al. 1998). Chitosan can be modified into nanoparticles, microspheres, sponges, membranes, and rod shapes (Bhattarai et al. 2010). Ko et al. (2002) reported the preparation of chitosan microparticles using tripolyphosphate (TPP) by an ion cross-linking method with particle range from 500 to 710 μm. Felodipine drug was

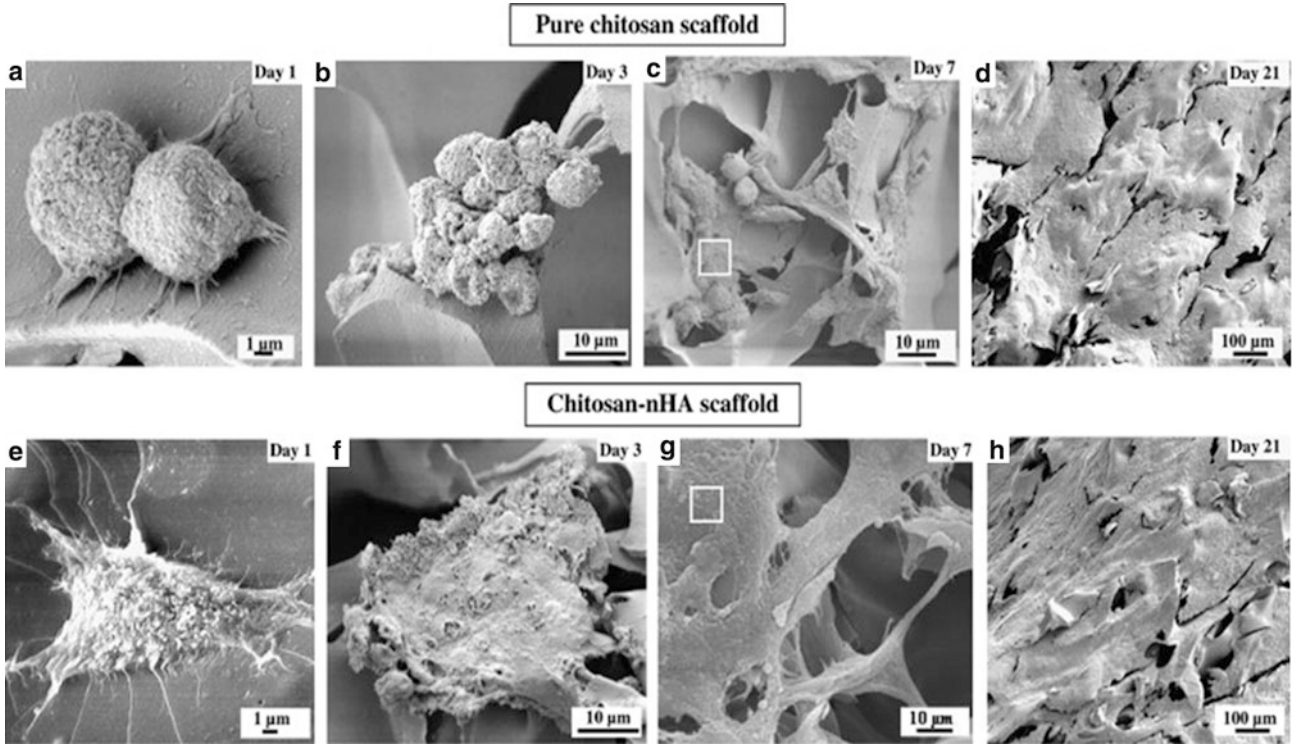

Fig. 4 Scanning electron microscopy images of pre-osteoblasts seeded on high-molecular weight chitosan and chitosan-nHA scaffolds. Pre-osteoblasts on chitosan surface after (**a**) day 1, (**b**) day 3, (**c**) day 7, and (**d**) day 21 of cell culture and on chitosan-nHA surface after (**e**) day 1, (**f**) day 3, (**g**) day 7, and (**h**) day 21 of cell culture (Reproduced the figure from Thein-Han and Misra (2009))

used as model in this study, and chitosan prepared with lower pH resulted in slower felodipine release from chitosan microparticles. Comparatively, with decreasing molecular weight and concentration of chitosan solution, release behavior was increased (Ko et al. 2002). Jameela and Jayakrishnan (1995) prepared chitosan microparticles by glutaraldehyde cross-linkage. Mitoxantrone was incorporated into the chitosan microspheres, where 25 % of the incorporated mitoxantrone drug was released over 36 days from the microspheres (Jameela and Jayakrishnan 1995).

Different kinds of methods have been extensively studied to develop micro- and nanoparticles of chitosan for drug delivery purposes including emulsion cross-linking, spray drying, emulsion-droplet coalescence method, ionic gelation, reverse micellar method, as well as sieving methods. Furthermore, colon-targeted, mucosal, cancer, gene, topical, and ocular deliveries have been extensively studied with chitosan (Agnihotri et al. 2004).

Lorenzo et al. (1998) reported the system consists of chitosan microcores entrapped with acrylic microsphere. Sodium diclofenac drugs were incorporated with chitosan microcores. The modification of chitosan microcores became a novel approach representing great potential in colonic drug delivery (Lorenzo-Lamosa et al. 1998). Chemical modification of chitosan is a possible alternative to associate drugs and used them as controlled release vehicles (Prabaharan and Mano 2004). Another author, Chen et al. (2004) developed a novel pH-sensitive hydrogel with water-soluble chitosan derivative (*N*, *O*-carboxymethyl chitosan) and alginate blended with genipin for controlling protein drug delivery (Chen et al. 2004). Nifedipine was embedded in a chitosan matrix to develop a prolonged release form. The release rate of nifedipine from chitosan matrix was slower for beads than granules (Chandy and Sharma 1992).

Transdermal drug delivery system could also be prepared using chitosan polymer gel (Thacharodi and Rao 1995). Meanwhile, extensive reviews have been written on chitosan for ocular drug delivery (Alonso and Sánchez 2003). Senel et al. (2000) reported chitosan gel for peptide drug delivery, where the hydrogel was prepared with 2 % chitosan in dilute lactic acid together with the transforming growth factor (Şenel et al. 2000). A new thermosensitive hydrogel was designed and prepared by simply mixing *N*-[(2-hydroxy-3-trimethylammonium) propyl] chitosan chloride and poly(ethylene glycol) with a small amount of α-β-glycerophosphate and used for nasal drug delivery system (Wu et al. 2007). Ionic interactions between positively charged amino groups in chitosan and the negatively charged mucus gel layer make it mucoadhesive. The favorable properties like biocompatibility, biodegradability, pH sensitiveness, mucoadhesiveness, etc. have enabled these polymers to become the choice of pharmacologists for use as oral delivery matrices for proteins (George and Abraham 2006).

4 Wound Dressing

Chitosan and chitins are the most promising biomaterials in wound dressing application. The adhesive nature of chitin and chitosan, together with their antifungal and bactericidal potentials as well as their permeability to oxygen, is a very

important property associated with the treatment of wounds and burns. Different derivatives of chitin and chitosan have been prepared for this purpose in the form of hydrogels, fibers, membranes, scaffolds, and sponges (Jayakumar et al. 2011). Mi et al. (2001) reported the asymmetric chitosan membrane prepared by immersion-precipitation phase conversion method. The asymmetric chitosan membrane showed controlled evaporative water loss and excellent oxygen permeability and promoted fluid drainage considerably. Wound covered with the asymmetric chitosan membrane is hemostatic and healed quickly. Histological examination confirmed that epithelialization rate was increased and the deposition of collagen in the dermis was well organized by covering the wound with this asymmetric chitosan membrane (Mi et al. 2001). Mi et al. (2002) developed bilayer chitosan for wound dressing, consisting of a dense upper layer (skin layer) and a sponge-like lower layer (sub-layer), which is very suitable for use as a topical delivery vehicle of silver sulfadiazine (AgSD) in controlling wound infections. Physical characterization of the bilayer wound dressing showed that it has excellent oxygen permeability, controls water vapor transmission rate, and promotes water uptake capability. AgSD dissolved from bilayer chitosan dressings to release silver and sulfadiazine. The release of sulfadiazine from the bilayer chitosan dressing displayed a burst release on the first day and then tapered off to a much slower release (Mi et al. 2002). A novel wound dressing composed of nano-silver and chitosan was fabricated using a nanometer and self-assembly technology. Sterility and pyrogen testing assessed biosafety, and efficacy was evaluated using Sprague-Dawley rats with deep partial-thickness wounds (Lu et al. 2008). Novel wound dressings composed of chitosan film and minocycline hydrochloride (MH) were prepared using commercial polyurethane film (Tegaderm) as a backing material (Aoyagi et al. 2007). Chemical modification of chitosan into *N*-carboxybutyl chitosan was used for wound management (Biagini et al. 1991).

Chitosan enhances the functions of inflammatory cells such as polymorphonuclear leukocytes (PMN) (phagocytosis, production of osteopontin, and leukotriene B4), macrophages (phagocytosis, production of interleukin (IL)-1, transforming growth factor β1, and platelet-derived growth factor), and fibroblasts (production of IL-8). In spite of application of chitosan to various species, this finding is observed only in dogs. Secondly, intra-tumor injection of chitosan on tumor-bearing mice increases the rate of metastasis and tumor growth. Therefore, it is important to consider these effects of chitosan, prior to drug delivery (Ueno et al. 2001). Chitosan membrane, prepared with a 75 % degree of deacetylation and a thickness of 10 μm, was used in non-mesh or mesh form. After 10 days, the chitosan-dressed area had been healed more promptly compared with the Bactigras dressed area. The data confirm that chitosan mesh membrane is a potential substitute for human wound dressing (Azad et al. 2004).

Chitosan fibers with different degrees of acetylation were prepared by controlling the ratio between the amount of acetic anhydride and the weight of the fibers during the acetylation process. Results showed that the partially acetylated chitosan wound dressing had a much higher absorption capacity than the original untreated chitosan samples (Qin 2008).

The chitosan hydrogel could completely stop bleeding from a cut mouse tail within 30 s of UV irradiation and could firmly adhere two pieces of sliced skins of

mouse to each other. Full-thickness skin incisions were made on the back of the mice, and subsequently, an Az-CH-LA aqueous solution was added into the wound and irradiated with UV light for 90 s. The application of the chitosan hydrogel significantly induced wound contraction and accelerated wound closure and healing (Ishihara et al. 2002), in both db/db and db/+mice. However, the addition of FGF-2 in the chitosan hydrogel further accelerated wound closure in db/db mice, although not in db/+mice (Obara et al. 2003).

Ueno et al. (1999) developed cotton fiber-type chitosan for wound healing and was evaluated histologically and immunohistochemically. Immunohistochemical typing of collagen I, III, and IV showed increased production of type III collagen in the chitosan group (Ueno et al. 1999).

The biochemical significance of the chitin/chitosan products was found to accompany their commercial viability in terms of time taken to heal and clinical labor costs (Muzzarelli et al. 2007). To measure this efficiently, a study was conducted to ascertain the mechanical and bioadhesive strength and biological evaluations of chitosan films for wound dressing (Khan et al. 2000).

Ong et al. (2008) developed chitosan containing different amounts and types of polyphosphate polymers and their hemostatic efficacies evaluated in vitro. The optimal chitosan-polyphosphate formulation (ChiPP) accelerated blood clotting, increased platelet adhesion, generated thrombin faster, and absorbed more blood than chitosan. Silver-loaded ChiPP exhibited significantly greater bactericidal activity than ChiPP in vitro, achieving a complete kill of *Pseudomonas aeruginosa* and a >99.99 % kill of *Staphylococcus aureus* consistently. The silver dressing also significantly reduced mortality from 90 % to 14.3 % in a *P. aeruginosa* wound infection model in mice (Ong et al. 2008). Analysis on the accelerating effects of open wound healing by chitin and chitosan was carried out in dogs (Okamoto et al. 1995).

5 Conclusions

Chitosan is one of the promising biomaterial for use in tissue engineering, drug delivery, and wound healing applications due to its biocompatible, biodegradable, and nontoxic nature. Chitosan can be modified into any form such as microsphere, hydrogel, porous scaffold, and nanofibers, thus expanding its biomedical applications into another area: biosensors construction.

Contents

Abstract

Edible fungi have been consumed as medicines and food in Asian countries since time immemorial. Health benefits of edible fungi are mainly associated to polysaccharides, which are major bioactive components. Contemporary phytochemical and pharmacological studies have proved that polysaccharides are one of the major active ingredients in different types of edible and medicinal fungi. It has been demonstrated that polysaccharides exhibit significant biological activities, including immunomodulation, antitumor, antioxidant, anticancer, and antiviral activities. The purpose of the present review was to summarize previous and current references regarding structural characterization and biological activities of different fungal polysaccharides.

1 Polysaccharides in Fungi

Polysaccharides are complex organic molecules, which are essential for pathogenic mechanisms as well as immune response during fungal infections (Roeder et al. 2004).

1.1 Structure of Polysaccharides

Unlike mammalian cells, fungi have a cell wall and a complex compartment, which are mainly composed of polysaccharides (Nimrichter et al. 2005). Glucans, chitin, and mannans (polymers consisting of repeating units of glucose, *N*-acetyl glucosamine, and mannose, respectively) are particularly abundant in the fungal cell wall. Polymeric structures of polysaccharides are composed of at least ten monosaccharides, which are sequentially connected by glycosidic bonds (Bertozzi and Rabuka 2009; Mulloy et al. 2009; Stanley and Cummings 2009). The characteristic branched or linear structures can be categorized when a monosaccharide constituent of a polysaccharide is involved in more than two glycosidic bonds. The polysaccharides consist of homopolymers, "polymer composed of identical monosaccharide," or heteropolymers, "polymer composed of two or more types of monosaccharides." Classic approaches for the determination of polysaccharide structure are chromatographic methods in association with spectrometric and spectroscopic techniques. These approaches allow determination of sequence and composition, anomeric configuration, type of glycosidic linkage, and presence of substituent (Mulloy et al. 2009).

The cellular structural components of polysaccharides are found in three domains of life. Several studies have shown that in microorganisms, these polysaccharides play crucial roles in the development of the cell envelope (Roberts 1996; Nimrichter et al. 2005). Both in prokaryotic and eukaryotic microbial pathogens, polysaccharides are important cell wall components (Roberts 1996; Nimrichter et al. 2005). This surface distribution is in agreement with the fact that host pathogenic interactions are influenced by polysaccharide molecules directly (Moxon and Kroll 1990; Smith 1990; Levitz 2004; Zaragoza et al. 2009).

1.2 Types of Polysaccharides

Polysaccharides are built up from monosaccharides which are ubiquitous biopolymers. They belong to carbohydrates (sugars), 99 % of which are found in plants. Sometimes, polysaccharides are not pure, but they are associated with other

polysaccharides, polyphenolics, or proteins either by covalent or by non-covalent bonds. Normally, there are two types of polysaccharide products in the markets: water extract and diluted alkali extract, out of which, the former is more prevalent. Despite their origin, the antitumor effect of polysaccharides is generally attributed to their 1,3-β-glucan structures (Yoshioka et al. 1985) or β-glucan protein complex (Kawagishi et al. 1990).

1.2.1 Cellulose

Cellulose is the most abundant carbohydrate in nature. The structural components of plants are formed primarily from cellulose, such as wood is largely composed of cellulose and lignin, while paper and cotton are nearly of pure cellulose. Cellulose is a polymer made with repeated glucose units bonded together by beta-linkages. In human and some animals, cellulose remains undigested due to the absence of cellulase enzyme required to break the β-linkages. However, certain animals such as termites can digest cellulose, because the bacteria possessing the enzyme are present in their gut. Cellulose is insoluble in water and does not change color when mixed with iodine. However, on hydrolysis, it yields glucose. About ca. 40 % of carbon in plants (10.5×10^{10} t) is actually present as cellulose. The annual regeneration of cellulose by biosynthesis (photosynthesis) is ca. 1.3×10^{9} t. Approximately, one tree generates ca. 14 g of cellulose/day.

In plants, cellulose functions as a fiber component of highly efficient biological compound materials, e.g., wood (Whistler and BeMiller 1993). Primary cell wall contains 8 % cellulose, while the remaining 92 % is hemicellulose and pectin, while the secondary cell wall contains 95 % of cellulose. Naturally, cellulose fibers are impure. Cotton fiber consists of 94 % cellulose, and its annual production is 20×10^{6} t (nearly equal to synthetic textile fibers). Annual production of cellulose for paper and cardboard manufacture is greater than 100×10^{6} t. Some bacteria produce highly pure cellulose (Lehmann 1996). In the case of animals, cellulose occurs only in some tunicates.

1.2.2 Pectin

Pectin is present in primary cell walls and in the nonwoody parts of terrestrial plants. It is a family of complex polysaccharides that contain 1,4-linked α-D-galactosyluronic acid residues.

1.2.3 Glycogen

Glycogen is the analogue of starch, a glucose polymer in plants, and is sometimes referred to as an animal starch, having a similar structure to amylopectin but more extensively branched and compact than starch. Glycogen serves as the secondary long-term energy storage in animal and fungal cells with the primary energy stores being held in adipose tissue. Glycogen is produced primarily in the cells of the liver and the muscles and produced in the process of glycogenesis within the brain and stomach as well. The glycogen polymer consists of α-(1-4) glycosidic bonds linked with α-(1-6)-linked branches. Many cell types have glycogen which is found in the form of granule in the costal cytoplasm and plays an important role in the glucose cycle.

Glycogen forms an energy reserve that can be quickly mobilized to meet a sudden need for glucose, but that is less compact and more immediately available as an energy reserve than triglycerides (lipids).

1.2.4 Starches

Starches which are the most important storage saccharide in plant cells occurred as large aggregates or granula (energy storage). Extreme hydration of starch molecules is due to external hydroxyl groups which undergo hydrogen bonding with water. Its worldwide huge production was 8×10^6 t which was recorded in 1976. By using acids or enzymes (glucosidases), degradation to glucose finally changed into sugar.

1.2.5 Chitin

Chitin is an important naturally occurring polymer, which forms structural component of many animals such as exoskeletons. Chitin is a primary constituent of crustacean shells, insect cuticles, and fungal cell walls (Ruiz-Herrera 1992). Chitosan, on the other hand, although not a component in animal species, is a major structural biopolymer in the cell walls of fungi, such as *Mucor*, *Absidia*, and *Rhizopus* genera (Ruiz-Herrera 1992; Khor 2001). Chemically, chitin is closely related to chitosan (a more water-soluble derivative of chitin) and cellulose in that it is a long unbranched chain of glucose derivatives. Both materials contribute structure and strength, which provides protection to the organism.

Chitin is biodegradable in nature, and its decomposition may be catalyzed by chitinase enzymes, secreted by microorganisms (bacteria and fungi) and some plants. Microorganisms get simple sugars during decomposition of chitin by releasing enzymes, which break down the glycosidic bonds in order to convert it to simple sugars and ammonia. Chitin and its deacetylated product, chitosan, have received much interest for potential application in agriculture, biomedicine, biotechnology, and food industry due to their biocompatibility, biodegradability, and bioactivity (Kurita 1998; Felse and Panda 1999; Kumar 2000; Tharanathan and Kittur 2003; Synowiecki and Ali-Khateeb 2003). The production of chitin and chitosan from fungal sources has gained increased attention in recent years due to their potential advantages over the current source. For example, crustacean waste supplies are limited by seasons and fishing industry locations, whereas fungal mycelium can be obtained by simple fermentation regardless of geographical location or season (White et al. 1979).

Furthermore, fungal mycelia have lower levels of inorganic materials compared to crustacean shells, and no demineralization treatment is required during processing (Teng et al. 2001). Considering the significant amounts of fungal-based waste materials accumulated in the mushroom production and fermentation industries and the expenses involved in managing the waste, production of highly functional value-added products may provide a profitable solution to the industry. *Agaricus bisporus* is one of the most popular mushrooms worldwide and especially in the United States. Depending on the size of the mushroom farm, the amount of waste, which mainly consists of stalks and mushrooms with irregular dimensions

and shapes, ranges between 5 % and 20 % of production volume (personal communication). In the United States alone, this results in 50,000 metric ton of waste material per year with no suitable commercial use. On the other hand, citric acid is the most widely used organic acid in the food, beverage, and pharmaceutical industries as an acidifying or flavor-enhancing agent and is commercially produced by submerged fermentation with *Aspergillus niger*. The annual world requirements for citric acid are estimated at 4×10^5 t (Kristiansen et al. 1999), which results in 8×10^4 t of *A. niger* mycelium waste per year (Ali et al. 2002).

2 Bioactive Fungal Polysaccharides

One of the most common and well-studied medicinal fungal polysaccharides is lentinan, a glucan elaborated by the edible mushroom *Lentinus* (or *Lentinula*) *edodes*, also known as the shiitake mushroom. It is composed of a main chain of β-(1,3)-D-glucose residues to which β-(1,6)-D-glucose side groups are attached (one branch to every third main chain unit) (Giavasis 2013; Wasser 2002; Mizuno and Nishitani 2013; Thakur and Singh 2013; Ganeshpurkar et al. 2010). A similar polysaccharide, schizophyllan (also called sizofiran), is produced by the edible mushroom *Schizophyllum commune*. These are probably two of the most well-studied immunomodulating microbial β-(1,3)-D-glucans, and both have been commercialized as novel therapeutics in cancer treatment, while *Lentinus edodes* is the most common edible mushroom in Japan (Giavasis 2013; Wasser 2002; Mizuno and Nishitani 2013; Thakur and Singh 2013; Ganeshpurkar et al. 2010). *Ganoderma lucidum* is another well-studied medicinal mushroom of the class *Basidiomycetes* which has been used in traditional East Asian medicine as a dry powder or as a hot water extract (a type of bitter mushroom tea).

Another edible and medicinal mushroom, *Agaricus blazei*, originating from Brazil, is the source of several antitumor polysaccharides contained in its fruit body (Giavasis 2013; Wasser 2002; Mizuno and Nishitani 2013). These include α-β-(1,6),β-(1,3) glucan, acidic β-(1,6),α-(1,3) glucan, and β-(1,6),α-(1,4) glucan. By contrast to most mushroom glucans, the above glucans have a main chain of β-(1,6) glucopyranose, instead of the more common β-(1,3)-linked main chain (Giavasis 2013; Wasser 2002; Mizuno and Nishitani 2013). The fruit body also contains an antitumor water-soluble proteoglycan α-(1,4) glucan main chain and β-(1,6) glucopyranoside branches at a ratio of 4:1 (Mizuno and Nishitani 2013; Fujimiya et al. 1998), as well as two immunostimulating hetero-glucans containing glucose, galactose, and mannose, one consisting of glucose and ribose and a xyloglucan (Giavasis 2013; Mizuno and Nishitani 2013).

Other immunostimulating biopolymers from *Basidiomycetes* include grifolan, a gel-forming β-(1,3)-D-glucan with β-(1,6) glucosidic bonds at every third glucopyranosyl residue, found in the edible fungus *Grifola frondosa* and Krestin, a proteoglycan with a β-(1,3)-D-glucan chain produced by the edible mushroom *Coriolus versicolor* (also known as *Trametes versicolor*), which has been commercialized in Asia, as an effective immunostimulative drug (Laroche and

Michuand 2007; Hobbs 2004). Another type of edible medicinal mushroom is the *Tremella* group of mushrooms (*T. mesenterica*, *T. fuciformis*, *T. aurantia*, *T. cinnabarina*) which are jelly mushrooms with an unusually high polysaccharide content (60–70 % of the fruiting body, as opposed to 10–30 % in other mushrooms). *Tremella* acidic polysaccharide is a glucuronoxylomannan composed of a linear backbone of α-1,3-linked D-rhamnose, to which xylose and glucuronic acid side chains are attached (Lu et al. 2006).

Scleroglucan is an extracellular glucan excreted by mycelia of *Sclerotium glucanicum* or *S. rolfsii* (Survase et al. 2007; Bluhm et al. 1982). It has a β-(1,3)-linked backbone, to which single D-glucosyl side group is linked via β-(1,6) linkage to every third or fourth unit of glucosyl backbone. Although scleroglucan is known and used mostly as a viscosifier for enhanced oil recovery, it also possesses antitumor and antiviral activity (Giavasis et al. 2002).

3 Health Benefits of Fungal-Based Polysaccharides

3.1 Immuno-functions

Depending on their structural particularities, cell wall polysaccharides function as regulators of virulence or activators of innate immunity (Roeder et al. 2004; Zaragoza et al. 2009). It has been reported that well-studied immune working polysaccharides produced by fungus have α- and β-glucans (Brown et al. 2003; Hohl et al. 2005; Bittencourt et al. 2006; Rappleye et al. 2007; Wheeler et al. 2008; van de Veerdonk et al. 2009; Chai et al. 2011) and complex mannans (Leitao et al. 2003; Cambi et al. 2008; van deVeerdonk et al. 2009). *Candida albicans*, *Aspergillus fumigatus*, *Histoplasma capsulatum*, *Cryptococcus neoformans*, and *C. gattii* are some of the fungal pathogens in which the immune functions of polysaccharides are available (Monari et al. 2006; Rappleye et al. 2007; Cambi et al. 2008; Chai et al. 2011).

Capsular polysaccharides are among the earliest microbial virulence determinants, which were reviewed in the classic Griffith's experiment (Smith 1990). This study established a direct relationship between the presence of protection against host defense and polysaccharide capsules in bacterial pathogens. Afterwards, over several decades, the linkage between capsular polysaccharides and microbial virulence has been joined together (Moxon and Kroll 1990; Monari et al. 2006; Vecchiarelli 2007; Zaragoza et al. 2009). Although it is clear that in some cases, these structures work in favor of the host (Mazmanian and Kasper 2006; Pletz et al. 2008; Kumar et al. 2009), consequently, microbial polysaccharides may work in favor of the pathogen or induce immune responses that promote infection control, depending on their chemistry and/or structural aspects.

Candida albicans, *Aspergillus fumigatus*, *Histoplasma capsulatum*, *Cryptococcus neoformans*, and *C. gattii* are examples of fungal pathogens in which the immune functions of polysaccharides are known in great detail (Monari et al. 2006; Rappleye et al. 2007; Cambi et al. 2008; Chai et al. 2011). *Cryptococcus*

neoformans and *C. gattii* are the etiologic agents of cryptococcosis, a disease that presumably begins in the lung. In immunocompromised individuals, *C. neoformans* can disseminate to the central nervous system and other organs (Bicanic and Harrison 2004). *C. gattii*, on the other hand, can cause disseminated disease in immunocompetent individuals (Byrnes et al. 2011). In Brazil, cryptococcosis is the fungal disease with the highest mortality rates among HIV-positive individuals. *C. neoformans* and *C. gattii* have polysaccharide capsules surrounding the cell body. Bacterial capsules are common in bacterial pathogens but relatively rare and still poorly defined among eukaryotic organisms. For construction of the capsule, yeast cells secrete polysaccharides into the extracellular environment by mechanisms that involve the release of vesicles for subsequent polysaccharide incorporation into the cell surface, for distal capsular enlargement (Zaragoza et al. 2006; Rodrigues et al. 2007).

Additionally, both cellular components and secondary metabolites of a large number of mushrooms have been shown to affect the immune system and therefore might be used to treat a variety of diseases (Wasser and Weis 1999). Mushrooms which appear to enhance or potentiate resistance to disease states are being sought for the treatment of cancer, immunodeficiency diseases (including AIDS), or generalized immunosuppression after drug treatment (Pujol et al. 1990; Clericuzio et al. 2004). The mycelia of *Irpex lacteus* contain many nutrition compounds, such as protein, polysaccharides, adenosine, glycoprotein, and cordycepic acid (Yang et al. 2005).

3.2 Anticancer/Antitumor Potential

Cancer is one of the major causes of human death worldwide. There are many anticancer therapies available, including chemotherapy and anticancer drugs. The great majorities of them are known to be cytotoxic to cancer cells but are also toxic to normal cells and harmful to the immune system (Yang et al. 2007). Thus, the discovery of a new safe compound, capable of potentiating immune function, has become an important goal of research in the biomedical sciences. Recently, mushrooms have attracted much attention in the biochemical and medical fields due to their useful therapeutic effects (Balkwill 2009). It is well documented that various mushroom-derived polysaccharides are used as remedies and prevention agents for cancer and immune disorders and so on (Goodridge et al. 2009; Kim et al. 2004). For instance, several polysaccharides isolated from *Lentinus edodes*, *Schizophyllum commune*, *Coriolus versicolor*, *Phellinus linteus*, etc., have been shown to possess immunostimulatory activities (Kim et al. 1996; Ooi and Liu 2000; Zheng et al. 2005).

Carcinogenesis is a process which normally takes several years during which progressive genetic changes occur, leading to malignant transformation. Cancer prevention is the best intervention in this process before an invasive disease develops. Over the last half century, our understanding of carcinogenesis has grown enormously, owing largely to recent technology, allowing exploration of

molecular pathways, cancer-associated genes, and tissue architecture and the use of drugs, biological compounds, and nutrients to prevent the development of cancer, i.e., to inhibit, delay, or reverse carcinogenesis (Kellof and Sigman 2000). Mushroom polysaccharides were likely to affect primarily the promotion and progression stages, according to the referred model of carcinogenesis. There are advantages of using mushrooms as sources of bioactive compounds, rather than plants. For example, the fruiting body can be produced in much less time, and the mycelium may also be rapidly produced (in a liquid culture that can be manipulated to produce optimal quantities of active products or from mycelial biomass and supernatant of submerged cultures using bioreactors).

Edible mushrooms have been consumed by the oriental world for a long history for their flavor, nutrition, and biological functions to satisfy the mouth feel and human body immune systems. *Agaricus blazei* Murill has been considered antitumor and anticarcinogenic, and extensive research has been carried out to explain its polysaccharide structures and their relationship with antitumor activity (Kobayashi et al. 2005; Mizuno et al. 1990).

It has been reported that polysaccharide glucan protein complex, presenting α- and β-glycosidic linkage with β-glucans being predominant over α-glucans, antitumor activity (Gonzaga et al. 2005). A lot of mushrooms have been studied for their antitumor activities (Yoshioka et al. 1985), and their extractions are used clinically as a drug for therapy (Liu et al. 1996; Ohno et al. 1986). *Ganoderma* is a therapeutic fungal bio-factory (Russell and Paterson 2006), which can inhibit tumor cell proliferation and induce their death (Xie et al. 2006). The methanolic extract of *Ganoderma lucidum* exhibited antimutagenic activity and hepatic damage effect, which is caused by benzopyrene (Lakshmi et al. 2006).

Majority of the *Basidiomycetes* mushrooms contain biological active protein-bounded polysaccharides or polysaccharides in fruit bodies, cultured mycelium, or culture stock, which exert antitumor and immunomodulating activity (Wasser 2002). A fungal polysaccharide "Huaier" obtained from *Trametes robiniophila* Murr, a sandy beige (light-grayish-brown) mushroom grown on the trunks of trees such as *Sophora japonica*, belonging to *Hymenomycetes-Basidiomycota* (Anithworth et al. 1973), has been applied in traditional Chinese medicine (TCM) for approximately 1,600 years (Li et al. 2006), first recorded by Shi-Zhen Li, who was a famous Chinese scientist in Ming dynasty. In recent decades, Huaier has been found and used as a complementary agent for cancer therapy. The water extract from Huaier is mainly a polysaccharide protein which has been proved to be the main active ingredient in respect of anticancer effects and immunity-enhancing actions (Cui et al. 2007). As an anticarcinogenic medicine, *T. robiniophila* has been used for the treatment of liver cancer with satisfactory results. Accumulated evidences suggest that the antitumor mechanism of Huaier may be associated with the inhibition of the growing of endothelial cells, interference with tumor angiogenesis (Xu et al. 2003), system immune activation (Chen et al. 2004; Jia et al. 2009), induction of tumor cell apoptosis, and suppression of tumor cell proliferation (Zhu et al. 2008). Irrespective of its efficient treatment for liver cancer, so far, there is no information available about the anticancer effects of Huaier on

cholangiocarcinoma, and its underlying mechanism of action is still largely unknown. As we know, cholangiocarcinoma is a malignant tumor arising from the bile duct epithelial cells or cholangiocytes of the intrahepatic and extrahepatic biliary system (de Groen et al. 1999; Shaib and El-Serag 2004), characterized by a poor prognosis, high recurrence rate, and resistance to radiotherapy or chemotherapy due to its special biological characteristics. More recently, some species of edible higher *Basidiomycetes* have been found to markedly inhibit the growth of different tumor cell lines. There are approximately 200 species of higher *Basidiomycetes* that were found to have this activity (Poucheret et al. 2006).

The cholangiocarcinoma is considered to be a multidrug and radioresistant tumor and has a high mortality ratio (Sirica 2005). The increasing global incidence of this tumor requires the urgent need for novel and effective therapeutic agents. Recently, much attention has been focused on medicinal plants to discover novel anticancer agents that lack the toxic effects associated with current therapeutic agents (Schwartsmann et al. 2002). However, since the last century, the Second Affiliated Hospital of Harbin Medical University had succeeded in administering Huaier extract to patients who suffered from cholangiocarcinoma to prolong their survival or reduce the recurrence rate. For the development of hospital pharmaceutical preparation to be an open access drug, it is intended to make a series of experiment-based research for identifying its efficiency on cholangiocarcinoma. From that observed study, they extracted a water-soluble polysaccharide from that fungus and preliminarily test its immunomodulatory and tumor-inhibitory activities in vitro.

3.3 Biological Activities

Polysaccharides and their conjugates, which are used in food industry and medicine for a long time, have attracted much attention in recent years because of various biological activities like antitumor and immunomodulating (Shao et al. 2004), antioxidant (Xu et al. 2009), anticoagulant, and antiviral activities (Pushpamali et al. 2008; Athukorala et al. 2006). A lot of mushrooms have been studied for their biological activities (Yoshioka et al. 1985). Extractions of these mushrooms have been used clinically as therapeutic drugs (Liu et al. 1996; Ohno et al. 1986). Modern scientific studies on the above called "medicinal mushrooms" have expanded exponentially during the last two decades, and scientific explanations to show how compounds derived from mushrooms function in humans are increasingly being established (Zaidman et al. 2005). Fungal fruiting bodies, fungal mycelium, and the culture fluid in which the mycelium has been cultivated may all be explored for biological activity. Polysaccharides are the most potent macro-fungi-derived substances from lingzhi (*Ganoderma lucidum*), shiitake (*Lentinus edodes*) (Chihara et al. 1970), and yiner (*Tremella fuciformis*). However, the polysaccharides from *Irpex lacteus* have been seldom reported.

Many active compounds have been identified in *Polygonatum odoratum* such as mucous polysaccharides and homoisoflavanones (Tomshich et al. 1997),

azetidine-2-carboxylic acid (Baek et al. 2012; Kim et al. 2006), saponin (Deng et al. 2012), and steroidal compounds (Sugiyama et al. 1984). Among them, polysaccharides are abundant in *Polygonatum odoratum* and considered as one of the most important bioactive components with antitumor, antidiabetic, and antioxidant functions. Extraction of polysaccharides from *Polygonatum odoratum* is an important approach to further research or scale application. Tomshich et al. (1997) reported extraction and purification of polysaccharides from ten medicinal plants including *Polygonatum odoratum*, and several reports were documented on extraction and bioactivities of polysaccharides from this species in recent years (Baek et al. 2012).

3.4 Antimicrobial Effects

Several fungal biopolymers are known to be active against bacterial and viral infections in vitro or in vivo, due to the stimulation of phagocytosis of microbes by neutrophils and macrophages. For instance, lentinan is active against tuberculosis and *Listeria monocytogenes* infection, as well as *Salmonella enteritidis* and *Staphylococcus aureus* infection (Sasidhara and Thirunalasundari 2012; Mattila et al. 2000). Interestingly, lentinan and an acidic proteoglycan from *G. lucidum*, as well as glucans from *G. frondosa* and *T. versicolor*, have been used as anti-HIV drugs, provoking an increased host resistance to HIV virus and limiting the toxicity of conventional anti-HIV drugs, a common drug used against AIDS virus (Markova et al. 2002; Lindequist et al. 2005). Different studies suggest that the antioxidant and anticoagulant abilities of polysaccharides are strongly dependent on the degree of sulfation, molecular weight, position of sulfate groups on the sugar backbone, sugar composition, and glycosidic branching (Rioux et al. 2007; Wang et al. 2010; Jiao et al. 2011; Jimenez-Escrig et al. 2012).

Research on antimicrobial activity of polysaccharides may contribute to valuable new information for future antibiotic development. Many authors have previously investigated the antimicrobial activity of polysaccharides from a wide range of organisms such as seaweeds, mushroom, and durian fruit (Lipipun et al. 2002; Zhu et al. 2012).

The results discussed above imply new concepts about the structure and function of fungal polysaccharides. These studies raised an important question: Do polysaccharide samples of identical composition but variable size and degree of polymerization present distinct biological functions? The findings discussed above imply new concepts about the structure and function of fungal polysaccharides. Besides structural aspects traditionally studied, such as sequence analysis, compositional determination, anomeric configuration, type of glycosidic linkage type, and presence of substituent, it becomes clear that other structural parameters, including molecular diameter and degree of polymerization, must be considered for functional studies. In fact, the conclusion that polysaccharide functions are influenced by these additional parameters was further supported by Cordero et al. (2011).

Using static and dynamic light scattering, viscosity analysis, and high-resolution microscopy of *C. neoformans* polysaccharides, this study demonstrated that spatial conformation (branching) influences phagocytosis, nitric oxide production by macrophage-like cells, and susceptibility to reactive oxygen species, serology, and clearance during infection. These previously unexplored parameters can generate new insights, for example, on immunogenicity assays of polysaccharides, as well as their use in therapy or prevention of diseases. Studies in this area are still embryonic, and unclearly, much remains to be discovered. For conceptual validation, future studies must include evaluation of the relationship between immune activity and molecular dimensions of polysaccharides synthesized by other organisms, as well as of fungus.

4 Conclusion

This review paper explores the functional properties of different fungi, as well as outlines the potential uses as active ingredients in medicinal purposes. In addition, here we discussed the bioactivities and biological activities and properties of fungal polysaccharides. The potent biological activities of different fungal polysaccharides may represent an interesting advance in the search for functional applications in the relevant medicinal uses including cure of different diseases such as cancer, HIV, and AIDS. Edible mushrooms have been consumed by the oriental world for a long history for their flavor, nutrition, and biological functions to satisfy the human body defense systems. There are different types of fungal polysaccharides which are very beneficial for our health in the form of oral uses such as mushrooms and also in the form of medicinal uses which is described in the chapter. Several studies have shown that in microorganisms, those polysaccharides play crucial roles in the development of the cell envelope (Roberts 1996; Nimrichter et al. 2005). It has been reported that many fungi used for medicinal purposes which has been discussed in the above chapter should need more analysis for further research.

For example, *Agaricus blazei* Murill has been considered as antitumor and anticarcinogenic, and extensive research has been carried out to elucidate their polysaccharide structure and its relationship to the antitumor activity (Kobayashi et al. 2005; Mizuno et al. 1990). Capsular polysaccharides were among the earliest microbial virulence determinants, which are reviewed in the classic Griffith's experiment (Smith 1990). As an anticarcinogen medicine, Huaier has been used for the treatment of liver cancer with satisfactory results. In recent decades, Huaier has been found and used as a complementary agent for cancer therapy. Another example is *Ganoderma* which is a therapeutic fungal bio-factory (Russell and Paterson 2006). *Agaricus blazei* Murill has been considered to have antitumor and anticarcinogenic activities. Interestingly, lentinan and an acidic proteoglycan from *G. lucidum*, as well as glucans from *G. frondosa* and *T. versicolor*, have been used as anti-HIV drugs, provoking an increased host resistance to HIV virus and limiting the toxicity of conventional anti-HIV drugs, a common drug used against

AIDS virus (Markova et al. 2002; Lindequist et al. 2005). Further research on the structural bioactivities is suggested to be needed.

Acknowledgments It remains only to express our gratitude for the efforts of Prof. Xiong Fu, Prof. Xuewu Zhang, and Associate Professor Lijun You, College of Light Industry and Food Science, South China University of Technology, who drew up the original chapter plan for this work on structures and bioactivities of fungal polysaccharides.

Biopolysaccharides for Skin Hydrating Cosmetics

60

Mayuree Kanlayavattanakul and Nattaya Lourith

Contents

Abstract

Skin hydrating polysaccharides are derived from several natural sources. This biopolymer is constructed with simple sugar building blocks that are easily hydrated in an aqueous environment, thereby creating the gel structure called hydrogel or hydrocolloid. Polysaccharide that is a biodegradable polymer is excellent in compatibility with the biological tissues and largely meeting the consumers' preferences toward natural products. In this chapter, applications of biopolysaccharides in cosmetics are subjected to be summarized especially skin hydrating biopolysaccharide that is incorporated as the active ingredient in cosmetic product. Mechanisms of skin hydrating effect and *in vivo* instrumental evaluation are addressed. Commercial biopolysaccharides are summarized for further reference in addition to some potential candidates, particularly botanical polysaccharides. The potential biopolysaccharides, with *in vitro* activities, are additionally included. Health benefits of this biopolymer in sufficiently suppressing dryness of the skin and potentially protecting from and/or treating wrinkles of the skin acting as antiaging ingredients are highlighted.

Biopolymer • Biopolysaccharide • Hydrogel • Hydrocolloid • Moisturizer • Polysaccharide • Skin hydration

1 Introduction

Polysaccharides are composed of multiple saccharides forming a large branched or unbranched chain. They are simply classified as homopolysaccharide (same monosaccharide unit) and heteropolysaccharide (different monomeric units). Thus, they are accounted as polymers. This naturally derived polymers constructed with simple sugar building blocks are hydrated in an aqueous environment, thereby creating a gel structure called hydrogel or hydrocolloid. This system, in which water is immobilized by insoluble polymers, is imparting moisturizing effect consequently. The moist gels are highly compatible with the biological tissues and are biodegradable according to their natural occurrence (Brode 1991), classifying them as biopolymer. These are inexpensive and vastly available from natural sources which enlighten their importance in health benefit applications, including cosmetics. These strengthen the consumers' preferences toward the safety and efficacy of biopolysaccharides. In this chapter, application of polysaccharides in cosmetics will be classified into functional and active polysaccharides. Functional polysaccharides in cosmetics are claimed on the basis of their functionalities in the formulation technology such as film former, gelling agent, thickener, suspending agent, conditioner, and emulsifier, of which it mainly relies on the physicochemical properties of the biopolymer. On the other hand, cosmetic active polysaccharides are role by the ability of hydrogel or hydrocolloid mobilizing water to the contacted skin (Goddard and Gruber 1999). The skin hydrating benefit is the main object to be exclusively discussed herein. Mechanisms of this skin hydrating agent are included with *in vivo* efficacy evaluation. Furthermore, biopolysaccharides with skin hydrating effect, including those of potential ones with in vitro activities, are also included, of which botanical polysaccharides are mainly the focus in this chapter. However, preparation, characterization and physicochemical analysis of polysaccharide, and modification will be out of the scope of this chapter. Antioxidant and antibacterial activities of biopolysaccharides will also not be included, as well as their application as delivery systems.

2 Classification of Polysaccharide in Cosmetics

Polysaccharides applied in cosmetics are classified on the basis of their actions in the products that are functional and active polysaccharides.

2.1 Functional Polysaccharide

Polysaccharides are incorporated into cosmetic product to function as gelling agent, viscosity adjuster, thickener, and emulsifier as well according to its polymerized network holding water by means of its swelling capability. Therefore, functional polysaccharide is traditionally classified on the basis of its electrochemical charges in the structure as follows.

2.1.1 Anionic Polysaccharide

Cosmetically interesting anionic polysaccharide is predominantly comprised of a group of naturally occurring materials. A majority of this group is xanthan gum with a β-(1–4)-D-glucopyranose glucan skeleton. It is naturally synthesized and composed in the cell wall of bacteria and is isolated by bacterial fermentation. In water, xanthan polymerizes forming viscous liquids which crystallized giving the unique ability to emulsify the suspensions. This pseudoplastic fluid, with a shear-thinning property, is commonly used in cosmetic preparation to enhance the stability against freeze-thaw challenge.

2.1.2 Cationic Polysaccharide

This cosmetic important group of polysaccharide mainly relied on synthetically altered polyglycans. They have unique advantage to bind tightly with protein (negative charge) of the human skin and hair. Cationic polysaccharide therefore has been found to be very useful as film-forming agent popularly applied for damage controls in hair and skin-conditioning products in addition to the vast application in hair fixative preparations. Among natural-derived cationic polysaccharides, chitosan is the main commercialized polyglycan with a cationic nature. This seminatural polysaccharide is partially deacetylated (>50 %) of naturally occurring chitin to improve solubility.

2.1.3 Nonionic Polysaccharide

This polysaccharide is not charged and thus less affected by negatively or positively charged compounds as surfactants. Starch as one of the most used and least expensive natural nonionic polysaccharides is mainly used as thickener. Guar gum is another nonionic polysaccharide which has found broader appeal as a natural thickener isolated from seed of plants in the Leguminosae family. Guar gum consists of two different sugars, which are mannose and galactose. Its chelating effect with metal ions enables gel thickening in alkaline media. Seminatural nonionic polysaccharides are mainly ethers of cellulose- or guar-based materials, for example, hydroxycellulose, methylcellulose, etc., that are widely used as thickeners and film formers in nail products.

2.1.4 Amphoteric Polysaccharide

Positive and negative charges are present in the same molecule naming the group of this biopolymer to amphoteric polysaccharides. There are few naturally

occurring amphoteric polysaccharides used in cosmetics. The most frequently applied are seminatural derivates which is carboxymethyl chitosan.

2.2 Active Polysaccharide

In addition to the above functioning polysaccharides, application of these biopolymers acting as active ingredient is widely adopted in cosmetics. Polysaccharides are pharmaceutically and cosmetically classified on the basis of skin hydrating effect as follows.

2.2.1 Cellulose

Cellulose is the most abundant renewable polymer composed of repeating units of monosaccharide that is known as cellobiose. This anionic water-insoluble polymer is extracted from natural source, mainly plants with hemicelluloses, lignin, and other extractives. It is a hygroscopic material that is implied in skin-conditioning products particularly skin hydrating cosmetics.

Although plant is the major producer of cellulose, microorganisms such as algae, bacteria, and fungi are of economically important sources as manipulation of the cellulose structure with different properties and functions can be controlled by means of the biosynthetic modification especially in skin tissue-repairing products (Fu et al. 2013). Cellulose ethers are the modified cellulose and enlarge cellulosic application in cosmetics with optimal physicochemical properties available for a wider choice of dosage forms particularly those of methyl and ethyl cellulose derivatives (Chen et al. 2012; Vandamme et al. 2002).

2.2.2 Starch

Starch is a glucose polymer biosynthesized in plants for energy preserving aspect. It is the modified flour with a primary constituent of carbohydrates that differentiated by the proportion of amylose and amylopectin varied by source in similar to size, structure, and pharmaceutical property. Commercial highly pure starch is mainly isolated from cereal (wheat, rice, corn, oat, sorghum, and barley), legume (lentil, bean, and pea), and tuber of potato and tapioca. Similar to cellulose, modified starches are widely used in cosmetics, for example, hydrolyzed corn starch, hydrolyzed wheat starch, hydroxypropyl corn starch, sodium carboxymethyl starch, etc. In addition, those of novel application forms of starch in microcapsules, nanoparticles, and composites are recently emerging in the cosmetic industry (Rodrigues and Emeje 2012).

2.2.3 Pectin

Pectin is a non-starch water-soluble linear polysaccharide found in higher plants, particularly in fruits and vegetables. Commercialized pectin mostly relied on food industry by-products, e.g., apple pulp and citrus peel. Its structure governs property with the appointed various applications depending on its source.

Table 1 Gum in skin nourishing cosmetics

Gum	CAS number	Mannose-galactose
Guar hydroxypropyltrimonium chloride	65497-29-2	2:1
C18-22 hydroxyalkyl hydroxypropyl guar		
Locust bean hydroxypropyltrimonium chloride		4:1
C. spinosa gum	39300-88-4	3:1
C. spinosa hydroxypropyltrimonium chloride	742071-24-5	
T. foenum-graecum hydrolyzed trimonium chloride	742071-24-6	1:1
Cassia gum		5:1

2.2.4 Gum

This plant hydrocolloid can be either anionic or nonionic polysaccharides including salt polysaccharide. It is biosynthesized as plant protector, following an injury or attack. This class of polysaccharide has long been served in pharmaceutical applications which are gum arabic or acacia gum from *Acacia* sp., gum tragacanth from *Astragalus gummifer*, gum karaya from *Sterculia urens*, and gum ghatti from *Anogeissus latifolia*, of which gum acacia and tragacanth were reported for their emollient property (Raymond et al. 2003) contributing to their hydrating effect.

In addition to the above gum, those of legume polysaccharides which are *Cyamopsis tetragonoloba* or guar gum, hydroxypropyl guar, C18–22 hydroxyalkyl hydroxypropyl guar, guar hydroxypropyltrimonium chloride, hydroxypropyl guar hydroxypropyltrimonium chloride, carboxymethyl hydroxypropyl guar, hydrolyzed guar, *Ceratonia siliqua* gum, locust bean hydroxypropyltrimonium chloride, hydrolyzed *C. siliqua* gum extract, *Caesalpinia spinosa* gum, *C. spinosa* hydroxypropyltrimonium chloride, hydrolyzed *C. spinosa* gum, *Trigonella foenum-graecum*-hydrolyzed trimonium chloride, cassia gum, and cassia hydroxypropyl trimonium chloride are used and commonly called galactomannans. Those of guar, carob, tara, fenugreek, and cassia gums with skin-conditioning effects are summarized in Table 1.

2.2.5 Mucilage

This viscous polysaccharide is extractable from Leguminosae plant such as okra, psyllium, and flax. Mucilage is traditionally applied in topical products as functional ingredient. This water-soluble polysaccharide, similar to gum, is widely used in cosmetics due to its high water absorption capacity.

2.2.6 Seaweed Polysaccharide

Alginates are one of the most well-known marine polysaccharides prepared from brown seaweeds in the Phaeophyceae family, out of which *Macrocystis pyrifera* is a major commercialized seaweed for alginate production. In addition, *Laminaria hyperborea*, *L. digitata*, and *L. japonica* are becoming important sources of good quality alginates.

Marine red algae (Rhodophyceae family) largely produces carrageenans. Carrageenan is a hydrocolloid that can be classified into κ-, ι-, and λ-carrageenans.

Red-purple algae of the Rhodophyceae additionally synthesizes agar of which *Gracilaria* and *Gelidium* spp. are the major grown genera for agar production.

2.2.7 Microbial Polysaccharide

This class is interchangeably known as exopolysaccharide. Xanthan gum produced by *Xanthomonas campestris* is highlighted as the main significant bacterial exopolysaccharide accounted for more than 6 % of the total market value of these categorized polysaccharides (Imeson 1997). Pullulan, a water-soluble extracellular polysaccharide, from *Aureobasidium* especially *A. pullulans* and gellan from *Auromonas elodea* are additional microbial polysaccharides that are also widely used in cosmetics. The principal commercialized pullulan is produced by Hayashibara, the Japanese company, that deals in this polysaccharide preparation since 1976. In addition, dextran, glucan, and fructan are microbial producible and largely used in cosmetics. Those of skin hydrating microbial polysaccharides that act as humectants used in cosmetics are included in Table 2 with the incorporated content as exemplified in Table 3.

Table 2 Microbial polysaccharides in moisturizing cosmetics

Polysaccharide	Strain	CAS number
Xanthan gum	*Xanthomonas campestris*	11138-66-2
Xanthan gum cross polymer		
Xanthan gum hydroxypropyl trimonium chloride		
Sclerotium gum	*Sclerotium rolfsii*, *S. glucanicum*	39464-87-4
Biosaccharide gum-1		223266-93-1
Biosaccharide gum-2		758716-52-8

NR no reported uses

2.2.8 Animal Polysaccharide

Chitin is the second most abundant biopolymer after cellulose with the similar structure formed in the exoskeleton of arthropods or in the cell walls of fungi and yeast including other lower plants and animals for reinforce and strength proposes. Chitosan is a chitin derivative which is vastly applied in pharmaceutics and cosmetics. Partial deacetylation of chitin in basidic condition or by enzymatic hydrolysis conducted by a chitin deacetylase yielded the modified compound chitosan. Chitin is not only used for chitosan production but also a raw material for glucosamine and oligosaccharide manufacturing (Sandford 2003). Significant water evaporation reduction of the skin treated with high molecular weight chitosan (10^4 to 10^6 Da) was reported (Dee et al. 2007). This skin hydrating effect is regulated by occlusion of chitosan on skin layer. Furthermore, chitin is claimed to reduce a risk of scar formation (McCarthy 1996) with an ability to enhance synthesis of skin matrix acting as the mucopolysaccharide templates as examined in mouse (Bakkers et al. 1997; Varki 1996).

In addition to chitin and chitosan, mucopolysaccharide is produced from the vertebrate particularly in mammalian. Mucopolysaccharides are the term designated to hexosamine-containing polysaccharides present in animal tissue in free sugar polymeric form or that bind with proteins (Meyer 1938). These heteropolysaccharides are different from cellulose, starch, and chitin that are based on a single monosaccharide by their structural repeating units of disaccharide. Hyaluronic acid or hyaluronan (HA) is a natural polysaccharide found in the intercellular matrix of most vertebrate connective tissues including the skin. Together with other glycosaminoglycans (GAGs) that are dermatan sulfate, chondroitin sulfate, and keratin sulfate are represented as the prominent fluid in the skin responsible for skin elasticity. HA is found in the dermis at a greater amount than the epidermis (≈0.5 and 0.1 mg/g wet tissue) (Koshiishi et al. 1999). This polysaccharide therefore mainly regulates elasticity of the skin. Commercialized HA isolated from the

synovial fluid, umbilical cord, skin, and rooster comb of animal source is available with various molecular weights, the highest being 5,000 kDa (Milas et al. 2001). This biodegradable viscoelastic polymer has several health benefits according to its physiological roles leading to versatile applications including cosmetics (Manuskiatti and Maibach 1996).

However, recent advance in biotechnology enables production of specific polysaccharides from the certain strain of microorganism that is more economically feasible with a shorter time of production of these biopolymers and within a reduced space. In addition, nanotechnology is highly emerging in cosmetics recently including skin hydrating products that nanovesicles and cubosomes showed superior efficacy over the casual cosmetic formulation (Esposito et al. 2007) including the liquid crystal moisturizer (Tsai et al. 2010). In addition, penetration enhancement would be greater than topical application of the classical product with massage that was misunderstood to improve the efficacy of the skin hydrating formulation (Hamed et al. 2012).

3 Skin Hydrating or Moisturizing Effect

Dryness of the skin aesthetically draws back the individual's confidence with adverse experiences as follows:

1. Sensory characteristics: feels dry, uncomfortable, painful, and itchy, stings, and tingles
2. Visible characteristics: redness, a lackluster surface, dry white patches, flaky appearance, cracks, and even fissures
3. Tactile characteristics: rough and uneven

Dryness of the skin further accumulates into a reduction of elasticity and wrinkles of the skin consequently as evidenced by biomechanical properties of the skin (Choi et al. 2013a). Therefore, application of skin hydrating cosmetics is not only to hydrate the skin, but their pleiotropic skin benefits ultimately enhance aesthetic preference of the skin (Rawlings et al. 2012). That is recently known as corneotherapy (Klingman 2011).

Moisturizers can immediately prevent excessive water loss from the skin, principally via their occlusive elements. The stratum corneum's barrier function prevents entry of foreign substances and the loss of internal substances, including water. The water content of the stratum corneum (SC) should be greater than 10 % in the skin having a normal appearance and not feeling rough, scaly, or dry. Ideally, SC should have 20–35 % water content. Moisturizers serve to return water content to the skin with the humectants and occlusive ingredients preventing transepidermal water loss (TEWL) (Flynn et al. 2001). Skin hydration is regulated by the SC components in particular corneocytes and natural moisturizing factor (NMF) and intercellular lipid bilayer matrix. NMF is a combination of several compounds created in the skin and comprising approximately 20–25 % of the keratinous layer

in which it retained the water content (Shai et al. 2009). A defective skin barrier function causes inflammation of the skin in addition to impairment of filaggrin initiating atopic dermatitis resulting in skin dryness. Filaggrin forms NMF in SC and is essential during formation of the cornified enveloped corneocytes (Rawlings and Harding 2004) that links between the adjacent corneocytes by corneodesmosomes. Filaggrin deficiency, therefore, abnormalizes the skin barrier in turn and severely enhances skin dryness causing atopic dermatitis accordingly (Wolf and Wolf 2012). In addition to protease degrading filaggrin, corneodesmosome degradation by proteolytic enzymes also enhances skin dryness causing desquamation that is visually noticed as skin flakes (Harding et al. 2000). Protection from excessive water and electrolyte loss from the skin is regulated by SC intercellular lipid. The occlusive oily layer therefore effectively suppresses TEWL by hydrogen bonding with water at the polar head lipids that are in orthorhombic (solid) and hexagonal (gel) packing.

Moisturizers can be considered safe in comparison with traditional drug used by dermatologists. However, inconvenient skin reactions from topical preparation may be encountered. Therefore, moisturizers that are usually free from irritating substances are highly in demand (Lodén 2004) particularly natural moisturizer. Thus, this chapter is exclusively devoted for skin hydrating biopolysaccharides.

3.1 Mechanism of Moisturizer

Moisturizing product is formulated and expected to suppress TEWL and retain or increase the content of water in SC in order to maintain the skin barrier. Although function mechanism of this active cosmetic category is complicated, simple classification on the basis of the actions would be by:

1. Occlusive effect: TEWL in SC which physically blocks thereafter the percolation of water from the inner viable epidermis is protected. In addition, emollience or lubricance that smoothens the skin by filling up the spaces between skin flakes is enhanced to retain the skin hydration. Occlusive ingredients generally used in personal care products are petrolatum, mineral oil, paraffin, and squalene including vegetable and animal fats.
2. Humectant effect: skin hydration in SC is improved by an attraction of water from viable skin tissues remoisturizing the skin from the inside out. Commonly used humectants in cosmetics are glycerin, propylene glycol, urea, sodium lactate, sorbitol, and pyrrolidone carboxylic acid (PCA).

Skin hydrating cosmetics usually combine the moisturizing effects from occlusants and humectants. Synergistic effects by water retaining in the skin and the prevention of TEWL compulsively sustain the skin barrier, therefore largely contributing to hydrating efficacy. Although skin moisturizing efficacy could be monitored by sensory evaluation, instrumental analysis would accurately reflect the efficacy with the practical validation between different studies.

3.2 Evaluation of Skin Hydrating Efficacy *In Vivo*

Skin barrier is a physical property referring to water content in the skin that can be assessed by several techniques. This chapter will be devoted to those of noninvasive methods that are the agreed standardized methods used in clinical evaluation of skin hydrating or moisturizing products which are TEWL, skin hydration, and skin image. The devices based on spectroscopic and microwave principles are not included.

3.2.1 TEWL

Transepidermal water loss is the outward permeation of condensed water through SC by diffusion, of which perspiration including other forms of water loss is excluded from TEWL. This transcutaneous water loss is generally measured by open and closed chamber methods that are commercially available. The open chamber type relies on Fick's diffusion law indicating the quantity being transported per specific area and time. TEWL is thereafter processed and shown in $g/m^2/h$. Although this method allows continuous measuring of TEWL, opening of the probe to the surrounding atmosphere turbulences the result. The closed chamber devices determining skin water flux density are therefore developed to limit the atmosphere influence, which are the condenser chamber and unventilated chamber. The unventilated closed chamber can occlude the skin and might be improper for continuous measurement as the normal evaporation of the skin is blocked. Therefore, the ventilated ones are implied by using dry or moistened carrier gas for continuous determination of TEWL.

TEWL conferring skin barrier function is routinely tracked by Tewameter® (Courage + Khazaka, Germany), the open chamber type, and unventilated closed chamber type, that is, VapoMeter® (Delfin, Finland) including the condenser closed chamber, AquaFlux® (Biox, UK). In addition, DermaLab® (Cortex, Denmark) and Evaporimeter® (ServoMed, Sweden) sharing the same principle with Tewameter® are also used. In the meantime AS-CT1® (Asahi, Japan) that is an unventilated closed chamber type is additionally used besides VapoMeter®.

In addition to direct measurement of skin water loss rate, SC water content or skin hydration can be determined indirectly by means of electrical properties of the skin.

3.2.2 Skin Hydration

The skin water content in terms of SC hydration reflecting skin barrier is measured on the basis of electrical capacitance, conductance, or impedance. These fundamentals rely on the dielectric medium nature of SC. The instrument is therefore developed on the basis of this electrical concept of the skin. Measurement of skin permeability to alternating electric current (impedance) reflects electromagnetic interaction with skin dipoles and electrolytes (Kajs and Gartstein 1991). A low resistance but high impedance correlates with a greater skin hydration (water content). Skicon® (IBS, Japan) operates at 3.5 MHz with the result expressed in microsiemens (μs) ranging from 0 to 1,999 μs. This conductance instrument consists of the concentric interdigital electrodes liberating a direct galvanic contact between the probe and skin surface. The noninvasive capacitance-based devices are based on the difference

of the dielectric constant of water and other substances brought in the electrical measurement field using low operating frequency (up to 1 MHz) (Darlenski et al. 2009). Examples of the capacitance principal are Corneometer® (Courage + Khazaka) and Nova® dermal phase meter or DPM (Nova, USA). The measurements are shown in arbitrary unit (AU). Corneometer® contains an interdigital grid of gold electrodes covered with a low dielectric vitrified material. The frequency shift of the oscillating system is detected referring to skin capacitance that is in contact with the probe ranging from 0 to 120 AU. Nova® DPM has two concentric brass ring electrodes separated by an isolator with a distance between the inner and outer probes of 1 mm and readout measurement ranging from 90 to 999 AU. In addition, Moist Sense® (Moritex, Japan) is also used to assess the relative skin moisture value with 0 to 99 AU. Furthermore, other devices measuring skin conductance, ASA-M2® (Asahi) in addition to Skicon®, are also used. In the meantime, Moisture Meter SC® (Delfin, Finland) exterminating SC hydration by means of skin capacitance and DermaLab Moisture Unit® (Cortex) sharing the same principle with Nova® DPM are also used to verify skin hydrating efficacy of topical products.

Skin hydration measurement is therefore assessable by capacitance- and conductance-based device regarding to their correlation. In addition, there are validations of different instruments that are developed by different manufacturers. For instance, Corneometer® and Skicon® are strongly correlated as examined *in vivo* ($r = 0.97$). However, conductance method is influenced by electrolytes with a lack of sensitivity at low hydration. In contrary, the sensitivity of the capacitance instrument is limited at high hydration values (Clarys et al. 2012).

Capacitance imaging (CI) of the skin surface is developed on the basis of silicon image sensor (SIS) technology that is previously developed for security reasons by fingerprint recoding. The resulting capacitance map is interpreted in terms of skin hydration/dryness. This skin recoding called SkinChip® (L' Oréal, France) composed of 92,160 microcapacitors on a 1.8×1.28 cm plate plugged directly to the USB port is recently proposed to determine skin hydration *in vivo* (Lévêque et al. 2006).

3.2.3 Skin Image

In addition to the above noninvasive techniques that determine skin condition relevant to cutaneous moisture, skin flakes resulting from desquamation are collected and analyzed by D-Squame® (CuDerm, USA). It is the test kit that validated with the above instruments' applicability for clinical efficacy evaluation of skin moisturizing products. Skin dryness resulting from desquamation is visually scaled following the application of the D-Squame® tape onto the skin with a moderate pressure using the thumb or fingertips. Scaliness of the skin is divided into a 1–5 score referring normal to very dry skin. The desquamated corneocytes collected by the stripping tape can be additionally analyzed using an image analyzer (Black et al. 2006; Gasser et al. 2004). Furthermore, the skin image that is directly taken from the volunteer's skin by Visioscan® (Courage + Khazaka) on SESc recording parameter alternatively used scaliness to assess skin hydrating efficacy of the cosmetic product. In addition, skin replica is also analyzed upon scaliness of the skin by Visiometer® (Courage + Khazaka).

3.2.4 *In Vivo* Assessment of TEWL, Skin Hydration, and Skin Image

Although there might be some differences resulting from the different instruments used, standard guidelines by EEMCO (European Group for Efficacy Measurements on Cosmetics and Other Topical Products) recommendation are adopted worldwide that make the results able to be validated in different analytical conditions. In addition, the measuring instruments should be calibrated routinely on the basis of the manufacturer guideline. Furthermore, TEWL is related with SC hydration. These determination concepts are therefore used interchangeably. However, clinical evaluation strictly relies on the same practice.

Prior to starting the measurement, the volunteer or the participant must be acclimatized in the temperature- and humidity-controlled environment to suppress turbulent effect from sweating that alters water evaporation rate of the skin. This volunteer preparation will take 15–30 min at 20–22 °C and relative humidity of 40–60 %. The measurement will be taken in the same climatized room without external air convection turbulence (du Plessis et al. 2013).

Clinical evaluation of skin hydrating efficacy is equivalently measured on the face or volar forearm. Therefore, the volar forearm is generally chosen in skin biomechanical property assessment with a minimal discomfort to the volunteer (Bazin and Fanchon 2006).

3.3 *In Vitro* Hydration Property

Hydration property of polysaccharide is determined by means of water absorption, water-holding capacity, and swelling properties. These parameters confer skin hydrating potential of the polysaccharides that should be conducted prior to clinical evaluation *in vivo* in terms of TEWL and/or SC water content.

Absorption of water refers to the structural network of polymer specifically the volume. Baumann apparatus is generally used to measure water absorption, that is, the kinetics of water uptake. However, measurement of water absorption capacity is routinely calculated as the percentage of weight increases of the sample dried over P_2O_5 *in vacuo* for 24 h by

$$\text{Water absorption capacity } (\%) = 100 \times \frac{(Wn - Wo)}{Wo}$$

where Wn and Wo are the weights of the sample before and after putting the saturated $(NH_4)_2SO_4$ desiccator (81 % RH) and the saturated K_2CO_3 desiccator (43 % RH) at 20 °C after 48 h of the test.

Water-holding capacity is the amount of water that is retained by the polymer at the specific weight commonly 1 g and determined under a specific temperature, humidity, time, and speed of centrifugation. This parameter sometimes is known as water-retaining capacity. However, centrifugation measurement is generally higher than the determination by Baumann apparatus. The standardized protocol determination is studied by hydrating a known polysaccharide weight in a centrifuge tube for 18 h

before pelleting the insoluble residue by centrifugation (3,000 g; 20 min). Following removal of the excess supernatant and/or soluble material, the hydrated polysaccharide residue is weighted prior to repeating the residue weight in the dry form. Consequently, the water retention capacity is calculated using the following equation:

$$\text{Water retention capacity}(g/g) = \frac{\text{Residue fresh weight} - \text{Residue dry weight}}{\text{Residue dry weight}}$$

In addition, the moisture-retention ability of polysaccharide can be calculated as the percentage of residual water of wet sample prepared by adding 10 % water to the sample dried over P_2O_5 *in vacuo* for 24 h by using the equation

$$\text{Water retention capacity}(\%) = 100 \times \frac{Wn}{Wo}$$

where Wn and Wo are the weights of the sample before and after putting the saturated K_2CO_3 desiccator (43 % RH) and the silica gel at 20 °C after 48 h of the test.

Swelling property is assessed by the bed volume technique by swelling the polysaccharides in water overnight using a volumetric cylinder. Generally a known weight of polymer (100–200 mg) hydrated with water in a graduated cylinder (10 ml) is dispersed with gentle stirring, covered, and left for saturation for 18 h at room temperature. Thereafter, the settled volume occupied by polysaccharide is recorded and swelling is calculated by the equation as shown below:

$$\text{Swelling} = \frac{\text{Volume occupied}}{\text{Polysaccharide dry weight}}$$

In addition to the above physicochemical properties that indirectly confer skin hydration potential of the polysaccharides, total polysaccharide content, the sugar constituents, molecular weight, porosity, and particle size also contribute to the moisturizing property.

4 Skin Hydrating Effect of Polysaccharides

Regarding the above classification of moisturizing polysaccharides, those of commercial available skin moisturizing polysaccharides are summarized as shown in Table 4 with the recommended concentrations and useable preparation as available. CAS (Chemical Abstracts Service) number and INCI (International Nomenclature of Cosmetic Ingredients) name are included for further reference.

In addition to the currently used commercialized moisturizing polysaccharides, candidate biopolysaccharide from different sources potential for skin hydrating cosmetics is also included. Those with *in vitro* (water-retaining and water absorption capacities and total polysaccharide content) and *in vivo* (human volunteers or animal model) results from accredited journal and patents are exclusively summarized and alphabetically listed. However, those of mushroom-derived polysaccharides are excluded from this article.

[b]Additionally used in makeup cosmetics
[c]Additionally used in sun care

4.1 Animal Polysaccharides

Hyaluronic acid (HA) is the predominant mucopolysaccharide of the skin acting as the key molecule that regulates skin hydration. It is therefore popularly formulated in moisturizing products at a concentration varying from 0.025 to 0.050 %, serving as skin hydrating agent (Stern and Maibach 2008). In addition to the common application of HA in the forms of dermal fillers (e.g., Hylaform®, Restylane®, and Dermalive®), it is topically applied to maintain SC function restoring skin barrier.

Comparative clinical evaluation of skin hydrating effect of HA (anionic polysaccharide) and ceramide in foam and emulsion cream was conducted by a randomized double-blind split body study in 20 female volunteers. The appearances relevant to skin dryness including moisturizing effect were significantly improved ($p < 0.05$) following 2 weeks as rated by the investigator. The improvement was enhanced at the end of the evaluation for 4 weeks ($p < 0.001$), although that of HA foam was more superior over the ceramide cream (1.5-fold at 2 weeks and 1.3-fold at 4 weeks) (Draelos 2011). However, concentrations of moisturizing agents were not addressed. In addition, formulation using the same dosage form including instrumental evaluation would additionally support the outcome of these moisturizers.

Moisturizers containing ceramide are included. Impruv®, Cetaphil RestoraDerm™, CeraVe™, Triceram®, EpiCeram®, Atopiclair®, and MimyX®

are commonly commercialized over-the-counter (OTC) products. GAGs with the molecular weight of 10^3–10^7 Da at the concentration of 0.05–5 % were patented into skin hydrating cosmetics (Bosco et al. 2013).

In addition to the above animal-derived skin hydrating polysaccharide, chitosan modified from shrimp (*Solemocera prominentitis*) chitin with the degree of substitution of 83.2 % and molecular weight of 2,420 KDa was formulated in the moisturizing mask. Skin water-holding capacity of the mask was examined in seven volunteers in a comparison with the control mask containing methylcellulose at the same concentration (2 %). Skin capacitance (Corneometer®) of the shrimp chitosan was better than that of methylcellulose (Chen and Hen 2000). Those of commercialized glycosaminoglycans (GAGs) including HA for skin hydration are included in Table 4.

4.2 Botanical Polysaccharides

4.2.1 *Abelmoschus esculentus*

Okra is regarded as the important source of polysaccharide according to its high content of the fruit mucilage. Its polysaccharides with physicochemical properties found more applications in cosmetics (Camciuc et al. 1998; Sengkhamparn et al. 2010). Moisturizing alcohol-based hand rub containing okra polysaccharide was formulated. This moisturizing product with 0.105 % polysaccharide maintained skin hydration significantly better than the placebo as instrumentally monitored (Moist Sense®) in 20 volunteers who are health-care workers in the hospital. Skin hydration was retained for 210 min of application. Therefore, it was recommended for application encouraging hand hygiene with antiseptic properties (Kanlayavattanakul et al. 2012).

4.2.2 *Aesculus hippocastanum*

Horse chestnut that is adopted in traditional German medicine is one of the important sources of polysaccharides including oligosaccharides that composed more than 50 % in the herb (Thornfeldt 2005). Thus, it is the candidate botanical source of skin hydrating polymers applicable for cosmetics. However, none of horse chestnut polysaccharide moisturizer is presented yet, including the skin hydrating efficacy. Thus, this botanical polysaccharide is worthy to be formulated and challenged for clinical evaluation.

4.2.3 *Aloe vera*

The leaf enriched with polysaccharides is largely implied in skin preparation and popularly sold over the counter (OTC) for skin nourishing effect. Aloe polysaccharide in topical product (0.1, 0.25, and 0.5 %) significantly increased skin capacitance (Corneometer®), although TEWL (Tewameter®) was insignificantly suppressed as examined in 20 volunteers monitored after 1 and 2 weeks of application (Dal'Belo et al. 2006). Aloe polysaccharide is therefore widely commercialized in several trade names as shown in Table 4.

4.2.4 *Aztec chia*

Chia native to Mexico was a polysaccharide gel isolated from the seed. Low molecular weight chia polysaccharide (150–250 KDa) exhibited moisturizing effect. It was therefore formulated with glucan (700–1,300 KDa) and HA (800–1,500 KDa) claiming as skin hydrating cosmetics at 0.5–3 % (Choi et al. 2010).

4.2.5 *Camellia sinensis*

Tea polysaccharide containing 64.27 % of neutral sugar and 27.95 % of uronic acid was shown to be a good moisturizer as it is able to retain water (*in vitro* test) comparable to glycerol at the same tested concentration. It is therefore highlighted as another important bioactives derived from tea in addition to phenolics that are widely formulated in aesthetic products (Wei et al. 2009). Tea polysaccharide with molecular weight range between 100 and 300 KDa was prepared and formulated (0.1–20 %) into moisturizing cosmetics as patented by the Korean cosmetic firm (Kwon et al. 2010).

4.2.6 *Carica papaya*

Papaya fruit is one of the important skin hydrating polysaccharides. Papaya polysaccharide with a molecular weight of 2,540 KDa having 76.9 % of total sugar and 10.92 % of uronic acid was characterized. Galactose (52 mol ratio) and arabinose (21.6 mol ratio) were found as the main monosaccharides followed by glucose, rhamnose, and xylose (11.0, 10.2, and <0.1 mol ratio). This antioxidant polysaccharide absorbed and retained moisture content (in vitro) comparable to HA and glycerol at the same tested concentration (100 mg) (Zhang et al. 2012). Papaya polysaccharide is commercialized by Rahn in Hydractin® (Table 4).

4.2.7 *Durio zibethinus*

Durian is one of the important tropical fruits that is enriched with polysaccharides in the hull. Durian polysaccharide consists of polygalacturonan branched with galactose, glucose, rhamnose, fructose, and arabinose with molecular weight approximately 500–1,400 Da (Hokputsa et al. 2004). The polysaccharide was therefore formulated into gel (10 %) and assessed on its skin hydrating activity in 18 volunteers for 8 weeks. A randomized single-blind split-face placebo-controlled study was directed to apply 0.139 % polysaccharide gel formulation or 0.3 g of product twice daily (morning and evening). Skin water content (Corneometer®) was significantly increased at the first examination following treatment of 4 weeks ($p = 0.024$) and largely achieved ($p = 0.003$) at the end of the study. The results additionally revealed that the efficacy in female volunteers was more superior over male. In addition, the product imparted excellent enhancement of skin hydration in the subjects who are younger than 30 years old than the older (Futrakul et al. 2010).

4.2.8 *Echinacea purpurea*

The root of the herb has polysaccharides which are isolated and characterized. Polysaccharides (xylan and galactan) with molecular weight approximately 35 and

450 KDa were obtained. This polysaccharide with biological activity was suggested to be incorporated in health benefit preparations (Dalby-Brown et al. 2005). The polysaccharide extract was further commercialized and claimed as skin moisturizer as shown in Table 4 by Carruba.

4.2.9 *Malva sylvestris*

Malva nut is widely applied in dermatological use due to its therapeutic effects relevant to the skin (Pieroni et al. 2004). The herb's potential in skin hydration is governed by its abundant mucilage. Polysaccharides in this herb consisted of glucuronic acid, galacturonic acid, rhamnose, galactose, fructose, glucose, sucrose, and trehalose with the minor constituents of uronic acid, arabinose, mannose, xylose, fucose, raffinose, and xylotriose (Barros et al. 2010; Classen and Blaschek 1998). Therefore, Malva mucilage was formulated into skin hydration products (Cauchard et al. 2010; Choi et al. 2005).

4.2.10 *Myrosma cannifolia*

Guapo, native tuber plant of Venezuela, is examined for its potential starch of cosmetic application. Its amylase and amylopectin ratio is corn resembling with optimal physicochemical properties for cosmetics in addition to safety and compatibility in cosmetic base. Its water absorption capacity is adequate and challenge to be verified on its skin hydrating efficacy (Rincón et al. 2005).

4.2.11 *Orchidaceae* sp.

Orchid, a plant of the genus *Odontoglossum* of the family *Orchidaceae* and/or a plant derived from a hybrid plant of the genus *Odontoglossum* and the genus *Cochlioda*, constituted 60–70 % polysaccharide in which mannose is the main neutral sugar (90 %) prepared. Cosmetics with moisturizing efficacy were formulated and claimed at the extract concentration of 0.1–15 % (Sasaki et al. 2013).

4.2.12 *Piptadenia colubrina*

A native leguminous tree of South American rain forest has isolated skin beneficial polysaccharide with the extractive yield of 0.05–0.25 %. The extracted polysaccharide was further formulated into a gel-cream product (5 %). Clinical evaluation on the basis of skin capacitance was examined by randomized single-blind placebo-controlled study in 15 volunteers for 14 days and tracked by Corneometer®. Skin capacitance was significantly achieved. Cellular skin hydrating effect was evidenced by expression of filaggrin enhanced by the polysaccharide in human skin explants (Pereda et al. 2010).

4.2.13 *Tamarindus indica*

Polysaccharide tamarind seed (65–73 % of the kernel) with the molecular weight of 600–750 KDa was formulated into cosmetics (0.1–1 %) with skin hydration activity claimed (Cocchi and Sanso 2010). Tamarind polysaccharide claiming skin moisturizing activity is commercialized with the trade name of PA Reviviscence® LS 9562 by Laboratoires Serobiologiques (Table 4).

4.2.14 *Ulmus davidiana*

The root of *U. davidiana* var. *japonica* that has been used traditionally in Oriental medicine was examined on its skin benefits. The polysaccharide derived from the plant root with molecular weight of 20 KDa consisting mainly of rhamnose (57.37 %) was preliminary water retaining *in vitro* including its safety and activity in human skin fibroblast. The noncytotoxic polysaccharide with water-holding capacity additionally suppressed inflammatory mediators as evidenced by the reduction of PEG2, IL-6, and IL-8 in the cultured cells. Moisturizing activity of the polysaccharide was further assessed in 10 female volunteers. Skin hydrating effect monitored by Corneometer® and VapoMeter® was almost the same as HA that was used as the positive control (Eom et al. 2006). This skin hydrating polysaccharide is further commercialized by Bioland and Presperse Incorporated as shown in Table 4.

4.3 Microbial Polysaccharides

4.3.1 *Aspergillus niger*

The mycelium was biotechnologically controlled to produce chitin-glucan with the ratio of these two polysaccharides between 30:70 and 50:50. The obtaining composite of biopolymer was formulated into oil in water emulsion at 0.5–2.0 % and clinically evaluated in 13 female volunteers for 6 weeks. That of 1.5 % polysaccharide significantly improved skin hydration by the suppression of TEWL (Tewameter®) with no erythema. Confirmatory skin moisturizing effect of the 1.5 % chitin-glucan formulation was further conducted in 20 male volunteers for 16 weeks. This natural polysaccharide significantly improved skin barrier by water-holding capacity in SC with additional effect on skin rejuvenation as skin roughness was decreased (Gautier et al. 2008).

4.3.2 *Aureobasidium pullulans*

β-Glucan from *A. pullulans* was prepared and further incorporated into skin moisturizing cosmetics at the amount of 5–20 % that enhanced skin hydration evidenced in 5 female volunteers (Moriya et al. 2011).

4.3.3 *Gluconacetobacter sacchari*

Bacterial cellulose produced from *Gluconacetobacter sacchari* composited with glycerin (1 %) showed a significant skin moisturizing effect as examined in 15 volunteers who contacted with the product for 24 h. TEWL was suppressed, whereas skin capacitance was increased as shown by Tewameter® and Corneometer® (Almeida et al. 2013).

4.3.4 *Klebsiella pneumoniae*

Polysaccharide from a nonpathogenic strain was formulated (10 %, 40 kDa) and assessed on its skin hydrating efficacy in 40 female volunteers. The formulation

significantly enhanced skin water content following 15 and 30 days of study as evidenced by Corneometer® with an ability to suppress TEWL as shown by Tewameter® (de Cargo and Gaspar 2012).

4.3.5 *Nostoc commune*

Cyanobacterium in *Nostoc* genus particularly *N. commune* largely synthesized the mucilaginous matrix. The polysaccharide plays an important role in the bacterium's defense mechanism, of which *Nostoc* polysaccharide is regarded as the biomedical potential natural product with a wide variety of therapeutic effects applied in traditional medicine of several countries. Furthermore, *Nostoc* polysaccharide showed a comparable in vitro moisture absorption and retention capacities to chitosan and urea studied at the same concentration. Consequently, its skin hydrating efficacy was confirmed in an animal model as the water content in mouse SC was improved (Li et al. 2011).

4.3.6 *Saccharomyces cerevisiae*

Baker's yeast is one of the important sources of glucan, moisturizing polysaccharides in cosmetics (Kanlayavattanakul and Lourith 2008). Glucan derivatives are widely used in topical preparations particularly carboxymethyl glucan. It improved skin barrier function as evidenced in enhancement of skin hydration (Corneometer®) in 5 volunteers whom were directed to apply the product containing carboxymethyl glucan (0.04–0.4 %) twice daily for 2 weeks (Zülli et al. 1998). Modifiers of β-glucan enlarge applications suitable for various preparations including sodium carboxymethyl β-glucan. Nano-cosmetics for eye hydration were formulated in a form of liposome containing 0.1–5 % of the active polysaccharides (Mercuri 2008).

4.3.7 *Zymomonas mobilis*

Levan, fructan polysaccharide, was prepared using *Z. mobilis*. The prepared polysaccharide with a molecular weight of 2,250 KDa was noncytotoxic in human skin cell cultures with the anti-inflammatory effects against IL-1α. Skin moisturizing effect was further evaluated in a comparison with hyaluronan at the same concentration by means of TEWL using VapoMeter® and skin capacitance using Corneometer® in 10 female volunteers. Skin hydrating efficacy of *Z. mobilis* polysaccharide was comparative to that of HA (Kim et al. 2005). This microbial polysaccharide is commercialized by BASF and Bioland (Table 4).

4.4 Seaweed Polysaccharide

In addition to the above skin hydrating polysaccharides from microbial source, the seaweed Rhodophyta (red algae) is an important source of sulfated galactans including carrageenans, whereas the brown seaweed (Phaeophyta) largely produces alginates. Carrageenan is exhibited as the excellent active polysaccharide. κ-Carrageenan was formulated (0.5–10 %) with starch (0.5–20 %) in skin mattifying cosmetics with

the moisturizing feeling (Cassin 2013). Furthermore, anionic polysaccharide with the average size of less than 500 KDa was prepared from cell culture of microalgae of the genus *Parachlorella* or *Chlorella* and commercialized by Codif (Table 4). The polysaccharide is composed of rhamnose, xylose, mannose, glucose, arabinose, and glucuronic acid at 15–55, 3–30, 1–25, 1–45, 0.5–10, 22, and 0.1–15 mol%. The polysaccharide (0.1 %) was formulated into a topical application product claiming safety and efficiency (Coragliotti et al. 2010).

4.4.1 *Gigartina stellata*

This red seaweed with the synonym of *Mastocarpus stellatus* enriched with polysaccharide mainly composed of galactose was revealed as the potential source for skin hydrating product according to the in vitro water absorption with the swelling capacity of 7.20 ± 0.42 ml/g and water retention capacity of 5.42 ± 0.06 g/g (Gómez-Ordóñez et al. 2010). Presperse Incorporated is the company that produces red seaweed polysaccharide as shown in Table 4.

4.4.2 *Himanthalia elongata*

Comparative *in vitro* water retention evaluation of edible seaweed of the Spanish coast was conducted. *H. elongata* was noted as the potential polysaccharide for skin moisturizing effect due to its water retention capacity of 7.26 ± 0.13 g/g and swelling ability of 10.97 ± 0.62 ml/g (Gómez-Ordóñez et al. 2010). Similar to *G. stellata* polysaccharide commercialization, *H. elongata* is commercialized by Presperse Incorporated (Table 4).

4.4.3 *Laminaria* sp.

Hydrocolloids extracted from 12 edible seaweeds including *L. japonica* or kombu were comparatively evaluated on skin moisturizing activity. Skin capacitance (Corneometer®) in 10 female volunteers was superiorly enhanced by *L. japonica* over the others at the same tested concentration (5 %). This edible seaweed extract was further formulated into cosmetic cream at various concentrations (1–15 %). Skin moisturizing effect was found significant and superior with the 10 % hydrocolloid algae as it prolonged the suppression of TEWL (Tewameter®) for 8 h (Choi et al. 2013b). This commercialized polysaccharide (Akott) is included in Table 4. In addition, sweet kombu or *L. saccharina* is additionally highlighted as the suitable moisturizing polysaccharide due to its high water retention and swelling capacities (8.93 ± 0.52 g/g and 10.20 ± 0.37 ml/g) (Gómez-Ordóñez et al. 2010).

4.4.4 *Monostroma nitidum*

These edible green macroalgae called aonori in Japanese were extracted to give humectant mucilage. The mucilage was formulated into cosmetic product in the form of a mask in combination with hydroxyethylcellulose (HEC). The equivocal amount of the algal mucilage and HEC (total 2 %) was found superior over that containing 2 % methylcellulose in terms of moisturizing effect as assessed in 7 volunteers monitored by Corneometer®. In addition, the mucilage functioned as thickening agent (Chen and Chen 2003). It is therefore accountable as multifunctional ingredient.

In addition to the above edible seaweed, *Ulva* sp. producing water-soluble sulfated polysaccharides with (ulvan) 8–29 % of the algal dry weight consisted mainly of rhamnose and is also one of the important sources of moisturizing polysaccharide. *U. lactuca* polysaccharide with variety of health benefits is also commercialized as skin moisturizing agent, Akomarine® Sea Lettuce (Table 4). In addition to *U. lactuca*, *U. compressa* is also claimed as a skin moisturizing polysaccharide (Carruba, Codif, and Presperse Incorporated). Furthermore, *Undaria pinnatifida* or wakame is one of the edible seaweeds producing polysaccharides with SC benefits.

5 Conclusion

Moisturizing or hydrating polysaccharides are derived from several natural sources of which botanical and edible hydrocolloids particularly botanical polysaccharides are largely meeting the consumers' preferences toward natural cosmetic products. In addition, advanced biotechnology preparation of skin hydrating polysaccharides affords those of economically feasible choices with animal and microbial polysaccharides. Furthermore, delivery system employing nanotechnology would enhance the skin hydrating efficacy. Those with *in vitro* water-retaining activity are encouraged for further clinical evaluation including those of candidate herbs or botanical sources enriched with polysaccharide content. Health benefits of this biopolymer in sufficiently suppressing dryness of the skin and potentially protects and/or treats wrinkles of skin acting as antiaging ingredients accordingly.

Contents

Abstract

Cancer is a main burden of disease worldwide since the past decades. About 11 million cancer cases are added every year. Cancer is also called malignant tumor which developed as abnormal cells in the body. And once the patient is diagnosed with a malignant tumor in the body, the survival ratios are very low. Thus, prevention and curation for tumor have become a significant part in tumor scientific research and disease control all over the world. Surgery, radiotherapy, and chemotherapy are the three dominant methods to treat tumor in recent decades. Among these treatments, chemotherapy is most frequently used. However, as these treatments have serious side effects in tumor carriers, efforts have been made to search other nontoxic biological macromolecules that have antitumor properties. Polysaccharides are one of the most important components in organic compounds and widely involved in many biological phenomena. Mushrooms have been valued as edible and medical provision for mankind for thousands years. Due to its diversity and diverse distributions, its medicinal

values are utilized by folks, especially in China and Japan. In recent years, special attentions are paid to mushroom-derived polysaccharides. Evidences have shown that mushroom polysaccharides have direct and indirect antitumor activities, mostly by way of immunomodulation. This chapter will discuss several aspects of mushroom polysaccharides such as its bioactivities, antitumor mechanisms, toxicity, and also the clinical trials conducted. The main aims of this review are to summarize the available information about mushroom polysaccharides and give a thorough understanding in this area and thus provide references for research and application in antitumor in the future.

Keywords

Cancer • Medicinal mushroom • Polysaccharides • Antitumor • Mechanism • Bioactivities • Toxicity • Clinical trials

Abbreviations

3D	Three-dimensional
5-FU	5-Fluorouracil
AKT	Protein kinase B
C. versicolor	*Coriolus versicolor*
CCl_4	Carbon tetrachloride
G. frondosa	*Grifola frondosa*
G. lucidum	*Ganoderma lucidum*
GLPP	*G. lucidum* polysaccharides peptide
Gl-PS	*Ganoderma lucidum* polysaccharides
HCC	Hepatocellular carcinoma
HIV	Human immunodeficiency virus
IL-10	Interleukin-10
IL-12	Interleukin-12
IL-2	Interleukin-2
IL-4	Interleukin-4
IL-6	Interleukin-6
INF-γ	Interferon-γ
L. edodes	*Lentinus edodes*
MTT	3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide
NK	Natural killer
P. eryngii	*Pleurotus eryngii*
PAC	Cyclophosphamide
PDP	Polysaccharide from *Pholiota dinghuensis Bi*
PEPE	Polysaccharidic extract of *P. eryngii*
PNPS-1	Polysaccharide isolated from *Pholiota nameko*
PSK	Protein-bound polysaccharide Krestin
PSP	Polysaccharide peptide
PSPC	Polysaccharides-protein complex
RFA	Radiofrequency ablation
ROS	Reactive oxygen species

S-GAP-P	Sulfated polysaccharide
SPG	Schizophyllan
STZ	Streptozocin
TACE	Transcatheter arterial chemoembolization
TNF-α	Tumor necrosis factor-alpha

1 Introduction

Cancer is a generic term for a large group of diseases that can be chronic and are responsible for a large number of deaths worldwide. Although there has been considerable progress in modern cancer therapy research, many problems exist in the treatment of cancer. The whole subject area is still problematic, with difficulties in understanding the molecular behavior of various types of cancers and the numerous side effects experienced by patients from treatments (De Silva et al. 2012). Cancer is characterized by uncontrolled proliferation of anaplastic cells which tend to invade the surrounding tissues and metastasize to other tissues and organs (Zong et al. 2012). In recent years, the treatments of cancer mainly include surgery, radiotherapy, and chemotherapy. These treatments usually exhibit serious side effects, killing both malignant cells and normal cells and bringing great pain to patients. Based on this tough situation, utilization of nontoxic drugs for cancer becomes an urgent demand. Mushrooms have been valued as highly tasty and nutritious food and medicine by many societies for thousands of years throughout the world. Traditionally, mushroom (member of the class Basidiomycetes) has been defined as a fleshy, aerial umbrella-shaped, fruiting body of macrofungi. To ancient Romans they were "the food of the Gods," to the early Egyptians they were "a gift from the God Osiris," and the Chinese considered them as "the elixir of life" (Smith et al. 2002). Medicinal mushrooms have an established history of use in traditional ancient therapies (Wasser 2011). In Asia, especially in China and Japan, several mushrooms are adopted due to its medicinal uses, such as *Ganoderma lucidum*, *Lentinus edodes*, and *P. tuber-regium*. In recent decades, researchers have focused more on the extracts of medicinal mushrooms. Among these extracts, polysaccharides are the most potent substance with antitumor efficacy. It is commonly obtained from fruit bodies, cultured mycelia, or culture broth of various mushrooms from the class of Basidiomycetes. These isolated natural products from mushroom include acidic and neutral ones with different types of glycosidic linkages, some of which are bound to protein or peptide residues such as polysaccharide-protein or polysaccharide–peptide complex which showed higher potent antitumor activities. Based on the summarization of Zhang et al. (2007) and the information we summarized, polysaccharides from 29 species of mushroom are listed in Table 1. The related polysaccharides have been extensively studied in the past 30 decades, and the sources of polysaccharides as well as the types also demonstrated. Furthermore, special attention is paid to the derivatives of polysaccharides in the recent studies. Chemical modification is often carried out to improve the antitumor activity of polysaccharides and their clinical qualities

Table 1 Source and type of some macrofungi polysaccharides

Fungi source	Polysaccharides source	Type of polysaccharides	References
Pleurotus tuber-regium	Sclerotium, mycelium	β-D-Glucan	Zhang et al. 2001, 2006, 2003
Ganoderma lucidum	Fruiting body, culture broth	Heteroglycan, mannoglucan, glycopeptide	Miyazaki and Nishijima 1981; Mizuno 1997
Auricularia auricula	Fruiting body	Glucan	Ukai et al. 1982, 1983

(mostly water solubility). Nie et al. prepared chemically sulfated polysaccharide (S-GAP-P), which was derived from water-insoluble polysaccharide of *Grifola frondosa* mycelia, and investigated it in vitro and vivo. The results demonstrated that S-GAP-P had higher antitumor efficacy and enhanced the peritoneal macrophage phagocytosis in S180-bearing mice (Nie et al. 2006).

Mushroom-derived polysaccharides often contain glucose, galactose, mannose, xylose, ribose, arabinose, and glucuronic acid in their α- or β-backbones and branches. Due to their different combinations, the conformation of polysaccharide might differ from each other in many ways. Polysaccharides from various species of Basidiomycetes which consist of β-1,3 glucopyranoside main chain with β-1,6-linked glucose branches possess antitumor activities. And it is also well known that the biological activities of polysaccharides are influenced by their solubility in water, molecular weight, branching rate, triple helical solution conformation, and β-1,6-bonding system in the β-1,3 backbones (Zaidman et al. 2005).

2 Bioactivities

In the 1960s, mushroom polysaccharides were proved to have antitumor activity for the first time (Zhang et al. 2012). Mushroom polysaccharides have shown widely inhibitory effects towards many kinds of tumors including Sarcoma 180 solid

cancers, Ehrlich solid cancer, Sarcoma 37, Yoshida sarcoma, Lewis lung carcinoma, and so on (Zhang et al. 2007). These polysaccharides mainly involve PSK, lentinan, schizophyllan, and polysaccharide peptide (PSP). They all have been proven to inhibit Sarcoma 180 which has been implanted in mice (Wang et al. 1995b). In addition, other polysaccharides derived from mushroom were also studied. In an investigation, the efficacy of *Ganoderma tsugae* which is a famous traditional medicine was proved; the polysaccharide fractions are possessing a significant antitumor activity against solid tumor Sarcoma 180 with inhibition ratio beyond 50 % (Peng et al. 2005). In a study, the antitumor activity of polysaccharides extracted from *Ganoderma lucidum* on the human breast cancer cell in vitro has been evaluated by MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay. Artificial derivatives such as sulfated *Pleurotus tuber-regium* polysaccharides exhibited relatively higher in vitro antitumor activity against human hepatic cancer cell line HepG2 than the native polysaccharides (Tao et al. 2006). It was also demonstrated that polysaccharides of rare species named *Antrodia camphorata* could inhibit the proliferation of U937 cells via activation of mononuclear cells (MNCs) (Liu et al. 2004a). All these results indicated the roles which mushroom-derived polysaccharides played in the inhibition effects on the cancer cells (Zhao et al. 2010).

Other than the purified polysaccharides, the polysaccharides-peptides complex is also a direction in the antitumor study. A polysaccharides-protein complex (PSPC) isolated and characterized from the culture filtrates of a mushroom called *Tricholoma* sp. was proved to significantly suppress the growth of Sarcoma 180 solid tumor in vivo, and the inhibitory ratio is 96 %. No deleterious effect is detected during the experiment (Liu et al. 1996). The protein-bound polysaccharides PSK also evidenced to effect on gastric cancer by immunomodulation (Nio et al. 1991).

3 Mechanism of Action

Numerous studies suggested the mechanisms of antitumor activity of polysaccharides from mushrooms, which included immunomodulation in host organism associated with numerous agents, the inhibition of metastasis, and the promotion of apoptosis in cancer cells. All these mechanism are illuminated as follows.

3.1 Immunomodulation

Mushroom-derived polysaccharides are thought to provide antitumor action primarily by activating the immune response of the host organism rather than attacking the tumor cells directly to achieve their effects. It is well known that mushroom polysaccharides work best when it is used in adjuvant chemotherapies which have high side effects and affect the immune system. Unlike traditional antitumor drugs, they cause no harm and place no additional stress to the body,

acting as biological response modifier in the body and helping to upregulate the suppressed immune system. For example, the Maitake MD-fraction extract from fruit body and cultured mycelia of *G. frondosa* can decrease the cisplatin-induced immunosuppression and nephrotoxicity in mice (Masuda et al. 2009). But polysaccharides did not show massive efficacy while administrated under normal condition (Wasser 2011). Innate immune system and adaptive or acquired immune system are the two major functional units in the human body (De Silva et al. 2012); both of them participate in the action of this macromolecule.

The mechanism that polysaccharides activate innate immune system is assumed to conduct through signal pathway via Toll-like receptors. Dentin-1-deficient mice would cause dramatically reduction in cytokine production in bone marrow-derived dendritic cells (Yamanaka et al. 2012). Macrophage is a pivotal factor in the process, while polysaccharides act as nonself substances in the body to activate the receptors in the macrophage surface. Lentinan can enhance the absolute quantity and phagocytosis of macrophage, which lead to the reduction of tumor size and prolong the living life of tumor cell-inoculated mice (Yang 2002). During the process, polysaccharides can also activate the neutrophil and complement system, which are important in innate immunity. The use of mushroom polysaccharide could lead to the production of cytokine produced by monocyte-macrophages (Wang et al. 1997). Lentinan could trigger a cascade of cytokine release, such as tumor necrosis factor-alpha (TNF-α) and various types of interleukins resulting in the maturation, differentiation, and proliferation of immunocompetent cells for host defense mechanisms (De Silva et al. 2012). And a unique polysaccharide component from *Antrodia camphorata* was evidenced to enhance the concentration of Th1-type cytokines (TNF-α, IFN-γ, and IL-12) and Th2-type cytokines (IL-4 and IL-6) (Liu et al. 2004b).

Natural killer (NK) cells are large granular lymphocyte, and they are considered to be part of the innate defense system. They are able to kill certain tumor cell without prior sensitization. The basal activity of NK cells increases dramatically following stimulation with interferons. In addition, NK cells display Fc-receptors for IgG and are important mediators of antibody-dependent cell-mediated cytotoxicity (Lin 2005). The study of *Pleurotus eryngii* showed that polysaccharides were found to significantly enhance the killing activity of NK cells in tumor-bearing mice, suggesting that it could enhance the specific and nonspecific cytolytic activities against autologous tumor cells (Yang et al. 2013).

Adaptive immune system includes humoral- and lymphocyte-mediated immune responses. Mushroom polysaccharides are known to stimulate B-lymphocyte and T-lymphocyte. Report showed that lentinan was able to restore the suppressed activity of helper T cell in tumor-bearing host to their normal state, resulting in complete restoration of humoral immune response (Ooi and Liu 1999). In addition, the study also indicated that lentinan could promote potentiation of response of precursor T cells. Moreover, it had been reported that the delayed-type hypersensitivity response induced at tumor sites by lentinan and the subsequent infiltration of immune effector cells, such as natural NK cells and cytotoxic lymphocytes, are important mechanisms of antitumor action for lentinan (Zhang et al. 2007).

3.2 Inhibiting Metastasis

Most deaths caused by cancer are not due to primary tumor growth but dissemination of tumor cells to secondary sites by a series of events known collectively as metastatic cascade (Jeon et al. 2011). Metastasis is responsible for 90 % of deaths caused by cancer which comprises three independent processes including tumor growth, angiogenesis, and invasion. All three processes may be suppressed by polysaccharides via the inhibition of AKT signaling (Patel and Chen 2012; Dai et al. 2010). Tumor growth and metastasis have been found to be associated with angiogenesis. *G. lucidum* polysaccharide peptide (GLPP) was tested for its anti-angiogenic properties using chick chorioallantoic membrane assay. The result shows that GLPP might be a potent inhibitor of angiogenesis and subsequent metastasis (Weng and Yen 2010).

3.3 Inducing Apoptosis

Aside from preventing metastasis, mushroom polysaccharides also have shown efficacy of inducing apoptosis in tumor cells. By upregulating the immune system as mentioned above, mushroom polysaccharides can inhibit cancer cell proliferation, arrest cell cycle in various checkpoints, and enhance apoptosis. In previous studies, polysaccharide PSK was demonstrated to act as a growth inhibitor for pancreatic cancer cells, known otherwise to be highly resistant to conventional chemotherapies (Rosendahl et al. 2012). By upregulating cell cycle regulatory p21WAF/Cip1 and proapoptotic protein Bax levels, PSK could arrest pancreatic cancer cell cycle and induce apoptosis. Similar study also showed that *Phellinus gilvus* could exhibit antitumor effects by significantly increasing the melanoma apoptosis rate (Bae et al. 2005)

4 Toxicity

One of the benefits of mushroom polysaccharides in antitumor treatment is that this agent exhibits modest side effects. Other methods such as surgery, radiotherapy, or chemotherapies show numerous adverse actions that may affect patients' mood and quality of life and often inevitably cause at least one form of therapy-associated tissue injury or systematic side effect, such as hepatotoxicity (McWhirter et al. 2013), mucositis (Thorpe et al. 2013), late gastrointestinal and urogenital side effects (Schmid et al. 2012), skin reaction, fatigue, pain, etc. (Ragaz et al. 1997). In Tong's study, using a cytotoxicity assay, the two fractions of *Pleurotus ostreatus* polysaccharides had obvious effects on the inhibition of the growth of Hela cells, suggesting they might be a potential candidate for cancer therapy. Meanwhile, the inhibition ratio of human embryo kidney 293 T cell was significantly lower than the control group treated with 5-FU, which killed human normal cell when killing tumor cell. But no antiproliferative

effects of these polysaccharides on human embryo kidney 293 T cells were observed, implying that they had no direct cytotoxicity to noncancerous cells (Tong et al. 2009). In an antiviral clinical trial study, lentinan, which is isolated from *L. edodes*, was reported to have generally good tolerability. During the trial, only a few patient drop out because of side effect or personal preferences. And most side effects resolved promptly after the discontinuation of medication, and all of them were relieved within 24 h (Roupas et al. 2012). In addition, a *Maitake* extract clinical phase I/II trial was deployed in breast cancer patient, and there were only a little number of patients who withdrew prior to the completion of the study due to the side effects, such as mild nausea and joint swelling or grade I allergic reaction (Deng et al. 2009a). These studies proved that mushroom polysaccharide is a promising and safe medicinal agent in medication of antitumor therapy.

5 Other Bioactivities

5.1 Antioxidant Activities

Antioxidation is another complimentary characteristic that mushroom polysaccharide possesses. As we have learned, oxidation is essential to many organisms for the production of energy to fuel biological processes. However, reactive oxygen species (ROS) are often overproduced under pathological conditions (Guo et al. 2010), thus leading to increased risk of chronic disease. Antioxidants have been shown to inactivate ROS and thus protect from oxidative damage. Among various natural substances, polysaccharide extracts from mushrooms may prove to be one of the useful candidates in search for effective, nontoxic substances with free radical scavenging activity. And polysaccharide extracts from *Jisongrong* mushrooms were reported to have scavenging effects on superoxide and hydroxyl radicals (Zhou and Chen 2011). In a report which studied four widely used mushrooms, the radical scavenging ability of semi-purified polysaccharide extract from *G. lucidum* can be up to 94.8 % when the concentration was set at 2.5 mg/mL, which was also the maximum efficacy among the four polysaccharides. The study also reported that the radical scavenging ability of polysaccharides was associated with the concentration of available hydroxyl group, and antioxidant activity was in a strong relationship with the monosaccharide ratios (Kozarski et al. 2012). In our previous studies, polysaccharides from mushroom *Inonotus obliquus* showed good antioxidant activities in the in vitro assays including 1,1′-diphenyl-2-picrylhydrazyl (DPPH) assay, ferric reducing power assay, and lipid peroxidation inhibition assay (Ma et al. 2013). Antioxidant activities after physical modifications and chemical modification have also been tested, such as modification by acid or alkali hydrolysis and thermal and ultrasonic treatment. The result showed better antioxidant effect after these treatments (Ma et al. 2012; Zhang et al. 2013).

5.2 Antiviral Effects

Antiviral efficacy is also one of the notable abilities of mushroom polysaccharide. For example, it is known that HIV is a virus which caused immunodeficiency problem in human and no efficient treatment is available in the world at the moment. A polysaccharide extracted from *Grifola frondosa* was reported to act as adjuvant in HIV infection therapy. In a study, about 85 % of HIV-infected patients exhibit an upregulated sense of well-being associated with a series of symptoms and secondary disease caused by HIV (Gu et al. 2006). This character of mushroom polysaccharides provides a way for future HIV treatment and also finds a new way for antivirus study on the basis of traditional therapies.

5.3 Hypoglycemic Effects

Diabetes mellitus is a serious chronic metabolic disease, which now afflicts 3 % of global population. Diabetes mellitus is a chronic condition characterized by high blood glucose levels that result from insulin resistance in peripheral tissues or impaired insulin synthesis in the pancreas. In addition to impairment in glucose and carbohydrate metabolism, the disease causes abnormalities in the metabolism of lipids and proteins (Liu et al. 2013). Though immunomodulation and antitumor properties of mushroom polysaccharides were firstly studied, more and more attention is paid on their hypoglycemic effects in recent studies. There were already investigations that demonstrated that *Ganoderma lucidum* polysaccharides (Gl-PS) exhibited potential antihyperglycemic effects in rats. And in Zheng et al.'s study, the mechanism of hypoglycemic effect exhibited by Gl-PS was also discussed. The results showed that after 8 weeks' oral administration, plasma concentrations of fasting glucose, triacylglyceride, total cholesterol, and nitric oxide significantly decreased compared with the control. In addition, the Gl-PS had a hypoglycemic effect in STZ-induced diabetic rats through preventing apoptosis of pancreatic β-cells and enhancing β-cells regeneration (Zheng et al. 2012). The mushroom polysaccharides might become potential nontoxic candidates for hyperglycemic treatment.

5.4 Anti-inflammatory Effects

Inflammation is a multiple and complex process enacted by activated immune-associated cells, such as macrophages, tumor necrosis factor-alpha (TNF-α), and interleukin-6 (IL-6) (Wu et al. 2014). *Geastrum saccatum*, a mushroom cultivated in Brazil, was produced under natural conditions in the unexplored reserve of Mata. An extract of *Geastrum saccatum* which contained high amount of glucose and traces of galactose was reported to possess an anti-inflammatory activity. The research studied the inhibition activity of this extract on the ear edema induced by croton oil. The results showed that administration of glucan extract reduced edema (Guerra Dore et al. 2007).

5.5 Hepatoprotective Effects

Liver is an important organ for detoxification. However, liver diseases are becoming a serious health problem worldwide. Most of the hepatotoxins induce tissue injury after having been metabolized to free radicals and cause subsequent cell damage through mechanism of covalent binding and lipid peroxidation (Nitha et al. 2013). Hepatoprotective effect is also one of the characters of mushroom polysaccharides which can be promising hepatoprotective drugs. *Pleurotus eryngii* is an edible mushroom which has biological functions as described in Chinese traditional medicine. Chen et al. investigated hepatoprotective effects of water-soluble polysaccharidic extract from *P. eryngii* (PEPE) by using in vivo mouse models and in vitro biochemistry assays (Chen et al. 2012). The results indicated that PEPE enhanced the antioxidant activity in a liver-injury mouse model and effectively prevented excessive lipid formation in liver tissue. This result suggested that PEPE could be a valuable functional food additive for hepatoprotective treatments. Hepatoprotective effects were also found in mycelial polysaccharide from *Pholiota dinghuensis Bi* (PDP). Biochemical assay and histopathological analysis showed that crude PDP exerted significant hepatoprotective effect in a dose-dependent manner against carbon tetrachloride (CCl_4)-induced acute liver injury (Gan et al. 2012).

5.6 Anti-thrombus Effects

Anti-thrombus effects are rarely reported in mushroom polysaccharides. Only Huang noted its anti-thrombus effects in his studies on a mushroom polysaccharides extracted from *Tremella fuciformis* (Huang 1982). Thus, anti-thrombus effect could be another direction in the mushroom polysaccharide research.

5.7 Hypolipidemic Effects

Hyperlipidemia is a key factor in the development of some serious disorders, such as atherosclerosis, fatty liver disease, and cardio-cerebrovascular disease (Qiu et al. 2013). Lowering of high serum and liver lipid level plays a significant role in prevention, arrest, and even reversion of atherosclerosis (Li et al. 2010). Several mushroom polysaccharides possess hypolipidemic effect as reported. In Chen's research eight mushroom polysaccharides were subjected to macrophage-derived foam cell system to screen for and identify the biologically functional polysaccharides. These eight mushrooms included *Pleurotus eryngii, Lentinus edodes, Pleurotus ostreatus, Pleurotus nebrodensis, Hypsizygus marmoreus, Flammulina velutipes, Ganoderma lucidum,* and *Hericium erinaceus.* According to the results, different types of edible mushrooms had diverse polysaccharide components. Among them in selected edible mushrooms, *P. eryngii* polysaccharide had the strongest ability to inhibit lipid accumulation (Chen et al. 2013). *Pholiota nameko*

is a widely cultivated mushroom in China and Japan. The hypolipidemic effects of polysaccharide isolated from *Pholiota nameko* (PNPS-1) were studied. Hyperlipidemic Wistar rats were treated with PNPS-1 and the results evidently demonstrated that PNPS-1 significantly possessed cholesterol-lowering effects on the serum of hyperlipidemic rats (Li et al. 2010). Similar result can be obtained in other mushroom polysaccharides. All these results indicated that mushroom polysaccharides could be a promising agent for hyperlipidemic therapy.

6 Clinical Trials of Mushroom Polysaccharides

Although there are approximately 1,400 species of mushrooms described and many mushroom polysaccharides have been studied, only a few of them have clinical uses such as lentinan from *L. edodes*, schizophyllan from *S. commune*, polysaccharides from *G. frondosa*, and compounds from *T. versicolor* (protein-bound polysaccharide Krestin/PSK and polysaccharide peptides/PSP) (Chatterjee et al. 2011).

6.1 Lentinan

Polysaccharide works best when used as adjuvant chemotherapies. In this respect, lentinan has been studied best both in animal model and in human clinical practices (Wasser 2011). Yang et al. had evaluated the efficacy of the combination of transcatheter arterial chemoembolization (TACE), radiofrequency ablation (RFA), and lentinan in treated hepatocellular carcinoma (HCC) patients. The results showed that tumor necrosis was significantly higher in the combination group than those purely treated with TACE or RFA or the combination of TACE and RFA. And the tumor recurrence rate was also lower than other groups. Lentinan was showed to be helpful to the patients (Yang et al. 2008).

6.2 Schizophyllan

Schizophyllan (SPG) is another β-glucan derived from the culture broth of *Schizophyllum commune* fries. Remarkable improvement of schizophyllan in the conjugation with chemotherapies was also reported. In the study of Masaki Inoue and Yoshiaki Tanaka, 68 ovarian cancer patients were randomly assigned in four groups treated with, respectively, cisplatin, adriamycin, and cyclophosphamide (PAC) or a PAC plus SPG. The results revealed the fact that SPG could activate host immunity which had been damaged by chemotherapy and, as a result, could improve the long-term prognosis (Inoue et al. 1993). As to the gastric cancer, SPG seemed to function in the control or elimination of microscopic metastatic foci and/or small-sized macroscopic foci which were present in the stage III patients (Fujimoto et al. 1984).

6.3 Protein-Bound Polysaccharide Krestin (PSK)

PSK is a protein-bound polysaccharides extracted from the mycelia of *Coriolus versicolor* which is well known by its immunity-enhancing properties. Similar to lentinan and schizophyllan mentioned above, PSK was also tested as an adjuvant chemotherapy for cancer patient. For example, in a long-term study in Japan, patients with curatively resected colorectal cancer were orally administrated with mitomycin C intravenously on the day of and the day after surgery, followed by oral 5-fluorouracil (5-FU) administration for over 6 months compared with patients receiving PSK for over 3 years on the basis of control group. The results assured the efficacy of PSK as an adjuvant chemotherapy on curatively resected colorectal cancer (Mitomi et al. 1992).

6.4 Polysaccharides from *Grifola frondosa*

Polysaccharides extracted from *Grifola frondosa* (*Maitake* extract) are also an important agent in cancer therapy. In Gary Deng's study, this agent was subjected to a phase I/II trial in breast cancer treatment. The results showed that at an intermediate dose, oral administration of polysaccharides from *G. frondosa* could upregulate the production of IL-2, IL-10, TNF-α, and IFN-γ by subsets of T cells in patients (Deng et al. 2009b). This indicated its promising immunomodulating role in cancer therapy.

7 Conclusions

Polysaccharide is a macromolecule which is notably well known by its conformational diversity due to its primary structure consisted of different monosaccharides and also due to its special 3D structures. Such variability provides the mushroom polysaccharide with antitumor activities armed with various mechanisms. The antitumor efficacy is well established by many studies and the results confirmed its feasibility in antitumor treatment. Its unique property also compensates the deficiency of chemotherapies, which in a way prolongs the patients' life and alleviates the pain during the curing process. In the past decades, such polysaccharides had provoked tremendous interests in researchers to study its antitumor efficacy, and numerous mushroom polysaccharides or their derivatives were extracted and subjected to studies both in vitro and vivo. Depressively, among this group, an accountable number of polysaccharides were approved for commercial production and have been used on cancer patients, such as lentinan, schizophyllan, PSK, polyporus polysaccharide. As such resource is a promising and new direction in cancer therapies, there is an urgency to fully tap its potential and it requires more advanced investigation, such as the more elucidating antitumor mechanism and the relationship between structure and activities and also the use of high-resolution equipment to define the 3D structure of polysaccharides.

Mushroom has a long-established history both in food and medicinal uses; the recognition of the ability of mushroom-derived polysaccharides is of much significance. Challenges may lie ahead, but surely it will start a new era of medicine.

Contents

Abstract

Resistant starch (RS) is a recently recognized source of fiber and is classified as a fiber component with partial or complete fermentation in the colon, producing various beneficial effects on health. RS also offers an exciting new potential as a food ingredient, mainly as a prebiotic ingredient. RS can be fermented by human gut microbiota and provides the colonic microbiota with a fermentable carbohydrate substrate. As a functional fiber, its fine particles and bland taste make the formulation of a number of food products possible with better consumer acceptability and greater palatability than those made with traditional fibers. Technically, it is possible to increase the RS content in foods by modifying the processing conditions such as pH, heating temperature and time, the number of heating and cooling cycles, freezing, and drying. RS shows improved

1 Introduction

Polysaccharides in foods consist of starch and plant cell wall constituents (Perera et al. 2010; Sánchez-Zapata et al. 2009, 2012). Starch is the major source of carbohydrate in the human diet (Ratnayake and Jackson 2008). It occurs in many plant tissues as granules, usually between 1 and 100 μm in diameter, depending upon the plant source. Chemically, starches are polysaccharides composed of α-D-glucopyranosyl units linked together with α-D-(1–4) and/or α-D-(1–6) linkages and are comprised of two molecular types: amylose, the straight chain polyglucan comprised of approximately 1,000, α-D-(1–4) linked glucoses, and amylopectin, the branched glucan, comprised of approximately 4,000 glucose units with branches occurring as α-D-(1–6) linkages (Haralampu 2000; Sharma et al. 2008).

X-ray diffraction differentiates various patterns and structures of starch. Two crystalline structures of starch have been identified (an A and B-type), which contain differing proportions of amylopectin. A-type starches are found in cereals, while B-type and amylose-rich starches are found in tubers. A third type called C-type appears to be a mixture of both A and B forms and is found in legumes (Fuentes-Zaragoza et al. 2010). In general, digestible starches are broken down (hydrolyzed) by the enzymes α-amylases, glucoamylase, and sucrase-iso-maltase in the small intestine to yield free glucose that is then absorbed (Nugent 2005). However, not all starch in the diet is digested and absorbed in the small intestine (Ratnayake and Jackson 2008).

On the basis of its digestibility, starch was classified into three groups, namely, readily digestible starch, partially resistant starch, and resistant starch (Englyst and Cummings 1987). According to this classification, starch that is not accessible to digestive enzymes, such as that protected by hard to digest coatings in whole and coarsely milled grains, starch in raw banana and potato exhibiting B- or C-type X-ray diffraction patterns, and retrograded amylopectin, is considered to be partially resistant starch. Retrograded amylose that can be solubilized in potassium hydroxide and which subsequently becomes susceptible to hydrolysis by amyloglucosidase is referred to as resistant starch (Perera et al. 2010).

Resistant starch (RS) refers to the portion of starch and starch products that resist digestion as they pass through the gastrointestinal tract. RS is an extremely broad and diverse range of materials and a number of different types exist (RS1-4).

At present, these are mostly defined according to physical and chemical characteristics (Nugent 2005).

Resistant starch is the fraction of starch that is not hydrolyzed to D-glucose in the small intestine within 120 min of being consumed, but which is fermented in the colon. Many studies have shown that RS is a linear molecule of α-1,4-D-glucan, essentially derived from the retrograded amylose fraction, and has a relatively low molecular weight (1.2×10^5 Da) (Tharanathan 2002).

Currently, naturally occurring resistant starch (such as found in whole grains, legumes, cooked and chilled pasta, potatoes, rice, and unripe bananas) is considered dietary fiber, while resistant starches added to foods for health benefits are classified as functional fiber under the American Association of Cereal Chemists (AACC) and the National Academy of Sciences (NAS) definition (Sajilata et al. 2006).

The increased awareness of consumers concerning the relationship between food, lifestyle, and health has been one of the reasons for the popularity of food rich in fiber; so resistant starch (RS) has gained importance as a new source of dietary fiber (Fuentes-Zaragoza et al. 2010). The general behavior of RS is physiologically similar to that of soluble, fermentable fiber, like guar gum. The most common results include increased fecal bulk and lower colonic pH (Slavin et al. 2009). Additional observations suggest that resistant starch, such as soluble fiber, has a positive impact on colonic health by increasing the crypt cell production rate or decreasing colonic epithelial atrophy in comparison with non-fiber diets. There are indications that resistant starch, like guar, a soluble fiber, influences tumorigenesis and reduces serum cholesterol and triglycerides. Overall, since resistant starch behaves physiologically as a fiber, it should be retained in the total dietary fiber assay (Haralampu 2000). The recent increased interest in RS is related to its effects in the gastrointestinal tract, which in many ways are similar to these of dietary fiber. Like soluble fiber, RS is a substrate for the colonic microbiota, forming metabolites including short-chain fatty acids (SCFA), i.e., mainly acetic, propionic, and butyric acid. Butyric acid is largely metabolized by the colonocyte and is the most import energy source for the cell (Elmstahl 2002). RS consumption has also been related to reduce postprandial glycemic and insulinemic responses, which may have beneficial implications in the management of diabetes (Tharanathan and Mahadevamma 2003). Therefore, there is wide justification for assuming that RS behaves physiologically like fiber (Sajilata et al. 2006).

The advent of novel and innovative products is a strategic field in the food industry. With an increasing trend toward health and nutrition, consumers are not merely interested in traditional nutritional aspects of the food, but are also concerned with supplementary health merits derived from its regular ingestion. In response, food manufacturers, researchers, and producers have aimed to improve the digestion and health benefits of starch as it is the main carbohydrate in the human diet and serves as an energy source (Viuda-Martos et al. 2010; Sánchez-Zapata et al. 2013). Due to its physiological effects, RS is considered to be a promising and innovative food ingredient, which could be parallel with dietary fibers (Fuentes-Zaragoza et al. 2011; Li et al. 2011).

2 Resistant Starch Classification

RS escapes digestion in the small intestine and passes to the large intestine where it is fermented by bacteria in healthy individuals. Prospective physiological benefits and high quality of the final food products make RS much important to the food formulators and nutritionists. Importance of RS is disease prevention including modulation of glycemic index, diabetes, cholesterol lowering capability, and weight management (Aktar Nasrin and Anal 2014). RS has physicochemical properties, particularly the low water holding capacity, stability in high processing temperatures, bland flavor, and white color, which provide better appearance, texture, and mouthfeel than do conventional fiber sources and improve expansion and the crispness in certain food applications. Native starches are modified with chemical, physical, and enzymatic methods for the formation of RS indigestible residues. RS is the fraction of starch which is not hydrolyzed to D-glucose in the small intestine within 120 min of being consumed, but which is fermented in the colon. Many studies have shown that RS is a linear molecule of a-1,4-D-glucan, essentially derived from the retrograded AM fraction, and has a relatively low MW (1.2×105 Da). RS is an extremely broad and diverse range of materials and a number of different types exist. At present, these are mostly defined according to physical and chemical characteristics (Haralampu 2000; Sharma et al. 2008). Resistant starch is generally categorized in five forms based on the nature of starch and type of sources RS1-RS5 (Fuentes-Zaragoza et al. 2011).

Type 1 (RS1) includes physically inaccessible starch that is locked within cell walls and food matrixes, thus preventing amylolysis. Milling and chewing can make these starches more accessible and less resistant. RS1 is heat stable in most normal cooking operations, which enables its use as an ingredient in a wide variety of conventional foods.

Type 2 (RS2) is composed of native starch granules from certain plants containing uncooked starch or starch that was gelatinized poorly and hydrolyzed slowly by R-amylases (e.g., high-AM cornstarches) (Hernández et al. 2008; Ratnayake and Jackson 2008; Sanz et al. 2009; Yao et al. 2009). RS2 describes native starch granules that are protected from digestion by the conformation or structure of the starch granule. This compact structure limits the accessibility of digestive enzymes (has low bioaccessibility) and various amylases and accounts for the resistant nature of RS2 such as ungelatinized starch. In the diet, raw starch is consumed in foods like banana (Sajilata et al. 2006). A particular type of RS2 is unique as it retains its structure and resistance even during the processing and preparation of many foods; this RS2 is called high-AM maize starch (Wepner et al. 1999).

Type 3 (RS3) refers to retrograded or crystalline non-granular starch formed after cooking, like the starch found in cooked and cooled potatoes, bread crusts, cornflakes, and retrograded high-AM maize starch. RS3 refers to non-granular starch-derived materials that resist digestion (Wepner et al. 1999; Sanz et al. 2009; Yao et al. 2009). RS3 is of particular interest, because of its thermal stability. This allows it to be stable in most normal cooking operations and enables

its use as an ingredient in a wide variety of conventional foods. During food processing, in most cases in which heat and moisture are involved, RS1 and RS2 can be destroyed, but RS3 can be formed (Faraj et al. 2004). Storey et al. (2007) classified a soluble polysaccharide called "retrograded resistant maltodextrins" as type 3 RS. They are derived from starch that is processed to purposefully rearrange or hydrolyze starch molecules, and subsequent retrogradation, to render them soluble and resistant to digestion. This process results in the formation of indigestible crystallites that have a molecular similarity to type 3 RS but with a smaller degree of polymerization as well as a lower MW (Storey et al. 2007), converting a portion of the normal α-1,4-glucose linkages to random 1,2-, 1,3-, and 1,4-α or β linkages (Mermelsteim 2009).

Type 4 (RS4) includes chemically modified or re-polymerized starches (e.g., chain linkage altered dextrins, ethers, or esters) used by food manufacturers to alter the functional characteristics of the starch (Ratnayake and Jackson 2008; Sanz et al. 2009; Yao et al. 2009) and includes starches which have been etherized, esterified, or cross-bonded with chemicals in such a manner as to decrease their digestibility (Nugent 2005). RS4 can be produced by chemical modifications, such as conversion, substitution, or cross-linking, which can prevent its digestion by blocking enzyme access and forming atypical linkages (Sajilata et al. 2006; Kim et al. 2008).

Type 5 (RS5) is an AM-lipid complexed starch (Jiang et al. 2010; Fuentes-Zaragoza et al. 2011), which is formed from high-AM starches that require higher temperatures for gelatinization and are more susceptible to retrograde (Cummings and Stephen 2007). In general, the structure and amount of starch–lipid in foods depend on their botanical sources (Siswoyo and Morita 2003). Also, Frohberg and Quanz (2008) defined as RS5 a polysaccharide that consists of water-insoluble linear poly-α-1,4-glucan that is not susceptible to degradation by alpha-amylases. They also found that the poly-α-1,4-D-glucans promote the formation of short-chain fatty acids (SCFA), particularly butyrate, in the colon and are thus suitable for use as nutritional supplements for the prevention of colorectal diseases.

3 Methods of RS Determination

Determination of RS in food ingredients and processed foods has become vital to the provision of nutritional information to consumers and others (Fuentes-Zaragoza et al. 2010, 2011; Perera et al. 2010). To enable effective use of the research output on RS for food processing and nutritional applications, analytical procedures for the determination of RS need to be compared. At present, significant differences exist among procedures with respect to sample preparation, the enzymes used, and the establishment of experimental conditions that mimic gastrointestinal digestion of starch. Ongoing improvements in analytical methodology are essential, but frequent modifications in protocols reduce the availability of comparable data to assess the efficacy of methods and the nutritional quality of foods. Added to this,

food analyses used in the various procedures have differed in their genetic origin, composition, and processing history.

In vitro methods for the analysis of RS in foods are based conceptually on the gastrointestinal digestion of starch in foods. Enzyme hydrolysis is a common feature of all methods, combined with chemical hydrolysis or gravimetric isolation. Differences in sample preparation are significant and range from mechanical methods (milling, grinding, and homogenization) to mastication.

The type of RS quantified is dependent on the protocol. Most methods are focused on the determination of total RS, but specific methods have been developed to quantify RS1, RS2, RS3, RS4, or RS5. Methods for the determination of RS proposed by Englyst et al. (1982) and Englyst et al. (1992) are the basis for this discussion.

Significant modifications proposed by other authors are compared and contrasted. As proposed by Englyst et al. (1982), RS and other nonstarch polysaccharides are first separated from the enzyme-hydrolyzable starch. Then, RS is solubilized in alkali and thereby separated from the other enzyme-resistant polysaccharides. Even though Englyst et al. (1982) labeled this fraction as RS, the analytical protocol used reveals that it measures RS3 only. Briefly, in this method 100–200 mg of homogenized wet sample or ground dry sample is mixed with sodium acetate buffer at pH 5.4 and heated for 1 h at 100 °C to gelatinize starch. Having included homogenization and boiling steps, this protocol eliminates the contribution of RS1 and RS2 to the final RS value. An enzyme mixture containing α-amylase, pullulanase, and amyloglucosidase is added and hydrolysis is carried out for 16 h at 40 °C. Absolute ethanol is added to terminate enzyme activity and to precipitate nonhydrolyzed starch. The pellet is collected after centrifugation and washed twice with 80 % ethanol. The residue is dried with acetone and then treated with 2 M potassium hydroxide for 30 min at room temperature to solubilize retrograded starch (RS3). An aliquot of alkali digest is mixed with 2 M acetic acid and amyloglucosidase and the contents are incubated at 65 °C for 1 h. After cooling and centrifuging, neutral sugars (glucose, galactose, mannose, xylose, and arabinose) in the supernatant are analyzed by gas–liquid chromatography (GLC). The quantity of glucose detected by GLC represents the amount of RS (RS3) in the sample.

The above procedure was modified later by the authors (Englyst et al. 1992) to measure total glucose, free glucose, total RS, and RS1, RS2, and RS3 as separate fractions. The determination of total RS is carried out in stepwise fashion. Total glucose (TG) and free glucose (FG) contents are determined, in order that total starch (TS) may be calculated as $TS = (TG - FG) \times 0.9$. In this protocol for TS determination, RS1 and RS2 are eliminated by mincing/milling/homogenizing the food sample and subsequently heating the sample at 100 °C for 30 min, respectively. Any retrograded starch that contributes to RS3 is eliminated by treating the sample with 7 M potassium hydroxide at 0 °C. The rapidly digestible starch (RDS) and slowly digestible starch (SDS) contents of the sample are determined separately, and total RS is calculated as $RS = TS - (RDS + SDS)$. In this method, 0.8–4.0 g of sample is minced only to minimize structural changes. The low

viscosity of samples leads to the release of considerably higher amounts of glucose during enzyme hydrolysis, especially in the absence of other polysaccharides, than is the case with the in vivo digestion of starch. Thus, guar gum is added to increase the viscosity. Glass beads are added to samples to ensure proper mixing and to break cell walls during enzyme hydrolysis. For the determination of RDS and SDS, samples are equilibrated with 20 mL of acetate buffer at 37 °C, and then starch is hydrolyzed with an enzyme mix containing pancreatin as a source of α-amylase (30,000 BPU/g), amyloglucosidase (400 AGU/mL), and invertase (3,000 EU/mL). Englyst et al. (1992) proposed that enzyme hydrolysis be carried out at 37 °C instead of at 40 °C, as previously used in the Englyst et al. (1982) protocol, to better mimic human physiological conditions of digestion. A significant reduction in the duration of enzyme digestion is used in the Englyst et al. (1992) protocol. After 16 h of sample digestion with uses sequential removal of aliquots of enzyme digest at 20 min (as the rapid release of sugars ended at 20 min of digestion with pancreatin) and at 120 min from the beginning of the digestion. The rationale to terminate enzyme hydrolysis at 120 min is that the release of glucose reached a plateau at 120 min. The glucose content of the 20 min enzyme digest (G20 fraction) represents RDS and is calculated as RDS = (G20 − FG) × 0.9. The difference in glucose contents between the 120 min and 20 min digests represents SDS and is calculated as SDS = (G120 − G20 − FG) × 0.9. Instead of directly measuring glucose originating from RS as in Englyst et al. (1982), this method indirectly estimates total RS as RS = TS − (RDS + SDS). As 37 °C is the highest temperature at which a sample is treated in this protocol, any RS2 in the food sample would not be hydrolyzed by α-amylase. RS1 also is preserved in the unhydrolyzed fraction as the sample is only minced, and no milling or homogenization is employed. As a result, this indirect measurement of RS includes any RS1, RS2, and RS3 in the sample.

Englyst et al. (1992) devised protocols for determination of RS1, RS2, and RS3. By definition, RS1 is the fraction of starch that is inaccessible to enzymes due to physical impediments, e.g., large-sized particles and cell walls. The analytical procedure for RS1 determination differs from that of Englyst et al. (1982) with respect to the method of reduction of particle size. One portion of the sample (A) is minced once and the other portion (B) is either milled or homogenized, as appropriate, to obtain particles b 0.2 mm in diameter. Then, using the protocol for the determination of RDS and SDS, glucose released after 120 min of enzyme hydrolysis (G120) is determined for each portion. RS1 is calculated as RS1 = [G120 (B) − G120(A)] × 0.9. Starch in raw foods and foods cooked with little water (preventing complete gelatinization of starch) contribute to RS2.

The method for the determination of RS2 compares the amount of glucose released enzymatically from a cooked sample to that from a raw sample (Englyst et al. 1992). One portion (C) of a raw food sample is heated in 0.1 M sodium acetate buffer, pH 5.2, in a boiling water bath for 30 min, while another portion (D) is used directly without a heat treatment. The samples are hydrolysed with amylase, amyloglucosidase, and invertase and the glucose released after 120 min (SDS). RS2 is calculated as RS2 = [G120(C) − G120(D)] × 0.9.

Determination of RS3 is limited to samples containing retrograded starch (Englyst et al. 1992), and the protocol is similar to that of Englyst et al. (1982) in many ways. In contrast to the protocol for the determination of RDS and SDS for the estimation of total RS, where α-amylase, amyloglucosidase, and invertase are used, the protocol for RS3 determination uses α-amylase and pullulanase at 40 °C. After removing the enzyme-hydrolyzable starch from the sample, retrograded starch is solubilized in 4 M potassium hydroxide at room temperature, whereas Englyst et al. (1982) used 2 M potassium hydroxide. However, this concentration is lower than that used (7 M) in the protocol for the determination of TG. The temperature at which retrograded starch is solubilized in potassium hydroxide also is different in the two procedures: 0 °C for TG and room temperature for RS3 determination (Englyst et al. 1992).

Goñi et al. (1996) cautioned about the possible effect of sample preparation in RS protocols as drying and cooling, and conditions of storage can alter the level of RS in foods. In this procedure, a 100 mg sample is milled or homogenized before use and by doing so RS1 is eliminated. Sample pH is decreased to 1.5 with HCl–KCl buffer to simulate gastric pH. As a major modification to the procedure of Englyst et al. (1992), hydrolysis with pepsin at 40 °C for 1 h is introduced. Sample pH is adjusted to 6.9 with tris–maleate buffer to simulate conditions in the small intestine. Instead of using a cocktail of enzymes as in Englyst et al. (1992), samples are hydrolysed with α-amylase only for 16 h at 37 °C. As this method is focused on the determination of RS (not SDS and RDS), products from enzyme hydrolysis are discarded at this point. As 40 °C is the highest temperature to which the sample is exposed, any RS2 in raw foods is included in the unhydrolyzed fraction. The pellet is dispersed in 4 M potassium hydroxide at room temperature for 30 min to solubilize RS3. Dextrin in the alkali digest is hydrolyzed to glucose with amyloglucosidase at 60 °C for 45 min. Glucose content is determined using a colorimetric assay. Based on the analytical procedure of Goñi et al. (1996), the presumed definition for RS is starch that is not hydrolyzed by α-amylase within 16 h at body temperature, which is in contrast to the Englyst et al. (1992) definition where RS is starch that is not hydrolyzed by pancreatin, amyloglucosidase, and invertase within 120 min.

Other modifications to the Englyst et al. (1992) method have been proposed, but the essence of the method (to remove hydrolyzable starch with enzymes) remained unchanged. Chung et al. (2006) modified the Englyst et al. (1992) protocol to eliminate redundancy and to introduce a reduction in sample size (to 0.5 g). Instead of adding guar gum separately to each sample tube with subsequent dissolution in acetate buffer, Chung et al. (2006) prepared a solution of guar gum in HCl (to increase its solubility) and then added aliquots to each sample. The volume of sodium acetate is decreased to 5 mL by increasing its molar concentration to 0.5 M (20 mL of 0.1 M sodium acetate is used in the Englyst et al. (1992) protocol). Chung et al. (2006) deleted invertase from the enzyme mix. The digests collected (0.5 mL) after 20 and 120 min were mixed with 4 mL of 80 % ethanol, which replaced the 20 mL of 66 % ethanol in the Englyst et al. (1992) protocol. RS was calculated as the difference between total starch and starch not hydrolysed at 120 min as in Englyst et al. (1992).

The Megazyme® kit for RS determination is widely used in analytical laboratories and is the basis of both AOAC method 2002.02 and AACC method 32–40 (Megazyme 2008; Perera et al. 2010). This method, in many ways, is similar to that of Englyst et al. (1982). Samples are ground to pass a 1 mm sieve which generates a coarse meal; thus RS1 is accounted for in this method. The Megazyme® protocol eliminates the initial boiling of samples in acetate buffer and the use of pullulanase. Instead, it employs a mixture of α-amylase (3 Ceralpha units/mg) and amyloglucosidase (3,300 U/mL) to hydrolyze starch in raw or processed food samples. Hydrolysis is carried out for 16 h at 37 °C as proposed by Englyst et al. (1982). As a result, RS2 in raw foods would not be hydrolyzed during this procedure. After inactivation of enzymes with 99 % ethanol, glucose in the sample is removed by two washings with 50 % ethanol. Similar to Englyst et al. (1982), the pellet collected from digestion is treated with 2 M potassium hydroxide to extract RS3 from the fiber-rich matrix. Dextrins thus produced are hydrolyzed to glucose with amyloglucosidase. The incubation time with amyloglucosidase is reduced to 30 min at 50 °C (Megazyme 2008) from 1 h at 65 °C (Englyst et al. 1982). The Megazyme® method uses the glucose oxidase–peroxidase colorimetric assay to determine the glucose concentration in the final hydrolysate, as did Englyst et al. (1992). The Megazyme® protocol for RS does not enable the determination of SDS and RDS.

Eerlingen et al. (1993) proposed enzymatic gravimetric isolation of RS from wheat starch pre-gelatinized at 121 °C and subsequently stored at 0 °C, 68 °C, and 100 °C. In this method, samples are placed in boiling phosphate buffer, pH 6, and hydrolyzed with Termamyl® (heat stable α-amylase) at 100 °C for 30 min. After cooling to room temperature, the pH is adjusted to 4.5 with 2 % phosphoric acid. Samples are hydrolyzed with amyloglucosidase at 60 °C for 30 min and then centrifuged. The pellet is washed with deionized water, dispersed in phosphate buffer at pH 7.5, and incubated with protease at 42 °C for 4 h. The residue after digestion is collected by filtration and oven-dried at 80 °C. The weight of the enzyme-insoluble residue represents the RS content of the starch sample. Faraj et al. (2004) also isolated RS gravimetrically but introduced a preliminary hydrolysis with lichinase and β-glucosidase. Then, samples are treated with a fungal protease at 42 °C, Termamyl® at 100 °C, and amyloglucosidase at 50 °C, respectively. RS is collected by drying the enzyme-resistant residue. It is important to note that the gravimetric separation of RS is acceptable only for analytes free of nonstarch polysaccharides.

Other modifications have been made to the sample preparation step of RS determination with the intent of more closely simulating in vivo digestion. Åkerberg et al. (1998a, b) employed chewing of food samples to initiate hydrolysis by salivary amylase. According to these authors, the number of times a food sample is chewed has a significant effect on the end result. Briefly, the chewed food sample (15 chews in 15 s) and subsequent mouth wash are expectorated into a beaker containing pepsin in Na/K phosphate buffer. Then, the pH is adjusted to 1.5 with HCl and the sample is incubated for 30 min at 37 °C to simulate gastric conditions. Sample pH then is adjusted to 5 with sodium acetate buffer (0.5 M, pH 5) and sodium hydroxide.

Subsequently, starch hydrolysis is carried out with a mixture containing $MgCl_2$, $CaCl_2$, 2-propanol, pancreatin, and amyloglucosidase for 16 h at 40 °C. Then, 95 % ethanol at 60 °C is added in excess, leading to the formation of a precipitate at room temperature. The precipitate, collected by filtration, is dehydrated with 95 % and 99 % ethanol and solubilized in 2 M potassium hydroxide. The total starch content of the alkali digest is determined and expressed as RS. Muir and O'Dea (1992) also employed chewing for sample preparation. Sample pH is then adjusted to 2 and the sample is hydrolysed with pepsin for 30 min at 37 °C. After neutralizing the pH with sodium hydroxide, pancreatin and amyloglucosidase are added to samples in acetate buffer at pH 5 and incubated for 6 h at 37 °C. According to the authors, this reduction in hydrolysis time (6 h instead of 16 h) is intended to represent better the movement of food through the small intestine. The Muir and O'Dea (1992) protocol significantly deviates from the approaches already discussed as the pellet collected after pancreatin hydrolysis (at 37 °C) is further treated with thermostable α-amylase (Termamyl) at 100 °C, presumably to hydrolyse RS2. The pellet recovered after Termamyl hydrolysis is boiled with dimethyl sulfoxide (DMSO) for 1 h. The supernatant from Termamyl hydrolysis (RS2) and the digest from DMSO treatment (RS3) are mixed, and the glucose content of the mixture is determined. Introduction of DMSO in lieu of potassium hydroxide for solubilization of RS3 is a novel feature of the Muir and O'Dea (1992) protocol. Saura-Calixto et al. (1993) determined RS in dietary fiber. Instead of using pancreatin as the source of α-amylase, they used heat stable α-amylase at 100 °C to eliminate traces of starch. The pellet from enzyme digestion is sequentially hydrolyzed using a protease and amyloglucosidase for 35 min at 60 °C. The residue is collected and dehydrated with ethanol and acetone and subsequently dispersed in 2 M potassium hydroxide at room temperature. After adjusting the pH to 4.75 with acetate buffer, dextrins in the solution are hydrolyzed with amyloglucosidase at 60 °C for 35 min. The glucose oxidase–peroxidase system is used to measure glucose in the supernatant collected after centrifugation.

It is important to note that very little information is available on the in vivo digestibility of foods for which in vitro RS data is available. From a nutritional point of view, this is a drawback. Grinding and homogenization would certainly produce food particles much smaller than those resulting from chewing. Englyst et al. (1992) compared chewing of samples against mincing and reported that differences in results were more related to the source of starch than to the method of mincing. Individuals differ in their chewing habits and may not chew the same number of times as in an experimental procedure. Therefore, available RS1 may vary from person to person as its level depends on particle size.

It is important to consider possible variability in RS data associated with the technique employed to sample the enzyme hydrolysate, because the colorimetric glucose assay is sensitive to inaccuracies in sample volume. Englyst et al. (1992) proposed drawing of 0.5-mL volumes of the hydrolyzate after 20 and 120 min to determine RDS and SDS, respectively. Then, RS is computed as the difference between total starch and enzyme-hydrolyzed starch. Chung et al. (2009) reduced the volume of sample drawn to 0.1 mL. It has been observed that undigested food particles interfere with pipetting (especially at the 20-min sampling point) more

frequently than one might expect. This would significantly influence the reproducibility of the colorimetric assay of glucose. The advantage of using gas–liquid chromatography to measure glucose is such errors can be corrected by using an internal standard, as did Englyst et al. (1982). In this connection, the Megazyme® protocol eliminated variability related to sample volume by employing the total volume of the digest after potassium hydroxide treatment for centrifugation and then drawing an aliquot for color development. The availability of RS controls from Megazyme® is useful for understanding experimental errors.

It is reasonable to expect that variations in analytical procedures, including differences in the enzymes used and in their concentration and sequence of application, and dissimilarities in the conditions of experiments, would significantly alter the levels of RS detected in similar foods. RS values of selected foods as reported by some authors (Szczodrak and Pomeranz 1991; Englyst et al. 1992; Muir and O'Dea 1992; Åkerberg et al. 1998a; Faraj et al. 2004; Chung et al. 2006; Tribess et al. 2009; Perera et al. 2010). Englyst and Hudson (1996) reported RS values of a large number of different food items, but the non-availability of information on handling and storage pre- and post-processing prevent any useful comparison. The analysis of resistant starch in Englyst et al. (1982) is limited to a few sources including white bread, whole wheat bread, and corn flakes (0.8 %, 0.8 %, and 2.9 % RS, respectively, on a dry weight basis) because the main focus of this study was to propose a method to determine nonstarch polysaccharides in foods, not RS.

4 Prebiotic Effects

The definition of "prebiotics" as a concept in nutrition was proposed in 1995, by semantic analogy with the term "probiotics" (Fuentes-Zaragoza et al. 2011). Even if slightly different definitions are proposed and discussed by several international instances, prebiotics always refer to the fact that food ingredients or nutrients escape the digestion in the upper part of the digestive tract and are selectively fermented by bacteria, thereby changing the composition and/or activity of the gastrointestinal microbiota. An important point of the definition is that it must confer benefits upon host health (Roberfroid 2007; Delzenne 2009; Fuentes-Zaragoza et al. 2010, 2011; Sánchez-Zapata et al. 2013; Viuda-Martos et al. 2010).

Prebiotics are utilized to promote the survival of probiotics. Prebiotics are nondigestible carbohydrates that are not absorbed in the intestine, such as RS (Coskun 2006; Fuentes-Zaragoza et al. 2010, 2011; Sánchez-Zapata et al. 2013). RS is not absorbed in the small intestine; it provides the colonic microbiota with a fermentable carbohydrate substrate. It has been suggested that RS promotes a higher proportion of butyric acid than other indigestible carbohydrates. Butyrate constitutes a major energy substrate for the colonocytes and is associated with benefits in relation to colonic health (Scourboutakos 2010; Leeman et al. 2006). They travel to the colon where they promote the growth of specific advantageous microbiota (probiotics) by supplying food/energy, while simultaneously influencing the microbiota's gene expression (Lee et al. 2009).

RS is currently attracting widespread interest for its potential health benefits leading to growing demand for robust, cost-effective RS assays for industrial, regulatory, and research use. Unlike other dietary fiber components, RS is neither intrinsically indigestible nor a fixed entity and is determined by an individual's upper gut digestive capacity as well as food processing and storage conditions so any analysis needs to accommodate physiological factors such as transit time (Fuentes-Zaragoza et al. 2011).

The possible applications of RS such as prebiotic constituents in functional food formulations could be summarized (Charalampopoulos et al. 2001):

(i) As fermentable substrates for growth of probiotic microbiota, especially lactobacilli and bifidobacteria
(ii) As dietary fiber promoting several beneficial physiological effects
(iii) As encapsulation materials for probiotic in order to enhance their stability

Short-chain fructooligosaccharides (FOS) and RS may act synergistically (by combining, and thus increasing, their prebiotic effects) (Rodríguez-Cabezas et al. 2010); the administration of the combination of FOS and RS induced changes in the intestinal microbiota, by increasing lactobacilli and bifidobacteria in cecum and colonic contents. Several types of prebiotic fibers can be distinguished considering their rate of fermentability. Such role depends on the carbohydrate chain length as it has been demonstrated in vitro in a fermentation system, showing that FOS are rapidly fermented whereas long chain prebiotic, like inulin, are steadily fermented. These observations have been confirmed in vivo once the different prebiotics reach the large intestine: FOS are rapidly fermented, whereas RS is slowly degraded. In consequence, the particular kinetics would determine the region of the intestine where the effects will be clearer. Thus, FOS would be more active in the first parts of the large bowel, whereas RS would reach the distal part of the colon. In fact, Le Blay et al. (2003) have reported that administration of FOS or raw potato starch induces different changes in bacterial populations and metabolites in the cecum, proximal, and distal colon, as well as in feces. As compared with RS FOS doubled the pool of cecal fermentation products, like lactate, while the situation was just the opposite distally. These observations confirm that each prebiotic shows particular properties, which should be considered before their application for intestinal diseases; thus, rapidly fermentable prebiotics are particularly useful in those affecting the proximal part of the large intestine, while slowly fermentable prebiotics should be chosen for more distal intestinal conditions. Moreover, an association with different prebiotics with complementary kinetics should be considered when a health-promoting effect throughout the entire colon is required. So, functional foods based on the combination of two different dietary fibers, with different rate of fermentability along the large intestine, may result in a synergistic effect and, thus, in a more evident prebiotic effect that may confer a greater health benefit to the host (Younes et al. 2001).

Also, RS and inulin combination showed synergistic effects on intestinal calcium and magnesium absorption and balance in rats. The fermentation of these

substrates in the large bowel to SCFA is the main reason for this increase in mineral absorption (Younes et al. 2001).

Functional foods have changed and increased the role of food in health. Probiotics are the fastest-growing sector of the functional food industry, through their role in increasing the number of beneficial bacteria in the gut. These living microorganisms are primarily derived from lactic acid bacteria, comprising multiple strains from the genera *Lactobacillus* and *Bifidobacterium*. Some foods combine several microorganisms (Scourboutakos 2010). Beneficial health effects attributed to probiotics are shortening of the duration of rotavirus diarrhea, relief of signs and symptoms of lactose intolerance, decreasing the risk of allergy in atopic individuals, cancer prevention, lowering of serum cholesterol levels, prevention of urogenital infections, and synthesis and enhancement of the bioavailability of nutrients. Probiotic bacteria may compete with pathogens for nutrients and mucosal adherence, produce antimicrobial substances, and modulate mucosal immune functions. The beneficial effects of probiotics are strain-specific; therefore, the definition of which probiotics (as a single strain or a combination) are most effective in specific diseases is needed (Coskun 2006).

The breakdown of prebiotic molecules by bacterial enzymes into SCFA (acetate, butyrate, and propionate) is crucial for gut integrity and function, modulation of the immune system, calcium and magnesium absorption, and maintenance of normal serum cholesterol levels. The end products of this fermentation are consumed by both these bacteria and intestinal epithelium as fuel. Symbiotic refers to nutritional supplements which contain probiotics and prebiotics in combination. Since it has been hypothesized that prebiotics ensure the survival of some beneficial bacteria, their effects might be additive or symbiotic (Coskun 2006). Prebiotics selectively can stimulate probiotic strains. Prebiotics may improve the survival of bacteria crossing the upper part of the gastrointestinal tract, thereby enhancing their effects in the large bowel (Iyer and Kailasapathy 2005).

The best model of prebiotic–probiotic symbiosis is the encapsulation (Fuentes-Zaragoza et al. 2011). Encapsulation is often mentioned as a way to protect bacteria against severe environmental factors. The physical protection of probiotics by microencapsulation is a new approach to improve the probiotic survival. Encapsulation helps to isolate the bacterial cells from the effects of the hostile environment and gastrointestinal tract, thus potentially preventing cell loss (Homayouni et al. 2008). The goal of encapsulation is to create a microenvironment in which the bacteria will survive during processing and storage and be released at appropriate sites (e.g., small intestine) in the digestive tract. The benefits of encapsulation to protect probiotics against low gastric pH have been shown in numerous reports and similarly for liquid-based products such as dairy products (Weinbreck et al. 2010).

Microcapsules consist of a liquid core surrounded by a semipermeable membrane which retains the cells inside, reduces mass transfer limitation, and minimizes phage contamination. For the encapsulation of viable cells, the materials and formulation conditions used should be gentle and nontoxic. In this respect, the antibacterial properties of chitosan limit its use as a core solution.

However, alginate and starch liquid core capsules offer the possibility to immobilize lactic acid bacteria without loss of viability and fermentation ability (Jankowski et al. 1997). Starch and its derivative (RS) are widely used in the encapsulation of various food components, as probiotics. Indeed the use of starch in many encapsulation processes has provided solutions to problems such as thermal stabilization, process-induced controlled release, and extended shelf-life of sensitive compounds (Shimoni 2008). The (micro)encapsulation of probiotics has received attention from food companies interested in producing probiotic-containing consumer products, but faced with the difficulty of maintaining cell viability over the shelf-life of the product (Weinbreck et al. 2010).

A symbiotic approach is often accomplished by co- encapsulation of RS in the form of high-AM maize starch together with the probiotic microorganisms within the microcapsule. Usually, 1–2 % insoluble starch grains are added to the probiotic–hydrocolloid precursor directly before the encapsulation process, with the aim to further maintain the viability of probiotics (Sultana et al. 2000; Iyer and Kailasapathy 2005).

RS had been used to improve encapsulation of viable bacteria in yogurt. Sultana et al. (2000) reported that the incorporation of Hi-Maize1 starch (commercial RS) improved encapsulation of viable bacteria (*Lactobacillus acidophilus* and *Bifidobacterium* spp.) in yogurt, as compared to when the bacteria were encapsulated without the starch.

Iyer and Kailasapathy (2005) selected three different complementary prebiotics and were separately coencapsulated with *Lactobacillus acidophilus* and tested for their efficacy in yogurt. Addition of Hi-maize1 starch to capsules containing *Lactobacillus* spp. provided maximum protection to the encapsulated bacteria after 3 h of incubation at pH 2.0 compared with other two prebiotics, Raftiline1 and Raftilose1. Viable counts of *Lactobacillus* spp. increased significantly ($p < 0.05$) with Hi-maize concentration of up to 1.0 % w/v the viability of bacteria under in vitro acidic conditions. Addition of Hi-maize (1.0 % w/v) to capsules containing *Lactobacillus* spp. and further coating with chitosan significantly increased ($p < 0.05$) the survival of encapsulated bacteria under in vitro acidic and bile salt conditions and also in stored yogurt compared with alginate encapsulated cells.

Homayouni et al. (2008) have shown that encapsulation can significantly increase the survival rate of probiotic bacteria in ice cream over an extended shelf-life. They manufactured two types of symbiotic ice cream containing 1 % of RS with free and encapsulated *Lactobacillus casei* (Lc-01) and *Bifidobacterium lactis* (Bb-12). The addition of encapsulated probiotics had no significant effect on the sensory properties of non-fermented ice cream in which the RS was used as prebiotic compound and *L. casei* and *B. lactis* survive in high numbers in the encapsulated samples. Encapsulation thus may enhance the shelf-life of probiotic cultures in frozen dairy products.

Probiotic cell concentrates are often required to be stored over longer periods prior to food manufacture and ingestion. Hence, it is often required to dry the probiotic microcapsules after production. This is particular important for dry foods, such as cereal products or beverage powder where probiotics are added in dry form.

Nevertheless, the impact of microencapsulation on drying and storage of dried probiotic microorganisms prior to application in food systems is barely investigated, since efforts with respect to increase in survival are mainly focused on the application of protective substances. Heidebach et al. (2010) studied the viability of probiotic cells (*Bifidobacterium* Bb12 and *Lactobacillus* F19) with dried protein–hydrogel microcapsules during a freeze-drying step as well as during subsequent storage in the dried state and the influence of RS granules in the protein matrix. In the case of *Bifidobacterium* Bb12, no difference in survival was found between free and encapsulated samples with and without RS. In the case of *Lactobacillus* F19, survival rates of microencapsulated cells without RS were significantly higher compared to free cells as well as cells that were encapsulated together with RS corns.

5 Evaluation of the Fermentation Properties and Potential Prebiotic Activity

The prebiotic effect of a substrate can be measured as a selective effect upon growth of major bacterial groups commonly found in human gut, in particular a selection for increased numbers of bifidobacteria and lactobacilli in comparison with "undesirable" microorganisms, such as certain clostridia and bacteroides (Gómez et al. 2010). There are a number of methods currently in use to determine the prebiotic properties of a substrate, from pure culture studies to human trials (Vulevic et al. 2004; Mandalari et al. 2007; Gómez et al. 2010; Rodríguez-Cabezas et al. 2010; Parkar et al. 2010). However, a defining characteristic of prebiotic is the selective nature of certain groups of colonic bacteria seen as beneficial toward human health. This can only be determined in studies using mixed microbial culture which mimic the microbial ecology of the human intestinal tract. For a rapid comparative evaluation, anaerobic batch fermentations inoculated with fecal slurries are used. Because they represent the diverse gut microbiota, but are completed rapidly with several sets running simultaneously, these anaerobic batch fermentations present an excellent mode for small-scale screening of novel substrates. Until recently, growth of specific bacteria in such fermentations was measured through colony counting on selective agars. This approach, however, suffers from several drawbacks (time-consuming, labor-intensive, and non-recovery of uncultivable organisms). As a result, molecular techniques such as fluorescence in situ hybridization (FISH) have been developed to study microbial communities (Parkar et al. 2010).

6 The Rat as a Model for Starch Digestion in Humans

Animal models have been used in some RS research studies, and thus it is important to discuss briefly the dependability and/or applicability of the results obtained (Perera et al. 2010). Animal models used in biomedical research should be either analogous or homologous to humans considering the anatomy and physiology of the organ or system under investigation. Other criteria include, but are not limited to,

the selected animal should be easily available in substantial numbers, should be easy to handle, and should be manageable with the resources available, and the life span should be sufficiently long to carry out the research. In keeping with these criteria, omnivores such as the rat and the pig are used to simulate the gastrointestinal tract and liver functions of the human (Chow 2008; Perera et al. 2010). In a comprehensive review, DeSesso and Jacobson (2001) compared the similarities and differences between the gastrointestinal tracts of the human and the rat. Some significant differences are listed here. The human pharynx is a single tube that is the passageway for both food and air, whereas the rat pharynx is separated into two compartments for respiratory and digestive purposes. The human stomach is a single chamber where food is mixed with enzymes and acid. The rat stomach, although a single chamber, is functionally divided into two areas. The stomach is the site of bacterial digestion, whereas the glandular stomach secretes enzymes and acid. Bacterial digestion is absent in the human stomach. Although the rat is used to imitate digestion in the human, there is the likelihood of species differences in enzyme activity. The small intestine has three functionally different regions, the duodenum, the jejunum, and the ileum. Compared to the human, where the gallbladder secretes bile, the rat liver secretes twice as much as bile into the duodenum per kg of body weight per day.

Nutrient absorption takes place in the duodenum and the jejunum of both rats and humans through diffusion, active transport, and solvent drag mechanisms. Compared to the total length of the digestive tract, the jejunum of the rat is proportionally longer than that of the human. The jejunum of the rat represents 90 % of the length of the small intestine and that of the human, 38 %. The transit time of food through the rat small intestine is slower than that in the human.

Despite the human small intestine being 5.5 times longer than that of the rat, the transit time of food through the small intestine of the human and the rat is similar, 3–4 h. The surface area of the human small intestine is 200 times greater than that of the rat, which is significant given the difference in their lengths. Water and nutrients formed through bacterial metabolism are absorbed in the large intestine. The human large intestine is divided into the cecum, ascending colon, transverse colon, descending colon, sigmoid colon, rectum, and anus. The sigmoid colon is absent in the rat. The cecum is responsible for most of the microbial digestion of food in the rat and represents up to 26 % of the length of the large intestine. In contrast, the human cecum is only 5 % of the length of the large intestine. In addition, the types of microorganisms naturally occurring in the digestive systems of the human and the rat may be different (DeSesso and Jacobson 2001). The differences described above indicate that the rat model may not provide reliable data on RS digestion in humans, but it may be useful in understanding the fate of RS within the digestive tract.

7 Other Biological Activities

Scientific interest upon RS has increased significantly during the last decades, mostly due to its capacity to produce a large amount of butyrate all along the colon. Butyrate has been observed to have a range of effects on cell metabolism,

differentiation, and cell growth as well as inhibition of a variety of factors that underlie the initiation, progression, and growth of colon tumors (Champ et al. 2003).

Starch processing can increase its prebiotic properties. The digestibility of starch in cooked potatoes changes when the potatoes are cooled after cooking, and these changes may be of considerable nutritional significance. When potato is cooled after cooking, the starch undergoes profound changes in digestibility: the content of rapidly digested starch (RDS) decreases; the content of slowly digested starch (SDS), defined as starch digested between 20 and 120 min in vitro, increases markedly and the proportion of RS increases. The increase in RS means that the loading of non-digested polysaccharide ("dietary fiber") into the colon is greatly increased, making the cooled potato a valuable source of dietary fiber which, moreover, is enriched in a type (RS) that has demonstrated benefits as a prebiotic (Mishra et al. 2008).

Without heat gelatinization the starch remains in granular form, highly resistant to enzymic attack (RS2) (Fuentes-Zaragoza et al. 2010). In such a state the potato would have little glycemic impact but may contribute to prebiotic effects, although its use would be limited to products of low water content in which the granular form of the starch would remain intact. As a result, this type of RS (RS2) is almost completely transformed into RDS upon cooking, but upon cooling, the content of RS again increases. Because this form of RS must have been regenerated from the almost completely digestible form (RDS) present in the potatoes immediately after cooking, it is RS type III (RS3), or retrograded starch Mishra et al. 2008).

Shimoni (2008) studied a fraction of RS, from high-AM cornstarch, called RS type III (RS III). RS III is fermented by the microbiota in the colon, and it indicates that it may have health benefits such as modifying lipid metabolism and reducing the risk of colon cancer. RS III can be produced by heat-induced gelatinization of starch followed by recrystallization. The amount of RS III produced is affected by its composition, heat treatment, and recrystallization conditions. Understanding the relation between RS III polymorphism and its resistance is critical for the development of RS with improved prebiotic properties. The crystallite polymorphism and the lamella structure of RS III affect its enzymatic resistance, thus changing its prebiotic activities (e.g., its properties as an enzymatic substrate). This hypothesis was formulated based on studies that found correlation between starch crystallinity and its resistance to enzymatic digestion and on other studies showing the effect of crystallization conditions on RS polymorph type.

8 Conclusion

Functional foods have revolutionized and augmented the role of food in health. Probiotics are the fastest-growing component of the functional food industry, through their role in increasing the number of beneficial bacteria in the gut. Resistant starch (RS) is a recently recognized source of fiber and is classified as a fiber component with partial or complete fermentation in the colon, producing

various beneficial effects on health. RS also offers an exciting new potential as a food ingredient. As a functional fiber, its fine particles and bland taste make the formulation of a number of food products possible with better consumer acceptability and greater palatability than those made with traditional fibers. Technically, it is possible to increase the RS content in foods by modifying the processing conditions such as pH, heating temperature and time, the number of heating and cooling cycles, freezing, and drying. RS shows improved crispness and expansion in certain products, which have better mouthfeel, color, and flavor than products produced with traditional insoluble fibers. RS can be fermented by human gut microbiota and provides the colonic microbiota with a fermentable carbohydrate substrate. Scientific interest upon RS has increased significantly during the last decades, mostly due to its capacity to produce a large amount of butyrate all along the colon. Short-chain FOS and RS may act synergistically by combining, and thus increasing, their prebiotic effects. The best model of prebiotic–probiotic symbiosis is the encapsulation. Starch and its derivative (RS) are widely used in the encapsulation of various food components, as probiotics. A symbiotic approach is often accomplished by co-encapsulation of RS in the form of high-amylose maize starch together with the probiotic microorganisms within the microcapsule.

Pharmaceutical Applications of Various Natural Gums

63

Anand Shankar Deshmukh and Tejraj M. Aminabhavi

Contents

Abstract

Gums are the important ingredients in many pharmaceutical preparations owing to their biodegradability, abundant availability, non-toxicity, and low cost. In today's scenario, these are competing with many synthetic polymers for use as various pharmaceutical products and have made a remarkable journey from just being an excipient to novel drug delivery carriers. Particularly, the better understanding of their physiochemical properties and establishment of safety profile data has attracted researchers and pharmaceutical industries worldwide to unveil the hidden potential of natural gums. Although modification of natural gums has generated the entirely new class of polymeric materials useful in

advanced drug delivery applications, exploration of natural gums in the design for development of nanomedicine and gene therapy has widened their applications as novel delivery materials. In this chapter, we have highlighted both basic and novel pharmaceutical applications of natural gums along with their future potential.

Keywords
Natural gums • Pharmaceutical applications • Drug delivery • Nanomedicine

1 Introduction

Polysaccharide hydrocolloids including mucilages, gums, and glucans are abundant in nature and are commonly found in many higher plants. These polysaccharides constitute a structurally diverse class of biological macromolecules with a broad range of physicochemical properties, which are widely used for various applications in pharmacy and medicine. In the last few decades, these have gained the reputation of being pharmaceutically acceptable excipients in a variety of dosage forms such as dietary fiber, diluents, binders, disintegrants in tablets, thickeners in liquid orals, protective colloids in suspensions, gelling agents in gels, and bases in suppository (Zatz and Kushla 1989). The niche, however, lies in their untapped potential in the design and development of novel drug delivery systems. Therefore, attention has been paid by the researchers worldwide to explore the potential of plant-based polymers in the design and development of various pharmaceutical dosage forms such as matrix controlled systems, film-coating agents, buccal films, microspheres, nanoparticles, viscous liquid formulations like ophthalmic solutions, suspensions, and implants (Pandey and Khuller 2004; Chamarthy and Pinal 2008; Alonso-Sande et al. 2009). This has proved their worth (applicability and efficacy) in drug delivery.

Even though polysaccharides offer distinct advantages like hydrophilicity, non-toxicity, biodegradability, low cost, and abundant natural availability over those of synthetic materials, their use in pharmaceutical industries is quite limited, and therefore, the natural gums are expected to play a very basic role in pharmaceutical preparations such as excipient in the preparation of cosmetics and conventional drug-loaded formulations. For any polysaccharide to be used as an excipient, they must meet the criteria of "safety for human use" as laid down by the health governing regulatory authorities of various countries. From the regulatory perspective, a thorough investigation of toxicity profile of any new material is necessary before its approval as an excipient for human use. Pharmaceutical industries are well aware of this (regulatory) directive, and therefore, before selecting any potential polysaccharide as an excipient, a detailed investigation of its toxicity profile is established by the well-designed preclinical studies. The data generated by these studies (acute, short-term, and chronic toxicity) are then to be submitted to the respective food and drug administrative bodies of the country for approval. Many gums and mucilages are however obtained from edible sources such as mango

(*Mangifera indica* L., family Anacardiaceae), papaya (*Carica papaya* L., family Caricaceae), banana (*Musa acuminata*, family Musaceae), carambola (*Averrhoa carambola* L., family Oxalidaceae), and guava (*Psidium guajava* L., family Myrtaceae) (Chin et al. 1999), and this makes them a suitable candidate for use in oral drug delivery applications where the toxicity-related regulatory issues can be easily addressed on the ground of their generally recognized as safe (GRAS) status.

2 Gums

Chemically, natural gums and mucilage are polysaccharides or complex carbohydrates, containing one or more types of monosaccharide units or their derivatives linked together in bewildering way and in a variety of linkages and structures to create the macromolecular structure. Upon hydrolysis, they yield simple sugar units such as arabinose, galactose, glucose, mannose, xylose or uronic acids, etc. Natural gums are exudates or pathological products often produced by higher plants as a result of their protection mechanisms following an injury which do not form part of the cell wall. The mucilages, on the other hand, are a part of the cell and are the physiological products (Kulkarni et al. 2002a, b).

The word "gum" often used as an adjective seems to acquire a different meaning. Ideally, there is no chemical category of gums or mucilages, but was once used to describe any substance that produces slimy or tacky aqueous dispersions, whose properties are manifested by many types of water-soluble plant, animal, and microbial polysaccharides, including starches and modified starches. The term "gum" is therefore an umbrella term used commonly to different areas with different definitions in each field. For example, when applied to water-soluble substances, it refers to all water-soluble, non-starch polysaccharides (NSP), whether natural or those that are made from natural NSP by structural modification. Generally, gums are thought to have the ability to produce highly viscous aqueous solutions at low concentrations, but again there are exceptions to this principle. Gum arabic and "low viscosity grades" of certain gums are the most notable exceptions; they require rather high concentrations to produce highly viscous aqueous solutions.

Other exception of the term gum is resinous products; the gum obtained from pine pitch (produced by the parenchyma cells of softwoods) is conventionally known as "gum turpentine" and "gum rosin." The "gum reins" as gum benzoin, gum camphor, and others are also few such examples. The alleged "ester gum" is a semisynthetic reaction product of rosin and a polyhydric alcohol. All these are actually resinous products having properties greatly different from those of natural gums. Further complicating, the word "gum" is also used to address such plant lattices (chicle and natural rubber), which are quite different from both carbohydrate gums and resins.

The starch polysaccharides (amylose and amylopectin) and their derivatives are water soluble and are capable of forming viscous gel, but they are not considered to be gums, and rather they are put in a separate category, whereas water-soluble

polysaccharides (other than those from starches) that are used industrially are referred as industrial gums (BeMiller 2012). Therefore, it is necessary for the reader to understand the term "gum" in its relative field of application.

3 Classification of Natural Gums

Gums constitute a structurally diverse class of biological macromolecules with a broad range of physicochemical properties, and for this reason, they are widely used for various applications in pharmacy and medicine. Like any other chemical substances, it would be helpful to discuss the properties of gum to classify them. But it is not so simple and there is no single useful way to classify gums (BeMiller 2001). Different authors have classified gums in different ways; one such way to classify them is on the basis of their source. The sources of some pharmaceutically useful gums are seaweeds, higher plants, microorganisms, and derivatives of cellulose as shown in Table 1.

Another way to classify gums is on the basis of their charge, shape, gelation behavior, and chemical structures (as shown in Table 2). However, one has to keep this fact in mind that none of these classifications are effective when used alone due to multiple properties of gums. For example, it is suitable to classify the gums on the basis of their structures (Table 2), but here again it is complicated due to two reasons: first, majority of gums have similar structures, and second, in most cases, the structure of a given gum is sufficiently unique that it needs to be placed in a category by itself (BeMiller 2012).

Because of better understanding of structural chemistry, various gums have now received a tremendous attention in the design and development of advanced drug delivery systems. But from the viewpoint of pharmaceutical industries, the use of natural gums in formulations is mainly governed by the regulatory norms of the state or country they are working in. Therefore, detailed knowledge not only of the physical and chemical properties but also of the safety, handling, and regulatory status of these materials is essential for formulation scientists. This requirement creates a new way of classification of gums on the basis of their safety status for human use (Table 3). Regulatory status of gums changes from one country to another, and therefore, for detailed information and further clarification, websites of regulatory bodies of referred country should be consulted for guidance.

4 Advantages and Limitations of Natural Gum

Natural polysaccharide gums are renewable biopolymers found abundantly in nature. They are non-toxic, biodegradable, economic, and independent of fossil sources, which make them an ideal candidate for use in non-food industries over the synthetic molecules (Chang et al. 2009). Furthermore, most of the natural gums are safe enough for oral consumption in the form of food additives or drug carriers. Gums are metabolized by intestinal microflora and ultimately degraded to their individual component sugars. The enzymes available in the intestine can cleave the

Table 1 Classification of gum on the basis of source (Taken from BeMiller (2012) http://www.springerreference.com/index/chapterdbid/135002)

Origin/source	Gums
Marine algae	Agars, alginates, carrageenans, and furcellaran
Higher plants	
Extract	Larch arabinogalactan, pectins
Seeds	Guar gum, locust bean (carob) gum, tara gum
Tubers and root	Inulin, konjac glucomannans
Exudates	Gum arabics
Microorganism	Curdlan, dextrans, gellans, xanthans
Cellulosics (by chemical modification)	Carboxymethylhydroxyethylcelluloses, cetylhydroxyethylcelluloses, ethylhydroxyethylcelluloses, hydroxyethylcelluloses, hydroxyethylmethylcelluloses, hydroxypropylcelluloses, hydroxypropylmethylcelluloses, methylcelluloses

Basis	Class	Examples
Charge	Nonionic gums	Guar gum, locust bean gum, tamarind gum, xanthan gum
	Anionic gums	Gum arabic, karaya gum, gellan gum, carrageenans
Shape	Short branch	Xanthan gum, guar gum
	Branch on branch	Gum arabic, tragacanth gum
Origin	Seed gums	Guar gum, karaya gum, ipomoea, fenugreek, locust bean gum, premcem gum, Lesquerella fendleri gum
	Plant exudates	Chicle gum, konjac, gum arabic, gum ghatti, gum karaya, acacia gum, tragacanth
	Microbial exudates	Dextran, gellan gum, xanthan gum, tara gum, spruce gum
	Seaweed	Sodium alginate, alginic acid, carrageenans, agar–agar
Gelation behavior	Cold set gels	Gellan gum, flaxseed gum, gelatin
	Heat set gels	Konjac
	Re-entrant gels	Xyloglucan
Chemical structure	Galactomannans	Fenugreek gum, guar gum, locust bean gum, tara gum, dhaincha gum, cassia gum
	Glucomannans	Konjac
	Uronic acid containing gums	Xanthan gum
	Tri-heteroglycans	Gellan gum
	Tetra-hetroglycans	Gum arabic, psyllium seed gum
	Penta-hetroglycans	Gum ghatti, tragacanth

Table 3 Classification based on regulatory status

Class/category	Regulatory status	Gums
Food/food additives	GRAS[a], CLNAI[b]	Acacia, gaur gum, gum ghatti, carob bean gum
Licensed pharmaceuticals	FDA inactive ingredients, excipient in nonparenteral medicine	Sodium alginate, acacia, gaur gum, xanthan gum

[a]Generally recognized as safe
[b]Canadian list of acceptable non-medicinal ingredients

gums at specific sites. For example, α-galactosidase can hydrolyze terminal non-reducing galactose residues to produce free α-D-galactose (Rana et al. 2011). These properties make gums to stand tall over the synthetic polymers. In spite of these advantages, the use of polysaccharides as industrially useful raw material at a large scale is impeded by some drawbacks associated with gums like uncontrolled rate of hydration, microbial contamination, reduced viscosity on storage, pH-dependent solubility, and batch-to-batch variation (Jani et al. 2009; Rana et al. 2011). Therefore, researchers are now prompted to work on the chemical modification of natural gums to overcome these limitations without the loss of their inherent characteristics. Modification of natural polysaccharides gives tailor-made materials suiting the various needs of drug delivery systems and thus can compete with the available synthetic excipients.

5 Pharmaceutical Applications

Due to intricate molecular structure, gums show diverse physicochemical properties, and such properties are highly useful in the design of various pharmaceutical preparations such as in suspensions and emulsions as suspending and emulsifying agents, respectively, in liquid orals as thickening and stabilizing agent, in conventional tablet dosage form as binder and disintegrating agent, in gels as gelling agent, and in cosmetics as emollient and demulcent. The list of commonly used gums for pharmaceutical applications is shown in Table 4.

From application viewpoint, pharmaceutically gums can be categorized into two major classes: (a) as excipient for conventional dosage form and (b) as polymeric material for novel drug delivery application. Initially, gums were explored as excipient in pharmaceutical industries for their cohesive and adhesive properties, and till today, many commercial formulations include gums as one of their important ingredients. Literature review revealed several applications of gum in pharmaceutical industries.

5.1 As Excipient for Conventional Dosage Form

Excipients are the materials used to: (a) increase the bulk of formulation, (b) improve the physicochemical characteristics of the product, and (c) increase

the stability of formulation without affecting the drug or active ingredient adversely. Pharmaceutically, gums have received a special attention as promising excipients in various dosage forms.

5.1.1 Binder and Disintegrating Agent in Tablet Dosage Form

The role of gums as a binder is attributed to its adhesive property when mixed with water. Gums are used for binding the powder blend into a cohesive mass for the preparation of the granules, which is then compressed to form a tablet. A large number of gums are reported to be used as a binder in tablet formulations (see Table 4). Due to hydrophilic nature, gums imbibe a large quantity of water and swell enormously before they solubilize. This feature makes them an ideal disintegrating agent. When gums are added into tablet formulation as disintegrating agent, they increase the internal pressure (by absorbing the dissolution fluid) to an extent that the structural integrity of tablet disrupts, leading to disintegration and disaggregation of tablet into fine particles, resulting in a rapid solubility and, hence, rapid dissolution of admixed drug(s).

5.1.2 Hydrophilic Gelling Agent

In recent times, the potential of natural gums as gelling agent has been realized. They can form hydrophilic gels all alone or in combination with other natural gums and synthetic polymers. Gellan gum, carrageenan, pectin, sodium alginate, and gelatin are the widely used gelling agents in pharmaceutical industries. The multiple sugar units in gums, apart from hydroxyl groups, may also contain carboxylic groups (uronic acid derivatives), and these hydrophilic groups can enter into both H-bonding (inter and intra) and weak van der Waal forces with water molecule to make three-dimensional network aggregates capable of holding a large quantity of water. Researchers have also reported the physical (like pH and temperature) and chemical (ionic solutes and cross-linkers) methods to transform natural gums into gels. For example, the gelation of gellan gum with citrate ions is reported to produce soft gels for the delivery of paracetamol (Gohel et al. 2009). Most of the natural gums, due to their branched structure, need higher concentrations to reach a satisfactory gelling strength. In addition, the ratio of gelling component versus non-gelling component in gum structure decides its gel strength. A study on gum ghatti by Pass and Phillips (1977) has demonstrated the effect of change in gelling component on the overall gelling capability of gum ghatti. Xanthan gum, on the other hand, is an example of natural gum, which forms a strong gel at much lower concentrations as compared to many natural gums and synthetic polymers. Various examples of natural gums as gelling agent are given in Table 4.

5.1.3 Emulsifier and Suspending Agent

As can be seen from Table 4, numbers of gums are reported to be used as emulsifier and suspending agents in pharmaceutical preparations. Principally, gums stabilize the emulsions by slowing down the thermodynamically favored breakdown and suspensions by discouraging the crystallization by means of increasing the viscosity

of the medium. The other probable factors behind stabilizing property of gums in emulsion includes: (a) the structural heterogeneity of gums, which may lead to self-aggregation (as in gum ghatti and gum acacia) at higher concentrations, and (b) the presence of protein impurity, which may undergo electrostatic interaction with the gum (polyelectrolyte). Both these factors lead to the formation of colloidal system capable of increasing the miscibility of oils and water by reducing the interfacial tension between them (http://www1.lsbu.ac.uk/water/hydro.html). However, in case of suspensions, it is believed that natural gum increases the tensile strength of the hydration layer formed around the suspended particles by H-bonding and molecular interactions. Since these agents do not reduce the surface and interfacial tension, they function best in the presence of wetting agents (Prajapati et al. 2013). But increase in viscosity of the system is the most accepted reason for suspension stability.

5.1.4 Coating Agent

Gums are the good coating agents used in pharmaceutical preparation for two purposes: (a) to protect the drug from degradation in specific part of gastrointestinal tract (GIT) and (b) to sustain the drug release. Both granular coating (Mitul et al. 2012) and tablet coating (Joshi et al. 2010) are reported in the literature (see Table 4). In a study carried out by Ogaji and Okafor (2011), the potential of grewia gum extract as aqueous film-coating material for pharmaceutical application was demonstrated, wherein the aqueous dispersion of gum was used to coat the praziquantel tablet. The study showed that coating of grewia gum extract remained intact, durable and resistant to chipping and other coating issues when challenged to catastrophic fall or rubbed on a white paper (Ogaji and Okafor 2011; Ogaji et al. 2013). In another study, compression coating of tablet using guar gum and xanthan gum for colon targeted drug delivery is reported (Niranjan et al. 2013). Both these gums have provided the satisfactory delivery of drug in the colonic region by protecting the premature release of drug in the upper part of GIT. One of the major advantages of employing natural gum in oral drug delivery is its biodegradability. As gums are composed of repeating sugar units, they get easily digested by microflora of colonic region giving biocompatible metabolites and thus ensuring complete drug release and biocompatibility together.

5.2 Gums in Drug Delivery

With the advancement of technology and better understanding in fields like molecular biology, pharmacokinetics, and drug discovery, in the last 5 years, drug market has witnessed the availability of better therapeutic alternatives over the conventional therapies. These advanced drug delivery systems not only ensured improved efficacy and safety of pharmaceutical preparations but also improved the overall therapeutic experience of the patient. Interestingly, natural gums have captured their share in this technological pursuit and were evaluated for the development of a variety of novel dosage forms.

5.2.1 Matrix Tablets and Patches

The formulation of matrix-based delivery systems such as tablet and patches is widely accepted pharmaceutically, due to better patient compliance and ease of formulation procedures. Matrix-type delivery system is the specific type of release system, which prolongs and controls the release of a drug that is either dissolved or dispersed into it. Many natural gums have been investigated as matrix forming materials for the design and development of oral tablet to achieve sustained and controlled drug delivery. Both matrix dispersion type (Demiröz et al. 2004) and encapsulated or coated type (Joshi et al. 2010) matrix tablet are studied for the delivery of drugs in GIT. The drug transport mechanisms from this type of matrix system are governed by mathematical models like diffusion controlled, swelling controlled, and erosion controlled, either alone or in combination (Ritger and Peppas 1997). The gel layer formation at the interface between dry polymer and surrounding dissolution fluid by hydration of polymeric chains is assumed to be responsible for retarding the drug release. Tables 4 and 5 represent the examples of various natural gums used as matrix tablet formulation.

Patches are thin-film-type formulation applied either on the skin or mucous membrane for prolonged drug delivery. The mechanism of drug release is similar as discussed for the matrix tablet. A number of reports are available mentioning the utility of natural gums for the design of mucoadhesive and dermal patches (refer to Tables 4 and 5). Being hydrophilic, viscous solution of gums can be easily prepared in water and cast to prepare films or patches of different dimensions. Furthermore, based on the features of retarding gum, they are used alone or in combination with other polymers to meet the desired specifications. The preparation of mucoadhesive patches by polyelectrolyte cross-linking called inter-polymer complex (IPC) (Kaur and Kaur 2012) is relatively new and is a niche area for active researchers. One such a study performed by Singh et al. (2010) reported the novel IPC formulation formed between xanthan gum and cationic gaur gum to develop novel mucoadhesive films for sustained delivery of domperidone. The developed IPC bio-adhesive films released the drug for 8 h as well as enhanced the bioavailability of the drug compared to the orally administered conventional tablet.

In another study, the bilayer nicotine mucoadhesive transdermal patches were prepared using xanthan gum and Carbopol 934 as mucoadhesive polymers and ethylcellulose as the backing membrane. The results have shown significant improvement in mucoadhesive strength, drug–polymer compatibility, and controlled biphasic drug release for up to 10 h using xanthan gum compared to Carbopol (Abu-Huwaij et al. 2011).

5.2.2 Microparticulate Systems

Microparticles or microbeads are multi-unit drug delivery systems ranging in size between 10 and 2,000 μm. These are widely studied for oral, parenteral, and ocular drug delivery applications. A number of synthetic, semisynthetic, and natural polymers have been used to prepare microparticles using various techniques. For oral drug delivery, microparticles have received much popularity because of more uniform distribution of drug in the GIT, more uniform drug absorption, reduced

local irritation, and elimination of unwanted intestinal retention of polymeric material compared to non-disintegrating single-unit dosage form such as tablets. The gums are mostly polyanionic in nature (except few neutral gums) and thus offer a number of suitable sites for reaction with a variety of chemical agents to develop microparticles. Furthermore, their aqueous solubility reduces the concern of residual solvents in the final formulation and improves the biosafety of formulations. Locust bean gum (Deshmukh et al. 2009), Mucuna gum (Anthony and Obichukwu 2007), and xanthan gum (Ray et al. 2010) are some of the commonly used gums for the design of microparticles based oral controlled drug delivery systems and have gained a worldwide interest, mainly because of their biocompatibility.

Gellan gum is one of the extensively studied biopolymers used for parenteral applications. A number of studies have demonstrated its utility in parenteral preparation. Mahajan and Gattani (2009) reported microparticles of metoclopramide hydrochloride prepared by spray drying technique using gellan gum as a biocompatible material for intranasal drug delivery. The results showed that the process was simple, reproducible, and easy to scale up. The microencapsulation of drug was particularly less dependent on the solubility characteristics of polymer, and gum-based microparticles effectively delivered the drug through the nasal mucosa.

In another study, gellan gum was used to prepare novel microparticles/hydrogel matrices for use in intervertebral disc regeneration that improved mechanical properties. However, their cell culture studies (in L929 cells) demonstrated noncytotoxicity of the formulated discs that makes them a strong candidate for nucleus pulposus regeneration (Pereira et al. 2011). Odeku et al. (2013) recently investigated four natural gums, viz., albizia, cissus, irvingia, and khaya gums, to develop microbeads for the controlled delivery of diclofenac sodium. Gel blends of natural gums and sodium alginate at different ratios were tested. Drug release from the beads containing polymer blends of four gums and sodium alginate fitted the Korsmeyer–Peppas model and sustained the release of drug for 5 h. However, overall characteristics of the microbeads depended on the material property of individual gums.

5.2.3 In Situ Gels

In situ gels are relatively new type of pharmaceutical preparations, wherein drug-loaded viscous polymeric solution called sol, when comes into contact with stimulus (such as pH, temperature, enzyme, and ionic concentration.), present at the various locations of human body, get transformed into a gelled mass instantly (in situ) to prolong the drug release. In situ gels are administered by various routes, viz., oral, ocular, rectal, vaginal, subcutaneous, and intraperitoneal. Natural gums, being water soluble, biocompatible (except few), and polyionic in nature, find obvious advantages over those of the synthetic polymers. Gellan gum and xyloglucan are the widely studied gums for the preparation of in situ gels, and when xyloglucan is partially degraded by β-galactosidase, the resultant product exhibits thermally reversible gelation by the lateral stacking of rodlike chains (Miyazaki et al. 2001a). The sol–gel transition temperature varies with the degree of galactose elimination. Xyloglucan-based in situ gels have been used for oral, intraperitoneal, ocular, and rectal drug delivery (Miyazaki et al. 1998; Suisha et al. 1998; Kawasaki et al. 1999; Miyazaki et al. 2001a). The thermoreversible gelation behavior of xyloglucan is quite similar to poloxamer, but the major advantage of using xyloglucan is its capacity to gel at much lower concentrations as compared to poloxamer (Miyazaki et al. 1998).

Gellan gum (also known as Gelrite^{TM} or Kelogel^{TM}) is an anionic polysaccharide having both thermal- and ionic-induced gelling capacity (Crescenzi et al. 1990). The in situ gel of gellan gum prepared by calcium ion-induced gelling for the oral delivery of theophylline has been investigated that showed better

bioavailability and prolonged release in rabbits compared to the marketed sustained release liquid formulation (Miyazaki et al. 1999). In another study, Cao et al. (2009) developed in situ gel using gellan gum as a carrier for nasal administration of mometasone furoate. The histopathology of rat nasal cavity showed that in situ formulation of gellan gum was non-toxic to the nasal mucosa. The drug release was equally effective in controlling the nasal symptoms of rhinitis compared to the marketed formulation Nasonex^{TM}.

5.2.4 Nanoparticles

In the past decade, rapid development of nanotechnology has brought many fascinating ideas and opportunities to the diagnosis and treatment of a disease. Nanotechnology has revolutionized the whole concept of drug delivery from nonspecific drug delivery to highly target-specific drug delivery. The utilization of natural gums in the design of nanostructures is still in its infancy and relatively few studies are reported where natural gums are evaluated for the development of nanomedicine. One such a study was carried out by Yadav and Ahuja (2010) where novel polymer-surfactant nanoparticles of gum cordia (as the polymeric carrier) were evaluated and optimized for ophthalmic delivery of fluconazole using a response surface model. A w/o/w emulsion containing fluconazole and cordia gum in aqueous phase, methylene chloride as the oily phase, and di-octyl sodium sulfosuccinate and polyvinyl alcohol as the primary and secondary emulsifiers, respectively, was cross-linked by ionic gelation technique to produce fluconazole-loaded nanoreservoir system. Comparison of in vitro release profiles of the optimized nanosuspension formulation (containing gum cordia 0.85 %) with commercial formulation provided a comparable corneal permeability of fluconazole across the isolated goat cornea. These results have demonstrated the importance of gum cordia in the design and development of nanosuspensions.

In another study, Kumar and Ahuja (2013) have studied the interaction between carboxymethyl gum kondagogu (also known as hupu gum) and chitosan to prepare polyelectrolyte complex-based nanoparticles for sustained delivery of ofloxacin as model drug. The optimized batch of nanoparticles (285.9 nm) successfully delivered the drug in a sustained manner for 24 h, following the Higuchi's diffusion-controlled kinetic model. This study opened new possibilities for further investigation on this gum for many other potential pharmaceutical applications. On the other hand, the possibility of using guar gum for the synthesis of nanoparticles as drug carrier has been recently explored by Gupta and Verma (2014), wherein carboxymethyl guar gum nanoparticles were synthesized by using nanoprecipitation and sonication method. The size of the nanoparticles was 12–30 nm and these nanoparticles may have utility in medical, cosmetics, biosensors, pharmaceuticals, and food supplements areas.

5.2.5 Hydrogels

Hydrogel is a three-dimensional cross-linked network with high water retention capacity. It neither disintegrates nor dissolves in excess amount of water. Nowadays, natural gum-based hydrogels as drug delivery systems have gained a much

wider attention. Although natural gums are the potential candidates in the design of hydrogels, but due to their high water solubility and drop in viscosity upon storage, the functionalization/modification is needed to overcome these problems. Further modification helps to control the interaction of the polymer with drugs, to enhance the load capability, and to tailor the release profiles of the drug (Nishimura et al. 1993). In view of the pharmacological importance of sterculia gum and drug delivery devices based on hydrogels, Singh and Sharma (2008) synthesized sterculia gum- and polyacrylamide-based hydrogels. The release dynamics of model antiulcer drug (ranitidine hydrochloride) from these hydrogels was studied to evaluate the release mechanism and diffusion coefficients in different media. The results showed that the release of drug from the sterculia gum-based hydrogels was of Fickian nature in distilled water and in pH 2.2 buffer and was non-Fickian in pH 7.4 buffer.

D'Arrigo et al. (2012) have demonstrated the usefulness of gellan gum in the preparation of nanohydrogels. They developed and characterized self-assembling nanohydrogels based on sonicated gellan gum chains. Prednisolone, a poorly water-soluble anti-inflammatory drug, was chemically conjugated to carboxylic groups of gellan gum that served as the hydrophobic moiety responsible for self-assembling process. From the results, it was concluded that these nanohydrogels represent an interesting and innovative carrier system that improved the bioavailability of poorly water-soluble prednisolone.

In another study, D'Arrigo et al. (2014) have developed gellan gum nanohydrogels to deliver simultaneously anti-inflammatory and anticancer drugs (as a combination therapy) for the treatment of cancer. However, the anti-inflammatory drug prednisolone was chemically linked to carboxylic groups of gellan gum to serve as a hydrophobic moiety promoting nanohydrogel formation, whereas paclitaxel was physically entrapped in it by the hydrophobic core–shell mechanism. These nanohydrogels improved the drug performances by acting as solubility enhancer, thus favoring the drug uptake into the cells. Moreover, nanohydrogels allowed increased cytotoxic effect in vitro on several types of cancer cells due to synergistic effect of the combination of anti-inflammatory and anticancer drugs.

6 Modified Gums in Pharmaceuticals

As discussed in Sect. 4, natural gum suffers from various limitations, and hence, it is to be chemically modified (to improve the functionality) for their use in specific drug delivery purposes (Rana et al. 2011). A list of some chemically modified gums used in pharmaceuticals is presented in Table 6. The science of chemical modification is very exhaustive, and hence, we restrict our discussion to some of the commonly used chemical modification techniques and their relevant pharmaceutical applications in drug delivery area. Gums can be chemically modified by three techniques: (a) chemical cross-linking, (b) substitution of functional group, and (c) grafting modification.

Table 6 Examples of modified gum for pharmaceutical applications

Gum	Type of chemical modification	Pharmaceutical applications	References
Gaur gum	Carboxymethylation	Microbeads for sustained drug delivery	Thimma and Tammishetti (2001)
Konjac glucomannan	Carboxymethylation	Microbeads; polymeric carrier for site-specific bioactive drug delivery	Jiangyang et al. (2008)
Cashew gum	Carboxymethylation	Carrier for controlled drug delivery	Silva et al. (2004)
Gaur gum	Phosphate cross-linked	Colon targeted drug delivery	Kabir et al. (2000)
Gaur gum	Cross-linked with glutaraldehyde	Microbeads for controlled drug delivery	Soppimath et al. (2000)
Tamarind gum	Cross-linked with epichlorohydrin	Rectal drug delivery	Sumathi and Ray (2002)
Cashew gum	Cross-linked with epichlorohydrin	Controlled drug delivery	Silva et al. (2006)
Gellan gum	Acetalated gellan gum cross-linked with aluminum ions	Hydrogel network beads for prolonged drug release	Maiti et al. (2011)
Gaur gum	Grafting of polyacrylamide chains by microwave-assisted method	Matrix for colon targeted drug delivery	Sen et al. (2010)
Gum kondagogu	Grafting of polyacrylamide chains by microwave-assisted method	Controlled release matrix tablet	Malik and Ahuja (2011)
Locust bean gum	Grafting of polyacrylamide chains by microwave-assisted method	Controlled release matrix tablet	Kaity et al. (2013)
Tamarind gum	Grafting of polyacrylamide chains by microwave-assisted method using carboxymethyl derivative of tamarind gum	Microbeads; polymeric carrier for pH-responsive site-specific drug delivery	Setty et al. (2014)

Chemical modification by substitution of functional groups such as carboxymethylation and carbamoylethylation is the more commonly employed technique to increase both hydrophilicity and solution clarity of gums and make them more soluble in aqueous systems. Even though the process of carboxymethylation/carbamoylethylation of natural gums can be accomplished quite easily, the degree of substitution is usually low. Furthermore, this method is expected to be more suitable for gums containing (1, 4)-linked units because carboxymethylation/carbamoylethylation occurs primarily at the free $–CH_2OH$ groups (C6 position) due to steric reasons. The steric hindrance by –OH groups present in gum needs to be considered while attempting such modifications in order to achieve significant degree of substitution. Konjac gum (Jiangyang et al. 2008)

and gaur gum (Thimma and Tammishetti 2001) are modified in this way for their applications in the development of ionically cross-linked microbeads.

Cross-linking of gum by chemical agent is an easy technique and mostly used in the design of microbeads and hydrogels and for colon-specific drug delivery. A number of cross-linking agents based on charge, size, and chemical nature are used to cross-link the gums. Cross-linking decreases the solubility and increases the water retention capacity of gums and this feature serves to be useful for drug delivery applications. However, cross-linking of gums requires the availability of active functional groups in their basic structure. Therefore, guar gum, cashew gum, or sterculia gums that possess free alcoholic and/or carboxylic units are the good choice for cross-linking modification. Moreover, it is essential to investigate the vulnerability of cross-linking in different pH conditions to ensure the modified molecule for site-specific delivery.

Glutaraldehyde has been used extensively for cross-linking of hydroxyl groups in gums. It was observed that with an increase in the concentration of glutaraldehyde, there is an increase in cross-linking density, and as a result, there is a decrease in swelling of polymer. In an investigation carried out by Soppimath et al. (2000), interpenetrating network microspheres of poly(vinyl alcohol) and guar gum were prepared by cross-linking with glutaraldehyde, wherein aldehyde groups of glutaraldehyde reacted with hydroxyl groups of gum to form acetal cross-links. The in vitro release of nifedipine from these microspheres was observed to be dependent on the extent of cross-link density. The solvent uptake by these microspheres decreased with increased cross-linking and drug release continued for several hours. Similarly, in a study by Kabir et al. (2000), phosphate ion cross-linked gaur gum matrix was developed for colon targeted delivery.

The grafted gums (or copolymers) are an entirely different class of modified gums, wherein the chains of synthetic polymers are grafted onto the backbone of gums using free radical initiators like chemicals, enzymes, radiation, or their combinations. Most of the graft copolymers are prepared through graft polymerization of vinyl or acryl monomers onto biopolymer backbone as they can be grafted under mild reaction conditions. Among all types of vinyl monomers, grafting of polyacrylamide chains is quite simple and economic. Furthermore, the use of radiation such as microwave as compared to conventional chemical method for grafting of polyacrylamide chains on natural gum is cleaner, simpler, straightforward, highly reproducible, and eco-friendly (Sen et al. 2010).

Much of the research has now been carried out on polyacrylamide grafted natural gums for various types of drug delivery systems. The work reported by Sen et al. (2010) demonstrated the application of microwave for grafting of polyacrylamide chains onto gaur gum. The degree of grafting was precisely controlled by the time of exposure to microwave radiation and by virtue of which different matrix compositions (% grafting) were synthesized and evaluated for their potential in colon-specific drug delivery. Malik and Ahuja (2011) have reported the microwave-assisted grafting of polyacrylamide chains onto gum kondagogu by employing two-level, four-factor full factorial experimental design. Microwave power, microwave exposure time, and concentration of ammonium persulfate

showed significant synergistic effect on grafting efficiency. Comparative evaluation of in vitro release study of diclofenac sodium from matrix composed of either gum kondagogu or gum kondagogu-*g*-polyacrylamide revealed the faster release of drug from tablet prepared from gum kondagogu-g-polyacrylamide. The drug release from commercial tablet and matrix tablet composed of gum kondagogu was found to fit into zero-order release kinetics, while matrix tablet composed of gum kondagogu-*g*-polyacrylamide followed the Higuchi's square-root kinetics. A study by Soppimath et al. (2001) demonstrated the application of hydrolyzed polyacrylamide-*g*-gaur gum as an anionic microgel for pH-specific drug delivery. The pH-sensitive microgels were loaded with two different anti-hypertensive agents, viz., diltiazem hydrochloride (water soluble) and nifedipine (water insoluble), and studied for their release in both simulated gastric and simulated intestinal pH media. Results showed that irrespective of drug solubility, the release of drugs from microgels was pH specific, i.e., higher in alkaline medium compared to acidic medium.

7 Miscellaneous Pharmaceutical Application

7.1 As a Stabilizing Agent in Nanopharmaceuticals

Metal nanoparticles, especially those of gold and silver covered with appropriate stabilizing agents, are actively considered for drug delivery applications. The stabilizing agents are expected to provide stability to the nanoparticles against aggregation and help them to survive in both alkaline and acid media. In addition, if the stabilizing agent provides the functionality necessary for drug to be efficiently loaded onto the nanoparticle surface, it would be an added benefit.

A natural gum acts as a good stabilizing agent since they stabilize inorganic nanoparticles by two mechanisms: first, by adsorbing to the surface of nanoparticles, which creates steric repulsion among the particles, and second, they increase the viscosity of nanoparticle suspension and, therefore, slow down the aggregation process (Tiraferri et al. 2008; Comba and Sethi 2009; Xue and Sethi 2012). Furthermore, natural gums are used as a template for the synthesis and stabilization of metal nanoparticles due to: (i) natural availability and low cost, (ii) non-toxicity, (iii) abundant availability of hydroxyl, acetyl, carbonyl, and carboxylic functional groups, and (iv) metal-biosorption properties.

It was demonstrated that plant-based exudate gum such as gum acacia can be utilized as a reducing and stabilizing agent for silver nanoparticle biosynthesis (Mohan et al. 2007). In a study, a facile and eco-friendly method was developed for the synthesis of silver nanoparticles from silver nitrate using gum kondagogu (*Cochlospermum gossypium*), a natural biopolymer as a reducing and stabilizing agent. The influence of different parameters such as gum particle size, concentration of gum, concentration of silver nitrate, and reaction time on the synthesis of nanoparticles was studied. The formed silver nanoparticles were highly stable and had significant antibacterial action on both the Gram classes of bacteria (Kora et al. 2010).

Gum gellan (Dhar et al. 2008) and xanthan gum (Pooja et al. 2014) were also employed similarly for the synthesis of gold nanoparticles.

The potential of xanthan gum in the synthesis of gold nanoparticle as both reducing and stabilizing agent was studied by Pooja et al. (2014), wherein gold nanoparticles were synthesized using natural and biocompatible xanthan gum as a reducing and capping agent. Xanthan gum at very low concentration of 1.5 mg/mL converted the ionic gold to neutral gold particles with a particle size of 15–20 nm. These nanoparticles were found to be non-toxic and biocompatible in hemolysis study. Doxorubicin as a model drug was loaded into these nanoparticles through non-covalent interaction. Finally, the prepared carbohydrate-rich gold nanoparticles showed high drug loading, good colloidal stability, and enhanced cytotoxicity in A549 lung cancer cells. This has shown that natural gum-based approach is a better method for the synthesis of gold nanoparticles.

7.2 As a Therapeutic Agent

It is rare to see natural gum as therapeutic agent, but sterculia gum is one such example, which is used as a therapeutic agent in various medical conditions like diarrhea (Huttel 1983), ulcers (Love-Mignogna and Wind 1978; Zide and Bevin 1980; May 1982), irritable bowel syndrome (Capron et al. 1981), and chronic colonic diseases (Guerre and Neuman 1979; Hunold 1979), and in reducing cholesterol and improving glucose metabolism without adversely affecting most mineral balances (Behall et al. 1987; Behall 1990). Sterculia gum is also an effective bulk laxative. Similar to isabgol husk, the coarse particles of gum absorb a large quantity of water (about 100 times of its original volume) and start swelling enormously, forming a discontinuous type of mucilage that is very effective as a laxative (Meier et al. 1990; Verbeken et al. 2003).

7.3 As a Gene Delivery Agent

Among the non-viral vectors designed for the safe delivery of therapeutic genes to target sites, polymeric vectors are a leading class of gene carriers due to several advantages including safety, low immunogenicity, and capacity to deliver larger genes and cost-effectiveness (Curiel et al. 1991; Lehrman 1999; Felgner 2007). Polyethylenimine, 25 kDa (PEI), is particularly a promising candidate as a vector for its relatively high level of transfection in a number of target organs by various routes of delivery (Boussif et al. 1995; Abdallah et al. 1996; Erbacher et al. 2004). But very high positive charge density on PEI appears to be the primary cause of its marked toxicity, consequently limiting its use as a gene delivery vector in vivo. To circumvent PEI toxicity, natural gums containing anionic groups are used for partial neutralization of its excess positive charge. It helps to increase the transfection efficacy by mitigating its positive charge. Goyal et al. (2011) reported PEI blended with gellan gum (an anionic heteropolysaccharide) to form gellan

gum–polyethylenimine nanocomposites for efficient intracellular delivery of plasmid. The results showed that gellan gum blended PEI nanocomposites have improved transfection efficiency in comparison with PEI alone and the standard commercial transfection reagents in all the cell lines and also in primary mouse keratinocytes with negligible toxicity. This has shown that natural gum blended PEI approach holds great promise for future applications in gene delivery.

8 Conclusion

Natural gums, due to their biodegradability, plenty availability, non-toxicity, and easy processing conditions, are the materials of choice for various pharmaceutical applications. Initially, gums were utilized in formulations as excipient for improving the physiochemical property and stability. Hitherto many pharmaceutical preparations use natural gums as one of their key ingredients. The role of gum in novel drug delivery systems has changed the entire perception of gums and earned them an identity as potential matrix/carrier material for a wide variety of novel drug delivery systems. The modified gums are a new type of polymeric materials explored for pharmaceutical applications, and these widened the scope of gums in formulation development. Recently, we have witnessed some niche applications of gum in the area of nanotechnology and gene delivery, which opens up a new avenues for further investigations and applications of natural gums in the design and development of advanced drug delivery systems.

Cationic Polymers for the Delivery of Therapeutic Nucleotides

64

Contents

Abstract

In the last decade, insertion of a therapeutic gene and nucleotide into cells termed as gene therapy has shown tremendous potential to cure life-threatening severe diseases. This therapy involves carrying the therapeutic gene to the nucleus of an affected cell through a vector. Initially viral vectors were employed for this purpose, but low production yield, limited carrying capacity, and long-term safety concerns associated with viral vectors led to the development of nonviral vectors as gene carriers. Currently, used nonviral carriers include polymers and lipids with cationic charge. Cationic polymers provide

an excellent alternative for gene delivery due to their water solubility, biodegradability, ease of modification, and excellent compatibility with body systems, but challenges still persist to optimize them as ideal vectors. This chapter provides an overview of present status of cationic polymers and challenges associated with their use for gene delivery.

Keywords

Cationic polymers • siRNA • Gene delivery • Toxicity • Chitosan • Dextran • Cyclodextrin • Polyethyleneimine • Poly-L-lysine • SPG • Pullulan • Dendrimers

Abbreviations

PEI	Polyethyleneimine
PLL	Poly-L-lysine
ROS	Reactive oxygen species
siRNA	Small interfering RNA
FITC	Fluorescein isothiocyanate
DNA	Deoxyribonucleic acid
PEG	Polyethylene glycol
CD	Cyclodextrin
SPG	Schizophyllan
PAMAM	Poly(amidoamine)

1 Introduction

Gene therapy has been considered to be a promising treatment for many diseases ranging from acquired disease (such as AIDS) and cancer to inherited illnesses. The basic concept of gene therapy revolves around the transfer of genetic material into specific cells of a patient to replace or supplement defective genes responsible for disease development (Khan et al. 2013; Swami et al. 2013). This therapy, which began with the successful treatment of an X-linked severe combined immunodeficiency in the year 2000, is now gaining attention (Horino et al. 2013). This statement can be supported by the approval of Glybera® by European Union Marketing Authorization to treat lipoprotein lipase deficiency and the existence of more than 1800 clinical reports in more than 31 countries for the treatment of incurable diseases (Yla Herttuala 2012).

The main purpose of gene delivery is to deliver the genetic material to the target cell while surviving an array of biological defenses present in the body. This process requires the development of an efficient delivery vector. Viral vectors such as retroviruses, adenoviruses, and adeno-associated viruses are very effective in terms of transfection efficiency, but immunogenicity, inflammatory effects, and safety concerns restrict their usefulness (Nishikawa and Huang 2001; Lim et al. 2006; Mao et al. 2010). Subsequently, researchers moved towards the development of nonviral vectors, and cationic polymers and lipids gained a

significant place as nonviral vectors. Cationic polymers interact with DNA to form a polyplex (particulate complex) due to charged interactions between negatively charged DNA and positively charged polymers (El Aneed 2004).

Water solubility, ease of manipulation of polymer properties such as molecular weight (MW), geometry (linear vs. branched), and ligand attachment have been explored regarding the extensive structure/function relationships of cationic polymers. In addition, the small size of polyplex compared with cationic lipid complex (lipoplex) also helps them reach otherwise difficult to reach sites (Ruponen et al. 1999; Elouahabi and Ruysschaert 2005).

Gene delivery with cationic polymers provides a number of research opportunities, but at the same time challenges also exist. These challenges include strong interaction of cationic delivery vehicles with blood components, uptake by the reticuloendothelial system (RES), toxicity, managing bioactivity, targeting ability of the carriers with respect to cells of interest, and the metabolic fate of these systems in the body (Guo and Huang 2011). Cationic polymers for gene delivery can be divided into two main categories: polysaccharide cationic polymers and non-polysaccharide cationic polymers. Cationic polysaccharides include chitosan, cyclodextrins, dextran, dextran–spermine, schizophyllan, and pullulan, while non-polysaccharide cationic polymers include poly-L-lysine, polyethyleneimine, and cationic dendrimers (Fig. 1).

2 Mechanism of DNA Polyplex Formation

Due to the surface charge of cationic polymers, they rapidly form stable charged complex (polyplex) with oppositely charged DNA molecules. Multiple binding sites on DNA provide an integrated stabilization to polyplexes. These polyplexes can be administered into the body through different routes (intravenous and oral have been most widely explored so far). Apart from that polyplex can also be adsorbed on the surface of polymeric films or can be designed into layer-by-layer assembly carrying alternate layers of DNA and cationic polymers (De Smedt et al. 2000). After administration, polyplexes were taken up by cells through endocytosis (Luo and Saltzman 2000). Cellular entry of these polyplexes is followed by endosomal escape and dissociation, which release nucleic acid into the nucleus for gene expression (Smyth Templeton 2002). Figure 2 gives an overview of polyplex formation and release of DNA followed by expression.

With viral vectors, endosomal escape proceeds easily due to the inherent property of a virus to undergo conformational change in the coat proteins, but nonviral vectors require the addition of lysosomotropic agents like chloroquine, membrane-destabilizing peptides such as synthetic N-terminal, and peptides of rhinovirus VP-1/influenza virus HA-2 to mediate endosomal release. Alternatively, some macromolecules that have amine groups with low p*K*a values display the phenomena of "proton sponge effect" and thus mediate endosomal escape (Bron et al. 1993; Behr 1997).

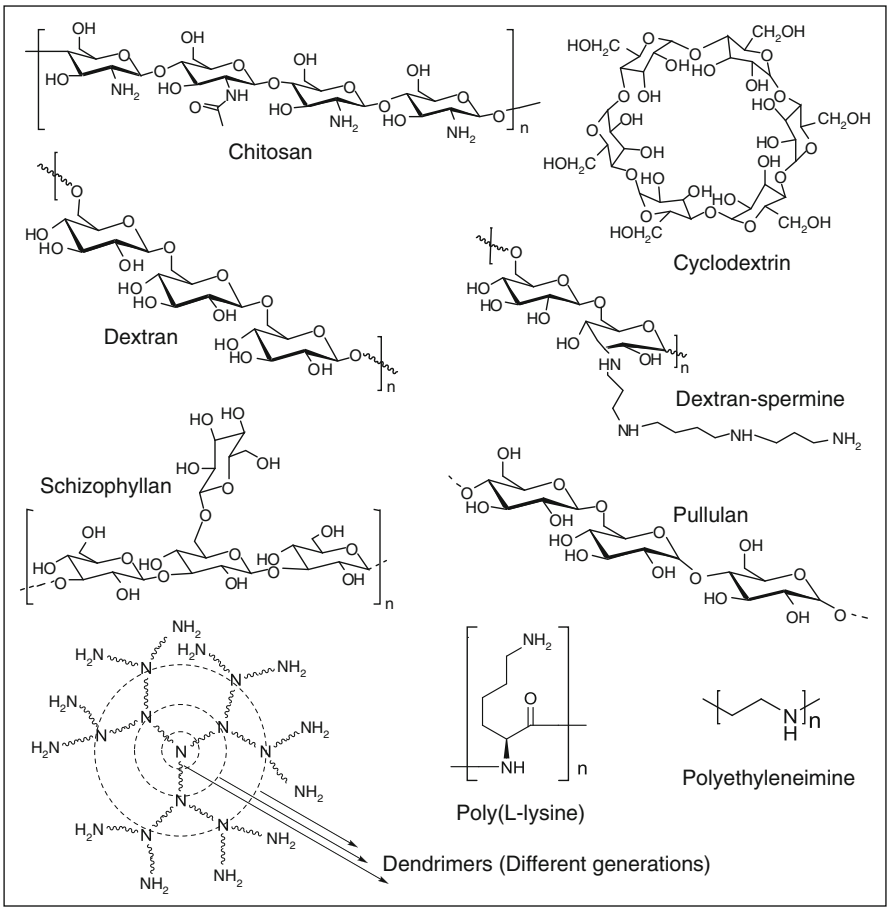

Fig. 1 Chemical structures of polysaccharides used in gene delivery

3 Bioactivity of Cationic Polymers

Bioactivity can be defined as the effect of a given agent upon a living organism or on living tissue. For the activity of cationic polymers as gene delivery vector, cationic charge is the basic requirement which facilitates the formation of a charged complex due to electrostatic interactions. However, the positive charge of polymer allows these complexes to interact with anionic serum proteins, resulting in the formation of undesirable aggregations or premature release of nucleic acids. PEGylation has been suggested as a solution for this problem due to its ability to protect the complex from RES system by increasing circulation time and by neutralizing surface charge, which minimizes the undesired interaction of polyplex with plasma components. On the other hand, PEGylation has been found to prevent

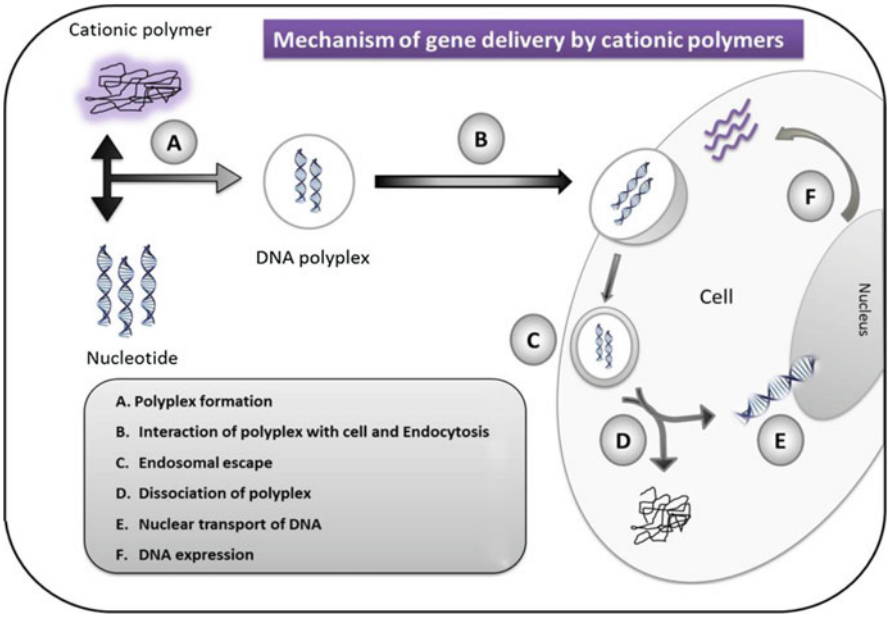

Fig. 2 Mechanism of polyplex formation and gene delivery by cationic polymers

gene vectors from interacting efficiently with cellular membranes and/or endosomal membranes due to steric hindrance and neutral charge. This results in lower transfection efficiency of a gene vector (Wang et al. 2012).

Efforts are being made to offer the advantage of both cationic charge and PEGylation by designing a pH-responsive PEG conjugate (Romberg et al. 2008), enzyme-sensitive PEG conjugate (Coussens et al. 2002), etc. Cationic polyplexes protect DNA from degradation by forming stable complexes. It is necessary to prevent premature release of nucleic acids in the extracellular environment and in maintaining the integrity of the complex for targeting and intracellular delivery of nucleic acids. However, the strong affinity of polymers towards nucleic acid can be a problem for release of nucleic acid at its site of action; this results in low transfection efficiency (Grigsby and Leong 2010).

4 Cationic Polymers for Delivery of Nucleotides

Gene delivery has a potential to cure many heretofore incurable diseases, but the lack of a suitable vector has hampered its clinical progress. An ideal vector for gene delivery must be stable in its systemic circulation, able to escape the reticuloendothelial system and to extravasate tissues, escape lysosomal degradation, and transport DNA to the nucleus to be transcribed. The advantages of a cationic polymer lie in the ability to accept structural modification. Numerous studies are underway to

explore the application of rational design into their structure. The goal is to overcome barriers in gene delivery. This section gives a brief introduction to cationic polymers, their properties, toxicity, and degradation behavior.

4.1 Polysaccharide Cationic Polymer

4.1.1 Chitosan

Chitosan is a chitin-derived cationic linear polymer composed of β(1–4)-glucosamine and randomly located *N*-acetyl-D-glucosamine. It is obtained by deacetylation of chitin. The degree of deacetylation for commercial chitosan can range from 70 % to 95 % with MW ranges between 10 and 1,000 kDa (Khan et al. 2013). Chitosan received approval to be used as a dietary supplement in Japan, Italy, and Finland (Ilium 1998). Also, bandages impregnated with chitosan and chitosan granules have been approved by the FDA to control blood loss in emergency situations (Wedmore et al. 2006).

When used for gene delivery, the toxicity of chitosan was found to be directly proportional to the charge density of the molecule. Chitosan in small amounts was found to be relatively less toxic; also, chitosan with a degree of deacetylation between 40 % and 60 % has been reported to have significantly less toxicity. A general trend of increasing toxicity with an increasing degree of trimethylation has been reported. However, higher toxicity has been seen in polymeric chitosan derivatives than oligomeric chitosan derivatives at similar degrees of trimethylation (Kean et al. 2005). Various drug delivery applications of chitosan have been reported with or without noticeable toxicities. Hirano et al. report no detrimental effects of chitosan oligosaccharides when injected (dose of 7.1–8.6 mg/kg over 5 days) for about 65 days (Hirano et al. 1991). When implanted subcutaneously, no toxic effect has been observed with 200 μl of 30 mg/ml photocrosslinked azide–chitosan–lactose gel (Ono et al. 2000). Upon oral administration of trimethyl chitosan/pDNA nanoparticles, slight toxicity has been observed (diarrhea); this was relieved by stopping administration (Zheng et al. 2007). Also, no oral toxicity was found in mice treated with 100 mg/kg chitosan nanoparticles (80 kDa, 80 % DD) (Sonaje et al. 2009). Biodistribution studies of ultrafine chitosan particles after intravenous injections of a dose 3.3–4 mg/kg in mice report no adverse effects (Banerjee et al. 2002). A phase II clinical trial involving percutaneous injection of chitosan–166 holmium complex for the treatment of hepatocellular carcinoma also reports safe and efficacious results (Kim et al. 2006). Also, nasal administration of chitosan solutions (0.5 % w/v) over 1 h produces no significant changes in mucosal cell morphology (Illum et al. 1994).

The metabolic fate of any formulation and its constituents is an important aspect of drug delivery. In general, the degree of deacetylation affects both the rate and extent of chitosan biodegradation with a higher degree of deacetylation; it also decreases the degradation rate in living organisms (Yang et al. 2007b). For oral delivery, in vivo studies show gut-mediated digestion of chitosan, which has been found to be species dependent. Hens and broilers are more efficient digesters

(67–98 % degradation) than rabbits (39–83 % degradation) (Hirano et al. 1990). FITC-labeled chitosan was administered to mice by i.p. route, and the low MW products were detected mostly in urine (Onishi and Machida 1999). Reports on degradation after i.v. administration are rare, and reports on human beings are not available due to lack of approval for human use. In vitro, both chemical as well as enzymatic degradation has been suggested for chitosan. Enzymes such as lysozyme (Onishi and Machida 1999), proteases (Rao and Sharma 1997), pectinase, (Kittur et al. 2003), rat cecal and colonic bacterial enzymes (Zhang and Neau 2002), porcine pancreatic enzymes (Verheul et al. 2009), and enzymes present in human fecal preparations (McConnell et al. 2008) have been reported for degradation of chitosan.

4.1.2 Cyclodextrin

Cyclodextrins (CDs) are cone-shaped natural cyclic oligosaccharides found as α-, β-, or γ-CD. They are composed of 6, 7, or 8 D(+)-glucose units, respectively, joined by α-1,4 linkages (Davis and Brewster 2004). The emergence of CDs in gene therapy has been considered since 1999 (Davis et al. 2004). For gene delivery purposes CDs have been explored either as part of the backbone of polymer (CD-embedding polymers) or grafted with polymer (CD-pendant polymers). Polymers containing CDs in their backbone are advantageous, since they are able to be further modified by forming an inclusion complex and adopting versatile properties (Reineke and Davis 2003; Davis et al. 2004; Liu et al. 2007; Muntimadugu et al. 2013). Cytotoxicity of these complexes has been found to be dependent on the alkyl chain length between CD units; it generally decreases with longer chain lengths (Hwang et al. 2001). Further, polymers containing 4–10 carbon alkyl chains between CD units have been found to display less toxicity, higher transfection efficiency, but less water solubility (Popielarski et al. 2003).

CDs are nephrotoxic at a reported dose of 0.7–1 g/kg (Frank et al. 1976). With this, few in vitro studies also report slight hemolytic effect of CDs. In vitro hemolytic activity of CDs follows the order β-CD > α-CD > HP-β-CD (TDS 4.2) > γ-CD > > HP-γ-CD ≥ HP-α-CD in erythrocytes freshly collected from human and P388 murine leukemic cells (Leroy-Lechat et al. 1994). Kiss et al. studied the cytotoxic and hemolytic properties of various beta-CDs in correlation with their cholesterol-solubilizing capacities to expose the mechanism of toxicity. Introduction of both ionic and methyl substituent shows less cytotoxicity than the parent compounds, but cell toxicity of methylated β-CDs is higher than ionic derivatives. Further, they also report significant cholesterol extraction for CD-mediated cell toxicity. However, the in vivo toxicological implications are considered negligible (Kiss et al. 2010).

Oligoethyleneimine (OEI)-based cationic star polymers for gene delivery in which OEI is conjugated with α-CD core also result in a lower in vitro cytotoxicity and excellent gene transfection efficiency in HEK293 and Cos7 cells (Davis et al. 2004; Yang et al. 2007a). Similarly, OEI-grafted β-CDs display a superior delivery system for gene delivery when combined with pluronic, polycaprolactone, and PEI (Shuai et al. 2005).

Polyrotaxane-based CD-containing gene carriers have attracted significant attention in the past few years. Cytocleavable necklace-like structures with many α-CDs containing cationic groups were threaded onto a succinimidyl succinate (SS)-terminated PEG chain. Under reducible conditions, the SS bond cleavage results in dissociation of the non-covalent linkages between α-CDs and PEG, which finally triggers pDNA release. The main advantage with these carriers is reduced cytotoxity compared with high MW polymers. This might be due to dissociation behavior and relatively fewer cationic groups in these carriers (Ooya et al. 2006; Yui et al. 2009; Mellet et al. 2011).

4.1.3 Dextran and Dextran–Spermine (D-SPM)

Dextran is a highly water-soluble biodegradable and biocompatible polysaccharide composed predominantly of α-1,6-linked glucopyranose units with a low degree of 1,3-branching (Varshosaz 2012; Raemdonck et al. 2013). Low MW dextrans have achieved significant importance in the biomedical field due to flexibility in chemical modification and the network-forming ability of dextran (van Dijk-Wolthuis et al. 1995; Heinze et al. 2006; Van Tomme and Hennink 2007).

Intravenous administration of dextran has been reported with mild hemotoxicity and thrombocytopenia (Flexner et al. 1991). For gene delivery, dextran-induced toxicity has been reported due to undesired interactions with blood components. Chemical modification of dextran with spermine improves the stability and transfection efficiency of polyplex. However, it does not overcome the problem of undesired interaction with blood components. PEG/oleate residues are, therefore, attached to polymers, which results in better transfection efficiency in serum-rich medium (Azzam et al. 2004). Dextran–spermine for the delivery of pDNA to mouse lungs by intranasal route exhibits mild toxicity (Yeo et al. 2014). Polyelectrolyte complexes (PECs) with dextran sulfate have also been developed to minimize interaction with blood components. These complexes were made from the interaction of cationic polymers with negatively charged dextran sulfate in which the outer coat of dextran sulfate minimizes electrostatic interactions, while the inner positively charged polymer provides stability to nucleic acid (Tiyaboonchai et al. 2003; Zorzi et al. 2011; Cho et al. 2012). Dextranated bioreducible cationic polyamide was developed for systemic gene delivery. Polyplex formed between this polymer and nuclear material displayed near-neutral surface charge which is advantageous to avoid interaction with blood components. Moreover, the reducible nature of polymers allows sufficient gene release from the polyplexes in response to an intracellular reducing environment. The copolymer reveals low cytotoxicity in vitro and no death of mice upon intravenous administration (Lin et al. 2014).

4.1.4 Schizophyllan

Schizophyllan (SPG) is a natural β-(1–3)-D-glucan with one β-(1–6)-glycosyl side chain per three glucose residues. It is produced by the fungus *Schizophyllum* and shows potential antitumor effects (Kitamura et al. 1994; Khan et al. 2012). Binding of SPG with polynucleotide is driven by nonionic hydrogen bond interactions

(Sakurai and Shinkai 2000). SPG possesses several biological and immunopharmacological properties. These properties vary with MW, degree of branching, and confirmation. Systemic administration of soluble glucan over a wide dose range does not induce any significant toxicity (Williams et al. 1988). In vivo studies with i.p. injections of SPG/CpG-DNA complexes show an increase in the immune responses in mice twofold to ninefold that of uncomplexed CpG-DNA. Chemically modified SPG results in stable complexes with antisense oligonucleotides and negligible in vitro cell line toxicity (Takedatsu et al. 2012; Matsumoto et al. 2004).

SPG cannot bind to the heteronucleotide sequence of DNA, and hence homonucleotide sequences were usually attached to DNA which can form a stable complex with SPG. Takeda et al. suggested an alternative method to stabilize the complex of SPG with DNA. They prepared the complex of DNA with PEI, and this complex was further incorporated into SPG to form a ternary complex which exhibited better stability than SPG–DNA complex and less aggregation behavior than unencapsulated PEI–DNA complexes (Takeda et al. 2007). In fact, PEGylated cationic SPG also resulted in greater transfection efficiency for pDNA and long-term gene expression than PEI complexes (Nagasaki et al. 2004). Karinaga et al. developed galactose–PEG dual conjugation of β-(1 → 3)-D-glucan SPG for delivery of antisense oligonucleotides. This dual conjugation facilitates enhancement in cellular uptake along with endocytosis escape (Karinaga et al. 2006). Blood clearance of SPG was found to be confirmation dependent. Clinically used SPG was mostly found in triple-helix confirmation. Comparison of blood clearance of triple-helix SPG with single-helix SPG upon i.v. and i.p. administration resulted in faster clearance of single-helix form (Miura et al. 1995).

4.1.5 Pullulan

Pullulan is a water-soluble polysaccharide with repeated units of maltotriose condensed through the α-1, 6 linkage. It is nontoxic, non-immunogenic, non-mutagenic, and noncarcinogenic in nature (Hosseinkhani et al. 2002). Pullulan, due to its inherent affinity towards liver, is also used for gene transfection into liver. For this purpose pullulan is conjugated with spermine. This cationized pullulan derivative is complexed with a plasmid DNA and intravenously injected for in vivo gene transfection. This polyplex enhances survival time of mice and reduces the number of tumor cells compared with free plasmid DNA injection (Jo et al. 2006). Cellular uptake of pullulan–spermine DNA polyplex is mediated by clathrin- and raft/caveolae-dependent endocytotic pathways (Kanatani et al. 2006). Priya et al. developed a pullulan–protamine conjugate gene delivery system which is nontoxic and hemocompatible (Priya et al. 2014). Pullulan nanoparticles encapsulating pBUDLacZ plasmid have been prepared by w/o microemulsion method. Cytotoxicity studies demonstrated that cells incubated with nanoparticles remain more than 100 % viable even at a nanoparticle concentration of 1,000 μg/ml. Further, β-galactosidase expression in COS-7 cells resulting from pullulan nanoparticles is comparable to commercially available Lipofectamine 2000 (Gupta and Gupta 2004). Pullulan in combination with spermine has been used for transfection of pDNA to rat brain endothelial cells and human brain

microvascular endothelial cells (Thomsen et al. 2011), rat sensory neurons (Thakor et al. 2009), and mesenchymal stem cells (Jo et al. 2010).

4.2 Non-polysaccharide Cationic Polymers

4.2.1 *Polyethyleneimine*

Polyethyleneimine (PEI) is one of the most widely used polymers for gene delivery due to its high transfection efficiency, but some cytotoxicity has also been reported (Godbey et al. 1999a). It was first introduced by Boussif and coworkers for gene delivery application (Boussif et al. 1995). The most extensively used PEIs are linear and branched PEI polymers with MW ranging from 22 to 25 kDa. PEI–DNA polyplexes form due to electrostatic interaction. This process seems to be essentially entropy driven together with the contribution of other interactions such as hydrogen bonding and van der Waals forces (Bronich et al. 2001). Complete condensation of DNA with PEI has been reported at nitrogen to phosphate (N/P) ratios above 2. This complexation results in the formation of small nanoparticles with size ranging from 50 to 100 nm in optimized conditions (Tang and Szoka 1997).

PEI-associated cytotoxicity during gene transfection can be of two types: (1) immediate toxicity associated with free PEI and (2) delayed toxicity associated with cellular processing of PEI–DNA complexes (Godbey et al. 1999b, 2001). Free PEI exerts its toxic effect by interacting with negatively charged serum proteins (such as albumin) and red blood cells followed by clumping with other cells. The delayed toxicity by the PEI–DNA complex is associated with the release of DNA from PEI. PEI tends to restore inside the cell after release of DNA, and it thus interacts with various cellular components and inhibits normal cellular process (Godbey et al. 2001). Structurally branched PEI has been found to exert more cytotoxicity than deacetylated PEI (Thomas et al. 2005). Also, low MW (10 kDa), moderately branched polymers provide efficient delivery with low toxicity in comparison with commercial high MW PEI (Godbey et al. 1999c). Regional delivery of plasmid DNA through intrapericardial administration of DNA–PEI polyplex yields significant toxicity towards the myocardium, which hampers efficiency evaluation (Jeong et al. 2007).

To overcome these toxicity issues, many efforts have been made such as PEGylation (Kircheis et al. 1999), modification of PEI with acid-labile imine linkers (Kim et al. 2005), lipopolymers (Wang et al. 2002), etc. Adsorption of PEI–DNA complexes to silica nanoparticles results in comparable transgene expression in vitro with reduced toxicity (Kneuer et al. 2000). CD- and PEI-functionalized mesoporous silica nanoparticles were also developed for the delivery of siRNA. Here, PEI forms an electrostatic bond with siRNA, while cyclodextrin eliminates the charge-induced toxicity of PEI (Shen et al. 2014).

More attention must be given to develop peptide-grafted PEIs such as mannosylated cell-penetrating peptide-graft-polyethyleneimine (Hu et al. 2014) and TAT peptide-modified PEI (Yamano et al. 2014). The genotoxicity of

endocytosed PEI NPs is associated with the production of reactive oxygen species (ROS), which causes DNA damage without apparently affecting cell viability. This genotoxicity of PEI-based nanoparticles is reduced by the acetylation of PEI (Calarco et al. 2013).

PEI is nondegradable in nature and can accumulate in the body and induce long-term undesirable effects. Efforts have, therefore, been made to develop biodegradable and less toxic polymers with high transfection efficiency (Park et al. 2005). Some modifications for this purpose include hydroxyethyl starch–PEI (Noga et al. 2014), poly(vinyl alcohol)–PEI (Goyal et al. 2011), and poly(ethyleneimine-co-L-lactamide-co-succinamide) (Petersen et al. 2002).

4.2.2 Poly-L-Lysine

Poly-L-lysine (PLL) is one of the first polymers to be used for DNA condensation. PLL has a sufficient number of primary amines with positive charges to interact with the negatively charged phosphate groups of DNA. PLLs are biodegradable linear polypeptides of amino acid lysine. After entering into systemic circulation, rapid binding to plasma proteins causes their rapid clearance and results in lower transfection efficiency (Ward et al. 2001; Khan et al. 2011). Although use of high MW PLL increases the transfection efficiency, it also causes undesirable toxicity (Wolfert et al. 1999). PEGylation and palmitoyl group attachment result in the reduction of toxicity without compromising gene delivery efficiency (Brown et al. 2000). PLL-modified silica nanoparticles have shown their potential towards oral gene therapy. Efficient reporter gene expression was detected in mucous membrane cells of stomach and intestine with no obvious sign of toxicity (Li et al. 2005). In fact, Poly-L-lysine–Fe_2O_3/silica nanoparticles have been designed very recently for the delivery of siRNA. This system results in remarkable encapsulation efficiency and targeted gene silencing with negligible cytotoxicity (Cui et al. 2014). Dendritic poly-L-lysine of the sixth generation has shown high transfection efficiency without significant toxicity or cell specificity (Ohsaki et al. 2002).

Recent research has focused on the co-delivery of drug and gene. To co-deliver docetaxel (DOC) and MMP-9 siRNA plasmid for nasopharyngeal cancer therapy, a star-shaped porphyrin–arginine-functionalized PLL copolymer has been designed. This system induces a more significant apoptosis than DOC or MMP-9 alone, better blood compatibility, and lower cytotoxicity compared with PEI-25k (Ma et al. 2014). Similarly, a star-shaped cyclodextrin–poly-L-lysine derivative has also been used to co-deliver docetaxel and MMP-9 siRNA plasmid for the treatment of cancer (Liu et al. 2014b).

Degradation of PLL is an enzymatic process. Leclercq et al. report degradation behavior of PLL when complexed with polyanion. For this study polyanions poly (acrylic acid) and poly-L-lysine citramide were taken as a representative model of DNA in polyplexes. The researchers found that trypsin (an endopeptidase) degraded PLL into trilysin and tetralysin. However, exopeptidase like aminopeptidase does not cause degradation of PLL (Leclercq et al. 2010). Further, Ren et al. report PLL degradative behavior in the presence of α-chymotrypsin.

They prepared a layer-by-layer self-assembly of PLL and DNA and found that 90 % of DNA within the films is released almost linearly under α-chymotrypsin in PBS at 37 °C in 35 h (Ren et al. 2006).

4.2.3 Cationic Dendrimers

Dendrimers have gained significant importance in gene delivery due to their well-defined nanoscale polymeric scaffold with low polydispersity index and controlled surface functionalities. A complex formed between DNA and dendrimer is known as a dendriplex. PAMAM dendrimer is most widely used for gene delivery applications. Regardless of the extensive pharmaceutical and biomedical applications, toxicity associated with dendrimers due to terminal NH_2 groups and multiple cationic charge limits their candidatures for clinical applications (Jain et al. 2010). Dendrimers are reported with slight cytotoxicity (Jevprasesphant et al. 2003), hemolytic toxicity (Agrawal et al. 2007) and weak immunogenicity (Roberts et al. 1996). They also display concentration and generation-dependent toxicity of free amine groups present at their periphery (Chen et al. 2004).

Most commonly used dendrimers for nonviral gene delivery are synthesized via the divergent strategy and represent sixth generation Starburst™ PAMAM dendrimers either in intact (PolyFect®) or fractured (SuperFect®) form. A comparative in vitro cytotoxicity study with different water-soluble, cationic macromolecules used for gene delivery application was performed. Results were evaluated based on MTT assay and release of the cytosolic enzyme lactate dehydrogenase (LDH), which indicate the highest toxicity with poly(ethylenimine) comparable to poly-L-lysine followed by poly(diallyl-dimethyl-ammonium chloride), diethylaminoethyl-dextran, poly(vinyl pyridinium bromide), Starburst™ dendrimer, cationized albumin, and native albumin in descending order. According to this study Starburst dendrimers are the least toxic among cationic polymers (Fischer et al. 2003).

Liu et al. use fluorination to reduce the cytotoxicity of poly(propylenimine) (PPI) dendrimers. They also claim comparable or superior transfection efficacies with fluorinated G3, G4, and G5 PPI dendrimers as compared with Lipofectamine 2000, branched poly(ethyleneimine), SuperFect®, PolyFect®, as well as arginine-modified dendrimer on both HEK293 and HeLa cells (Liu et al. 2014a). The ternary complex of plasmid DNA polyamidoamine dendrimer and chondroitin sulfate results in no agglutination activity and no cytotoxicity against B16-F10 cells (Imamura et al. 2014). PEGylation is the well-known method to improve biocompatibility and transfection efficiency (Sun et al. 2014). Shen et al. tried a charge-reversal approach to convert PAMAM primary amines to negatively charged acid-labile amides in order to inhibit nonspecific interaction with cells; this again regenerates the active PAMAM in acidic environments (Shen et al. 2010). Cationic water-stable carbosilane dendrimers containing ammonium groups at the periphery are reported to be nontoxic for gene therapy against HIV and hepatocarcinoma (de Las Cuevas et al. 2012). AuPAMAM conjugates are reported to exhibit high yield, high transfection efficiency, and low cytotoxicity (Figueroa et al. 2014).

Table 1 Recent patents on gene delivery using cationic polymers

S. no.	Title	Patent no.	Remarks
Chitosan in gene delivery			
1	Nanoparticles for delivery of bioactive agents	US8461316 (B1)	Describes nanoparticles composed of chitosan, polyglutamic acid, and at least one DNA, RNA, or bioactive agent characterized with a positive surface charge and their enhanced efficiency for gene delivery and bioactive agent delivery
2	Preparation method of controllable arginine coupled chitosan	CN103539866	Arginine-modified chitosan carriers were used for gene delivery
3	Dually derivatized chitosan nanoparticles and methods of making and using the same for gene transfer in vivo	WO2013138930 (A1)	Chitosan was dually derivatized with arginine and gluconic acid which produced synergistic effect for gene delivery. This synergistic effect was found to be maximum for arginine and gluconic acid at a final functionalization degree of 26 % and 5 %, respectively
4	Mucosa M-cell targeted viral myocarditis gene vaccine and preparation method thereof	CN103341179 (A)	Vaccine was prepared by compounding a mucosa delivery system made of chitosan and b3-type Coxsackie virus antigen encoding plasmids through cross-linking copolymerization. This vaccine was administered by intranasal route and found to effectively induce specific immune response
5	Chitosan derivative used as gene vector, and preparation method and application thereof	CN102260356 (A)	Chitosan derivative was synthesized by introducing *N*, *N*, *N*-trimethyl-(1,2,3-triazol-4)-methyl ammonium bromide groups into the 6-site of chitosan. This derivative was found to be nontoxic and biocompatible with great improvement of water solubility, efficacy, and transfection efficiency

S. no.	Title	Patent no.	Remarks
Cyclodextrin in gene delivery			
6	Nano non-viral gene delivery system and application thereof	CN102417914 (A)	Polyethyleneimine and cyclodextrin complex was used as gene transfection agent
			High transfection efficiency and low-toxicity profile for gene transfection
7	Polyamides for nucleic acid delivery	US2011183417 (A1)	Polymers comprising an oligoamine shell, a cyclodextrin core, and carbohydrate-containing degradable polyesters were used as gene delivery vectors
8	RNA delivery reagent specific to hepatocyte	JP2011103811 (A)	Hepatocyte-specific gene transfer agent comprising a conjugate of cyclodextrin with a dendrimer and lactose was synthesized
9	Cyclodextrin-polyethyleneimine-mediated supramolecular delivery system and preparation method	CN101991862 (A)	Cyclodextrin–PEI-based system for delivery of gene and adriamycin simultaneously
			Solubility and toxicity problems associated with adriamycin were resolved
10	Biodegradable copolymer and nucleic acid delivery system	US2004185564 (A1)	PEI–cyclodextrin copolymer formed through ester linkage
Dextran in gene delivery			
11	Dextran–maleic acid monoesters and hydrogels based thereon	US6476204 (B1)	Hydrogel made by photocrosslinking of dextran–maleic acid monoesters. It was used for encapsulating viral vector in gene therapy
12	Nucleic acid condensing agents with reduced immunogenicity	WO9621036 (A2)	Dextran and other polysaccharides were conjugated with polyethylene glycol to reduce immunogenicity and used to deliver the gene into cells
13	Biocompatible cancer cell-specific delivery system	KR20110013681 (A)	System contained a viral gene delivery vector along with soluble natural polymer (chitosan, heparin, hyaluronic acid, or alginate) connected to cancer cell-targeting moiety and PEG

Table 1 (continued)

S. no.	Title	Patent no.	Remarks
Polyethyleneimine in gene delivery			
14	Applications of diamino carbamate cross-linked polyethyleneimine in gene therapy	CN103421846 (A)	Patent describes the method for preparation of polyethyleneimine for gene delivery applications
15	Folate-chitosan-graft-PEI copolymer and gene delivery carrier by using the same	KR20110068033 (A)	Folate–chitosan-graft-PEI copolymer was synthesized which exhibited excellent composite forming ability and a platform for an aerosol gene delivery system
16	Degradable imine polycation and synthetic method thereof, and nanoparticle	CN102516535 (A)	Invention describes the method of preparation of degradable derivatives of PEI for gene delivery application
17	Method for introducing siRNA into cells by photochemical internalization	RU2008150847 (A)	PEI–siRNA polyplex combined with photosensitizing agent to induce stimuli-responsive gene delivery
Poly-L-lysine in gene delivery			
18	PEG-PLGA-PLL polymer and method for preparing and using the same as the drug and gene carrier	US2013052134 (A1)	PEG–PLGA–PLL copolymer was reported for gene and drug delivery application
			The carrier was capable of passive targeting through control of the carrier particle size
19	Hepatocyte targeting polyethylene glyco-grafted poly-L-lysine polymeric gene carrier	US6177274 (B1)	PEG–PLL–lactose/galactose was synthesized for gene delivery application. PEG provided better solubility, improved transfection efficiency, and reduced cytotoxicity, while lactose or galactose acted as targeting moiety for hepatoma cell
20	Gene transfer system comprising cationic macromolecule and lipoprotein	KR20000023602 (A)	Poly-L-lysine was used with a lipoprotein for gene delivery application
21	Carrier system for specific artery wall gene delivery	US7264969 (B1)	An artery wall-binding peptide (AWBP) was conjugated to a cationic backbone of PEG–PLL. This composition enhanced gene transfer to artery wall cells

Table 1 (continued)

S. no.	Title	Patent no.	Remarks
Pullulan in gene delivery			
22	Bioactive agent delivery system comprising modified pullulan-polyethyleneimine conjugate and method for producing it	KR20120001214 (A)	Bioactive delivery system was designed which contained pullulan derivatives and polyethyleneimine and capable of delivering gene efficiently to its target site
Dendrimers in gene delivery			
23	Poly(ether imine) dendrimers and uses thereof	WO2012090223 (A1)	Nonviral poly(ether imine) dendrimer-based gene delivery systems were designed which significantly reduced toxicity, over a broad concentration range
24	RNA delivery reagent specific to hepatocyte	JP2011103811 (A)	Patent described an RNA delivery reagent in which cyclodextrin was attached to dendrimer followed by surface modification with lactose for gene delivery to hepatic cells

5 Clinical Trials

Even though many clinical trials are ongoing, experiments with gene therapy using viral vectors and experiments using nonviral vectors such as cationic polymers are still limited. To the best knowledge of the authors, one clinical trial application using PEI as vector has thus far been filed (NCT No. NCT01274455). The purpose of the study is to evaluate the feasibility, tolerance, and antitumor effect of repeated intra-tumoral injection of a gene therapy product in combination with gemcitabine for the treatment of unresectable pancreatic carcinoma. The gene therapy product used for this purpose is CYL-02 plasmid DNA pre-complexed to linear PEI. This phase I study has been completed, but study results have yet to be published. Few recent patents on gene delivery using cationic polymers are given in table 1.

6 Conclusion

The progress in molecular biology has prepared the way for the introduction or replacement of missing as well as malfunctioning genes. Previously viral vectors have been used for this purpose, but immunogenicity associated with viral vectors has inspired researchers to find new alternatives. The emergence of cationic polymers as gene delivery vectors offers advantages of negligible immunogenicity and

biodegradability and proves their enormous potential for this purpose. Yet problems such as toxicity and low transfection efficiency require further efforts to bring these cationic polymeric vectors to a commercial level.

Contents

Abstract

Polysaccharides from fungi and plants are of great economic and clinical interest and exhibit a wide variety of biological activities. They have emerged as an important class of bioactive natural products with nutraceutical and chemopreventive properties and are relatively nontoxic. The activity of polysaccharides is

determined by their conformation, composition, and size. Among polysaccharides with higher biological activity, β-glucans are the most important, and they vary in conformational complexity, molecular weight, and number of branches. These characteristics can alter the biochemical and solubility properties and also influence their biological properties, such as immunomodulation and antitumor activities; metastasis inhibition; increased host resistance to bacterial, viral, parasitic, and some microbial infections; and have antimutagenic, antiallergic, regenerative, antithrombogenic, anticoagulative, antioxidant, hypolipidemic, radioprotective, and antidiabetic effects. This chapter summarizes the immune mechanisms, biological properties, pharmacokinetics, and toxicity of dietary polysaccharides primarily from fungi.

Keywords

Dietary polysaccharides • β-glucans • Macrophages • NK • Cytokines • Innate immunity • Cellular immunity • Infection • Inflammation • Cancer

Abbreviations

AbM	*Agaricus blazei* Murill water extract
ABP-AW1	Low molecular weight polysaccharides isolated from *Agaricus blazei* Murill
AdvAMB	Advanced ambrotose
AMB	Ambrotose complex
APCs	Antigen presenting cells
BG	β-1,3/1,6-glucans derived from *Saccharomyces cerevisiae*
CD	Crohn's disease
CR3	Complement receptor 3
DAMPs	Damage-associated molecular patterns
DCs	Dendritic cells
DNA-PK	DNA-dependent protein kinase
DSS	Dextran sulphate sodium
GALT	Gut-associated lymphoid tissue
IBD	Inflammatory bowel disease
IFN-γ	Interferon-gamma
IgA	Immunoglobulin A
IL	Interleukin
MAPK	p38 mitogen-activated protein kinase
NF-κB	Nuclear factor kappa B
NK	Natural killer cells
NO	Nitric oxide
NOAEL	No observed adverse effect level
OVA	Ovalbumin
PAMPs	Pathogen-associated molecular patterns
PRRs	Pattern-recognition receptors
SG	Soluble glucans
SP1	Sulfated polysaccharides isolated from *Caulerpa lentillifera*

TCR	T cell receptor
TGF-β	Transforming growth factor-beta
TLRs	Toll-like receptors
TNF-α	Tumor necrosis factor-alpha
UC	Ulcerative colitis

1 Introduction

Polysaccharides from fungi and plants are of great economic and clinical interest and exhibit a wide variety of biological activities, including antitumor, antioxidant, and immunostimulant activity. Thus, they have emerged as an important class of bioactive natural products with nutraceutical or chemopreventive properties, being relatively nontoxic. Worldwide, they have attracted attention as a functional food and a source for the development of new immunomodulator compounds due to their dietary and medicinal benefits (Ooi and Liu 2000; Bertozzi and Kiessling 2001; Wasser 2002). The polysaccharide is localized in the intermediate layer of the cell wall, adjacent to the plasma membrane, with the function of maintaining the rigidity and shape of the cell (Angeli et al. 2006). Carbohydrate is a major component in mushrooms, and its total content ranges from 35 % to 70 % dry weight, with variations in different species (Manzi et al. 1999; Cheung 2010). In addition, fungal polysaccharides can be found in the fruiting bodies, mycelium, and fermentation broth of large edible and medicinal fungi (Wasser 2002). Fungal polysaccharides are long carbohydrate molecules of repeating units joined together by glycosidic bonds. They are often linear but may also be highly branched (Wasser 2002). Most of these polysaccharides are homoglycans (polysaccharides that contain residues of only one type of monosaccharide molecule) or heteroglycans (polysaccharides that contain residues of two or more types of monosaccharide molecules) and are able to combine with other proteins to make peptidoglycan or polysaccharide–protein complexes. This chapter summarizes immune mechanisms, biological properties, pharmacokinetics, and toxicity of dietary polysaccharides mainly from fungi.

2 Brief Overview of the Immune Activation

Cells from the immune system have the ability to discriminate nonself antigens, their released products, and other compounds present in the environment and dietary substances. The initial interaction between environment and host is mediated by innate immune nonspecific sensors called pattern-recognition receptors (PRRs), such as toll-like receptors (TLRs) (Beutler 2004; Joffre et al. 2009), which are present in innate immune response cells, which recognize the expression of pathogen-associated molecular patterns (PAMPs) or damage-associated molecular patterns (DAMPs). The activation triggered by these receptors leads to secretion of cytokines, chemokines, and microbicidal molecules and to the development

of adaptive immunity. This occurs via the uptake of dendritic (DC) and others antigen-presenting (APCs) cells and the process of antigen presentation to T lymphocytes (Kapsenberg 2003; Martin and Frevert 2005; Murray and Wynn 2011). Furthermore, DCs are essential for differentiation of T helper (Th) 1, Th2, Th17, and T-regulatory cells, which secrete different cytokines that modulate the immune response and the outcome of disease. For instance, Th1 cells secrete interferon-gamma (IFN-γ), tumor necrosis factor-alpha (TNF-α), and interleukin-12 (IL-12) and are involved in the control of intracellular pathogens. On the other hand, Th2 activation is determined by production of IL-4, IL-5, IL-9, and IL-13 (Zhu and Paul 2008; Jutel and Akdis 2011) and plays a role in hypersensitivity type I reactions and helminthic infections. The response mediated by Th17 cells (source of IL-17A, IL-17F, IL-22, IL-21), in some cases associated with Th1 cells, have an important function in host protection against extracellular bacterial and fungal pathogens. Indeed, Th17 and Th1 cells can also mediate deleterious effects in patients with autoimmune and inflammatory diseases (Aarvak et al. 1999; Weaver et al. 2006; Bettelli et al. 2008; Jäger and Kuchroo 2010). Regulatory T cells regulate the immune response by inhibiting the activity of Th1, Th2, and Th17 cells, mainly by the secretion of transforming growth factor-beta (TGF-β) or IL-10. T-helper cells are essential for activation of naive $CD8^+$ T cells (Guidotti and Chisari 2001), B lymphocytes, and phagocytes (Bachmann and Zinkernagel 1997). The gut-associated lymphoid tissue (GALT) is the largest immune compartment in the body and consists of both organized lymphoid tissues, such as mesenteric lymph node and Peyer's patches, and diffuse scattered lymphocytes in the intestinal lamina propria and epithelium. The immune system is regulated not only by its symbiotic relationship with microbiota, but is very sensitive to diet. In this context, the roles of dietary polysaccharides in modulating immune responses are herein analyzed.

3 Effects of Dietary Polysaccharides on Immune System

We are always asking how and which kind of food impacts the immune system. Recently, Wichers (2009) indicated that maybe the better question is which food components do not have an impact on immune function? Both APCs, such as macrophages and DCs, and intestinal epithelial cells express receptors involved in the recognition of carbohydrate (glycan) present in microorganisms, including bacteria, dietary components, or glycosylated proteins in many cells. Thus, migratory and resident DCs within the intestine have a crucial role in the regulation of immune response, considering that they can induce Th1, Th2, Th17, and T regulatory – cell subpopulations following activation (Coombes and Powrie 2008; Rescigno and Di Sabatino 2009). C-type lectins expressed in APCs, including DCs, have specificity for mannose-, fucose-, galactose-, and N-acetylgalactosamine-terminating glycans. In general, activation of DCs by the recognition of glycans leads to the uptake of antigen and T-cell activation (for review, see de Kivit et al. 2011). In addition, immunomodulatory mechanisms of polysaccharides involve natural killer cells (NK), T cells, B cells, neutrophils, and macrophages.

Table 1 Effects of β-glucans on innate and adaptive immune cells

Receptor involved	Effects on immunity
Dectin-1	Enhances:
	Phagocytosis
	Production of proinflammatory cytokines
	Pathogens elimination
	Human peripheral blood mononuclear cells proliferation
	Dendritic cells maturation and T cell-stimulation
Scavenger receptor	Triggers phosphatidylinositol-3 kinase (PI3K), Akt kinase and p38 mitogen-activated protein kinase (MAPK) signaling pathways in myeloid cells
Complement receptor 3	Induces lysis of iC3b-coated tumor cells by neutrophils
Lactosylceramide receptor	Induces proliferation of myeloid cells
	Stimulates the neutrophils activation and their microbicidal activity

In this regard, β-glucans, which are among the most abundant polysaccharides present in the cell wall of bacteria, fungi, and yeasts, have an immunostimulatory effect, which is probably associated with the activation of macrophages, T-helper, and NK cells; with differentiation of T lymphocytes; and with activation of alternative complement pathway (Agarwal et al. 2011; Municio et al. 2013). Moreover, β-glucans are modulators of both humoral and cellular immunity and are implicated in both the initial phase of immune activation and in the effector phase of the immune response (Falch et al. 2000; Tokunaka et al. 2000; Brown and Gordon 2003; Chan et al. 2009).

Most β-glucans are considered nondigestible carbohydrates, being fermented by the intestinal microbial flora, and are used as prebiotic supplements to augment innate immunity (Reynolds et al. 1980; Miura et al. 2003; Brown and Gordon 2003). Therefore, their immunomodulatory properties may be attributed to a microbial-dependent effect or to its binding to specific receptors on immune cells. Some dietary fibers such as β-glucan modulate the immune response by binding to PRRs present on cells of the innate immune system. The main receptors involved with the recognition of β-glucans are dectin-1, complement receptor 3 (CR3), lactosylceramide, scavenger receptors, and TLR-2, 4, and 6, as shown in Table 1 (Zimmerman et al. 1998; Brown et al. 2002, Rice et al. 2002; Macpherson and Harris 2004; Huang et al. 2009; Ren et al. 2012).

Moreover, some studies demonstrated that dietary polysaccharides can bind to PRRs on gut cells, such dendritic cells and intraepithelial lymphocytes (Abreu 2010; Abadie et al. 2012). Among the PRRs, dectin-1 receptor is the most important and is highly expressed in immunocompetent cells such as DC, neutrophils, eosinophils, macrophages, monocytes, and T lymphocytes (Brown and Gordon 2001; Taylor et al. 2002). Thus, after the binding of β-1,3/1,6 glucans to dectin-1 or CR3, a series of signaling events that modulate innate and subsequently adaptive immune responses are activated. This produces proinflammatory cytokines (IL-1α/β, IL-6, IL-8, IL-12, TNF-α) and reactive nitrogen and oxygen species, such as nitric oxide (NO)

and hydrogen peroxide (H_2O_2), which protect against pathogenic microbes, toxins, and carcinogens (Vetvicka and Yvin 2004; Brown and Gordon 2005; Goodridge et al. 2011).

Orally administrated β-glucans are taken up by macrophages via dectin-1 and transported to bone marrow, lymph nodes, and spleen (Hong et al. 2004a). Volman et al. (2010a) showed that β-glucans modulate the intestinal immune response. They also showed that oral administration of 3 mg dietary oat (1 → 3), (1 → 4)-β-D-glucans twice a day for 3.5 days increases intestinal nuclear factor kappa B (NF-κB) transactivation in leukocytes and enterocytes (dectin-1 negative cells) of the ileum. It also enhanced secretion of IL-12 protein in intestinal tissue lysates, and decreased the concentration of IFN-γ in the proximal small intestine of treated animals. These findings suggest that dietary oat β-glucans activate leukocytes from the intestine, which in turn activates enterocytes. In addition, macrophages are able to degraded large β-1,3-glucans into β-1,3-glucan soluble fragments, which can be taken up via CR3 by circulating granulocytes, monocytes, or macrophages (Chan et al. 2009). On the other hand, soluble β-glucans can be internalized directly by intestinal epithelial cells and cells from GALT (Rice et al. 2005).

Indeed, the receptor–glucan interaction triggers phagocytosis, respiratory burst, and secretion of cytokines such as TNF-α and IL-10 (Chen and Hasumi 1993; Kelly et al. 2010). Studies in vitro showed that sulfated polysaccharides purified from *Caulerpa lentillifera* (SP1) stimulated the NO production by murine macrophage RAW 264.7 cells, activates both NF-κB and p38 mitogen-activated protein kinase (MAPK) signaling pathways, increased the phagocytosis of latex beads, and induced the expression of proinflammatory cytokines IL-1β, TNF-α, and IL-6, which are important activities for the innate immune protection (Maeda et al. 2012). In addition, the nutritional supplement β-glucan in mice led to growth and improved nutrient retention and immune system function, stimulating cytotoxic T lymphocytes, B cells, and macrophages (Cross et al. 2001).

Carpenter et al. (2013) demonstrated that nutritional supplementation with defined β-1,3/1,6-glucans (BG) derived from *Saccharomyces cerevisiae* (BG: 250 mg/10 days) increased the total number of proinflammatory monocytes ($CD14^+/CD16^+$) and levels of plasmatic cytokines (IL-7, IL-4, IL-8, IFN-γ) induced by exercise (49 ± 6 min of a bout cycling, in a hot 38 ± 2 °C, 45 ± 2% humidity), altering the postexercise immunosuppressive condition induced by strenuous exercise. Furthermore, it was reported that supplementation with BG (VegeCap® capsules) for 28 days after completion of a marathon reduced the number of cold/flu symptom days postmarathon by 37 % during the supplementation period. On the other hand, a 10-day supplementation with BG prevented suppression of IgA secretion 2 h after strenuous exercise (cycling 49 ± 6 min, 45 ºC, 50 % relative humidity) by 32 % (McFarlin et al. 2013), reducing symptoms of upper respiratory tract infection and improving IgA-dependent mucosal immunity. Regarding the function of NK cells, oral supplementation with β-glucan from *Pleurotus ostreatus*, commercially available as Imunoglukan (100 mg β-glucan plus 100 mg of vitamin C) prevented the reduction of NK activity in elite athletes after 2 months of supplementation (Bobovčák et al. 2010).

Furthermore, low molecular weight polysaccharides isolated from *Agaricus blazei* Murill (ABP-AW1), used in folk medicine as antihypertensive and antitumor (Kim et al. 2009) remedies, present potential adjuvant activity. It was demonstrated that immunization of mice with ovalbumin plus ABP-AW1 (50, 100, and 200 μg) caused a significant antigen-specific $CD4^+$ T cell activation and IFN-γ production after challenge in vitro with ovalbumin (OVA), suggesting that ABP-AW1 significantly stimulates Th1 immunity (Cui et al. 2013). In addition, data corroborating its role in the induction of Th1 immune response were published. In this regard, *A. blazei* Murill water extract (AbM) presented significant antileishmanial activity in vivo. The daily oral administration of AbM at 100 mg/kg (day 0–20 days) after *Leishmania amazonensis* infection caused a 60 % reduction in lesion size and 60 % and 66 % reductions in parasite burden of the footpad and draining lymph nodes, respectively. In addition, the control of cutaneous leishmaniasis was correlated with higher levels of IFN-γ and NO production and lower levels of IL-4 and IL-10 in the spleen and lymph nodes (Valadares et al. 2012). Also, extracts from *A. bisporus*, a mushroom rich in β-glucan-rich polysaccharide, also induced NO production in bone-marrow-derived macrophages of mice (Volman et al. 2010b).

4 Bioactivity of Polysaccharides

The activity of polysaccharides is determined by their conformation, composition, and size (Zhang et al. 2007). Among the polysaccharides with higher biological activity, β-glucans that are homopolymers of D-glucose are the most abundant carbohydrates in the cellular walls of several microorganisms, such as mushrooms, yeast, algae, bacteria, lichens, and plants, and exhibit immunomodulatory, antitumor, and anti-infective activities. They are therefore used clinically for tumor immunotherapy in several countries (Wasser 2002; Falch et al. 2000; Barsanti et al. 2011). However, the fungal cell wall also contains other polysaccharides, such as chitin and cellulose, but glucans (glucose polymers) are the most important of this group of carbohydrates (Fig. 1). These carbohydrates display different types of glycosidic linkages, such as an α- or β-configuration, and at various positions, such as β-(1 → 3), β-(1 → 6), β-(1 → 4), or β-(1 → 2), and α-(1 → 3) glucans, or heteroglycans, and mostly bind to protein, forming a protein–glucan complex, such as glucomannan and galactomannan (Ooi and Liu 2000), and differences in their composition resulted in various biological activity. Table 2 summarizes some biological activity from mushrooms, besides antitumor and immunomodulatory activity, such antioxidant, antimicrobial, antiatherogenic, and hypoglycemic properties. The main molecule responsible for these activities are polysaccharides, mainly β-glucans, which normally are used in extracts; however, sometimes, they act together with other molecules, such phenolics, sterols, fibers, lectins, and others (Wasser 2011). Polysaccharides chitin and chitosan do not present antitumor activity (Mizuno et al. 1995); however α- or β-glucans present high antitumor activity. On the other hand, isolation of the protein from glucan resulted in reduced activity (Mizuno et al. 1999).

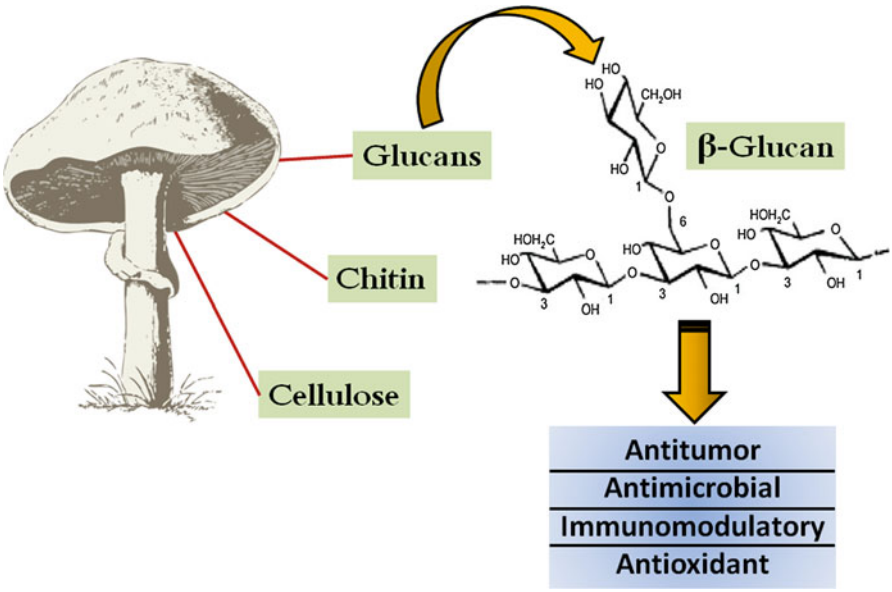

Fig. 1 Main cell wall polysaccharides of mushrooms and some biological activities of β-glucans

Variation in conformational complexity, molecular weight, and number of branches of β-glucan alters the biochemical and solubility properties and also influences their biological properties, such as immunomodulation both in vitro and in vivo (Brown and Gordon 2003; Miura et al. 2003; Volman et al. 2008; Huang et al. 2009). Regarding solubility, β-glucans can be classified according to their solubility properties: (a) alkali-insoluble, acetic-acid insoluble (1 → 3)-β-glucan; (b) alkali-soluble (1 → 3)-β-glucan; and (c) highly branched (1 → 6)-β-glucan. These properties may limit application and extrapolation of in vitro experimental data in humans (Zeković et al. 2005; Mantovani et al. 2008). Furthermore, other effects of β-glucans also are effective against cancer; inhibit metastasis; increase host resistance to bacterial, viral, and parasitic infections and some microbial infections; have antimutagenic, antiallergic, regenerative, antithrombogenic, anticoagulative, antioxidant, hypolipidemic, radioprotective, and antidiabetes properties (Reynolds et al. 1980; Meira et al. 1996; Wasser 2011; Chang and Wasser 2012).

Certain glucose polymers, such as (1 → 3), (1 → 6)-β-glucans, were recently proposed as potent immunomodulation agents (Ooi and Liu 2000; Falch et al. 2000; Barsanti et al. 2011). In this regards, glucans extracted from the mycelium of *A. subrufescens* are usually β-(1 → 6)-glucans, whereas the structure of those extracted from basidoma are β-(1 → 3)-glucans. Zong et al. (2012) notes that molecule-linked β-(1 → 6)-glucans are structurally important in the biological activity, whereas chains-linked β-(1 → 4) or β-(1 → 2) reinforce activity of the immunomodulatory body. Ahn et al. (2004) and Oba et al. (2009) report the

Table 2 Biological activity of polysaccharides from mushrooms

Activity	Mushroom	Reference
Antitumor	*Agaricus subrufescens*	Sugiura et al. (1980), Leifa et al. (2007), Jumes et al (2010)
	Agaricus bisporus	Grube et al. (2001)

Hypoglycemic activity	*Agaricus subrufescens*	Hsu et al. (2007)
	Ganoderma lucidum	Zhou et al. (2005)
Hypocholesterolemic	*Agaricus subrufescens*	Kwon et al. (2002)
	Lentinula edodes	Kwon et al. (2002)
	Pleurotus ostreatus	Khatun et al. (2009)
Antiviral	*Agaricus subrufescens*	Faccin et al. (2007)
	Ganoderma lucidum	El Dine et al. (2009)

increase activity of NK cells from extracts of *A. subrufescens* and *Lentinula edodes*, respectively, and showed that immunochemotherapy with lentinan was effective in increasing the survival rate of patients with gastric cancer with lymph node metastasis. Grube et al. (2001) reported a reduction in estrogen production related to a breast cancer cell line.

The antitumor effects of fungal β-glucans seem to be related to their structural features and conformation; the triple helical conformation plays an important role in enhancement of antitumor activities and is more effective than single flexible chains (Falch et al. 2000). Several soluble β-glucans (SG) showed antitumor activity, such as (1 → 3)-β-D-glucan, which can be obtained from *Sclerotinia sclerotiorum* (Kurachi et al. 1990), *Schizophyllum commune* (Tabata et al. 1981),

and *Grifola frondosa* (Kodama et al. 2003). Polysaccharides can inhibit tumor growth via several mechanisms, such as prevention of tumorigenesis by oral consumption of active preparations, direct anticancer activity by inducing tumor cell apoptosis, and inhibition of tumor metastasis and immunopotentiation activity in combination with chemotherapy (Zong et al. 2012). In this regard, glucans may inhibit tumor growth and metastasis in mice models via modulating the immune function, inducing expression of cell receptors, and inducing cell apoptosis via activation of the proapoptotic Bak-1 protein and DNA-dependent protein kinase (DNA-PK), which are responsible for inducing cancer cell arrest at the G1 cell-cycle checkpoint (Pyo et al. 2008; Louie et al. 2010).

Other antitumor activity was reported by Leifa et al. (2007), who reported that exopolysaccharide extract of *A. subrufescens* inhibited sarcoma 180 in mice by 72.2 % compared with the control group, and complete tumor regression was observed in 50 % of mice. Similar results were observed by Sugiura et al. (1980) who evaluated the antitumor action of exopolysaccharide and the basidioma of *A. subrufescens* on sarcoma 180 induced in mice. On the other hand, the administration of A. brasiliensis extracts and pure powdered basidiocarp by gavage (136 mg/kg × 14 days) in rats with Walker 256 tumor promoted a 92.2 % tumor reduction with pure extract and 72.2 % with purified extract (Jumes et al. 2010).

Peptidoglucan from *Ganoderma lucidum* led to an antiproliferation effect on and apoptosis of human breast cancer cell lines (Wan et al. 2008), and anti-inflammatory function in human carcinoma cells (Hong et al. 2004b). Bauerova et al. (2009) observed a positive immunomodulating effect of β-(1 → 3) and β-(1 → 6)-glucans of *Pleurotus ostreatus* on all cytokines present in rheumatoid arthritis, thereby preventing disease progression. Other mushrooms also presented immunostimulatory activity, such as *Grifola frondosa, Coriolus versicolor*, and *Trametes versicolor* (Sakamoto et al. 2006; Deng et al. 2009; Ramberg et al. 2010).

Studies have demonstrated the antimicrobial action of mushroom extracts against Gram-positive and Gram-negative bacteria in vitro. When shiitake (*L. edodes*) and oyster mushrooms (*P. ostreatus*) were tested for their antibacterial and antifungal properties, it was verified that shiitake extract presented more antimicrobial effect than ciprofloxacin (Hearst et al. 2009). In addition, the antimicrobial effects in vivo may be due to its effects on the immune system, as suggested, for example, by Bernardshaw et al. (2005) who reported the effect of *A. subrufescens* extract against systemic *Streptococcus pneumoniae* infection in mice. Some mushrooms promote anti-HIV action, one of which is *G. lucidum*, due to the presence of ganomycin. Another example is the polysaccharide of *A. subrufescens*, which acted in the initial phase during poliovirus infection (El Dine et al. 2009; Faccin et al. 2007).

Mushroom extracts induces alterations in the diabetic state and in parameters related to the disease. For example, *A. subrufescens* extract (in combination with metformin and gliclazide) improve insulin resistance, potentially by the mechanism that caused an increase in adiponectin concentration after taking the extract for 12 weeks (in vivo) (Hsu et al. 2007); *G. lucidum* extract resulted in hypoglycemic activity (in vivo) (Zhou et al. 2005).

Hypocholesterolemic properties of mushrooms are involved in the fatty acid pattern of edible mushrooms, which seems to contribute to reduce serum cholesterol. Several investigations have shown the influence of eating mushrooms in improving some cardiac metabolic markers, such as high-density lipoprotein (HDL) cholesterol, fasting triacylglycerol, homocysteine, very-low-density lipoproteins, and lipid metabolism, consequently preventing the development of atherosclerosis (Fukushima et al. 2000; Cheng et al. 2002; Hossain et al. 2003). Antioxidant and anti-inflammatory compounds in mushrooms may also contribute to reduce atherosclerosis risk. Moreover, their high-fiber and low-fat content, with low trans isomers of unsaturated fatty acids, low concentration of sodium, presence of eritadenine, phenolic compounds, sterols (such as ergosterol), chitosan, and triterpenes are properties responsible for reducing cardiovascular diseases (Hu et al. 2006; Guillamón et al. 2010).

Antioxidant properties of ethanolic extracts of oyster mushrooms were identified and were shown to be more powerful than the commercial antioxidant butylated hydroxyl toluene (BHT), indicating their possible use as food supplement or pharmaceutical agent (Jayakumar et al. 2009). The fungi *Hericium erinaceous* produces hericenones, which stimulate the synthesis of nerve growth factor, and studies demonstrate that this mushroom protects against neuronal-cell death caused by β-amyloid peptide toxicity, endoplasmic reticulum (ER) stress, and oxidative stress, and retards disease progression in patients with dementia (in vivo) (Kawagishi and Zhuang 2008).

Inflammatory bowel disease (IBD) is an inflammatory condition of gastrointestinal tract that is chronic, remitting, relapsing, and progressive. IBD comprises two major clinical entities: Crohn's disease (CD) and ulcerative colitis (UC), which may affect the entire gastrointestinal tract and the colonic mucosa, respectively. Ambrotose complex (AMB) and advanced Ambrotose (AdvAMB) powder are dietary supplement formulas that include polysaccharides derived from *Aloe barbadenis*, *Larix* species, *Anogeissus latifolia*, *Astragalus gummifer*, *Oryza sativa*, and *Undaria pinnatifida*, which are rich in fucose, rhamnose, arabinose, galactose, glucose, xylose, mannose, galacturonic acid, and glucuronic acid. Using a rat model of colitis induced by replacement of drinking water with a solution of 5 % dextran sulphate sodium (DSS), Koetzner et al. (2010) demonstrated that both AMB and AdvAMB decreased the activity of colitis. The authors showed that oral administration of AMB (377.1 mg/kg) or Adv-AMB (57.4 and 574 mg/kg) once a day for 14 days significantly inhibited shortening of the colon in DSS-treated animals, a characteristic finding in colitic animals and caused a significant decrease in the number of circulating monocytes.

5 Bioavailability and Metabolism

Pharmacokinetics for three different glucan polymers (glucan phosphate, laminarin, scleroglucan) were described after intravenous administration in rats, using estimates of compartment size and rate of change. The authors found significant

differences in pharmacokinetics due physicochemical properties such as molecular size and solution conformation, with glucan phosphate having a smaller volume of distribution and clearance than laminarin and scleroglucan, demonstrating higher blood levels are acquire with water-soluble glucans (Rice et al. 2004). Plasma levels after oral administration were measured and showed differences among polymers, such as bioavailability. Laminarin and scleroglucan had a bioavailability of 4.9 % and 4.0 %, respectively, whereas glucan phosphate bioavailability was tenfold lower (Rice et al. 2005).

Regarding molecular size, this feature can affect the biological activity of polysaccharides, and usually, those of low molecular weight are more effective. Thus, reduction in the particle size of drugs can lead to an increased rate of dissolution and higher oral bioavailability. Similar results were obtained with mushroom powder of the stipe of *Hericium erinaceus*, which was associated with an increase in disease resistance of shrimp: particle sizes of <74 mm were more effective than particle sizes of >74 mm, indicating that they modulate immune function (Yeh et al. 2011). The same occurs with soluble β-glucans, which appear to be stronger immunostimulators than insoluble ones (Xiao et al. 2004), although the reasons are not totally clear; large molecules and orally administered insoluble β-glucans may subsequently degrade into smaller bioactive oligomers after ingestion (Hong et al. 2004a).

Another important feature for the biological activity of polysaccharides is the administration route. Most polysaccharides are activated after oral (Suzuki et al. 1989, 1990; Nicoletti et al. 1992; Dritz et al. 1995; Cheung et al. 2002; Hong et al. 2004a), intraperitoneal, and subcutaneous (Yun et al. 1997, 1998, 2003; Volman et al. 2008) administration. To exert biological effects, glucans should be absorbed from the GI tract and enter the systemic circulation. This process varies according to certain parameters, such as molecular weight distribution, polydispersity, side-chain branching, root-mean-square radius, and solution conformation (Mueller et al. 2000). The organism kinetics is improved in macrophages due to internalization of polymer particulates, which transport glucan to various sites in the body and release a bioactive, soluble, glucan product (Hong et al. 2004a). Orally administered β-glucans arrive at the proximal small intestine and are taken up by macrophages for specific receptors (dectin-1) and carried to other organs, such as spleen, lymph nodes, and bone marrow, where macrophage glucans are degraded into small particles that then interact with complement receptors of marginated granulocytes, thus producing immunological activity (Hong et al. 2004a; Chan et al. 2009).

In a clinical trial of a new, soluble yeast product in healthy individuals, safety and tolerability of polysaccharides was evaluated for 4 days in order to assess clinical, hematological, biochemical, and mucosal tolerance after oral administration of doses ranging from 100 to 400 mg; it was found to be safe and well tolerated (Lehne et al. 2006). On the other hand, some studies reported that oral administration of purified fungal β-glucans have been used to treat human diseases, with no adverse effects; however, the interaction of some glucans with other drugs may be dangerous – drugs such as the nonsteroidal anti-inflammatory drug indomethacin (at doses 2.5–5 mg/kg), which has been reported to cause patient death due to maladjustment of cytokine production (Yoshioka et al. 1998; Takahashi et al. 2001).

6 Toxicity of Dietary Polysaccharides

Understanding the biological activities and adverse effects of natural products used in folk medicine are important to determine safety parameters, as there was once a popular belief that they present only minor adverse effects (Barbisan et al. 2002). Toxicity testing is necessary to provide the basis for substance regulation for clinical use to determine safety and biological effect of cosmetics, pharmaceuticals, food additives, pesticides, chemicals, and consumer products, the use of which toxicological effects can result from natural or manufactured substances and may manifest a variety of symptoms following both acute or chronic exposure (Gallagher 2003).

Dietary polysaccharides need to be evaluated for safety, due to their variability and high biological potential and to estimate the appropriate doses for human use and for clinical monitoring of adverse effects (Carbonero et al. 2006; Alavi et al. 2011; Velusami et al. 2013).

Some negative side effects have been observed in response to prolonged or large doses of polysaccharides, such as β-glucan preparations, as have the consequences of their modes of action and physical and chemical properties (Kwiatkowski and Kwiatkowski 2012). Fungal glucans are an important class of polysaccharides with positive biological activities, and most of them are used as dietary supplements and as food ingredients. Evaluating their safety is an important concern, especially in wild mushrooms due to their ability to accumulate radioactive substances in relatively high concentrations, i.e., heavy metals such as arsenic, lead, cadmium, and mercury (Borchers et al. 2004).

In addition, prolonged or large doses of β-glucan preparations may stimulate prolonged proinflammatory changes in cells, causing the development of autoimmune diseases. Indeed, since the human body is absent enzymes that hydrolyze β-glucans, their degradation occurs through the less efficient oxidative pathway, which prolongs their cellular half-life and thus may lead to the formation of granulomas in the liver, resulting in inflammation that may result liver cirrhosis. Therefore, careful clinical studies recommend caution in the use of glucans as a long-term food additive to prevent the accumulation of granulomas in these patients (Kwiatkowski and Kwiatkowski 2012).

Others studies suggest that polysaccharides are unlikely to cause severe adverse effects: based on acute- and chronic-toxicity testing in rodents, most polysaccharide products appear to be safe (Table 3), with some clinical studies suggesting reactions such as bloating or flatulence linked to a secondary effect of beneficially altering gut microflora (Kelly 1999).

7 Dietary Polysaccharides of Mushroom and New Trends

Mushrooms have long been used as dietary supplements and medicinal food in Asia, because they contain numerous biologically active compounds with antitumor and immune-stimulating action and hypocholesterolemic, antioxidant, and

Table 3 Toxicological studies involving polysaccharides from microorganisms and plants

Category	Source	Test	Animal	Dose	Result	Reference
Microorganism						
Glucans	*Ganoderma lucidum*	Subchronic toxicity, mutagenicity studies	Sprague Dawley rats	0, 500, 1,000 and 2,000 mg/kg body weight (bw)/ day for 90 days	NOAEL	Chen et al. 2011
Glucan (Curdlan)	*Alcaligenes faecalis* var. *myxogenes*	Acute toxicity	Male rats	10 g/kg body weight orally	Low acute toxicity, no deaths	Aomori and Tanida 1968
Glucan (Curdlan)	*Alcaligenes faecalis* var. *myxogenes*	Subchronic and chronic toxicity	Male rats	2.5, 8.5, 30 and 33.4 g/kg/ day, 1-month oral	No signs of toxicity	Yokotani 1969
Glucan (Curdlan)	*Alcaligenes faecalis* var. *myxogenes*	Month toxicity	Male and female Sprague Dawley rats	5 %, 10 % and 20 % for 12 weeks	No effects on hematology and no changes in histopathology	Nakaguchi et al. 1972
Glucan (lasiodiplodan)	*L. theobromae*	Sub-chronic toxicity (28 days)	Male and female Swiss albino mice	50 mg/kg/day	No signs of toxicity	Túrmina et al. 2012
Glucan	Agaricus blazei Murrill	90-day subchronic toxicity	Male and female F344 rats	2,654 and 2,965 mg/kg	No significant toxicity	Kuroiwa et al. 2005
Glucans	Ganoderma lucidum	Single dose toxicity	Sprague–Dawley rat	2,000 mg/kg i.p	No signs of toxicity	Kim et al. 2012
Chitin- glucans	Aspergillus niger	Subchronic toxicity (13 weeks)	Wistar rats	Diet 0; 1; 5; 10 % 6.6 and 7.0 g chitin-glucan/kg body weight/day)	No signs of toxicity	Jonker et al. 2010
Arabino-galactans	Argemone mexicana	Develomental toxicity	Pregnant rats	250, 500, or 1,00 mg/kg	No signs of toxicity	Tamboli et al. 2010

	A. blazei Murill (Aqueous extract)	Chronic carcinogenic bioassay	Male and female F344 rats	0, 6,250, 12,500, 25,000 ppm 1,176 mg/kg diet for 2 years	Not signs of carcinogenicity	Lee et al. 2008
	A. bisporus dry powder	Carcinogenic bioassay	Female Sprague–Dawley rats	30 % diet for 500 days	Not signs of carcinogenicity	Matsumoto et al. 1991
	Agaricus blazei aqueus extract	Hepatotoxicity	Male wistar rats	5,6 mg/mL for 2 weeks	Hepatoprotective effect	Barbisan et al. 2002
Plants						
Arabinogalactans	Larix sp. – plant	Acute toxicity	Mice and rats	5,000 mg/kg	No signs or symptoms of toxicity	Groman et al. 1994
Arabinogalactans	Larix sp. – plant	90 days toxicity	Mice and rats	500 mg/kg	No signs or symptoms of toxicity	Groman et al. 1994
Purslane crude polysaccharide	Purslane	Acute toxicity	Male and female mice	250, 500, 750 and 1,000 mg/kg	No symptom of toxicity or behavioral changes	Gong et al. 2009
Tea polysaccharide conjugate	Camellia sinensis	Acute toxicity	Kunming male mice	5,000 mg/kg	Low toxicity	Chen et al. 2007

hypoglycemic effects. Fungal β-glucan induces stimulation of the entire immune system, which could be an advantage in treating diseases. Furthermore, many of them can be administered orally and in combinational with other immune therapies, resulting in potentialization of results. For example, a synergistic effect is believed to occur when combining β-glucan with IFN-γ (Drandarska et al. 2005).

Several studies report that most orally ingested polysaccharide products (glucans, pectins, heteroglycans, glucomannans, fucoidans, galactomannans, Arabinogalactans, and mixed polysaccharides) in rodent models exerted significant stimulatory effects on the immune system. This led to increased interest in the use of mushrooms and mushroom extracts as dietary supplements and therapeutics. The main sources of mushroom polysaccharides are basidiomas and mycelia (Wasser 2002), which are used for cancer treatment together with surgery, chemotherapy, and radiotherapy (Mizuno et al. 1999; Wasser 2002; Gao et al. 2003; Zhang et al. 2007). These mushroom polysaccharides act as biological response modifiers primarily by stimulating the host immune system by activating dendritic cells, NK cells, T cells, macrophages, and cytokine production.

Among the main products developed from polysaccharides are Lentinan isolated from *Lentinula edodes*; schizophyllan (sonifilan, sizofiran, or SPG) from *Schizophyllum commune;* krestin (PSK) and polysaccharide peptide from *Trametes versicolor*; D-fraction from *Grifola frondosa*; Befungin from *Inonotus obliquus*; and *G. lucidum* polysaccharide fractions (Wasser 2011).

Mushrooms produce many other molecules of secondary metabolism, such as lectins, lactones, terpenoids, alkaloids, antibiotics, and metal-chelating agents, and together with the presence of polysaccharides produce >100 beneficial effects besides antitumoral mechanisms, such as immunomodulation, antioxidant, radical scavenging, cardiovascular, antihypercholesterolemic, antiviral, antibacterial, antiparasitic, antifungal, detoxifying, hepatoprotective, and antidiabetic actions (Wasser 2011). Therefore, new products based on mushrooms are used as dietary supplements, mycopharmaceuticals, and – to use a new term – mushroom nutriceuticals; which should not be confused with nutraceuticals, functional foods, and pharmaceuticals (Chang 2006; Wasser and Akavia 2008). Attention should be given to the fact that nutriceutical mushrooms are not food but refined, or partially refined, extract or dried biomass from mycelium or basidioma, which is consumed in the form of capsules or tablets as a supplement and has potentially therapeutic applications. Regular intake may enhance immune response, thereby increasing resistance to disease and, in some cases, causing disease regression (Wasser 2011). Most polysaccharide products appear to be safe, with no adverse effect level (NOAEL) based acute and/or chronic toxicity tests done mostly in rodents; these products are commercialized in the form of powders, extracts, and capsules, although they have not been fully characterized, and the impact of polysaccharide intake on absorption of nutrients and medications is not known (Ramberg et al. 2010).

Prebiotics are defined as "selectively fermented ingredients that allow specific changes, both in the composition and/or activity in the gastrointestinal microbiota that confers benefits upon host well-being and health" (Gibson et al. 2004).

Due their carbohydrate composition, such as chitin, hemicellulose, β-glucans, mannans, xylans, and galactans, mushrooms can be used as a prebiotic. *Pleurotus ostreatus* and *P. eryngii* extracts stimulate the growth of probiotic strains of *Lactobacillus*, *Bifidobacterium*, and *Enterococcus faecium*, benefic microorganism of the intestinal microbiota (Synytsya et al. 2008). Therefore, intake of mushroom extracts can be benefic due to their prebiotic activity and the medicinal benefits of immunomodulating properties of polysaccharides (Aida et al. 2009).

Another polysaccharide is sclerotium, a morphological form produced by some mushrooms, which has a compact mycelial structure under unfavorable conditions and remains dormant until the environment is suitable for its development of fruiting bodies for reproduction. The major cell wall components are chitin and β-glucan, with β-1,3 backbone and β-1,6-linked side branches (Cheung and Lee 2000). Their sclerotial cell wall components cannot be digested by human enzymes, and as it has ten or more monomeric units, it can be regarded as a novel source of dietary fiber (Codex Alimentarius 2010). This dietary polysaccharide is known to impact intestinal microbial ecology, and recent studies indicate its benefic effects on nutrition, immune modulation, pathogen resistance, intestinal epithelial development, and activity after regular intake (Ramberg et al. 2010).

Investigating new uses for and new products with biopharmacological and dietary benefits are ongoing. Some focus on simplifying and reducing the cost of production to provide access to a larger portion of the population or use in farm animals (Wasser 2011). Ingestion of myceliated wheat grains with *G. lucidum* and *A. subrufescens* or *A. brasiliensis* promote antitumor and hypocholesterolemic effects in sarcoma-180-bearing mice (Rubel et al. 2008; Dalla-Santa et al. 2012). Results of such trials led to the incorporation of many different myceliated grains, and later, using fruit and vegetable residues resulted in patents of processes and products. Some studies reported that extracted ergosterol from these alternative and complex substrates resulted in antitumor action in vitro (Takaku et al. 2001; Lv et al. 2012). It seems that this could be an economic and feasible tool to produce mushroom mycelia containing polysaccharides, ergosterol, and the other bioactive molecules.

In this regard, Wasser (2002) proposed the use of medicinal mushrooms as sources of active biological molecules, new types of food and dietary supplements, antibiotic replacement, and antiviral agents for farm-animal research. New technologies to improve the quality of such biologics resulted in the development in 2009 of a new method for nanoparticle extraction of water-soluble β-glucans from medicinal mushrooms by the Park group (Park et al. 2009) from South Korea for their use in the food, cosmetic, and pharmaceutical industries.

Another new use for mushroom extract, as a potential color stabilizer, showed doubled and tripled shelf life of beef and bigeye tuna (*Thunnus obesus*) by retarding browing: ergothioneine extracted from *Flammulina velutipes* prolonged storage of ground beef from 6 to 12 days and bigeye tuna from 2 to 7 days (Bao et al. 2008).

Consumption of edible mushrooms is beneficial due their nutritional value and because they are low in calories, sodium, fat, and cholesterol, while containing a high percentage of protein, carbohydrate, fiber, vitamins, and minerals.

Therefore, besides their innumerable medicinal properties, they can contribute to the formulation of a well-balanced diet (Manzi et al. 1999).

Fungal β-glucans and whole mushrooms in medicinal and dietary forms lead to significant health improvement and they are specially benefic for middle-aged people or those with impaired immune systems, those with active and stressful lifestyles, those with cancer and in chemotherapy and radiotherapy, and those with infectious diseases (Chen and Seviour 2007).

8 Conclusion

In conclusion, identifying foods that produce high levels of polysaccharides such as β-glucan may increase absorption and consequently efficacy of these beneficial polysaccharides by the production of functional foods with medicinal properties. Furthermore, foods and extracts containing β-glucans could support and enhance treatment of patients with certain pathologies, such cancer patients undergoing chemotherapy or radiotherapy by improving immunologic status and reducing untoward effects on normal tissues. However, careful clinical studies comparing the activity of polysaccharides remain necessary to determine whether they provide real clinical benefits. Also, negative side effects in response to prolonged or large doses of β-glucan preparations have been reported, and conclusive evidence is still lacking regarding the efficacy of medicinal mushrooms and their individual polysaccharides. However, preliminary evidence from studies of various dietary polysaccharides suggests that large, randomized controlled trials are needed, especially for determining toxicity with long-term use.

Bacterial Polysaccharides: Production and Applications in Cosmetic Industry

66

Filomena Freitas, Vítor D. Alves, and Maria A. M. Reis

Contents

Abstract

Cosmetics are complex multiphase systems that include different components with distinct functions on the final product. Bacterial polysaccharides are biocompatible, biodegradable, and usually nontoxic natural biopolymers that possess physicochemical properties suitable for use as cosmetic ingredients. Some of them, namely, hyaluronic acid (HA), bacterial cellulose (BC), and levan, have biological properties (e.g., skin regeneration and protection) and are used as active agents in cosmetic formulations. Other bacterial polysaccharides, such as xanthan gum and gellan gum, are mostly used as viscosity controllers and psychosensorial agents and are applied in cosmetic vehicles (e.g., emulsions, gels, and suspensions). The nontoxic nature of these bacterial polysaccharides has been thoroughly assessed by innumerous studies and their safety as cosmetic ingredients has been established.

Bacterial polysaccharide • Polysaccharide matrices • Skin care • Hydrogels • Emulsion • Suspending agent • Polymeric carriers

1 Introduction

Cosmetics are substances or preparations intended to enhance the human body appearance, and they include products of several categories, such as lotions, creams, emulsions, liposomes, shampoos and hair conditioners, sunscreens, and color cosmetics (Milstein et al. 2001). Hence, cosmetics are placed in contact with various parts of the human body (epidermis, hair system, nails, lips, etc.) or with the teeth and the mucous membranes of the oral cavity. Cosmetics are required not to affect the body structure or functions. In contrast with drugs that have extensive regulatory requirements, cosmetic products are relatively easy to market since no premarket approval is required (Milstein et al. 2001). However, if the cosmetic products contain a pharmacologically active ingredient in therapeutically active concentrations, such information is taken in consideration for the determination of the product's regulatory status.

Cosmetics are complex multiphase systems that include different components: base substances, active agents that have specific biological effects and additives that provide physical and microbiological stability to the final product. Several bacterial polysaccharides possess properties that render them suitable for use in cosmetic applications (Table 1). The most relevant are xanthan gum and gellan gum that are mostly used as base substances in cosmetic vehicles (e.g., emulsions, gels, and suspensions) and hyaluronic acid, bacterial cellulose, and levan, which are bioactive ingredients. Besides its biological activity, hyaluronic acid has been also applied in nanoemulsions as encapsulating agent of other bioactive substances. In contrast with nonbiodegradable polymers that are not metabolized or degraded by the human body and can accumulate in the tissues, biodegradable polymers, including polysaccharides, can be naturally eliminated by normal metabolic pathways. This is advantageous for use in cosmetics applications. Moreover, biodegradable polymers are usually nonreactive with the human body and their degradation products are also biocompatible (Ammala 2013).

2 Bioactivity

2.1 Bioactive Bacterial Polysaccharides

The most relevant bioactive bacterial polysaccharide currently used in cosmetic formulations is hyaluronic acid (HA). Recently, the ability of bacterial cellulose and levan to preserve and/or improve the skin's natural condition has also been extensively studied and proposed for commercial applications. On the other hand, numerous reports about novel bacterial polysaccharides with new or improved biological activities are continuously being published.

2.1.1 Hyaluronic Acid

Hyaluronic acid (HA) is a linear, high-molecular-weight glycosaminoglycan composed of alternating disaccharide units of *N*-acetyl-D-glucosamine (GlcNAc) and D-glucuronic acid (GlcA) linked by β-(1 → 3) and β-(1 → 4) glycosidic bonds (Fig. 1) (Chong et al. 2005; Liu et al. 2011). It is a major structural component of the intercellular matrix of mammalian connective tissues, where it controls tissue permeation and hydration, macromolecular transport between cells, and bacterial invasiveness. HA has a high swelling capacity (high hydrodynamic space in solution), being able to bind 1,000 times its volume in water (Allemann and Baumann 2008). These features, together with its chemical structure, confer a wide range of physicochemical and biological properties, such as lubricity, viscoelasticity, biocompatibility, and angiogenic and immunostimulatory effects (Chong et al. 2005; Vázquez et al. 2013) (Table 1). Although the activity of HA is dependent on the molecule's size, all ranges of molecular weights have specific applications. HA has great economical value with numerous applications, including the medical and cosmetic fields (e.g., antiaging agent) (Vázquez et al. 2013). Depending on the application, HA and its derivatives have market values within the range of US$ 2,000–60,000 per kg (Pires et al. 2010). Due to its biocompatibility, non-immunogenicity, biodegradability, and viscoelasticity, HA is a biomaterial widely used for cosmetic, medical, and pharmaceutical applications (Berkó et al. 2013).

Initially, commercial HA was obtained from mammalian tissues, such as rooster combs, synovial fluid, and umbilical cords. Due to public health concerns (e.g., animal-derived pathogens, interspecies viral, or prionic contaminations), microorganisms and marine organisms started to be investigated as sources of HA. Marine wastes (e.g., sponges, sea cucumbers, squids, mollusks, invertebrates, fish cartilage, and vitreous humor) have been explored, but the most important alternative in recent years has been the microbial production by pathogenic Lancefield group A and C streptococci (e.g., *Streptococcus equi* subsp. *zooepidemicus*), including wild-type and attenuated HA-high-producing mutants (Yamada and Kawasaki 2005).

Some efforts have been put on the development of alternative microbial systems, including the development of recombinant strains and the search for nonpathogenic microorganisms (especially Generally Recognized as Safe (GRAS) strains) for the production of HA to overcome the difficulty of using pathogenic strains (Kim et al. 1996). Izawa et al. (2010) reported that *Streptococcus thermophilus* YIT 2084, a GRAS strain isolated from a dairy food product, was able to produce HA from milk, although at a concentration lower than that achieved by *S. equi*. Recently, great effort has been put on the development of heterologous systems by transforming bacterial species that normally do not produce HA (e.g., *Escherichia coli*, *Lactococcus lactis*, or *Bacillus subtilis*) into HA producers (Mao et al. 2009; Prasad et al. 2010; Yamada and Kawasaki 2005; Yu and Stephanopoulos 2008; Widner et al. 2005). However, there are restrictions to the use of recombinant strains in some countries and the production achieved by heterologous HA-producer systems, as well as the polymer's molecular weight, was considerably lower than those obtained by wild-type streptococcal fermentation.

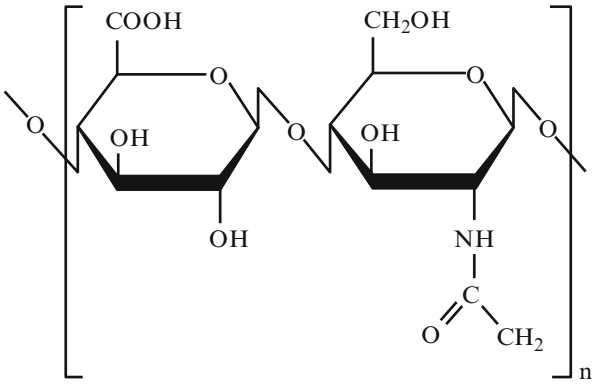

Fig. 1 Chemical structure of hyaluronic acid

Streptococci bacteria require complex nutrients, including organic nitrogen, which is also used by the microorganisms as carbon source for cell growth (Pires et al. 2010). The substrate costs are not a major concern in HA production due to the polymer's high market value. Considerably more focus has been put on strain and process development and on HA quality (molecular weight and purity) rather than on quantity (Chong et al. 2005). Cultivation is usually performed with complex growth media containing yeast or animal extract, peptone, and serum, but the use of chemically defined medium containing glucose, amino acids, nucleotides, trace elements, and vitamins has also been reported (Chong et al. 2005). Some agro-industrial wastes/by-products have been tested as carbon and/or nitrogen sources for HA production, including hydrolysate soy protein concentrate, whey protein concentrate, cashew apple juice, corn steep liquor, mussel processing wastewaters, and peptones obtained from fish viscera (Pires et al. 2010; Vázquez et al. 2009, 2010), but such substrates are still not used for commercial production of HA.

Although HA may be derived from several natural sources, only bacterial fermentation and rooster combs-derived HA is used in cosmetics, as skin-conditioning agents and viscosity-increasing agents. Due to its ability to provide skin water retention capacity and skin hydration, the main commercial application of HA is in cosmetic antiaging creams, which account for around 15 t/year (Marcellin et al. 2009). The use of HA and its salts has been reported in numerous cosmetic product categories (e.g., makeup, moisturizers, lotions, sprays, lipsticks), at concentrations up to 1 %, for HA, or up to 2 % for sodium hyaluronate (Becker et al. 2009). HA has been reported to have antiwrinkle effect by effectively moisturizing and enhancing the skin's elasticity (Allemann and Baumann 2008). In recent years, HA emerged as a dermal filler that rapidly replaced collagen in nonsurgical cosmetic procedures (Fakhar and Berkland 2013; Marcellin et al. 2009). Several dermal HA fillers have been approved by the FDA but only a few are available on the market, including Restylane® (Medicis, USA), Prevelle Silk® (Mentor Corp., USA), Anika® (Anika Therapeutics, Inc., MA), and Juvéderm™ (Allergan, USA) (Allemann and Baumann 2008; Ammala 2013).

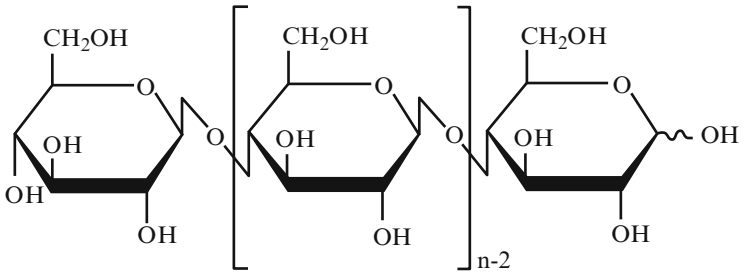

Fig. 2 Chemical structure of bacterial cellulose

The clinical characteristics of each filler is influenced by the characteristics of each product in terms of particle size, type of cross-linking agent used, degree of cross-linking, percentage of cross-linked HA, and amount of free HA and the elastic modulus. HA dermal filler competes with other fillers (e.g., collagen fillers and synthetic fillers) due to their longer clinical duration and no requirements for prior skin allergy testing (Allemann and Baumann 2008). Different cross-linking agents are used for preparation of HA gels to be used as dermal fillers, such as 1,4-butanediol diglycidyl ether (BDDE), divinyl sulfone (DVS), and 2,7,8-diepoxyoctane (DEO) (Allemann and Baumann 2008).

2.1.2 Bacterial Cellulose

Bacterial cellulose (BC) is a glucose homopolysaccharide, with β-(1,4) linkages (Fig. 2) (Chawla et al. 2009; Valla et al. 2009). It is a high-molecular-weight, water-insoluble biopolymer secreted by the bacterium *Gluconacetobacter xylinus* (formerly known as *Acetobacter xylinum*) (Table 1). There are other BC producing *Acetobacter* species (e.g., *G. hansenii*, *G. pasteurianus*) (Çoban and Biyik 2011; Mohite et al. 2013), as well as bacteria from several other genera (e.g., *Agrobacterium*, *Rhizobium*, *Pseudomonas*, *Alcaligenes*) (Barnhart et al. 2014; Chawla et al. 2009; Laus et al. 2005), but *G. xylinum* is the most extensively studied strain and considered for industrial production (Valla et al. 2009). BC exhibits a nanofibrous porous network structure with high strength and low density that makes it useful for the development of membranes for use in several applications, such a biomedicine, cosmetics, and electronics (Freitas et al. 2014).

BC production is performed using sugars as carbon sources, mostly under static conditions, which are not feasible for large-scale production due to the long culture periods. Stirred cultures may be used, but cellulose-negative mutants are generated due to rapid growth (Kim et al. 2007; Valla et al. 2009). Due to these process limitations, BC applications are currently limited to high-value products and specialty chemicals, where the polymer's superior performance justifies its high production costs (Chawla et al. 2009). Nevertheless, BC has valuable properties, which together with its GRAS status (Khan et al. 2007) render this biopolymer a huge potential for applications such as cosmetics, food, and biomedicine.

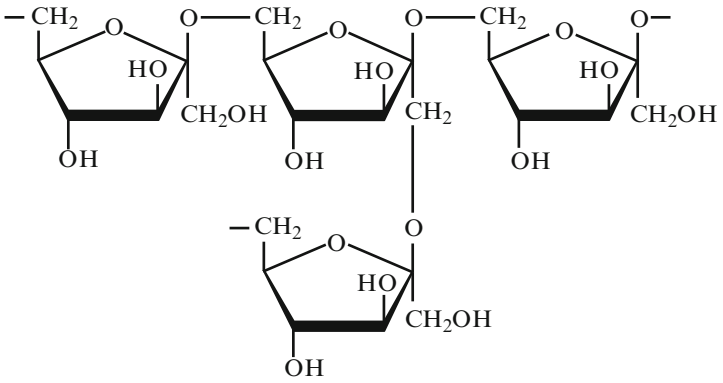

Fig. 3 Chemical structure of levan

The skin regeneration activity of BC has been described and the biopolymer has been proposed for the development of wound healing (Czaja et al. 2006; Solway et al. 2010), skin repair (Fu et al. 2013), and skin-moisturizing (Amnuaikit et al. 2011) materials. Due to its high degree of hydration, BC is used as an ingredient in moisturizing creams (Ioelovich 2008). BC dispersions are used as fingernail components and as the base of artificial nails (Gama et al. 2012). Due to its moldability, BC is also used for the preparation of masks for facial treatments, which can function also as carriers for skin care substance (Gama et al. 2012). Bacterial cellulose masks have been proposed for the treatment of dry skin, improving skin hydration (Amnuaikit et al. 2011). The *in vivo* efficacy of a BC mask after a single application has been evaluated by Amnuaikit et al. (2011) in a study involving 30 volunteers with ages between 21 and 40 years. Although the mask did not significantly change the skin's characteristics, the moisture uptake was increased by 7–28 %. BC has also been proposed for the formulation of a natural facial scrub, containing powdered BC, powdered glutinous rice, aloe vera extract, olive oil, and ascorbic acid. The facial scrub thus prepared was comparable to a commercial product (apricot facial scrub) in terms of viscosity profile, but it had no spreading capability (Hasan et al. 2012).

2.1.3 Levan

Levan is a homopolysaccharide composed of fructose residues joined by β-2,6 linkages with β-2,1 side branches (Fig. 3) that is found in many natural sources, including plants (e.g., grasses, wheat, barley), fungi (e.g., *Aspergillus sydowii*, *A. versicolor*), and bacteria (Kang et al. 2009). Microbial levan is synthesized from sucrose by the action of the enzyme levansucrase (Shih and Yu 2005), an extracellular enzyme synthesized by several bacteria, including species of the genera *Erwinia*, *Streptococcus*, *Pseudomonas*, and *Zymomonas* (Table 1) (Senthilkumar and Gunasekaran 2005). It is produced by Montana Polysaccharides Corp., in the USA (www.polysaccharides.us).

Levan has functional properties that render it suitable for use in a wide range of applications, such as food, feed, cosmetics, and pharmaceuticals. This polysaccharide does not swell in water and it has a very low intrinsic viscosity value (~0.14 dl/g) (Kasapis et al. 1994). It has been approved as a food additive in several countries, including the USA, Europe, Japan, Australia, and New Zealand. The safety of levan for use as a cosmetic ingredient has been evaluated (Kang et al. 2009).

The reported biological activity of levan include cell-proliferating, skin-moisturizing, and skin irritation-alleviating effects (Kim et al. 2003) and skin-whitening effects (Furukawa and Tsuboi 2006) (Table 1). The effect of levan as anti-inflammatory and protection agent against irritation was evaluated with a three-dimensional artificial skin model. Levan demonstrated good cell protective effects for irritation caused by sodium laureth sulfate (SLS). This outcome was probably related to the anti-inflammatory effect of levan, as shown by the reduced secretion of interleukin 1α (a proinflammatory mediator) compared to the control that was not treated with levan (Kim et al. 2005). The moisturizing effect of levan has been evaluated in a human volunteers test (ten 22–37-year-old female subjects). The polysaccharide has have a good moisturizing effect, decreasing significantly the water loss on the skin (Kang et al. 2009).

Despite its valuable biological properties, the use of levan in cosmetics is still limited, which is mainly due to its weak stability in aqueous solution. Levan is partially hydrolyzed to fructose and low-molecular-weight oligosaccharides at acidic conditions and/or high temperatures, making its processing and preservation considerably difficult (Kang et al. 2009).

2.2 Other Bacterial Polysaccharides Used in Cosmetics

Polysaccharides, such as xanthan gum and gellan gum, are commonly used in cosmetics due to their solution properties, being mainly used as base substances for viscosity control, emulsion stabilization, or moisturizing.

2.2.1 Xanthan Gum

Xanthan gum is a heteropolysaccharide composed of a glucose backbone linked through β-1,4 glycosidic linkages, with trisaccharide side chains on every alternate glucose residue (Fig. 4). The side chains contain a glucuronic acid residue between two mannose residues. About one half of the terminal mannose residues are linked to a pyruvil residue, while some of the nonterminal mannose is linked to acetyl residues (Becker and Vorholter; 2009; García-Ochoa et al. 2000; Imeson 2010). The level of acyl groups substituents in the molecule is highly dependent of the production conditions and has an impact on the polymer's rheological properties (García-Ochoa et al. 2000). It is the most widely accepted commercial microbial polysaccharide for both food and nonfood applications (Imeson 2010; Rottava et al. 2009). Xanthan gum is soluble in cold or hot water and forms highly viscous aqueous solutions, even at low concentration. Its aqueous solutions present a high

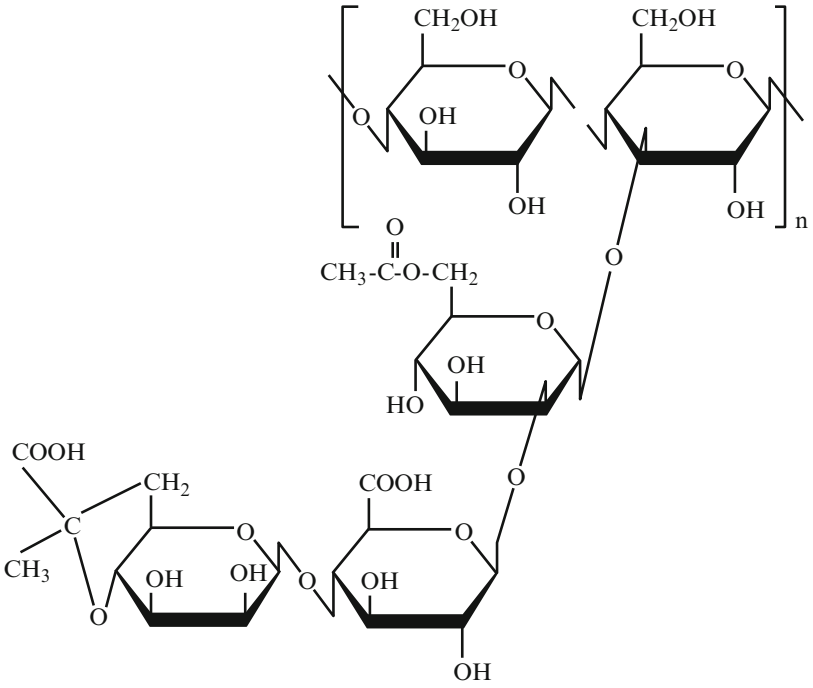

Fig. 4 Chemical structure of xanthan gum

low-shear viscosity, with a marked shear-thinning behavior. When compared to other hydrocolloids (e.g., guar gum, locust bean gum), it presents a higher low-shear viscosity and is more shear thinning at the shear rates typical of food processes (Imeson 2010).

Xanthan gum is synthesized by *Xanthomonas* sp. *X. campestris* is a very efficient polysaccharide producer because it is able to reach high productivities and substrate conversion into biopolymer. Sucrose or glucose are used as carbon sources in the industrial process. Nowadays, xanthan's major producers include CP Kelco, Merck, Pfizer, Rhône Poulenc, Sanofi-Elf, and Jungbunzlauer, and the polymer is marketed with different purity grades for applications ranging from food to personal care products and oil recovery (Freitas et al. 2013). Xanthan gum is the most used bacterial polysaccharide due to its high viscosity-enhancing ability at low concentrations, being the only significant bacterial biopolymer in the global hydrocolloids market (Imeson 2010).

Xanthan gum is used in almost every category of cosmetic products, including oral hygiene products, leave-on formulations, deodorants, baby products, etc. (Bergfeld et al. 2012). It is used for a wide range of functions, namely, as a binder, emulsion stabilizer, skin-conditioning agent, surfactant/emulsifier, and viscosity enhancer, in concentrations up to 4–6 % in dermal and mucous contact products,

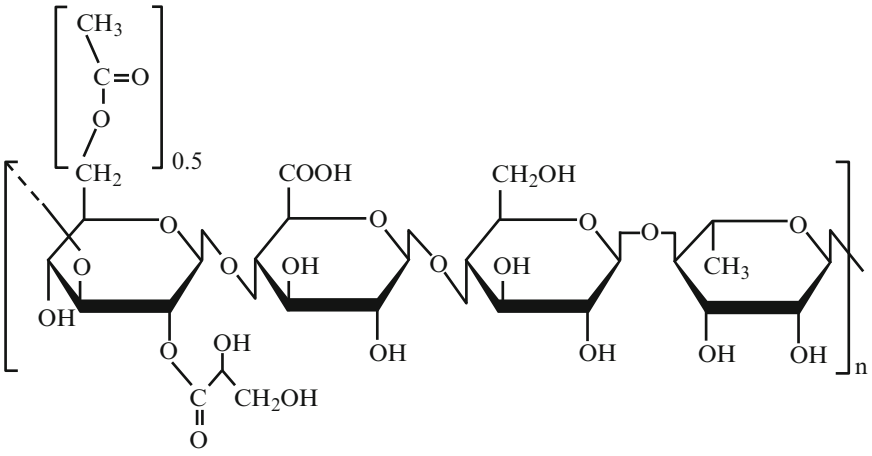

Fig. 5 Chemical structure of gellan gum

hair colorants, and nail products. Lower concentrations are used in deodorants (up to 0.6 %), baby products (0.2–0.6 %), and sprays (0.05 %) (Bergfeld et al. 2012).

2.2.2 Gellan Gum

Gellan is a heteropolysaccharide composed of a tetrasaccharide backbone with rhamnose, glucose, glucuronic acid, and glucose monomers and side chains of acetyl and glyceryl substituents (Fig. 5) (Coleman et al. 2008). Both substituents are located on the same glucose residue, and on average, there is one glycerate per repeat and one acetate per every two repeats. *Sphingomonas paucimobilis* ATCC 31461 is the bacterial strain used for industrial production of gellan gum (Bajaj et al. 2007). Simple sugars are the most common carbon sources. Gellan gum has received approval for use in the food industry and is marketed by CP Kelco under the trade name Kelcogel as a gelling agent (Bajaj et al. 2007).

Gellan gum forms gels upon cooling. Gel properties are dependent on gellan's acyl groups content. Generally, the high acyl form produces soft, elastic, non-brittle, thermo-reversible gels, whereas the low acyl form produces firm, nonelastic, brittle, and thermostable gels. The properties of the gels prepared with low acyl gellan are quite dependent on the pH and the presence of cations, while high acyl gellan gels are not as sensitive to the ionic environment (Freitas et al. 2013).

Gellan gum is used in cosmetic formulations mainly as an emulsion stabilizer and a viscosity-increasing agent. It is mostly used in leave-on and dermal contact products, in concentrations up to 0.3–0.5 %. Other uses include hair products, powders, and eye and mucous contact products, in which it is used in concentrations up to 0.0004 % (Bergfeld et al. 2012).

3 Mechanism of Action

3.1 The Human Skin

The human skin comprises three layers: the epidermis, the dermis, and the hypodermis (Fig. 6) (Elias 2001). The outer layer, the epidermis, consists of several cell layers that are continuously being regenerated from the basal cell layer to the stratum corneum. In the stratum corneum, the corneocytes (protein-rich cells) are embedded in a lipid-rich matrix composed of ceramides, cholesterol, and fatty acids. Corneocytes are linked together by corneodesmosomes that confer structural integrity to the multilamellar stratum corneum. The dermis is composed of collagen and glycosaminoglycans and contains blood vessels, nerves, glands, and hair follicles. The hypodermis or subcutaneous layer consists of adipose tissue and provides a thermal barrier (Ammala 2013; Elias 2001).

The stratum corneum is a highly impermeable lipophilic layer that protects the inner layers from environmental influence. It contains only around 13 % water, while the inner layers are significantly more hydrophilic (the water content in the viable epidermis is about 50 % and in the dermis it is higher than 70 %). The degree of hydration of the stratum corneum influences the skin's permeability. Moreover, the skin barrier function is influenced by age and external factors, and it also varies at different body locations (Ammala 2013). For example, after the age of 20 years, the amount of naturally occurring HA in the human skin continuously decreases, which results in decreased tissue elasticity and hydration, and contributes to the formation of wrinkles (Berkó et al. 2013).

When the water content of the skin is reduced below its normal moisture content (20–35 %), the skin becomes dry, rough, and scaly, often appearing reddish, with cracks and/or itching. In dry skin, the epidermis loses its moisture retention ability, and repair can only be achieved by specific treatments to enhance hydration and reduce water evaporation. The most common treatment is the topical application of a moisturizer. Occlusive masks from different sources are also commonly used.

The transport of molecules across the skin can follow different routes, namely, through the lipid bilayers between cells (the intercellular pathway), directly through the cells (the transcellular pathway), or through the hair follicles or gland ducts (Fig. 6). Only low-molecular-weight (<500 Da), moderately lipophilic molecules, with solubility in both the lipophilic stratum corneum and the hydrophilic inner epidermis layer, can be transported across the skin. Skin permeation can be enhanced by disruption of the structural organization of the intercellular lipid matrix of the stratum corneum by chemical enhancers (e.g., biodegradable polymers) or physical techniques (e.g., microneedling, electroporation) (Ammala 2013). Exposure of the skin to harmful environmental conditions, such as UV radiation, can lead to premature skin aging, mutation, or skin cancer. UV radiation causes peroxidation of the lipid matrix of the stratum corneum and leads to loss of this structure's barrier function (Trommer and Neubert 2005).

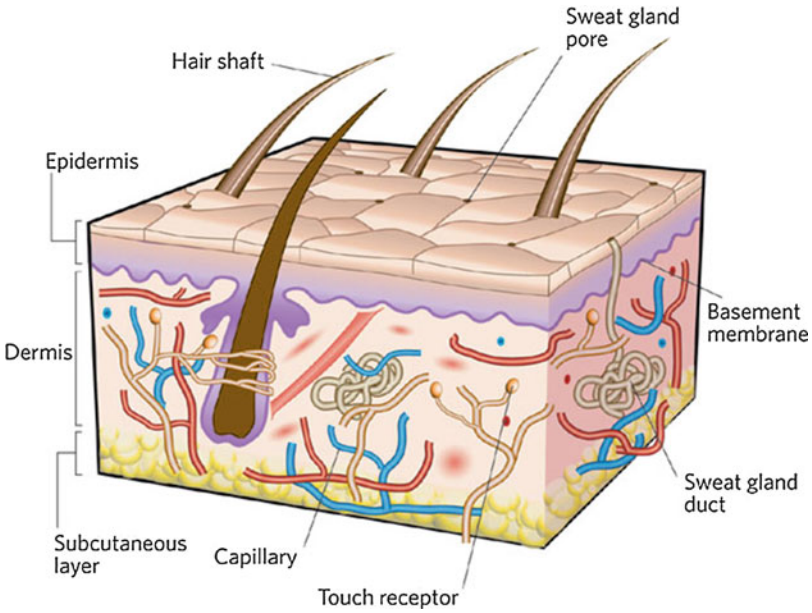

Fig. 6 Structure of the human skin (Reproduced with permission from MacNeil (2007))

3.2 Cosmetic Ingredients and Formulations

Cosmetic formulations include different types of substances, with distinct functions on the final product: base substances that are mainly natural skin components, such as oil-based substances (e.g., triglycerides, wax esters, fatty acids), barrier, and moisturizing substances; active agents that are substances that have specific effects, namely, protection, preservation, and/or improvement of the skin's natural condition; and additives that are used to provide physical and microbiological stability, protecting the product against microorganisms, temperature, oxygen, and light and improving shelf life (e.g., antioxidants, perfumes, emulsifiers) (Ekong et al. 2001; Lautenschlager 2002a, b, 2003; Siquet and Devleeschouwer 2001; Table 2). All additives, except UV filters and additives for consistency control, should be avoided because they may cause allergies under certain conditions. The microbiological stability of a cosmetic product may be assured by alternative processes (e.g., bottling under sterile conditions, additions of hydroxyl groups containing substances) that are seldom used due to their high costs.

By definition, active agents must not cause systemic effects on the whole body after its penetration into the skin. The effects of active agents on the skin include: smoothing and regeneration (e.g., antiwrinkle), influencing skin color (e.g., makeup), protection (e.g., sunscreens), and hygiene (e.g., cleansing) (Cunningham 2001; Lautenschlager 2003; Lodén 2001; Weber et al. 2001). The basic and minimal specifications for any cosmetic ingredient must include its chemical identity (chemical nature and structural formula; origin of the raw

Table 2 Type of substances in cosmetic formulations

Substances	Function	Ingredients
Base substances	Substances that every skin needs	Triglycerides (e.g., tristearin, tripalmitin)
		Fatty acids (e.g., caprylic acid, palmitic acid, linoleic acid)
		Wax esters (e.g., jojoba oil, shea butter, squalane)
		Glycols (e.g., glycerine, sorbitol, propylene glycol)
		Mineral oil products (e.g., vaseline, paraffin oil)
Active agents	Protection, preservation, and/or improvement of the skin's natural condition	Vitamins (A, C, E)
		Coenzyme Q10
		Hyaluronic acid
		Lactic acid
		Natural extracts (plants, algae)
Additives	Provide products physical and microbiological stability and improved shelf life	Perfumes
		Antioxidants
		Ethylenediaminetetraacetate (EDTA)
		Citric acid
		Thickening agents (e.g., xanthan)
		Emulsifiers
		Dyes and pigments
		UV filters

material, extraction method, etc.), physical form (powder, paste, gel, liquid), molecular weight, purity (including characterization of the impurities), solubility in water and/or in any other relevant organic solvent, and other additional relevant physical and chemical specifications (e.g., organoleptic properties, flash point, melting/boiling point, etc.).

3.3 Main Cosmetic Vehicles

The term vehicle is used both in cosmetics and pharmaceuticals upon the optimization of products formulation. It consists on the matrix into which the active principles are embedded. The role of the vehicle is to serve as carrier and to deliver the active principles on the application site or on the target organ where the desired effect is to be achieved. Even though cosmetic formulations are not allowed to contain pharmacologically active substances that treat diseases, they present a key role on exerting important effects on skin, such as care, cleansing, hydration, protection, and decoration. Furthermore, many cosmetically used compounds are bifunctional, by acting first as vehicle and then showing a positive effect on the skin

properties when applied. There is a wide range of cosmetic vehicles forms, with diverse physical and chemical properties depending on the application types and forms. The major vehicles systems, in which polysaccharides play an important role, are emulsions, hydrogels, encapsulating structures, and suspensions (Buchmann 2001).

3.3.1 Emulsions

Within the cosmetic care products, emulsions are probably the most commonly used vehicles. They are preferred to waterless oils and lipids due to their more appealing skin feeling and ease of application. If emulsions are flowing fluids, they are generally called lotions. By the contrary, if they occur in semisolid form, they are known as creams (Buchmann 2001).

Emulsions are systems constituted by two immiscible liquid phases composed of lipids (lipophilic components) and water (and/or hydrophilic components), in which one of them is dispersed within the other in the form of small droplets with a size in the range from 0.1 to 100 μm (Dickinson and Stansby 1988). According to the distribution of the two liquids, emulsions may be classified either as oil-in-water (o/w), in which the lipid is dispersed in the aqueous phase, or as water-in-oil (w/o), where droplets of the aqueous phase are dispersed within the lipid phase. In addition, two types of multiple emulsions are encountered in skin care: water-in-oil-in-water (w/o/w), where the internal and external water phases are separated by oil, and oil-in-water-in-oil (o/w/o), where the water phase separates two oil phases (Epstein and Simion 2001).

As the phases are immiscible, these biphasic systems are thermodynamically unstable. However, they are allowed to remain in a metastable mixed state by the addition of amphiphilic components (emulsifiers), which adsorb at the oil-water interface reducing the interfacial tension. There is the formation of a film that stabilizes the emulsion by slowing down the coalescence of the dispersed droplets, preventing phase separation (Epstein and Simion 2001).

In addition to emulsifiers, other classes of components are present on cosmetic emulsions, such as: (i) emollients, to improve sensory properties (e.g., silicon oils, isopropyl myristate); (ii) moisturizers and humectants (e.g., glycerol, urea); (iii) active substances (e.g., UV sunscreens, vitamins); (iv) antimicrobial agents; (v) perfumes and coloring agents; and (vi) viscosity-increasing agents (Buchmann 2001).

Polysaccharides, namely, those produced by bacteria, are especially important in (o/a) cosmetic emulsions. They form extended hydrogel networks, and their solvation properties serve to increase the interfacial viscosity and the viscosity of the continuous phase, which slows down the droplet motion. This enables a secondary stabilization, decreasing the occurrence of phenomena such as creaming (upward movement of oil droplets due to their lower specific gravity) and coalescence. In addition to that, polysaccharides act as rheology modifiers and control the consistency of emulsions. They are extremely important on the optimization of texture properties, which are known to be of great importance, as the consumers' preference is closely connected to it (Gilbert et al. 2013a). As such, texture of cosmetic products must be designed in order to meet sensory expectations of consumers.

Carbopol® polymers (high-molecular-weight homo- and copolymers of acrylic acid cross-linked with a polyalkenyl polyether) and Veegum (aluminum silicate material) are traditionally used as thickeners. In addition, natural biopolymers like alginates and cellulose-based polymers (e.g., carboxymethyl cellulose) are also used (Epstein and Simion 2001).

Xanthan gum is the most referred bacterial polysaccharide applied for these purposes. The physical properties of such cosmetic emulsions have been studied by rheology and texture analysis, in order to perceive the behavior of xanthan gum as viscosity controller and psychosensorial agent, in comparison with other natural and synthetic polymers (Gilbert et al. 2013a, b, c; Isaac et al. 2013). Beyond xanthan gum, Fucogel, hyaluronic acid, and gellan gum have also been applied (Prajapati et al. 2013; Vianna-Filho et al. 2013).

3.3.2 Hydrogels

Gels may be defined as dilute mixtures of at least two components, in which the components form separate continuous phases throughout the system. In most gels the minor component is a polymeric phase which forms a three-dimensional network structure surrounding a liquid phase. The network structure prevents the fluid from flowing, whereas the fluid prevents the structure from collapsing. The coexistence of a polymeric network structure together with a liquid phase differentiates gels from pure solids or fluid materials and gives gels their unique viscoelastic properties (Jung and Shinkai 2004).

Particularly, hydrogels are formed by a three-dimensional network structure made of hydrophilic polymers (e.g., polysaccharides) surrounding water molecules. The mechanical properties of these structures may vary from firm and brittle to soft and elastic, depending on the type of the polymer and on the nature of intermolecular interactions that hold the network structure together (e.g., hydrogen or covalent bonds, ionic interactions).

The bacterial polysaccharide hyaluronic acid has been widely used to develop hydrogels. Berkó et al. (2013) have compared hydrogels based on linear and cross-linked HA as potential semisolid drug delivery forms from the aspects of deep HA penetration through the skin.

Gellan gum has been applied successfully in toothpaste formulations, due to its binding properties and true-gel structure. It presents very good flavor release properties, enabling the use of significantly lower amounts of flavors and sweeteners in such formulations. At typical usage levels, gellan gum imparts a low viscosity during production, allowing the design of fluid formulations that form a gel after packaging. This low viscosity makes manufacturing and packaging easier and allows the incorporation of fragile ingredients, such as encapsulated flavors, that would not normally be possible with other binder systems. In addition, by using blends of low and high acyl gellan, it is possible to design a range of toothpastes with different binding, stand-up, and preparation viscosity (Prajapati et al. 2013).

Emulsion-filled gels are particular type of structures in between true emulsions and gels, widely used in cosmetic products. They are composed of a continuous semisolid phase (gel) with dispersed oil droplets, with an overall oil concentration

ranging between 2 % and 20 % (Buchmann 2001). Due to the elastic characteristics of the gel, oil droplets can be kept in suspension avoiding creaming. Lorenzo et al. (2013) have focused on the bacterial polysaccharide gellan gum to produce emulsion-filled gels. They studied the influence of oil and hydrocolloid concentrations on the viscoelastic behavior of emulsion-filled gels formulated with high acyl gellan gum.

3.3.3 Encapsulating Structures

Many biologically active compounds are unstable and sensitive to pH, temperature, light, and oxidation. As such, they require to be protected against unwanted degradation during formulation, storage, and application of the final product. In addition, topical- and transdermal-controlled delivery of active cosmetic ingredients is advantageous in many cases, which requires safe and nontoxic means of reaching the target sites without causing any irritation (Ammala 2013). This may be achieved with the encapsulation of biologically active compounds within a material forming mico-/nanostructures (e.g., micro-/nanospheres and capsules, micro-/nanoemulsions, liposomes, microsponges) (Patavale and Mandawgade 2008; Ammala 2013). Beyond the protection of the active compounds, reducing their reactivity with external factors, encapsulation also enables an easier handling, to mask the compounds aroma and to promote their dilution in the final product when they are toxic in large quantities.

There is a large variety of active cosmetic substances that have been encapsulated using a wide range of materials. Examples include nylon microparticles loaded with vitamins, sun filters, moisturizers, fragrances, and many other actives such as retinyl palmitate, D-panthenol, ascorbic acid, tocopheryl acetate, dihydroxyacetone, vitamin E, and dimethicone (Patavale and Mandawgade 2008). The attention has been driven to the use of biodegradable polymers as encapsulating agents for cosmetic applications. The main advantages of using biodegradable polymers over those nonbiodegradable are that they are generally nonreactive when in contact with the human body and can be metabolized and removed from the body via normal metabolic pathways. They include not only polysaccharides but also proteins, poly α-esters, polyalkylcyanoacrylates, and polyamidoamine dendrimers (Ammala 2013). As examples, agar is used commercially to produce microspheres containing emollient oils and vitamins for the enhancement of the tactile and visual appearance of cosmetic and personal care products (http://www.lipochemicals.com). Gomaa et al. (2010) used chitosan microparticles to incorporate phenylbenzimidazole sulfonic acid, a hydrophilic sunscreen agent. Egg album microspheres containing vitamin A were applied to prepare O/W creams, resulting in a prolonged release and higher bioavailability of that vitamin (Patavale and Mandawgade 2008). The use of polylactic acid has been recently reported to encapsulate retinyl retinoate as an antiwrinkle treatment (Kim et al. 2012). Furthermore, the encapsulation and stabilization of ascorbic acid using poly(lactic-co-glycolic acid) (PLGA) nanoparticles, as well as PLGA microparticles to stabilize urea (used as moisturizing agent) and provide effective means of controlled release, has been described (Haddadi et al. 2008).

HA is the most tested bacterial polysaccharide in delivery systems. Particularly, HA-based nanoemulsions and their application as transdermal carriers were recently reported. Encapsulation experiments with vitamin E demonstrated that these nanoemulsions were capable of carrying lipophilic additives (Kong et al. 2011a, b). In addition, HA was used successfully to stabilize gold nanoparticles (AuNPS). The biocompatibility of HA, along with the unique attributes of AuNPS, enabled the production of colloidal dispersions that may be potentially applied in cosmetics (Hien et al. 2012).

3.3.4 Suspensions

Suspensions are type of formulations in which particles, generally functional excipients, are dispersed in a liquid or semisolid media that functions as vehicle. As examples, it may be indicated for sun-protection products or nail pearlescent lacquers containing pigments. The main potentially negative phenomenon that may occur in suspensions is the sedimentation of particles with higher density than the liquid. Sedimentation should be reduced, or even hindered, during storage, which may be accomplished by increasing the viscosity of the liquid media. Among the polysaccharides, xanthan gum has been widely used as suspending agent due to its good thickening ability with shear-thinning behavior. In addition, gellan gum can provide effective stabilization of shampoo and conditioner formulas due to its thickening capacity and fluid gels formation (Prajapati et al. 2013).

4 Toxicity Requirements

4.1 Regulatory Requirements

The safety of a cosmetic product is based on the safety of its ingredients, the latter being evaluated by toxicological testing. The determination of the toxic potential of a cosmetic ingredient is based on a series of toxicity studies (Table 3). The minimal base set requirements include the following tests: acute toxicity (if available), irritation and corrosivity, skin sensitization, dermal/percutaneous absorption, repeated dose toxicity, and mutagenicity/genotoxicity (European Directive 93/35/EEC). Further tests (carcinogenicity, reproductive toxicity, toxicokinetics) may additionally be required, while photo-induced toxicity data is only necessary when the cosmetic product is expected or intended for use on sunlight-exposed skin. Although the use of human volunteers is subjected to great ethical concerns, it is extremely useful to have human data since animal tests and alternative methods are of limited predictive value with respect to the human response. Such tests are only performed when the toxicological profiles of the ingredients indicate that they are safe. When such studies are considered not needed or technically possible, a scientific justification is given. For complex ingredients derived from biotechnology, specific data must be available, such as

Table 3 Toxicity tests used for assessment of the safety of cosmetic ingredients, according to the European Directive 93/35/EEC

Toxicity test	Objective	Type of test
Acute toxicity	Health effects resulting from a single exposure to a substance by oral, dermal, or inhalation administration	*In vivo* tests:
		The fixed dose method
		The acute toxic class method (determination of exposure dosages, by performing a complex stepwise dosage with a reduced number of animals)
		The up-and-down procedure (estimation of the LD50-value)
Irritation	Reversible damage of the skin or mucous membranes (namely, the eye) following the application of a test substance	*In vivo* test (with rabbits); for reduction of the number of animals, several prior steps are performed (e.g., evaluation of existing human and animal data, analysis of structure activity relationships, taking *in vitro* and *ex vivo* tests)
Corrosivity	Irreversible damage of the skin (i.e., visible necrosis through the epidermis and into the dermis) or to the eye (i.e., tissue damage or serious deterioration of vision), following the application of a test substance	*In vitro* tests, using culture models for eye and skin cells or reconstructed membranes
Skin sensitization	Development of allergic contact dermatitis upon exposure to a test substance	*In vivo* tests (with mice or pigs)
Dermal/ percutaneous absorption	Passage of compounds across the skin, involving the penetration and permeation of a topically applied substance through the skin/mucous layers, and its resorption into the vascular system (lymph and/or blood vessel)	*In vivo* or *in vitro*
Repeated dose toxicity	Adverse general toxicological effects occurring as a result of repeated daily dosing with, or exposure to, a substance for a specific part of the expected lifespan of the test species	*In vivo* tests:
		Repeated dose (28 days) toxicity (oral, dermal and inhalation)
		Sub-chronic oral toxicity test (90 days) in rodents and in non-rodents
		Sub-chronic dermal toxicity test (90 days) in rodents
		Sub-chronic inhalation toxicity test (90-days) in rodents (rarely used)
		Chronic toxicity test

(*continued*)

Table 3 (continued)

Toxicity test	Objective	Type of test
Mutagenicity/ genotoxicity	Evaluation of mutagenicity of the substance at a gene level, chromosome breakage and/or rearrangements (clastogenicity), and numerical chromosome aberrations (aneugenicity)	*In vitro* (stage 1):
		Tests for gene mutation (bacterial reverse mutation test; in vitro mammalian cell gene mutation test)
		Tests for clastogenicity and aneugenicity (in vitro micronucleus test)
		In vivo (stage 2): depends on the results observed in the in vitro assays
Carcinogenicity	Induction of tumors (benign or malignant) or increase of their incidence, malignancy, or shortening of the time of tumor occurrence when a substance is inhaled, ingested, dermally applied, or injected	*In vitro* and *in vivo* (depending on the type of substance)
Reproductive toxicity	Adverse effects induced by a substance on any aspect of mammalian reproductive cycle (e.g., impairment of male or female reproductive function or capacity, induction of nonheritable adverse effects in the progeny such as death, growth retardation, structural and functional effects)	*In vivo*:
		Two-generation reproduction toxicity
		Teratogenicity test in rodents and non-rodents
		The whole embryo culture test (WEC)
		The MicroMass test (MM)
		The Embryotoxic Stem cell Test (EST)
Toxicokinetic studies	Time-dependent fate of a substance within the body (absorption, distribution, biotransformation, and/or excretion) leading to adverse effects	*In vivo* or *in vitro*
Photo-induced toxicity	Cytotoxicity of a substance when tested in the presence and in the absence of exposure to a noncytotoxic dose of UV/visible light	*In vitro* and *in vivo*
Human data	Confirm that there are no harmful effects when applying a cosmetic product for the first time to human skin or mucous membranes	Human volunteers tests for finished products

the description of the organisms involved, their pathogenicity, toxicity of any metabolites produced by the organisms, fate of viable organisms in the environment, etc. (Chew and Maibach 2001; Robinson et al. 2001; Van Essche 2001).

The last phase in the safety evaluation of a cosmetic ingredient is the determination of the margin of safety (MoS) that is calculated by dividing its lowest NO(A)

EL (no observed (adverse) effect level) value by its possible SED (systemic exposure dosage). NO(A)EL is the highest dosage for which no observed (adverse) effects can be observed, expressed as mg/kg body weight/day. SED is the amount expected to enter the blood stream per kg body weight and per day. The MoS value is used to extrapolate from a group of test animals to an average human being and subsequently from average humans to sensitive subpopulations. For a substance to be considered safe for use as cosmetic ingredient, its MoS must be at least 100 (European Directive 93/35/EEC).

The safety evaluation of cosmetic products is based upon the toxicological profile of the ingredients, their chemical structure, and their exposure level. Nevertheless, in some cases, additional information on the finished product is needed. The exposure level will depend on several factors, including the class of cosmetic product (e.g., hair care, bathing, skin care, etc.), the method of application (rubbed-on, sprayed, applied and washed off, etc.), the concentration of the ingredient in the finished cosmetic product, the quantity of product used at each application, the frequency of application, the total area of skin contact, the site of contact (e.g., mucous membrane, sunburnt skin), consumer target group (e.g., children, people with "sensitive skin"), etc. If the final product is not expected to cause any adverse effect under foreseeable conditions of use, compatibility testing is undertaken on a number of human volunteers prior to product marketing (Bashir and Maibach 2001).

4.2 Toxicity Assessment of Bacterial Polysaccharides

The Cosmetic Ingredient Review (CIR) Expert Panels have concluded that HA and its salts, xanthan gum, gellan, and levan are safe for use in cosmetic formulations (Becker et al. 2009; Bergfeld et al. 2012). BC was also considered nontoxic and biocompatible in several studies (Jeong et al. 2010; Moreira et al. 2009).

No adverse reactions were reported to HA applied topically, and the adverse reactions reported to injected HA for the treatment of osteoarthritis and tissue augmentation do not raise safety concerns regarding its use in cosmetics (Becker et al. 2009). Nevertheless, it can enhance the penetration of other ingredients through the skin. Hence, caution should be taken for its use in mixture with substances for which dermal absorption is a concern.

The toxicity of BC nanofibers was evaluated in vitro in human umbilical vein endothelial cells using viability and flow cytometric assays and in vivo using C57/Bl6 mice (Jeong et al. 2010). No toxicity was observed, indicating that BC a biomaterial suitable for biomedical and cosmetic applications. Moreira et al. (2009) evaluated that BC nanofibers were not genotoxic.

Levan is accepted as a nontoxic biopolymer, with a lethal dosage of 7.5 g/kg body weight and a NOEL value of 1.5 g/kg/day (Kang et al. 2009). The cytotoxicity of levan has been evaluated using human fibroblast and keranocyte cell lines. No cytotoxicity was shown in the human fibroblast cell line up to 100 μg/mL, and a considerable cell proliferation effect was observed in the keranocyte cell line at concentrations above 1 mg/mL (Kim et al. 2005).

The acute toxicity of xanthan gum was assessed orally in mice, rats, and dogs. There was no notable toxicity observed in those studies for xanthan gum concentrations up to 20 g/kg body weight (Booth et al. 1963; Eastwood et al. 1987; McNeely and Kovacs 1975; Robbins et al. 1964; Woodard et al. 1973). The reproductive and developmental toxicity of xanthan was evaluated in a three-generation study with albino rats fed with xanthan (0–0.5 g/kg body weight). There were no significant differences in the developmental parameters between test and controls, and no malformations were observed (Woodard et al. 1973). The dermal irritation and sensitization potentials of xanthan gum were evaluated in animal studies. Xanthan gum was neither irritating to rabbit and rat skin (in concentrations up to 1 %) nor a sensitizer in guinea pigs (at a concentration up to 0.1 %) (Bergfeld et al. 2012; Booth et al. 1963; Guillot et al. 1982). Xanthan gum (1 %) was also considered as nonirritant to the eyes of rabbits (Booth et al. 1963; Guillot et al. 1982).

The oral and acute toxicity of gellan gum, assessed in rats, dogs, and monkeys, demonstrated that it was not toxic (Anderson et al. 1988; Bergfeld et al. 2012). Gellan gum was considered noncarcinogenic based on studies with mice and rats fed with the polysaccharide (0–5 g/kg body weight), wherein no neoplastic or nonneoplastic lesions were observed (Bergfeld et al. 2012). Gellan gum (0.2–0.8 %) was also considered as nonirritant to the eyes of rabbits (Liu et al. 2010; Ramaiah et al. 2007).

Finally, in human studies, the daily ingestion of xanthan gum (150 mg/kg body weight) and gellan (175–200 mg/kg body weight) was shown not to have any significant adverse dietary, physiological, or allergenic effects (Eastwood et al. 1987). Gellan gum was also shown to be nonirritating to human eyes (Liu et al. 2010).

5 Conclusions

Although many bacterial polysaccharides possess physical-chemical properties and/or biological activity suitable for their use in cosmetic applications, only a limited number of such biopolymers are currently used as cosmetic ingredients. The most relevant is xanthan gum that is widely used in cosmetic products due to its high viscosity-enhancing ability at low concentrations. Other bacterial polysaccharides used in cosmetics are hyaluronic acid, bacterial cellulose, and levan, which are used as bioactive ingredients, and gellan gum that is used to produce hydrogels and as rheology modifier. Beyond its biological activity, hyaluronic acid has also been applied in cosmetic vehicles, such as hydrogels and nanoemulsions. Since there are no extensive regulatory requirements for marketing new cosmetic products, it is likely that other bacterial polysaccharides, with new or improved properties, may be developed as cosmetics ingredients. Nevertheless, their safety must be established by toxicological testing.

Contents

Abstract

The polysaccharides, mainly from natural sources, have been widely used in cosmetic area due to their multifunctional properties, playing a large role in the research and development of cosmetics products.

The knowledge of the skin biology allows the identification of which active ingredients are important for the maintenance of its integrality and barrier function, essential to skin health.

So due to the polysaccharides' protective effects on the skin, the development of cosmetic formulations with these ingredients like hyaluronic acid, algae, and others obtained by biotechnology process could improve the efficacy of the formulations, maintaining the skin in good conditions. In addition, some polysaccharides can also improve formulation stability and sensorial properties.

The data from clinical studies showed that the polysaccharide-based formulations promoted the transepidermal water loss reduction, protecting the skin

barrier function. This way, they are interesting active ingredients to develop effective cosmetic formulations for skin protection and maintenance of its structure integrality.

Keywords
Polysaccharides • Cosmetic formulations • Clinical efficacy • Skin hydration • Skin protection • Rheology • Biophysical techniques

1 Introduction

Many new active ingredients are being used in topical formulations due to the development of technology in the cosmetic industry and a better comprehension of the skin biology. However, the search for different active ingredients to be used in cosmetic is very important to develop stable, safe, and effective cosmetic formulations. The choice of adequate raw materials that will be part of its composition is fundamental, as they need to be compatible among themselves, and the selected ones also need to follow the product-use methodology, and that leads to the need of studies to assure this stability, safety, and efficacy in real conditions of use.

The skin is a complex and heterogeneous organ that covers the human body with a surface area of approximately 2 m^2, which is 10–15 % of the corporal mass, being, that way, the largest human organ. The skin is essentially composed of three layers: the first one, the epidermis, an intermediate, the dermis, and a deeper one, the hypodermis (Leonardi 2004).

The epidermis is the outermost layer and acts as a protective sheath against environmental influences. It consists of several layers starting with the stratum corneum to the basal cell layer and is continually being regenerated. The dermis lies beneath the epidermis and contains collagen and glycosaminoglycans. This layer is where collagen and elastin are synthesized and contains the blood vessels, nerves, sweat glands, hair follicles, and sebaceous glands. The hypodermis or subcutaneous layer contains the adipose tissue (subcutaneous fat) and provides a thermal barrier (Ammala 2013).

Skin aging is a result of the influence of a few factors that can be divided as intrinsic (or chronologic) and extrinsic (the early aging). The intrinsic aging happens as a result of the "genetically programmed" decline of vital functions that guarantee the organism's well functioning and can result in the epidermis thickening and its fragility, the thickness of the dermis, the decrease of the tissue vascularization, the reduction of fibroblasts and their metabolic capacity, and also a smaller response to growth factors. The extrinsic aging on the other hand is caused by external influence, especially UV radiation, atmospheric pollution, trauma, smoking habits, and ingestion or inhalation of metabolic substances (Sayre et al. 1994).

The relation between the intrinsic aging and the intensification of solar damages is called photoaging, which appears as an intensification of the chronological aging and also to the appearance of different characteristics from the usual aging beyond the pigmentation irregularity, wrinkles, skin texture modifications, and some malignant lesions (Beitner 2003; Yaar et al. 2002; Enjelke et al. 1997).

So the maintenance of the structural integrality of the skin as well as its barrier function is essential to skin health (Buraczewska et al. 2007), and cosmetic products are very important to preserve the good condition of the skin.

This way, new products containing different active substances appear every year, and the ones with natural origin are being widely used in association with vitamins in cosmetic formulations.

Natural-originated products have been broadly used in the cosmetics industry and have a good acceptance by the consumers that seek benefits related to these natural substances' properties. The antioxidant characteristic of botanical extracts and their composition, which is very rich in moisturizers, emollients, softeners, and others, could minimize the effects of aging from free radicals and skin dryness and also decrease damages caused by irritation.

Among the products that have a natural origin, the polysaccharides, which can be translated into "many sugars," can have either a natural origin or polymeric origin and are a highlight in cosmetic formulations for their properties that can provide different benefits to the skin (Bravo 1998). This way, they are a new trend in cosmetic formulations, bringing benefits as emulsion stabilizer, film former, binder, viscosity-increasing agent, rheology modifiers, and suspending agents. They can also have moisturizing effect on the skin (Gruber 1999).

Historically, their use is due to their availability from natural sources and multifunctionality, which is a growing research cosmetic area and very rare to find in a natural ingredient, playing then a large role in the cosmetic formulation technology.

Focusing on dermatological activities of carbohydrates, it has to be kept in mind that polysaccharides are often used as vehicles of dermatological formulations for the development of gels, ointments, or lotions (Deters et al. 2005).

Another benefit that justifies the use of polysaccharides in the development of cosmetic formulations is their interaction with other ingredients in a formulation as active substances, surfactants, and salts and their facile chemical modification which has allowed their preeminent use in cosmetics as well (Gruber 1999). In addition, polysaccharides, of natural and polymerical origin, are renewable and have a safety profile not accorded with synthetic-based polymers (Guillot et al. 1982).

Some studies have related the importance of polysaccharides to the stability of cosmetic formulations once the rheological properties are positively influenced when these polymers are used (Camargo Junior 2014).

According to Camargo and Maia Campos (2012), polysaccharide-based formulations have shown clinical effects in the transepidermal water loss reduction, protecting the skin barrier function and promoting a good sensorial.

In this context, the polysaccharides from different sources have a great potential to be applied in cosmetics as they can improve skin protection and hydration as well as for the development of stable formulations with pleasant sensorial properties.

2 Sources and Types Used in Topical Formulations

The polysaccharides that can be utilized in cosmetic formulations and have a natural origin can be found in many different sources.

Although genetic engineering has been offering new and interesting polysaccharides, the ones with cosmetic functions are still mostly from natural and seminatural origins.

The behavior of polysaccharides can be influenced by the nature of the substituent groups bound to the individual monosaccharides. These substituents can be of natural origin or may be synthesized, being called seminatural. Whether they are natural or seminatural, the polysaccharides can be organized into five categories, based primarily on its charge. These include: anionic, cationic, nonionic, amphoteric, and hydrophobic (Gruber 1999).

There are two cosmetically interesting polysaccharides available today that are made by human intervention, the cellulose gum (carboxymethylcellulose) and carboxymethylchitin (Gruber 1999), and among the polysaccharides used in cosmetic products, alginates, pectins, gums, and chitosan can be mentioned for their large application as rheological additives (Stelzer and Klug 1980). In addition, they have also been used for their protective effects on the skin, as different types of seaweed, as polysaccharides from *Klebsiella pneumoniae* and *Myrtus communis* extracts, and others.

Alginates are a class of polysaccharides that originated from the marine brown algae and from bacterial fermentation. They consist of two types of monosaccharides, the β-D-(1,4)-mannuronic acid and α -L-(1,4)-guluronic acid, and have the function to provide cellular support to the bacteria and algae cells, preventing them to collapse (Gacesa 1988).

Pectins are also polysaccharides that provide cellular support and can be industrially obtained by extraction from citrus fruit peels. Their structure is similar to the alginic acid except that pectins are composed of a repeating α-D-(1,4)-galacturonic acid unit which is interrupted at times by an α-L-(1,2)-rhamnose. Pectins are indicated for formulations with low pH, considering their citrus source (Gruber 1999).

Carrageenans are cellular structural polysaccharides with anionic characteristic and they are isolated from the marine red algae. They are indicated for topical formulations as they are very abundant in polysaccharides and with that, being a gelling, stabilizing, and thickening agent as they are biocompatible, with biodegradability and high capacity of water retention and mechanical strength of gels (Prajapati et al. 2014).

There are at least seven known varieties of carrageenans and their differentiation is made by a Greek letter. Due to its anionic substituents, the carrageenans are very functional and its structure is also quite diverse. The carrageenans that are more

utilized commercially are the kappa, iota, and lambda carrageenans and consist primarily of repeating monosaccharides as the β-D-(1,3)-galactose and α-D-(1,4)-galactose. The kappa carrageenan has an interesting and unique rheological feature, the synergistic viscosifying effect observed in blends with either a galactomannan, as the konjac mannan, or a glucomannan, as the locust bean gum. Some formulators have observed that although the addition of a glucomannan or a galactomannan to a solution with kappa carrageenan can increase the viscosity, the mixture of two synergistic polysaccharides and the salts of the formulation must be controlled with attention to achieve the maximum performance desired (Gruber 1999; Prajapati et al. 2014).

The xanthan gum is another polysaccharide that has bacterial fermentation origin and is available commercially. Its structure is made by a complex polysaccharide composition of a primary chain of β-D-(1,4)- glucose, which has, on alternating glucose halves, a branching trisaccharide side chain of β-D-(1,2)-mannose, attached to β-D-(1,4)-glucuronic acid, ending in a β-D-mannose. It was first discovered in the late 1950s in the United States Department of Agriculture (USDA) and is widely used today for many different areas for its unique rheological properties (Song et al. 2006).

As the xanthan has an anionic character, it is not compatible with most cationic surfactants. When a nonionic surfactant is present, the xanthan solution's viscosity is also relatively unaffected regardless of surfactant concentration. This fact helps the suspending capability of xanthan gum. The xanthan gum is also popularly combined with colloidal magnesium aluminum silicate (Veegum), an inorganic clay frequently employed to thicken cosmetic formulations, having then the xanthan's thickening efficiency synergistically enhanced (Laba 1993; Gruber 1999).

Wide varieties of the applications of β-glucan have been reported, including as thickening and stabilizing agents in chemical industries and immunostimulating and antitumor agents in clinical uses. Apart from these applications, β-glucan has been used as a substance that enhances the skin's natural ability to heal and protect itself against infection (Bae et al. 2005, Du et al. 2014).

The β-glucan is also used as a component of various cosmetics and is mainly produced from *Saccharomyces cerevisiae* as a water-soluble particulate or its chemically modified soluble forms such as carboxymethyl or phosphorylated glucan (Baschong et al. 2009). Another β-glucan, schizophyllan, which is produced from *Schizophyllum commune*, has been used as an immunotherapeutic agent for cancer treatment in Japan since 1986 (Lee et al. 2003).

The hyaluronic acid and chondroitin sulfate are polysaccharides with anionic characteristics isolated from animal tissue. The hyaluronic acid, specially, is much utilized in cosmetic formulations and can be obtained by bacterial fermentation. Its composition involves a linear polysaccharide formed from disaccharide units containing *N*-acetyl-D-glucosamine and glucuronic acid.

The hyaluronic acid has also interesting viscoelastic properties that are influenced by its polymeric and polyelectrolyte characteristics. Present in almost all biological fluids and tissues, it is a natural compound in the human skin and has

the capacity to immobilize water in tissue and, this way, change dermal volume and compressibility. It can also influence cell proliferation and differentiation and tissue repair (Kogan et al. 2007).

Naturally, the hyaluronic acid and the chondroitin sulfate make covalent bonds with several proteins in the animal tissue, and this union is called "proteoglycans," which have an important and diverse psychological role in the animal tissue. The hyaluronic acid, which is known to appear in the dermis of the skin, vitreous fluids, and in the body's synovial fluids, has many functions, with cellular turgidity and lubrication being the most important ones. Because of that, the hyaluronic acid and also the chondroitin sulfate, which have a similar function, are important ingredients to improve the appearance of the skin. This polysaccharide is also completely biocompatible with human tissue, but as it has an anionic charge, the glycosaminoglycans are not completely compatible with the anionic surfaces of the skin and hair (Sarpotdar 1993; Robbins 1994; Idson 1988). But it has further been shown that when combined with cationically charged polymers, the hyaluronic acid can enhance the binding to keratinized surfaces like the skin (Band et al. 1991; Pavlichko 1990).

The development of cosmetic formulations containing hyaluronic acid must be done very carefully as it establishes polyelectrolyte complexes with the interaction of anionic and cationic polymers, which is known to frequently form water-insoluble complexes (Gruber 1999).

The arabic, karaya, and tragacanth gums are very traditionally used gums and perhaps the most well-established anionic polysaccharides commercially available, but their complex molecular identities are still requiring study, as they are only superficially known (Whistler 1993). Their main difference from the previous polysaccharides is that they are a group of polysaccharides, with different molecular weight and structure, making it hard to determine their chemical identity (Gruber 1999).

The arabic gum consists of a chain of galactose sugars. Because of its low molecular weight, the arabic gum is mainly used in formulations where a high level of sugar solids is desired without a significant viscosity buildup (Gruber 1999).

The karaya gum is not a truly water-soluble material (Meer 1980; Clark 1993). It is composed primarily of a highly branched D-galacturonic acid backbone. Many of the acidic monosaccharides are acetylated, which causes the water insolubility.

Tragacanth gum is, perhaps, the best characterized of these commercial gums (Stauffer 1993; Clark 1993). It is composed of a highly branched complex of polysaccharides, the arabinogalactan, a water-soluble, neutral polysaccharide having a D-(1,6)-galactose backbone, and tragacanthic acid, an anionic polysaccharide polyglycan based on α-D-(1,6)-galacturonic acid (Gruber 1999). It can be used in cosmetic formulations as a stabilizer and as a protective coating, providing a smooth handfeel. When combined with glycerin, it has the function of a binding agent and when combined with water, forms viscous solutions, even at low concentrations (Verbeken et al. 2003).

The functional characteristics of many natural polysaccharides can be dramatically improved by chemical modification of the native polysaccharide. Cellulose gum, more precisely termed sodium carboxymethylcellulose (CMC), is a chemically altered cellulose (Feddersen and Thorp 1993; Idson 1988). Cellulose is a naturally occurring, structural polysaccharide found in all plants (BeMiller 1992, Majewicz and Podlas 1993). It is isolated commercially from cotton linters and also from wood after the removal of various other components such as lignin and hemicelluloses. Cellulose is composed of one repeating monosaccharide, β-D-(1,4)-glucose (Draget et al. 1997; Gruber 1999).

Chitosan is distinct among the cationic polysaccharides: it is the only naturally occurring, commercially available polyglycan that can carry a cationic charge. Chitosan, naturally available in noncommercial quantities from insect exoskeletons and various bacterial parasites, is more practically isolated by alkaline hydrolysis of the acetamide of crustacean chitin (Djabourov 1991).

Chitosan, employed as its salt, has strong substantivity to anionic surfaces like the skin and hair (Brode et al. 1991; Watcher et al. 1997; Julia et al. 1996; Onsoyen and Dybdahl 1991; Lochead 1988). It is also a film-forming polysaccharide that has been used in fixative formulations and 2-in-1 shampoos. Because chitosan is one of the few naturally occurring cationic polysaccharides, and because of its biocompatibility with the human body, it has been employed extensively in the development of anionic/cationic polysaccharide matrices for drug delivery (Onishi et al. 1997).

The hydroxyethylcellulose (HEC) is successfully used as a conditioning polysaccharide. Cellulose is composed of β-D-(1,4)-glucose monosaccharides and has a water-insoluble nature. Hydroxyethylcellulose is very utilized in industrial and personal care applications as an aqueous viscosifier (Laba 1993).

Guar gum is a polysaccharide that is commercially isolated from the seeds of several leguminous plants (Maier et al. 1993; Seaman 1980; BeMiller 1992). It is composed of linear chains of β-D-(1,4)-mannose (Yalpani 1988), with alternating mannose sugars having branching α-D-(1,6)-galactose units (BeMiller 1992). Guar is often referred to as a galactomannan because of its constituent monosaccharides (Gruber 1999). It is highly utilized in the cosmetic industry, especially in emulsions and lotions, as a protective colloid, increasing emulsion stability, water loss, and phase separation. An example is some shaving creams; beyond its use as a stabilizer, it can also improve facial skin feel after the shaving process (Chudzikowski 1971).

Cyclodextrins, on the other hand, are used extensively in cosmetic and drug delivery applications (Amann 1993; Szejtli 1984; Citernesi and Sciacchitano 1995; Romberger 1998; Motwani and Zatz 1997). Cyclodextrins, as the name implies, are cyclic amyloses composed of 6 (α-), 7 (β-), and 8 (γ-), α-D-(1,4)-glucose monosaccharides. They are also important components in many cosmetic formulations as they function as solubilizing agents for water-sensitive or water-insoluble materials (Gruber 1999).

Sclerotium gum or scleroglycan can be obtained from an exocellular fermentation product (Brigand 1993). Its composition is based on a main chain of

β-D-(1,3)-glucose residues to which, on approximately every third glucose, a branching β-D-(1,6)-glucose is attached. The combination of (1,3)-linkages and the branching glucose moieties reduces its crystallinity and increases its solubility compared to cellulose (Gruber 1999).

3 Cosmetic Formulation Development: Rheology

Systems with polysaccharides are interesting to scientists and technologists from different areas for their structural characteristics, rheological properties, and applicability.

Polysaccharides, as established before, have many cosmetic functions, such as the capacity of being a formulation rheology modifier. The flow limit values from emulsions are increased with the addition of the polysaccharides (Vianna Filho 2009).

This way, the polysaccharides are important ingredients to obtain cosmetic formulations with desired rheological properties. For example, emulsions with sodium hyaluronate and *Klebsiella pneumoniae* extract had low thixotropy when compared to the rest, and xanthan gum solutions are insensitive to a wide range of salt concentration, pH, and temperature. The most basic property of xanthan gum is its ability to form highly viscous solutions at zero or low shear rates, even at low polymer concentrations.

Figure 1 shows the rheological behavior of a gel cream formulation with and without (placebo) polysaccharides from a biotechnological source. The presence of polysaccharides in formulations increases the viscosity and improves its stability. Both formulations had pseudoplastic behavior, with a flow index below 1.

The rheological answers were influenced by the different types of polysaccharides and the other blends utilized. This way, the polysaccharides could increase the time-related stability of the emulsions under study and also increase the elastic modulus values (Vianna Filho 2009).

In the cosmetic industry specifically, the demand for natural-origin raw materials that add desired characteristics in terms of benefits in the physical, sensorial, and visual characteristics and functional compatibility with the skin and other components of the formulation is continually increasing.

The study of the effects caused by these biopolymers in the rheological properties in a specific formulation makes it possible to establish a connection between their physical, chemical, and sensorial characteristics and their rational and functional use in the industry. Also, the structural diversity and physical-chemical properties of the polysaccharides provide an alternative selection to the proper ingredients that leads to the development and improvement of new products.

The mannans and glucomannans are polysaccharides utilized to the emulsification of O/W cosmetic formulations and can have a greater emulsification capacity when compared to commercial emulsifiers like the Glyceryl Stearate and PEG-100 Stearate (Kuncheva et al. 2007). The polysaccharides, proteins, and lipopolysaccharides produced by bacteria such as *Klebsiella* sp., *Acinetobacter calcoaceticus*

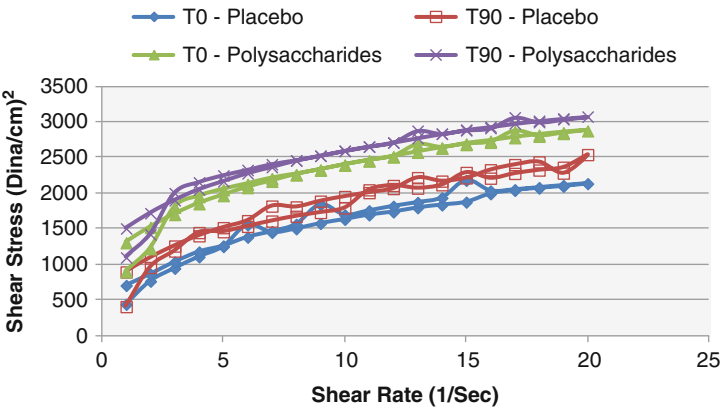

Fig. 1 Rheograms of placebo formulations and formulations with polysaccharides obtained by biotechnological process, stored at 45 °C, 90 days after preparation

RAG-1, *Candida utilis*, and *Methanobacterium thermoautotrophium* can stabilize and emulsify O/W emulsions used in the cosmetic and food industry (Rosemberg and Ron 1997). The whey protein can be used alone or combined with polysaccharides to form emulsified systems that are thermodynamically stable avoiding phase separation (Vianna Filho 2009).

The polysaccharides present numerous advantages over synthetic polymers besides being abundant and easily obtained from renewable sources as algae, plants, and microbial cultures selected and produced by recombinant DNA technique strains. These biopolymers have a wide variety of properties and compositions that can be easily obtained in laboratories (Vianna Filho 2009).

The sclerotium gum, xanthan gum, and polysaccharides from *Klebsiella pneumoniae* extract have shown a positive influence in the rheology of gel cream formulations as well as sensorial properties (Camargo Junior et al. 2011; Camargo Junior 2014).

Polysaccharides extracted from algae such as D-glucose, D- mannose, D-galactose, and D-glucuronic acid have been used as excipients in cosmetic formulations because of its high gelling, bonding, and viscosity-increasing properties (Kim et al. 2008).

Properties as high viscosity, gelling, compatibility with a variety of salts and a wide range of pH and temperature, great water solubility, and synergy with other polysaccharides are some of the features that differentiate the commercially available microbial polysaccharides from other gums.

Polysaccharides were used primarily as thickening, suspending, and stabilizing agents in aqueous systems. The industrial viscosity-increasing polysaccharides have been derived from algae and plant sources traditionally (Paul et al. 1986).

The fact that most polysaccharides can be easily obtained contributes to a lower price when compared to synthetic polymers (Nishinari and Takahashi 2003; Coviello et al. 2007), and they are also biodegradable and can be converted into several derivates (Renaud et al. 2005).

4 Clinical Studies

4.1 Clinical Evaluation by Biophysical and Skin Image Techniques

The clinical studies are essential to demonstrate the efficacy of polysaccharide-based formulations on the skin.

Noninvasive skin biophysical techniques are often used in the clinical studies since they allow evaluation of cosmetic products under actual conditions of use. The skin biophysical methods typically measure selected properties that depend on the measuring principle applied. Hydration, skin viscoelasticity and microrelief, barrier function, and skin thickness are examples of parameters that can be quantified noninvasively using these techniques (Maia Campos et al. 2008).

Some clinical efficacy studies of the cosmetic formulations by biophysical techniques and skin image have been used according to the following parameters: stratum corneum water content, transepidermal water loss (TEWL), viscoelastic characteristics (Ua/Uf, gross elasticity; Ur/Ue, neto-elasticity of the skin; Ur/Uf, biological elasticity; and Uv/Ue, the ratio of viscoelastic to elastic distension), and skin microrelief (roughness – RT, number and width of the wrinkles – SEW, skin smoothness – SESM) techniques (Maia Campos et al. 2008; Wissing and Muller 2003).

The stratum corneum moisture content is determined with a noninvasive, skin capacitance meter (Corneometer® CM 825, Courage-Khazaka, Cologne, Germany), which measures capacitance and is entirely dependent on the water content of the skin (Dal'Belo et al. 2006). Different capacitance changes are converted into a digital-measured value (arbitrary units), which is proportional to the skin's humidity.

Skin barrier function can be evaluated by measuring the TEWL (g/cm2h) using the Tewameter TM 210 (Courage-Khazaka, Cologne, Germany). TEWL is considered an important measure of epidermal barrier function. Evaporimetry consists of applying a probe with two sensors directly to the skin, with one sensor pair measuring humidity and the other temperature. The acquired data are used by integrated microcomputer to compute the water vapor partial pressures at the two parallel levels of each sensor pair and, via the partial pressure gradient, the rate of evaporation. To minimize outside interference, the measurements were carried out in an open-top chamber with closed sides (Huang and Chang 2008).

Skin microrelief parameters are evaluated using Visioscan® VC98, which is a special UVA light video camera with high resolution developed specially to study the skin surface directly, and the SELS (surface evaluation of the living skin) method. The images show the structure of the skin and the level of dryness and the gray level distribution of the image is used to evaluate the following skin roughness parameters: skin roughness (RT), skin smoothness (SESM – proportional to the width and form of the wrinkles), and number and width of the wrinkles (SEW) (Maia Campos et al. 2012).

The viscoelastic properties of the skin are investigated with a Cutometer SEM 575 (Courage-Khazaka, Cologne, Germany) and its measuring principle is by suction/elongation. An optical system detects the decrease of infrared light intensity

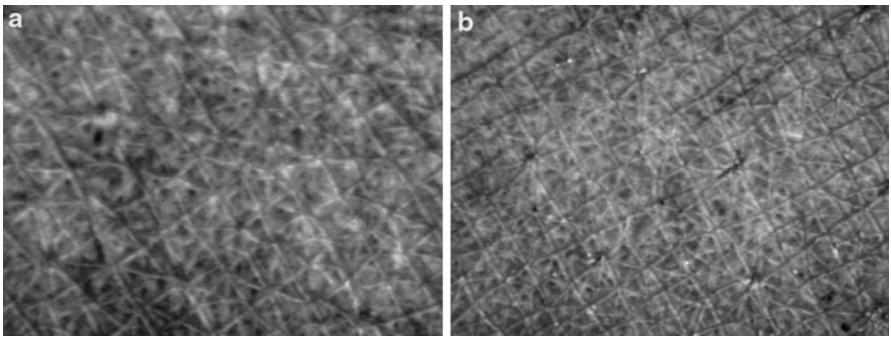

Fig. 2 Skin surface evaluation (skin microrelief). Surface of the skin before (**a**) and after 30 days (**b**) of treatment with a formulation containing polysaccharides. Skin surface was evaluated by Visioscan® VC98 software

depending on the distance the skin is being sucked into the probe. A probe with a 2-mm opening is usually used, and a pressure of 450 mbar is applied in order to suck the skin into the probe. Each measurement consists of five suction cycles (3 s of suction followed by 3 s of relaxation). The parameters Ua/Uf (gross elasticity), Ur/Ue (elasticity of the skin), Ur/Uf (biological elasticity), and Uv/Ue (the ratio of viscoelastic to elastic distension) are evaluated (Dobrev 2000).

Dermal echogenicity and morphological and structural epidermal features can be determined with a DermaScan C (20 MHz ultrasound) and a VivaScope 1500 reflectance confocal microscopy, respectively (Gonzalez and Gilaberte-Calzada 2014; Gianeti and Maia Campos 2014).

The 20 MHz ultrasound is a safe, noninvasive technique for the evaluation of the skin alterations in the dermis as thickness and echogenicity (Unholzer and Korting 2012).

The development of laser scanning confocal microscopy enabled the utilization of this technique in the noninvasive evaluation of the skin. Nowadays, in vivo laser confocal microscopy has a wide range of applications, because it obtains microscopic images in real time, with a resolution close to conventional histology (Gianeti and Maia Campos 2014).

The images below represent the skin microrelief (Fig. 2) and high-resolution photograph of the face (Fig. 3) before and after treatment with a formulation containing polysaccharides from algae. The polysaccharide-based formulation improved the skin microrelief and appearance.

5 Clinical Efficacy of Polysaccharide-Based Formulations on the Skin

In the cosmetic industry, there is a demand for natural-origin raw materials that can add desired characteristics in terms of benefits in the sensorial and visual characteristics and functional compatibility with the skin and other components. This way,

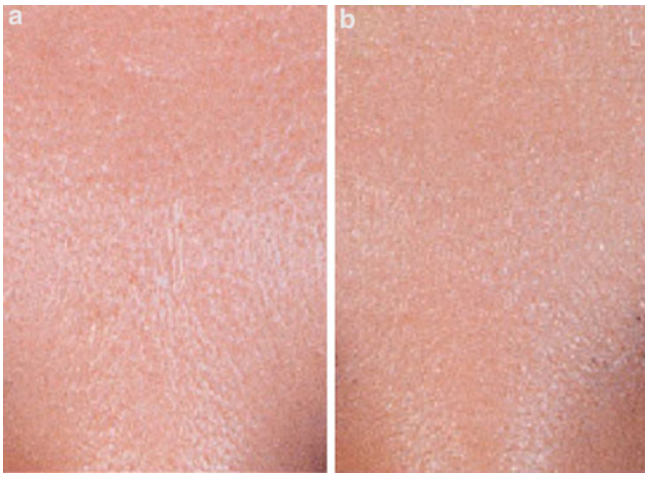

Fig. 3 High-resolution photographic images obtained from an inter-sourciliar area of the face before (**a**) and after (**b**) the application of a gel formulation with polysaccharides from a natural source

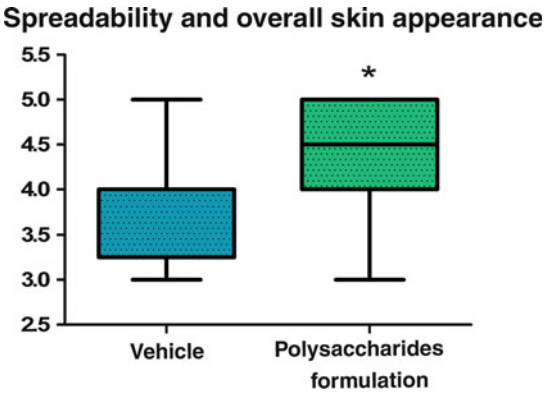

Fig. 4 Spreadability and overall skin appearance after the application of the formulations with and without (vehicle) polysaccharides obtained by biotechnological process. *Significantly different for vehicle formulation ($p < 0.05$)

the formulations containing polysaccharides lead to a higher degree of acceptance by the volunteers and, consequently, better sensorial attributes (Fig. 4)

Skin application of hyaluronic acid-containing cosmetics has been reported to achieve antiwrinkle effects via its ability to effectively moisturize and enhance the elasticity of the skin (Basavaraj et al. 2010; Pavicic et al. 2011). Hyaluronic acid is a very effective topical humectant, attracting water from the air to plump the skin. It is also commonly used as an injectable dermal filler.

In addition to its moisturizing properties, the biodegradability of hyaluronic acid also makes it very attractive for wound healing applications (Price et al. 2007; Teh et al. 2012; Abbruzzese et al. 2009). It is used as a delivery system to transfer keratinocyte cells from tissue culture to skin wounds, in particular burns, with high rates of healing (Price et al. 2007).

The stability of hyaluronic acid-based nanoemulsions as transdermal carriers was also recently reported (Kong and Park 2011). Electrostatic, steric, and hydrophobic effects were found to play a key role in the stability of the emulsions. Encapsulation experiments with vitamin E also demonstrated that the emulsions were capable of successfully carrying lipophilic additives.

Although the exact mechanism of action of topically applied hyaluronic acid has not been fully explored, Brown and Jones (2005) have described some key factors in a recent review article. It is known that the degree of hydration of the stratum corneum influences skin permeability and, with the excellent hydrating properties of hyaluronic acid, can lead to enhanced topical delivery of actives across the skin (Ammala 2013).

Chitosan has been widely reported for use in topical and transdermal delivery systems largely due to its nontoxicity and susceptibility to degradation. It has been reported that chitosan has the ability to enhance permeation across the skin by altering the structure of keratin. It also increases the water content of the stratum corneum and cell membrane fluidity. Further, due to its positive charge under slightly acidic conditions, it can depolarize the negatively charged cell membrane, and in doing so, it decreases the membrane potential and drives the active component or drug through the skin (Pawar and Babu 2010).

In addition to the structural changes to keratin described previously, the use of chitosan and its derivatives has also been demonstrated to increase the water content of the stratum corneum. The derivative *N*-trimethyl chitosan had the greatest effect in increasing water content. A study also demonstrated that the increased amount of water was able to be retained in the stratum corneum for significant lengths of time (He et al. 2009).

The encapsulation of active ingredients using chitosan is also possible. Controlled release has been demonstrated by increasing the viscosity of the polymer matrix (Cattaneo 2005). A skin permeability study confirmed that the encapsulation of retinoic acid with chitosan delivered the retinoic acid at much slower and controlled rates as compared to free retinoic acid (Cattaneo 2005). This ability to control the delivery of retinoic acid is important to reduce skin irritation (Ammala 2013).

Cyclodextrins and chemically modified cyclodextrins have been utilized for a wide range of applications in cosmetics and personal care markets including controlled release of fragrances, stabilization of drugs, encapsulation of vitamins, reduction of the dermal penetration of preservatives, and masking of odors (Matsuda and Arima 1999; Gommet et al. 2010).

Cyclodextrins have also been reported to enhance the effectiveness of sunscreen formulations (Scalia et al. 1998). The study reported an in vitro model, using ethanol-propylene glycol solution, as well as a more realistic model using an oil-in-water emulsion. It was demonstrated that the photostability of sunscreen agents could be improved by encapsulation (Taramici 2011).

Polysaccharides can also come from other sources, as algae, being the red and brown algae the ones most utilized in the industry (Cunha et al. 2009).

Chondrus crispus is an example of red algae rich in polysaccharides and minerals, including manganese, zinc, calcium, and magnesium which attributed to hydrating, soothing, healing, moisturizing, and conditioning effects (Kim et al. 2008).

Fucoidan, which is an active ingredient found mainly in various brown algae such as *Laminaria japonica*, *Fucus vesiculosus*, *Undaria pinnatifida*, *Cladosiphon okamuranus*, and *Hizikia fusiforme*, had its antioxidant and antiaging properties studied in epidemiological and experimental studies (Kim et al. 2008). It also inhibits ultraviolet B (UVB)-induced matrix metalloproteinase-1 (MMP-1) enzyme activity in human skin fibroblasts (Moon et al. 2008; Oresajo et al. 2008). Matrix metalloproteinases (MMPs) are responsible for the degradation and the inhibition of synthesis of collagenous extracellular matrix in connective tissues (Moon et al. 2008) and have demonstrated that fucoidan can mainly inhibit UVB-induced MMP-1 expression by inhibiting the extracellular signal-regulated kinases (ERK) pathways. That way, fucoidan is emerging as a popular natural cosmetic ingredient to be used as a potential agent in skin cosmetics for the prevention of skin photoaging (Wijesekara et al. 2011).

New clinical efficacy studies with *Spirulina*, which has a rich composition in provitamin A, B vitamins, proteins, and polysaccharides such as glucose, galactose, mannose, and ribose, have shown that an emulsion containing this type of seaweed has a potential to increase the stratum corneum water content and reduce the transepidermal water loss. Also shown was a significant reduction of the scaliness and the roughness of the skin (Maia Campos et al. 2013).

The polysaccharide from *Klebsiella pneumoniae* is also commercially available which is supposed to enhance cell renewal and improve skin hydration and microrelief. In addition, extracts of *Myrtus communis* leaves, which contain different types of sugars, may also provide the same benefits. Galacturonans, the main polysaccharides of hydrolyzed *Myrtus communis* extract, are polymers formed by units of galacturonic acid that can form gels in the presence of water. The enhancement of skin firmness (tensile strength) is related to galacturonan film formation (Gillon et al. 1999).

A clinical study showed that both polysaccharides added in gel formulation provoked an enhancement to the skin hydration and isolated or combined the active substances can improve the skin barrier function. So these results suggest that the daily use of formulations containing these substances is important for the protection of the skin barrier function. In the same study, a sensorial analysis also showed that formulations with the polysaccharides previously mentioned had a better acceptance regarding spreadability, skin appearance, and sense of skin hydration when compared to placebo formulation. The tests are useful to study the sensorial properties of the product by volunteers, predicting its future acceptance in the market (Camargo Junior et al. 2012).

Other studies from our research group (data not published) that evaluated the transepidermal water loss (TEWL) showed that formulations supplemented with polysaccharides from natural sources reduced this parameter after 15 and 30 days of daily application, resulting in an improvement of the skin barrier function (Fig. 5). In addition, those formulations presented better sensorial attributes regarding skin appearance, skin feeling, and skin hydration after the application.

Pillai et al. (2005) studied the penetration of oat β-glucan in human skin models to evaluate clinically its efficacy for reducing fine lines and wrinkles. After 8 weeks

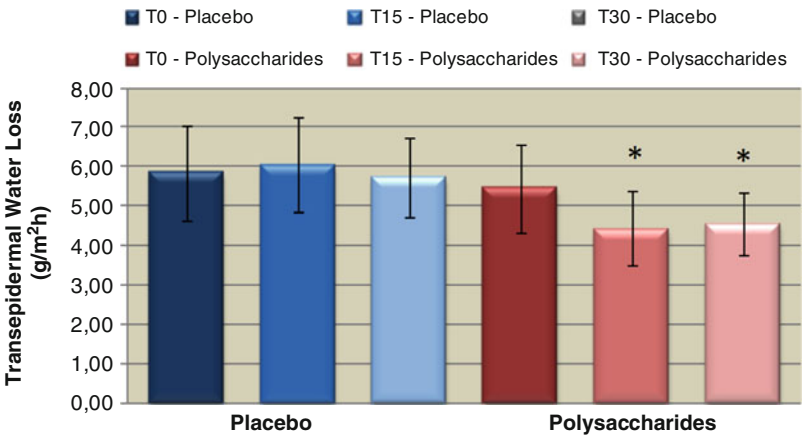

Fig. 5 Transepidermal water loss on the volunteers' forearm skin before (baseline values – T0) and 15 (T15) and 30 (T30) days after the application of the formulations: placebo formulation and a formulation containing polysaccharides from a natural source. * Significantly different for baseline values ($p < 0.05$)

of treatment, the results indicated a significant reduction of wrinkle depth and height and overall roughness (Humbert et al. 2012a). Nevertheless, the cause and occurrence mechanism of the coarser lines on an aging individual's skin are not fully understood yet (Humbert et al. 2012b).

The water content of the stratum corneum and skin surface lipids are important factors in the appearance and function of the skin (Cheng et al. 2007). Moisturizers decelerate the loss of skin humidity and minimize fine wrinkles (Baumann 2007). They also increase hydration of the stratum corneum and improve physical and chemical properties of the skin surface, making it moist, smooth, and soft (Kim et al. 2007). Traditional moisturizing ingredients, such as pantothenic acid (Kobayashi et al. 2011) and hyaluronic acid (Pavicic et al. 2011), are known to possess an effective moisturizing activity in cosmetic formulations. Additionally, some natural extracts from the root of *Lithospermum erythrorhizon* (Chang et al. 2008), okra polysaccharide (Kanlayavattanakul et al. 2012), and β-glucan (Kim et al. 2008) play important roles in the cosmetic and pharmaceutical industry.

Zulli et al. (1998) suggested that glucan from the baker's yeast cell wall could be used as an active ingredient for cosmetic and pharmaceutical purposes. This experiment showed that carboxymethyl glucan (CM-glucan) protected skin cells against the depletion of antioxidant molecules upon UVA irradiation.

6 Conclusion

The effects of polysaccharide-based formulations on the human skin have been demonstrated in some clinical studies. Sometimes these effects are associated with the improvement of the skin barrier function and hydration. However, the polysaccharides can also act on the skin viscoelasticity and microrelief.

In addition, the use of polysaccharides in cosmetic formulations is important to formulation technology, once it can act on the rheological properties and increase the formulation stability. The cosmetic sensorial properties can also be enhanced by the use of these ingredients in the formulation.

As previously mentioned, the polysaccharides obtained from different natural sources like hyaluronic acid and algae, obtained by biotechnological process and others, are interesting active ingredients to develop effective cosmetic formulations for skin protection and maintenance of its structure integrality and physiology.

So according to the benefits on the human skin described, polysaccharides have been extensively used in cosmetic formulations for their diverse range of benefits.

Finally, the use of polysaccharide-based formulations on the human skin is very important to maintain physiological skin conditions and to prevent skin disorders related to barrier function alterations.

Major Advances in the Development of Synthetic Oligosaccharide-Based Vaccines

68

Damiano Cancogni, Matteo Fusari, Niccolò Poggi, and Luigi Lay

Contents

Abstract

Because of their involvement in a variety of different biological processes and their occurrence onto pathogens and malignant cell surface, carbohydrates have been identified as ideal candidates for vaccine formulation. However, as free oligosaccharides are poorly immunogenic and do not induce immunological memory in the most at risk population (infants and young children, elderly and immunocompromised patients), glycoconjugate vaccines containing the same carbohydrate antigen covalently linked to an immunogenic carrier protein have gained a prominent role. Accordingly, a number of glycoconjugate vaccines mostly directed against infections caused by bacterial pathogens have been licensed and are currently available on the market. However, also glycoconjugate vaccines suffer from significant drawbacks. The challenging procedures required for the isolation and purification of the carbohydrate antigen from its natural source often lead to poor homogeneity and presence of biological contaminants, resulting in batch-to-batch variability. Moreover, in some cases, the overwhelming immunogenicity of the carrier protein may induce the

carbohydrate epitope suppression, causing hyporesponsiveness. The development of synthetic oligosaccharide-based vaccine candidates, characterized by the presence of pure and well-defined synthetic oligosaccharide structures, is expected to meet the requirement of homogeneous and highly reproducible preparations.

In the present chapter, we report on the major advances in the development of synthetic carbohydrate-based vaccines. First of all, we describe different strategies developed during the last years to circumvent the inherent difficulties of classical oligosaccharide synthesis, such as the one-pot glycosylation and the solid-phase synthesis, and their application to the preparation of carbohydrate antigens apt to conjugation with protein carriers. Next, we discuss the most representative methodologies employed for the chemical ligation of oligosaccharide structures to proteins. Finally, in the last section, we report significant examples of fully synthetic vaccines exploiting the multivalency effect. These constructs are based on the concept that the conjugation of multiple copies of synthetic oligosaccharide antigens to multivalent scaffolds, such as dendrimers, (cyclo)peptides, gold nanoparticles, and calixarenes, raises cooperative interactions between carbohydrates and immune receptors, leading to strong enhancement of the saccharide antigen immunogenicity.

Glossary

Adaptive immune response	The (antigen-specific) **immune response** is the response of antigen-specific lymphocytes to antigen, including the development of the immunological memory. The adaptive response is initiated and promoted by the innate immune system cells. The activated APCs travel into the draining lymph nodes where they present the peptide antigen to recirculating naïve T cells (immunological synapse), eliciting a T cell-dependent immune response. Depending on the antigen exposed on APC surface, the immunological synapse raises a complex cascade of events culminating in the activation and differentiation of T cells into **cytotoxic T lymphocytes** (CTL or CD8+ cells) and/or **T helper cells** (T_H or CD4+ cells). CTL are effector T cells responsible for the **cellular immunity** that destroy target cells infected by intracellular viruses and bacteria. T_H cells initiate the maturation process of resting B cells driving their differentiation into **plasma cells** (antibody-forming cells) and **memory B cells** (**humoral immunity**). While plasma cells secrete low-affinity IgM-type antibodies, memory B cells survive for a long time in the body and respond rapidly to subsequent exposures of antigen by eliciting high-affinity IgG antibodies, which represents the overall objective of the vaccination practice.
Adjuvant	**Adjuvant** is any substance that enhances the immune response to an antigen. Adjuvants can be categorized in delivery systems and immune potentiators. The delivery systems play the main function to localize vaccine components and to target them to APCs, whereas immune potentiators directly activate APCs acting as agonists of PRRs (mostly TLRs) facilitating the antigen uptake.
Antibody	An **antibody** is a protein that binds specifically to a particular substance, called **antigen**. While each antibody has a unique structure that enables it to bind specifically to its corresponding antigen, all antibodies have the same overall structure and are known collectively as **immunoglobulins** (Ig).

Antigenic determinant	An **antigenic determinant**, or **epitope**, is the portion of an antigenic molecule that is bound by a given antibody.
Antigen-presenting cells	**Antigen-presenting cells** (APCs): highly specialized cells that can process antigens and display their peptide on the cell surface. Antigen-presenting cells include **macrophages** and **dendritic cells** (DC), but also B cells can act as APCs.
B cell epitope	**B cell epitope** is the minimal portion of an antigenic molecule needed to induce the production of specific antibodies in the humoral immune response.
Hapten	**Hapten** is any small molecule usually unable to activate an immune response unless conjugated to an immunogenic carrier.
Innate immunity	The **innate immunity** is based on a variety of innate resistance mechanisms that recognize and respond to the presence of a pathogen. The innate response is mediated by APCs and it acts during the early stages of the infection. APCs detect and respond to pathogen-associated molecular patterns (PAMPs), structurally and chemically diverse compounds that are unique to foreign microorganisms, via a multiple set of pathogen recognition receptors (PRRs), including peptidoglycan recognition proteins, scavenger receptors, **C-type lectin** receptors typically including a carbohydr-binding domain, and **Toll-like receptors** (**TLRs**). Binding to PRRs induces the pathogen engulfment by APC and its intracellular processing, i.e., enzymatic degradation into short peptides that eventually bind the **major histocompatibility complex** (**MHC**) molecule and are exposed on cell surface to be presented to T cells.
T and B cells	**T and B cells** are the two subsets of lymphocytes defined by their development in the thymus and bone marrow, respectively.
T cell epitope	**T cell epitope** is the minimal portion of an antigenic molecule (typically a peptide) needed to elicit a T cell-dependent immune response.

1 Introduction

Together with proteins and nucleic acids, carbohydrates are a major class of biopolymers that mediate a wide range of biological processes in living organisms. It is now well established that, for example, carbohydrates play crucial roles in viral and bacterial invasion, angiogenesis and tumor cells metastasis, embryogenesis, inflammatory reactions, and, more generally speaking, in a large number of fundamental molecular recognition phenomena (Varki et al. 2009; Dwek 1996; Varki 1993). In particular, there is a growing interest towards what is known as glycoimmunology: this term derives from the merger of glycobiology with immunology, and it deals with the peculiar interactions of carbohydrates with the immune system, emphasizing the importance of using carbohydrates to induce protective immunity against microbial infections but also cancer metastasis. This relatively new field is based on the concept that diverse pathogens and malignant cells expose on their surface a dense array of often unique glycan structures that exert a protective function against the host's immune defense and are essential for their pathogenicity. Typical examples are lipopolysaccharides (LPS) of Gram-negative bacteria, the polysaccharide coat (capsular polysaccharides, CPS) of encapsulated bacteria, and diverse glycoproteins/glycolipids specifically expressed on viral and cancer cell surface. On the other hand, all these glycoforms are capable of interacting with the immune system, acting as cell antigenic determinants, and raising carbohydrate-specific antibodies production, and therefore they represent attractive targets for vaccine development.

Vaccination has certainly been a key breakthrough in the history of medicine and produced a tremendous impact on health-care systems. It is therefore not surprising that, despite the advent of more and more sophisticated antibiotics, vaccination is still considered by the World Health Organization as the most cost-effective approach for preventing infectious diseases and protecting public health, especially in developing countries. There is however a general concern about carbohydrate-based vaccines. Vaccines based on free and purified polysaccharides are poorly immunogenic in infants, in young children (under 2 years of age), in the elderly, and in immunocompromised patients, since they induce only short-lasting antibody responses in adults and fail to generate conventional B cell-mediated immunological memory (Gonzalez-Fernandez et al. 2008; Segal and Pollard 2004). Polysaccharide-based vaccines thereby possess limited clinical efficacy that has been largely ascribed to the T cell-independent immune response, hallmarked by the exclusive production of low-affinity IgM antibodies and no class switch to high-affinity protective IgG antibodies. This kind of immune response is typically triggered by antigens with polymeric structure composed of multiple repeating units, such as polysaccharides (Mond et al. 1995). The discovery that the polysaccharide immunogenicity can be strongly enhanced by their conjugation to an immunogenic carrier protein led to the development of glycoconjugate vaccines (Lesinski and Westerink 2001; Weintraub 2003). This strategy opened a new era in the field of vaccinology. Glycoconjugate antigens are able to induce T cell recruitment and immune memory B cell proliferation, with the production of long-lasting IgG antibodies specifically directed towards the carbohydrate strictly associated to

the pathogen (Ada and Isaacs 2003). The isolation and purification of carbohydrate antigens from their natural sources, and their subsequent manipulation for protein conjugation, are however a challenging task. In addition, the material available is often heterogeneous and not sufficient for the inclusion in a vaccine, and these represent major limitations to further expansion in this field. Hence, the development of cost-effective, fully synthetic carbohydrate vaccines would be of great importance, as witnessed by the spectacular success of the Cuban vaccine against *Haemophilus influenzae* type b (Verez-Bencomo et al. 2004). Synthetic carbohydrate antigens have, indeed, defined composition, and they can be produced as homogeneous compounds in a controlled manner with little or no batch-to-batch variability, affording highly reproducible biological properties. In addition, some microorganisms express carbohydrate structures that have close similarity to mammalian tissue-specific structures, and this molecular mimicry may induce tolerance by the host's immune system. One approach to evade this immune tolerance is to use a chemically modified version of the carbohydrate, an option available only with the recourse to the chemical synthesis. The unnatural structure will be perceived as a foreign antigen by the host, but at the same time, it should elicit antibodies able to cross-react with the natural glycan expressed on the pathogen cell surface.

On the basis of these considerations, the present chapter deals with the major advances in the formulation of synthetic carbohydrate-based vaccines, with a particular focus on the strategies and relevant synthetic methodologies that emerged during the last years.

First and foremost, for the sake of clarity and with the purpose to facilitate the comprehension of the contents by nonspecialized readers, we report a glossary defining the most significant terms referred to the complex machinery of the immune response and used throughout this chapter.

The following section highlights the most significant synthetic methodologies applied to the preparation of carbohydrate-based vaccine candidates. Finally, the new strategies (or new applications of the existing ones) carried out for the design of new, more efficient, and safer vaccines based on the conjugation of synthetic oligosaccharides with protein carriers and polyfunctional scaffolds (in order to exploit the multivalency effect) are described and critically discussed. It should be mentioned that a comprehensive review focused on the preparation of vaccines or vaccine candidates based on fully synthetic carbohydrate antigens but classified according to the target disease (infections from bacteria, viruses, parasites, fungi, and cancer) has been published by our group in 2011 (Morelli et al. 2011).

2 New Methodologies for the Synthesis of Oligosaccharides as Vaccine Candidates

Due to the enormous importance of carbohydrates in different biological processes (Varki et al. 2009; Dwek 1996; Varki 1993), the study of their functions and structure-activity relationships (SARs) needs homogeneous and well-defined

oligosaccharides. As stated above, the achievement of carbohydrate structures in high purity and quantity from natural sources is a tough and complex process. To overcome these problems, significant efforts have been carried out for the development of chemical and enzymatic synthesis of well-defined oligosaccharides and conjugates (Zhu and Schmidt 2009; Boltje et al. 2009; Fraser-Reid et al. 2008; Kamerling 2007; Wong 2003; Ernst et al. 2000; Nicolaou and Mitchell 2001; Koeller and Wong 2001; Seeberger and Werz 2007; Bertozzi and Kiessling 2001).

The synthesis of carbohydrates is more difficult than the synthesis of the other two major classes of biopolymers (peptides/proteins and nucleotides/DNA and RNA). In the construction of oligosaccharides, two major challenges have to be taken into consideration: the regioselective protection/deprotection of polyhydroxy groups and the stereoselective formation of glycosidic linkages.

The chemical synthesis of oligosaccharides requires monosaccharide building blocks with appropriate protecting groups and anomeric leaving group. The mammalian glycome includes a limited number of monosaccharides and linkages, so using only a limited number of building blocks, a large variety of oligosaccharides could be prepared by a proven synthetic strategy (Werz et al. 2007a). This will also be true for viruses, which use the host glycan machinery for the synthesis of their oligosaccharides. On the contrary, the bacteria glycome comprises much more complex structures (Adibekian et al. 2011), attainable only in assembling a large number of building blocks.

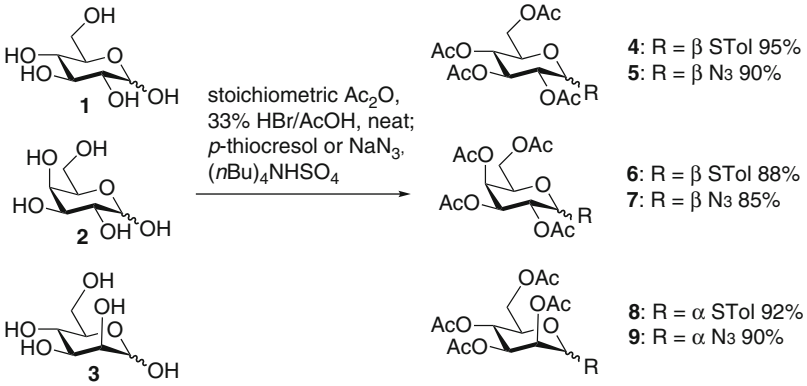
The chemical synthesis of oligosaccharides, as well as the development of new methodologies for the orthogonal protection of building blocks used in saccharide chain assembly, made enormous progress during the last two decades. Some significant examples of these techniques and their application to the preparation of carbohydrate antigen are described in the following section.

2.1 Regioselective Protection of Monosaccharides

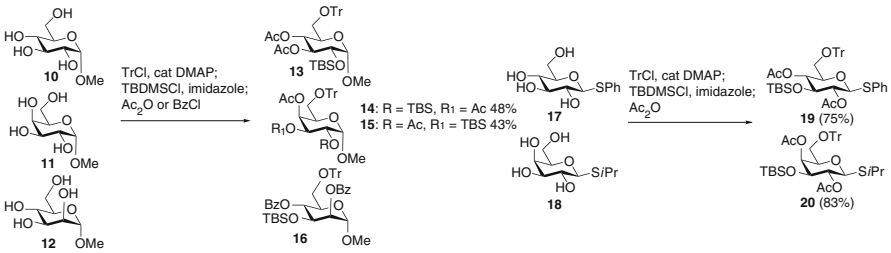
The correct choice of the protecting groups is the basis to design an ideal synthesis of complex oligosaccharides. One of the most common problems is the regioselective installation of orthogonal protecting groups. The protection of the different hydroxy groups of a monosaccharide influences the reactivity of a glycosyl donor/acceptor, the stereoselectivity of the newly formed glycosidic bond, and the ease of the final deprotection.

Besides the classical stepwise protection strategy, during the last years, different methodologies for the one-pot protection of monosaccharides have been developed.

An example of one-pot protection is the per-*O*-acetylation of sugars: with this reaction it is possible to obtain important precursors of monosaccharide synthons. In 2003 Hung and coworkers developed a procedure to obtain fully acetylated hexoses: the reaction proceeds under solvent-free conditions using a stoichiometric amount of acetic anhydride and a catalytic amount of $Cu(OTf)_2$ (Tai et al. 2003). Subsequently, another one-pot procedure to prepare thioglycosides and glycosyl azides from unprotected sugars was developed (Kumar et al. 2006). The reaction



Scheme 1 One-pot full acetylation and subsequent synthesis of thioglycosides or glycosyl azides



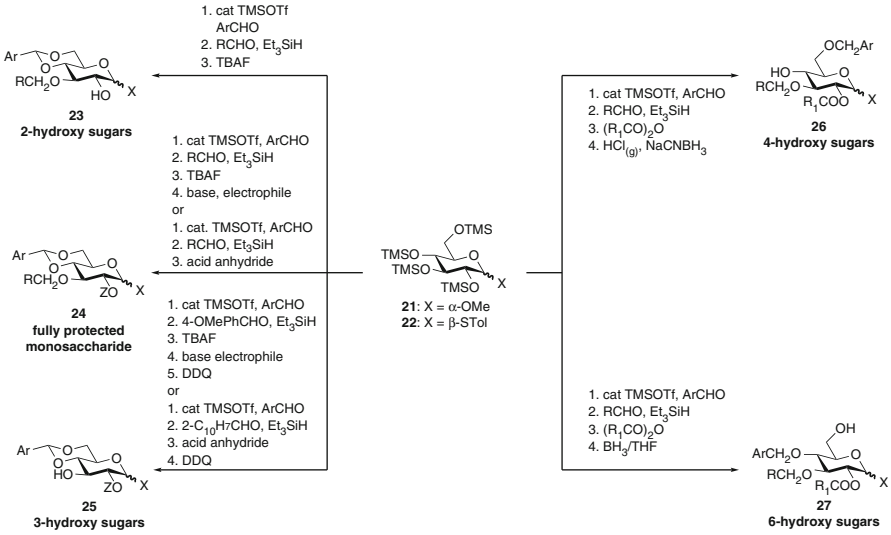
Scheme 2 One-pot tritylation/silylation/acetylation

proceeds under phase-transfer conditions using a stoichiometric amount of Ac_2O and 33 % HBr in AcOH: thioglycosides **4**, **6**, and **8** were obtained by further addition of *p*-thiocresol and $(nBu)_4NHSO_4$, while glycosyl azides **5**, **7**, and **9** were prepared by adding NaN_3 instead of *p*-thiocresol (Scheme 1).

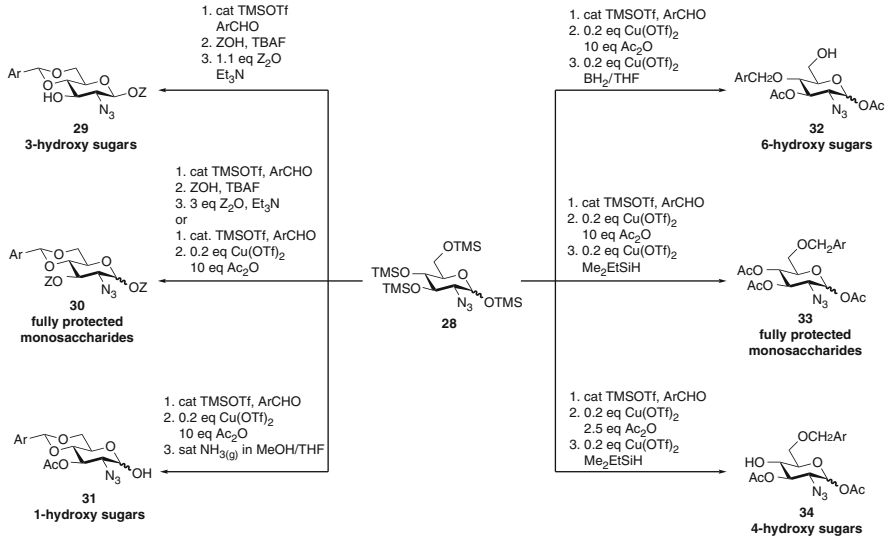
In order to prepare monosaccharides containing different and orthogonal protecting group, a one-pot tritylation/silylation/acylation sequence was employed (Scheme 2) by treatment with a catalytic amount of DMAP. Different results were obtained using methyl glycosides (**10**, **11**, **12**) or thioglycosides (**17**, **18**), but in all cases the fully protected monosaccharide was obtained in good yield (71–86 %) (Du et al. 2000).

Another possibility to obtain partially or fully protected glycosides is the combinatorial and regioselective one-pot protection. In this case the reaction is performed using 2,3,4,6-tetra-*O*-trimethylsilylated glucosides (α-Me-glucopyranoside **21** and β-*ρ*-tolylthioglucopyranoside **22**) (Wang et al. 2007, 2008). Starting from the fully silylated sugar, it is possible to follow five different routes to obtain 2-hydroxy sugars **23**, fully protected monosaccharides **24**, 3-hydroxy sugars **25**, 4-hydroxy sugars **26**, and 6-hydroxy sugars **27** (Scheme 3).

The same procedure can be also applied to the synthesis of fully protected monosaccharides (**30** and **33**) and 1-, 3-, 4-, 6-OH sugars (**31**, **29**, **34**,



Scheme 3 Synthesis of different orthogonally protected monosaccharide building blocks using combinatorial and regioselective one-pot protection



Scheme 4 Synthesis of different orthogonally protected glycosyl azide building blocks using combinatorial and regioselective one-pot protection

32, respectively) starting from 2-azido glucopyranoside **28** (Scheme 4) (Chang et al. 2010). The authors selected the azido group at C-2 because it can be converted into an *N*-acetyl or free amino group (found in different biologically important compounds) and it can control the stereoselective formation of the glycosidic bond.

2.2 Programmable One-Pot Oligosaccharide Synthesis

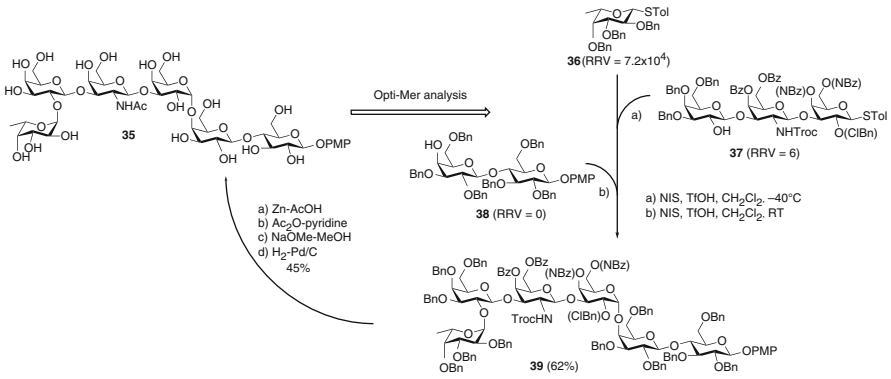
The one-pot glycosylation strategies enable the preparation of oligosaccharides without the isolation and purification of reaction intermediates that are time-consuming procedures typically affecting classical synthesis. For this purpose three different one-pot methodologies have been developed:

1. The chemoselective strategy: the less reactive donor is glycosylated with the more reactive activated donor providing a new glycoside that can act as a new donor itself (Raghavan and Kahne 1993; Ley and Priepke 1994; Yamada et al. 1994a).
2. The preactivation strategy: a donor is activated alone; then it is reacted with a second donor/acceptor with the same aglycon at the reducing end (Crich and Sun 1998; Codee et al. 2003; Huang et al. 2004).
3. The orthogonal strategy: a donor is selectively activated over another donor with different leaving group (Kanie et al. 1994; Yamada et al. 1994b).

Here we focus our attention on the first methodology, which in principle can become an automatic process.

The reactivity of the glycosyl donor and acceptor can be tuned by the manipulation of the protecting groups. The basic concept of the chemoselective glycosylation is that the product obtained using this strategy can be directly used in a subsequent glycosylation without modification of the aglycon at the reducing end. In 1990 the Fraser-Reid group developed the concept of "armed/disarmed" donor. Monosaccharides containing 2-*O*-ether protecting groups (armed) react preferentially than those with 2-*O*-ester group (disarmed) (Fraserreid et al. 1990). In 1998 the Ley research group developed a new concept, the "semi-disarmed" sugar. In this case the reactivity of the thioglycosyl donor is tuned by using a diacetal protecting group (Douglas et al. 1998).

The one-pot glycosylation proceeds starting from the nonreducing end to the reducing one. The first donor used is the most reactive one, while the last one is the less reactive. To design an ideal one-pot glycosylation, it is important to know the "relative reactivity" of a variety of glycosides. In 1999 Wong and coworkers performed a competitive HPLC experiment in order to obtain informations on the reactivity of different glycosyl donors (Zhang et al. 1999). The study was carried out using STol glycosides (easy to prepare) for their intrinsic characteristics, such as stability during protecting groups manipulations and the possibility to study the reactivity via HPLC due to the presence of an aromatic ring. The relative reactivity values (RRVs) for each thioglycosyl donor were obtained by comparison of peracetylated tolylthiomannoside (RRV = 1.0). In particular, high values of RRV represent donors with high reactivity. The authors revealed interesting trends in the reactivity of thioglycoside donors, in particular: (1) pyranosides show reactivities that differ as a function of the sugar (fucose > galactose > mannose > glucose > sialic acid), (2) the reactivity of amino sugars can be tuned by the *N*-protecting groups (NHCbz > NHTroc > NHPhth > N_3 > NHAc), (3) the protecting groups



Scheme 5 Programmable one-pot synthesis of Globo H antigen via [1 + 3 + 2] protocol using the OptiMer analysis

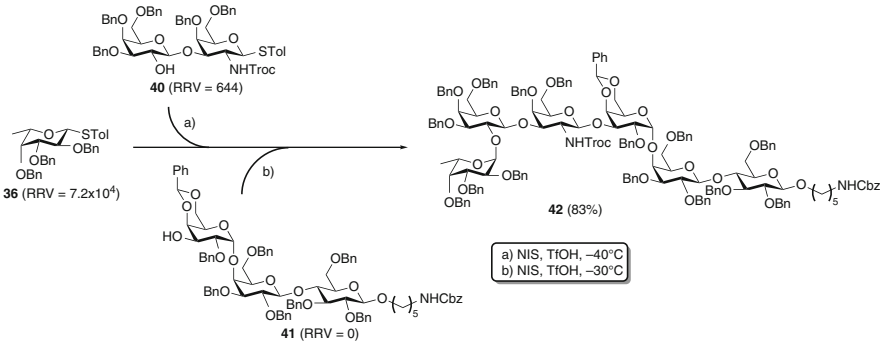
greatly influence the reactivity properties (in particular the substitution at C-2 plays a significant role), (4) the position that mostly affects pyranosides reactivity is not always the same for all sugars, (5) the magnitude of any protecting group reactivity effect is influenced by its position on the pyranoside, and (6) influence of leaving group like steric effects (the reactivity of the glycosyl donor can be tuned by changing the size of its leaving group) and electronic effects. In addition, it was found that, for each sugar, conformational effects (torsional effects) and solvent effects may be crucial to determine the RRVs.

The results of this study led to a computer database (OptiMer) in which RRVs of many donors and donors/acceptors are reported. Starting from the structure of the target oligosaccharide, the computer generates the best combination of building blocks for its preparation. Using this program/database, it is possible to prepare oligosaccharides containing three to six monosaccharides in minutes or hours, without isolation and purification of the intermediates.

An example is the synthesis of the Globo H hexasaccharide **35**, a carbohydrate antigen occurring in many epithelial tumors. The analysis of the oligosaccharide by the OptiMer program showed that the synthesis can be performed using three building blocks (**36**, **37**, **38**), tuning the different reactivity by electron-donating and electron-withdrawing groups (Scheme 5) (Burkhart et al. 2001).

The trisaccharide donor/acceptor **37** can be prepared by one-pot glycosylation. The glycosylation between the fucosyl donor **36** and the trisaccharide **37** and the subsequent glycosylation with the disaccharide acceptor **38** promoted by NIS/TfOH system provided the fully protected hexasaccharide **39** in 62 % yield that after deprotection led to the desired Globo H antigen **35**. The same authors developed another approach for the one-pot synthesis of Globo H hexasaccharide (Huang et al. 2006). In this case the synthetic strategy is based on [1 + 2 + 3] one-pot synthesis (Scheme 6). The challenging Galα(1 → 4)Gal bond was formed in a previous preparation.

Using this approach the fully protected hexasaccharide **42**, precursor of Globo H antigen, was obtained in 82 % yield. The trisaccharide building block **41**, bearing a



Scheme 6 Programmable one-pot synthesis of Globo H hexasaccharide via [1 + 2 + 3] protocol. Conditions: (**a**) NIS, TfOH, −40 °C and (**b**) NIS, TfOH, −30 °C

proper linker, is a valuable building block for the synthesis of a set of truncated Globo H sequences, used for the fluorescent-based binding analysis of the two monoclonal antibodies VK9 and Mbr1 and the identification of the optimal structure for the development of vaccines.

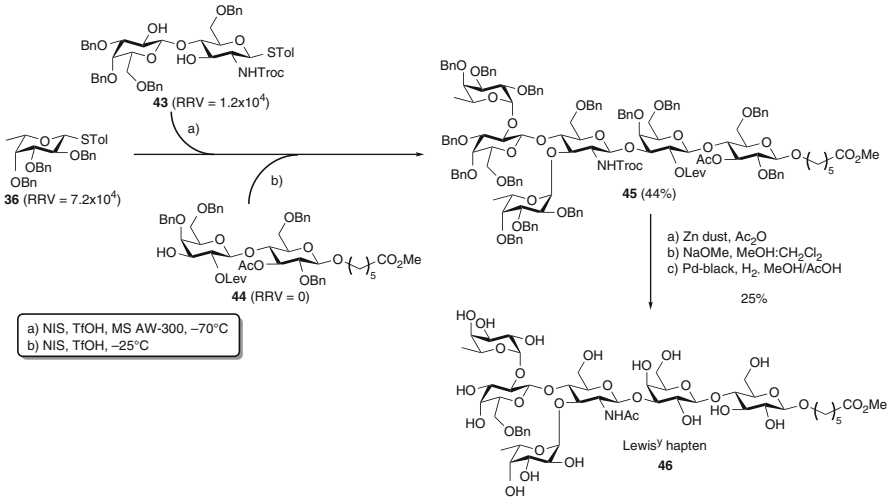
Based on the high reactivity of the fucosyl donor **36** used in the synthesis of Globo H fragment, Wong and coworkers developed another one-pot synthesis of fucose-containing oligosaccharides. In particular they synthesized the Lewis^y hapten **46**, a carbohydrate antigen expressed on the surface of many carcinoma cells. With the OptiMer analysis, three building blocks have been identified for the hexasaccharide synthesis (Scheme 7) (Mong and Wong 2002).

Also in this case the one-pot synthesis was performed using the NIS/TfOH system as a promoter. The first glycosylation was carried out at −70 °C in order to obtain the α glycosidic bond, while the second reaction was performed at −25 °C to facilitate the coupling between the two large and less reactive sugars. The hexasaccharide **45** was obtained in 44 % yield (81 % per glycosylation).

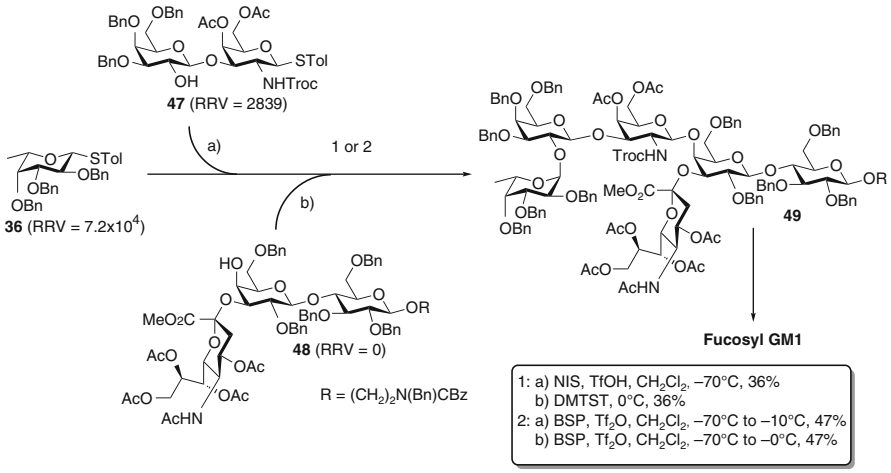
Although the NIS/TfOH system is used to promote the programmable one-pot glycosylation of thioglycosyl donors, in some cases, the succinimide generated by a stoichiometric amount of NIS can compete in the subsequent glycosylation. To overcome this problem, Crich and Smith used the reagent system 1-(benzensulfinyl) piperidine/trifluoromethanesulfonic anhydride (BSP/Tf_2O). The applicability of this reagent mixture was confirmed in the one-pot synthesis of fucosyl-GM1 **49** (Scheme 8), a tumor marker for small-cell lung cancer (Mong et al. 2003; Lee et al. 2006a).

Using the BSP/Tf_2O system, the overall yield increased from 13 % to 22 % and the reaction time decreased from 1 day to 5 h. This promoter system was also applied to the one-pot synthesis of the tumor-associated antigen N3 octasaccharide **52** (Scheme 9) (Lee et al. 2006b).

The one-pot oligosaccharide synthesis was then used for the preparation of oligomannoses, precursors of antigens recognized by 2G12, a human monoclonal antibody (mAb) specific for the oligomannose residues present on gp120



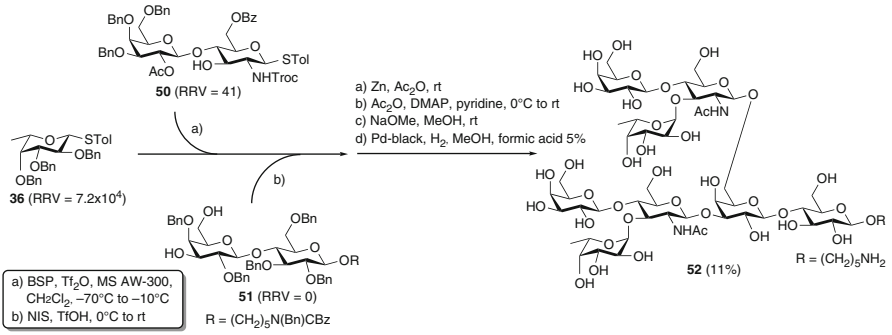
Scheme 7 Programmable one-pot synthesis of Lewis^y hapten



Scheme 8 Programmable one-pot synthesis of fucosyl-GM1 and comparison of NIS/TfOH and DMTST route and BSP/Tf_2O strategy

(the surface glycoprotein of HIV-1 virus) (Lee et al. 2004). On the basis of binding study between 2G12 and gp120, Wong and coworkers synthesized five different oligomannose structures **53**–**57** (Fig. 1) using the one-pot synthesis and a minimal number of building blocks.

The dimannose **59** and trimannose **60** structures, precursors of compounds **53**–**57**, were synthesized using a novel one-pot methodology based on the self-condensation of a mannosyl donor/acceptor (Scheme 10). The authors obtained



Scheme 9 Programmable one-pot synthesis of N3 antigen

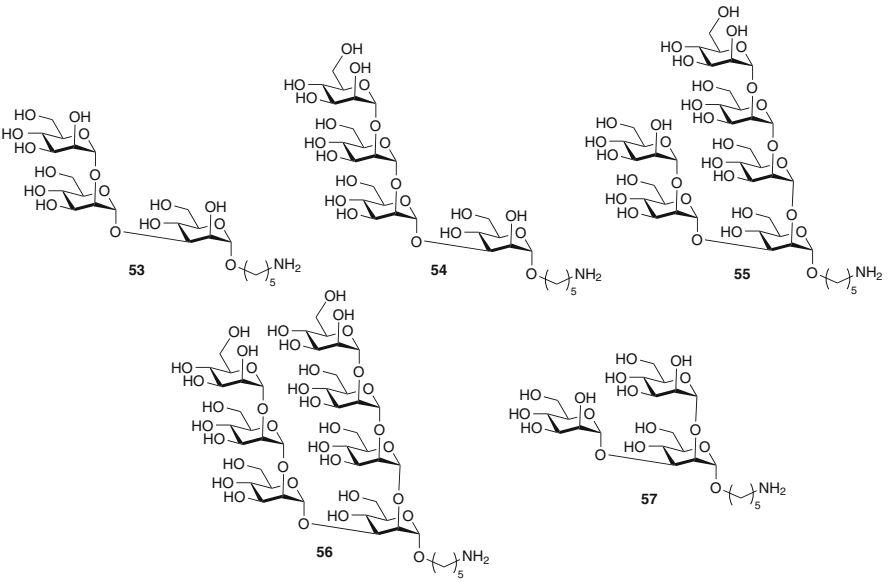


Fig. 1 Structures of oligomannose targets A–E

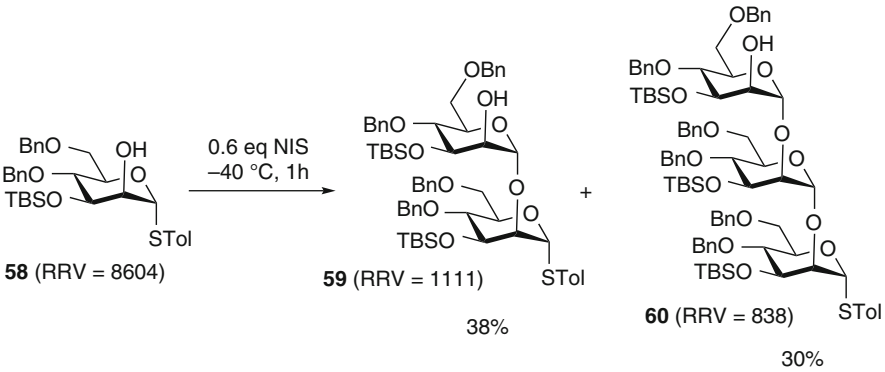
disaccharide **59** in 38 % yield and trisaccharide **60** in 30 % yield. As expected by RRV values, the most reactive monosaccharide provided the less reactive disaccharide by self-condensation, which could react with another monosaccharide providing the trimer. With the three donors in hand (mono-, di-, and trisaccharide), compounds **53**–**57** were prepared using a mannosyl acceptor bearing a suitable linker. Next the inhibition in the interaction between 2G12 and gp120 was studied using **53**–**57**. Compounds **53** and **57** were the less active, while **54** and **55** showed the highest inhibition values (79 % inhibition at 2.0 nM). Surprisingly, the heptamannose **56** showed a low value of inhibition, probably due to a nonoptimal conformation for 2G12 recognition.

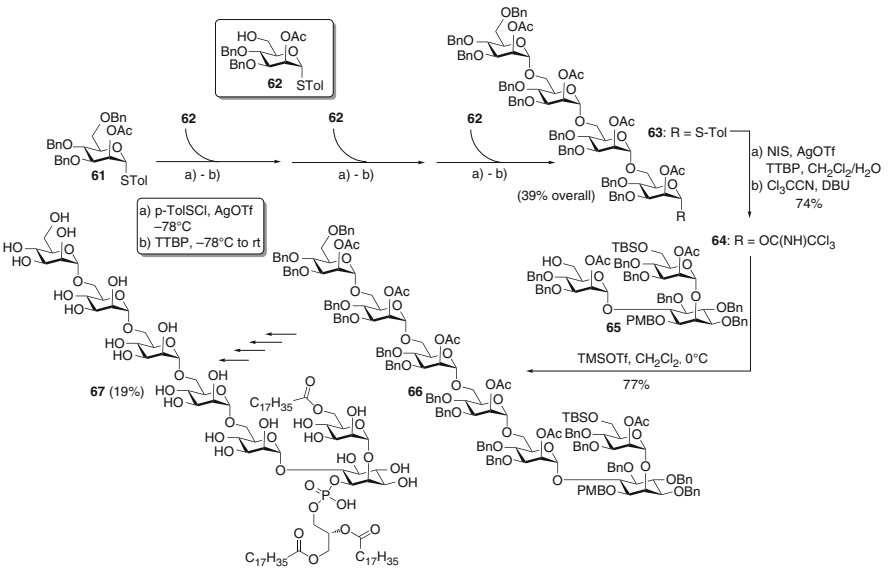


Scheme 10 One-pot self-condensation of mannosyl donor/acceptor

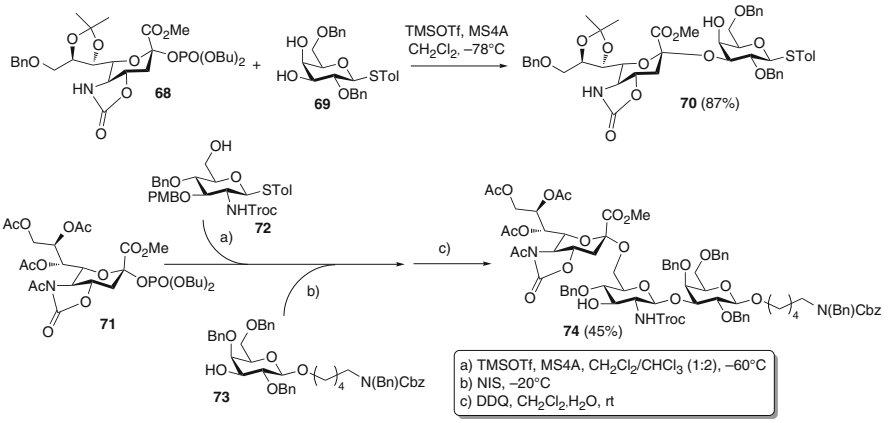
More recently, the synthesis of a lipomannan (LM), suitable for vaccine formulation, was developed using a convergent and efficient methodology (Gao and Guo 2013). Lipomannans (LMs), together with lipoarabinomannans (LAMs), are the major virulent factors of *Mycobacterium tuberculosis* (*Mtb*), the pathogen causing tuberculosis (TB), one of the most life-threatening diseases worldwide (more than two million deaths per year). The LM synthesized in this work is composed by a tetramannose residue and a trisaccharide containing a *myo*inositol derivative **67** (Scheme 11). The one-pot synthesis of the tetramannose building block **63** was carried out using thioglycoside monosaccharides. Each donor was preactivated with *p*-TolSOTf (generated from *p*-TolSCl and AgOTf) at −78 °C; then the glycosylation was performed by addition of 2,4,6-tri-*tert*-butylpyridine (TTBP) as a scavenger for TMSOTf generated during the reaction. Tetramannose **63** was obtained in 39 % overall yield (73 % for each glycosylation step) in a total time of 6 h. Due to the low reactivity of the tetramannose thioglycoside **63**, this compound was first converted into trichloroacetimidate **64** and then coupled with the trisaccharide acceptor **65** providing the fully protected LM precursor **66** in 77 % yield. The desired LM compound **67** was obtained after deprotection and derivatization, and its structure was confirmed by NMR and MALDI-TOF analysis. Starting from the fully protected intermediate **66**, it is possible to regioselectively introduce a proper linker in order to prepare LM-based vaccine by conjugation with carrier protein or other scaffolds.

In 2013 Wong and coworkers reported an elegant synthesis of the RM2 antigen, a glycosphingolipid (GSL) occurring in renal cell carcinoma (cell line TOS-1), and prostate cancer cell lines LNCap and PC-3 (Chuang et al. 2013). The authors developed a [1 + 2 + 3] one-pot synthesis of the hexasaccharide precursor. Initially, the disaccharide donor/acceptor **70** was synthesized using a regioselective glycosylation and the trisaccharide acceptor **74** was prepared itself by a one-pot strategy (Scheme 12).

Next an orthogonal [1 + 2 + 3] glycosylation allowed to obtain the desired hexasaccharide **76** in 32 % overall yield in a total time of 23 h (Scheme 13).

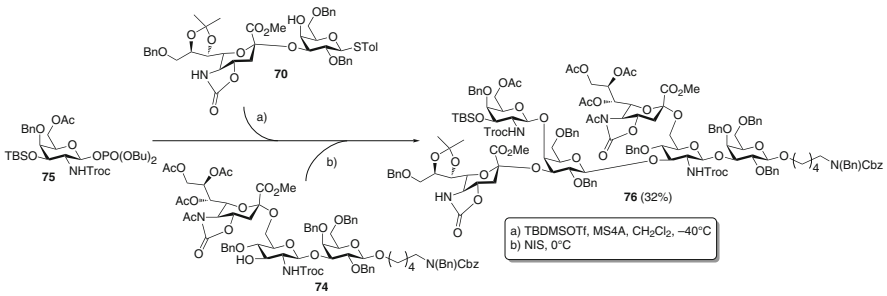


Scheme 11 One-pot synthesis of tetramannose and subsequent synthesis of *Mtb* lipomannan



Scheme 12 Regioselective synthesis of the disaccharide donor/acceptor and one-pot synthesis of the trisaccharide acceptor

Together with the hexasaccharide **76**, the authors also synthesized a panel of fragments of RM2 antigen. The deprotection of these compounds followed by the conjugation to a carrier protein (nontoxic cross-reactive material of diphtheria toxin, CRM_{197}) allowed to study the activity as vaccine. The biological tests were performed by immunization of mice with 2 μg of glycoconjugate together with 2 μg



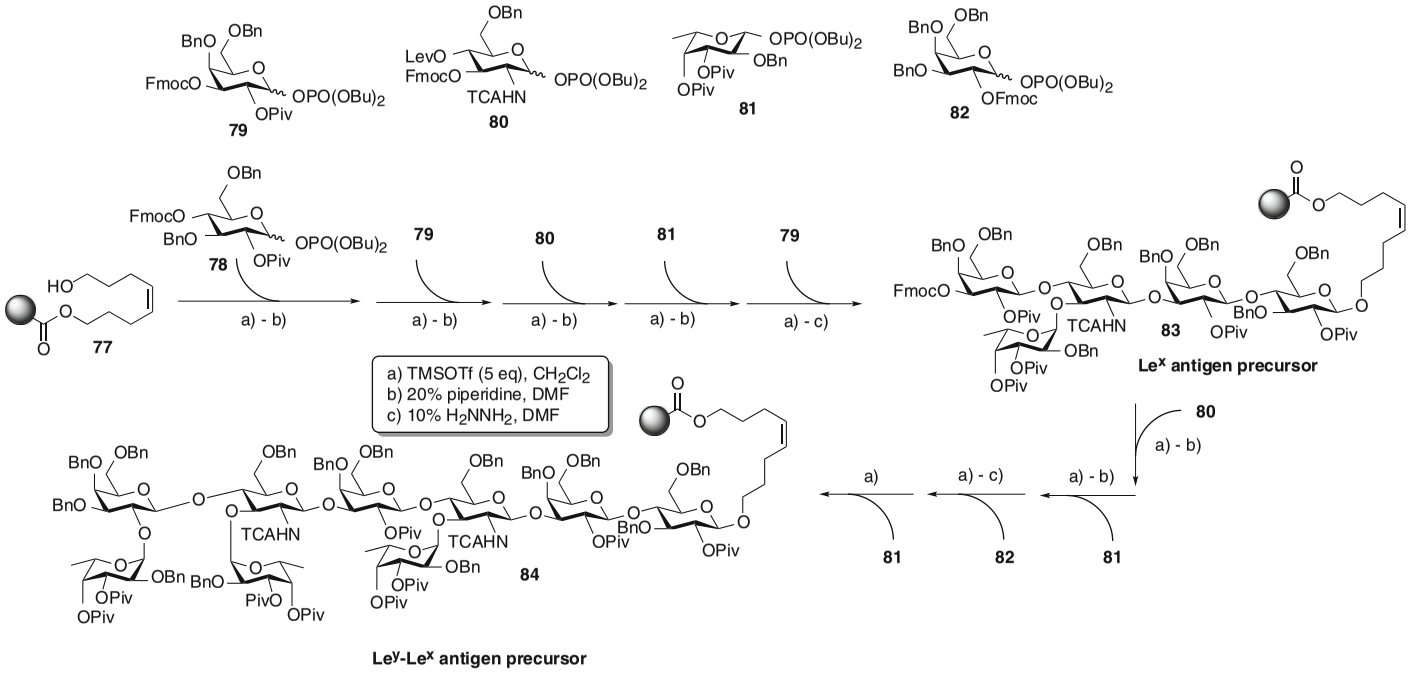
Scheme 13 One-pot [1 + 2 + 3] synthesis of hexasaccharide precursor of RM2 antigen

of adjuvant: the vaccination was carried out by giving three doses at 2-week intervals. After 2 weeks from the last injection, the sera were collected and analyzed with glycan microarray. The authors observed that the anti-RM2 IgG titers increased as vaccination proceeded: in particular the best results were obtained when glycolipid C34 (an α-galactosylceramide derivative) was used as adjuvant. In addition, the strongest anti-RM2 antigen titers were obtained with an antigen/protein ratio of 4.7 (CRM_{197}-$RM_{4.7}$), using the hexasaccharide RM2 as antigen (Chuang et al. 2013).

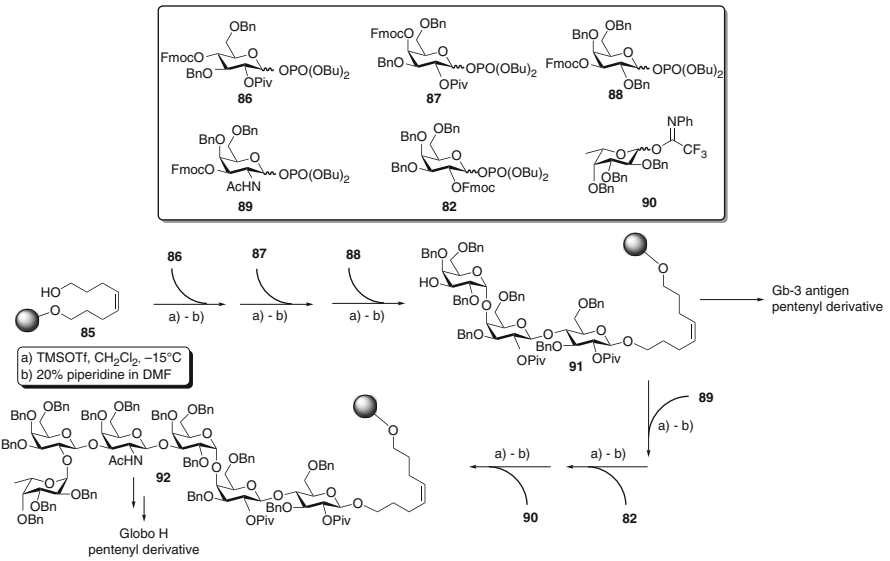
2.3 Solid-Phase Oligosaccharide Synthesis

Together with the programmable one-pot synthesis and other methodologies for the preparation of oligosaccharides (like fluorous-tag assisted solution-phase synthesis (Jaipuri and Pohl 2008)), the solid-phase oligosaccharide synthesis (SPOS) is another approach developed during the last years. SPOS offers two main advantages: (1) only a single purification by chromatography is needed in most cases at the end of the synthesis and (2) unwanted reagents and side products can be easily removed by washing and filtering. Due to the significant improvements in carbohydrate chemistry, during the past decade, there has been a great development of solid-phase oligosaccharide synthesis, confirmed by the numerous contributions reported in the literature (Seeberger and Haase 2000; Seeberger 2001; Danishefsky et al. 1993; Randolph et al. 1995; Rademann and Schmidt 1996; Roussel et al. 2000; Jonke et al. 2006; Nicolaou et al. 1997, 1998). In particular, an automated oligosaccharide synthesizer was developed by Seeberger and coworkers by modification of a peptide synthesizer (Plante et al. 2001; Seeberger 2008) and employed for the synthesis of the nonasaccharide of Le^y-Le^x (KH-1) antigen derivative **84** (Scheme 14) (Love and Seeberger 2004).

With a careful choice of the leaving group (glycosyl phosphates) and orthogonal protecting groups (permanent and temporary like Fmoc and Lev), the authors synthesized the nonasaccharide precursor **84**. The general strategy can be rationalized as follows:



Scheme 14 Automated solid-phase synthesis of Le^x and Le^y-Le^x precursors



Scheme 15 Automated solid-phase synthesis of Gb-3 and Globo H antigens

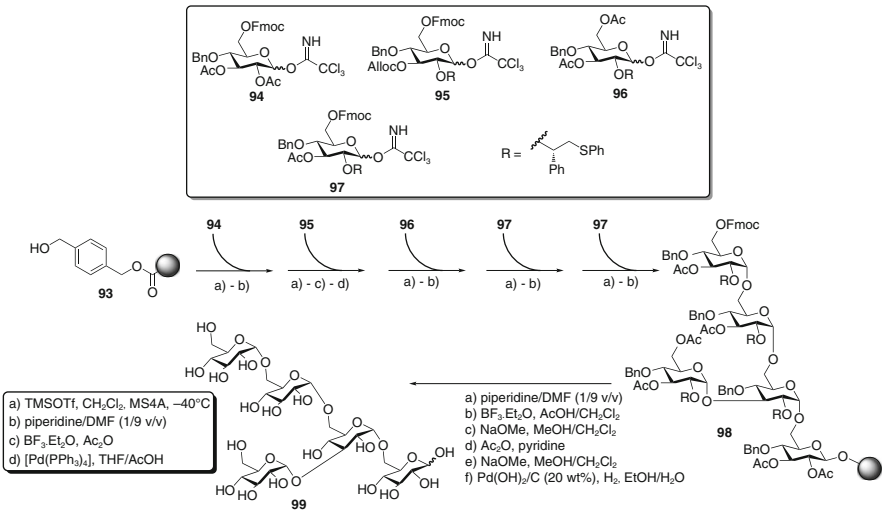
1. Coupling using TMSOTf (5 eq) as a promoter: the glycosyl phosphate was added twice to drive the reaction to completion.
2. Deprotection of the temporary group: Fmoc was removed by treatment with 20 % piperidine in DMF, while Lev was selectively removed using 10 % hydrazine in DMF.
3. Release of the oligosaccharide from the resin using sodium methoxide.

After purification by HPLC, the nonasaccharide was obtained in 6.5 % overall yield in a total time of 23 h. Using this strategy it is also possible to synthesize the Le^x antigen **83**.

Another application of the automated solid-phase oligosaccharide synthesis is the preparation of the tumor-associated carbohydrate antigens Gb-3 and Globo H by Seeberger group (Scheme 15) (Werz et al. 2007b).

In a total time of 12 h, the fully protected Gb-3 antigen was obtained in 46 % overall yield (after cleavage from the solid support and purification by chromatography), while the synthesis of the fully protected Globo H antigen required 23 h (30 % overall yield).

A significant challenge in SPOS is the formation of 1,2-*cis*-glycosides. Different progresses have been achieved in the synthesis of α-galactosidic (Gb-3 and Globo H SPOS) and β-mannosidic linkages (Codee et al. 2008). In 2010 Boons and coworkers developed a 1,2-*cis*-glycosylation strategy driven by the protection at C-2 with a chiral auxiliary (Scheme 16) (Boltje et al. 2010). Using *(S)*-(phenylthiomethyl)benzyl chiral auxiliary as a protecting group at position 2 of the glycosyl donor, the glycosylation proceeds via a trans decalin ring



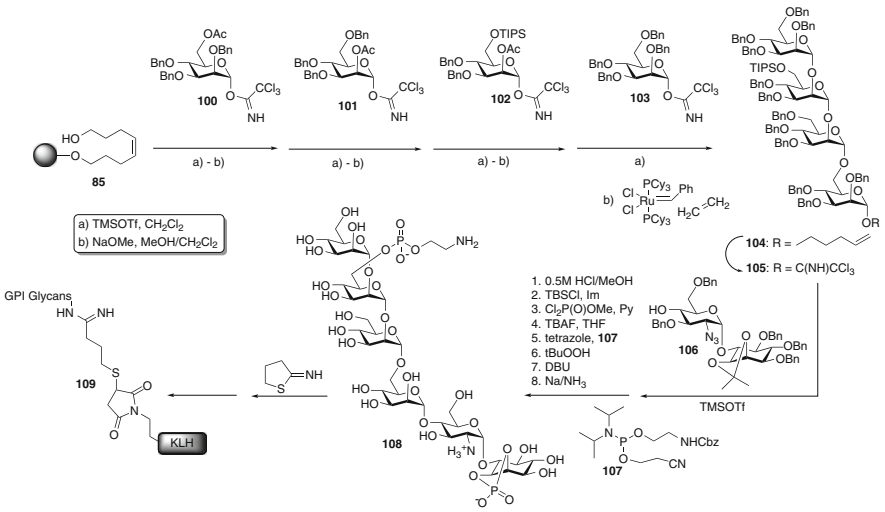
Scheme 16 Stereoselective solid-phase synthesis of tetraglucose residue

intermediate (equatorial sulfonium ion) allowing the stereoselective formation of 1,2-*cis*-glycosidic bond. In particular, with this procedure, the authors were able to synthesize a branched pentasaccharide **99** with different 1,2-*cis*-glycosidic linkages in 13 % overall yield (corresponding to 86 % yield per step). Another advantage of the chiral protecting group is that it can be converted into an acyl group on the solid support under conditions compatible with the removal of the temporary groups.

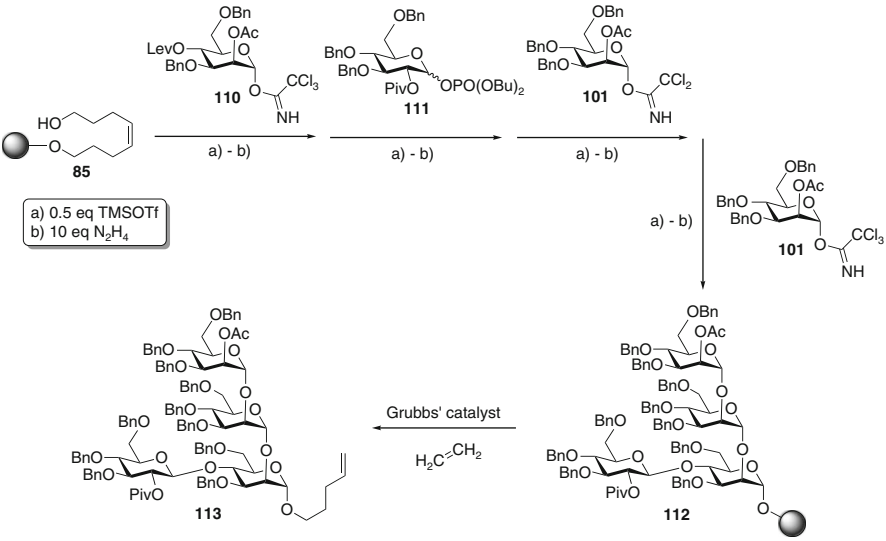
The solid-phase oligosaccharide synthesis was also employed for the synthesis of the *Plasmodium falciparum* glycosylphosphatidylinositol (GPI). This protozoan parasite is responsible for 95 % of the malaria deaths worldwide. Seeberger and coworkers synthesized the tetramannose **104** precursor of the hexasaccharide **108** (Scheme 17), which was then converted into the conjugate **109** by the treatment with maleimide-activated keyhole limpet hemocyanin (KLH) (Schofield et al. 2002).

The conjugate **109** was administrated to mice. The authors observed significant protection against the parasite-induced pathology (malarial acidosis, pulmonary edema, cerebral syndrome).

In 2001 Seeberger and coworkers reported the automated solid-phase synthesis of the branched *Leishmania* cap tetrasaccharide (Scheme 18) (Hewitt and Seeberger 2001). *Leishmania* parasites cause the leishmaniasis, a tropical disease affecting over 12 million people worldwide. The lipophosphoglycan (LPG) antigen of the parasite is composed of a GPI anchor, a repeating phosphorylated disaccharide, and an oligosaccharide cap. Previous promising immunological studies indicated the cap tetrasaccharide as an attractive vaccine target. The automated SPOS was performed using both glycosyl trichloroacetimidates (**110** and **101**) and the glycosyl phosphate **111** as donors with different esters as temporary protecting groups. The desired tetrasaccharide **112** was synthesized using three monosaccharide building



Scheme 17 Automated solid-phase synthesis of tetramannose residue and subsequent solution-phase synthesis of *P. falciparum* GPI-base malaria conjugate vaccine



Scheme 18 Automated solid-phase synthesis of *Leishmania* Cap tetrasaccharide pentenyl precursor

blocks (**101**, **110**, **111**) in a modified ABI 433A peptide synthesizer. After cleavage with the Grubbs catalyst and ethylene, the cap oligosaccharide **113** was obtained in 50 % yield (HPLC) in a total time of 9 h in the synthesizer and less than 4 days starting from the monosaccharide precursors.

3 Carbohydrate-Protein Conjugate Vaccines

As mentioned before, carbohydrate antigens could induce a strong, long-lasting, and protective immune response only after their transformation into T cell-dependent immunogens by conjugation of multiple copies of the saccharide antigen to the surface of a carrier protein (Lesinski and Westerink 2001; Weintraub 2003).

Carrier proteins must be nontoxic and non-reactogenic and should not share T cell epitopes with relevant capsular pathogens. Diphtheria toxoid (DT), CRM_{197}, keyhole limpet hemocyanin (KLH), tetanus toxoid (TT), recombinant exoprotein from *Pseudomonas aeruginosa* (rEPA), outer membrane protein from *N. meningitides* serogroup B (OMP), and more recently protein D derived from non-typable *H. influenzae* are among the most used proteins.

Commonly employed conjugation methods make use of chemoselective reactions between a suitable functional group available on the protein and another one on the carbohydrate moiety. Anchoring sites on the protein can be lateral amines (lysine residues), carboxylic acids (aspartic or glutamic acid), or sulfhydryls (cysteine). On the contrary, attachment sites on the carbohydrate portion can be the intrinsic carbonyl group at the reducing end or aldehyde groups inserted by random periodate oxidation of oligo- or polysaccharides. These random strategies however do not allow an accurate control of the conjugation reaction. Moreover, the precise structure of the carbohydrate portion eliciting the immune response cannot be established a priori, leading to low batch-to-batch reproducibility and difficult characterization of the products. The use of synthetic carbohydrates provided with a suitable linker ending with amino, carboxylic, sulfhydrylic, or olefinic groups ensures to preserve the structural integrity of the saccharide moiety. Examples of chemoselective conjugation of these functional groups are shown in Fig. 2 (Adamo et al. 2013). However, care must be taken in the choice of the linker. In particular, it has been shown that these moieties could be highly antigenic and therefore suppress antibody responses to weakly immunogenic saccharide antigens such as self-antigens (Buskas et al. 2004; Costantino et al. 2011).

Many well-known glycoconjugates employed for antibacterial vaccine formulation were synthesized, exploiting these approaches. For instance, vaccines against *H. influenzae* type b (PRP-TT, Sanofi-Pasteur) and *N. meningitidis* serogroup A (Menafrivac™) (Frasch et al. 2012) are approved and available on the market, whereas a 15-valent-CRM_{197} conjugate against *S. pneumoniae* from Merck and a 3-valent-CRM_{197} conjugate targeting Group B *Streptococcus* from Novartis are in advanced clinical trials. Other recent examples of glycoconjugates currently under study as vaccine candidates include the CRM_{197} conjugate of synthetic fragments of *Clostridium difficile* polysaccharide (Danieli et al. 2011; Adamo et al. 2012) and carba-analogues of *N. meningitidis* A capsular polysaccharide (Gao et al. 2012, 2013).

However, the conjugation chemistry still remains difficult to control, with random regio- and stereochemistry and unpredictable stoichiometry. Different methods have been recently developed in order to obtain well-defined

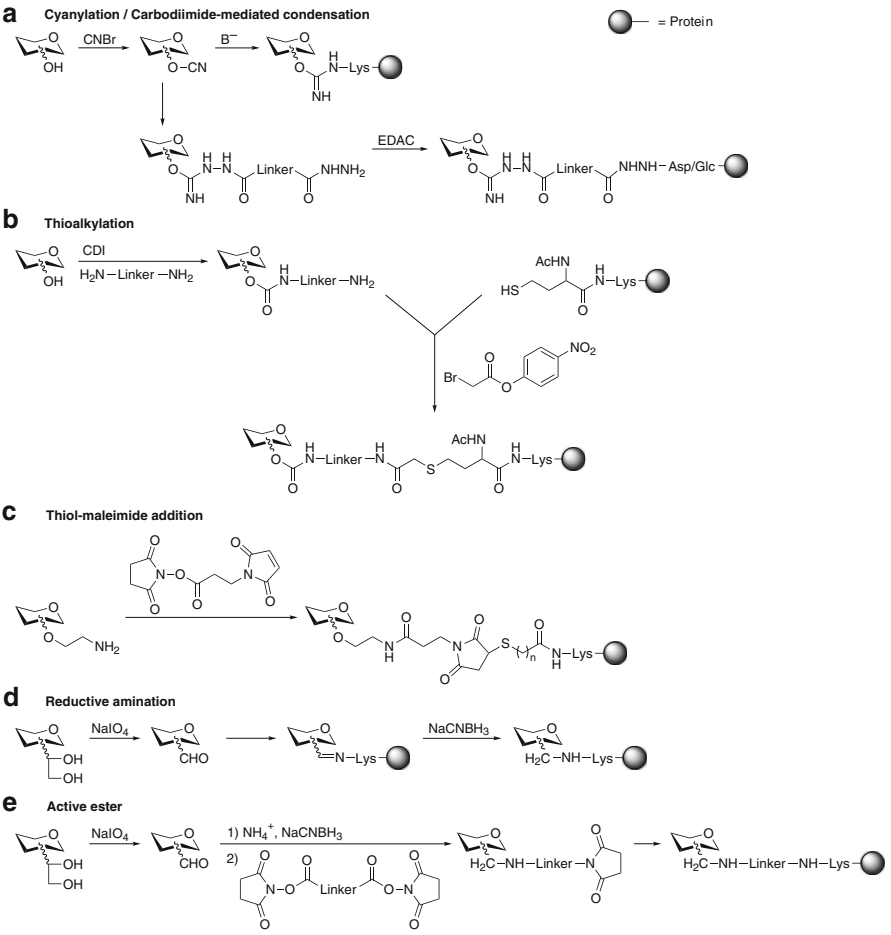


Fig. 2 Commonly employed strategies for the conjugation of carbohydrate antigens to carrier proteins

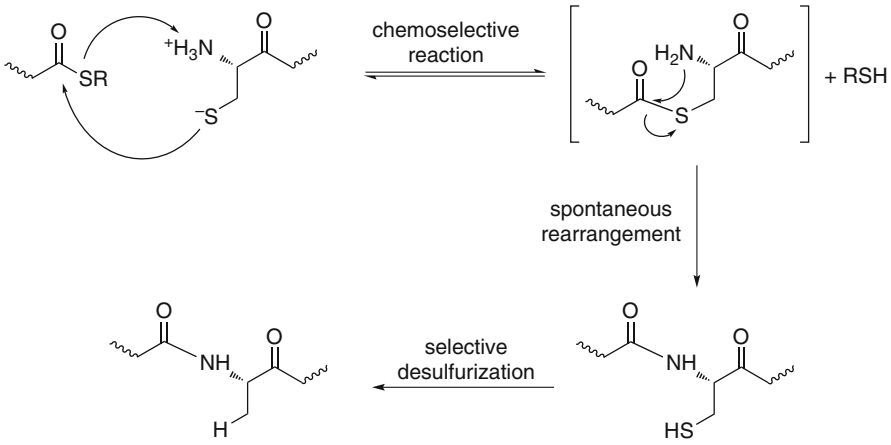
protein-carbohydrate conjugates. Among them, native chemical ligation, site-selective protein modification, and chemoenzymatic approaches are worthy of note (Adamo et al. 2013).

3.1 Native Chemical Ligation

Native chemical ligation (NCL) is a methodology that permits the construction of small proteins through the convergent chemoselective linkage of two unprotected peptide fragments: the first one containing a thioester as *C*-terminal residue and the



Scheme 19 Mechanism of the native chemical ligation

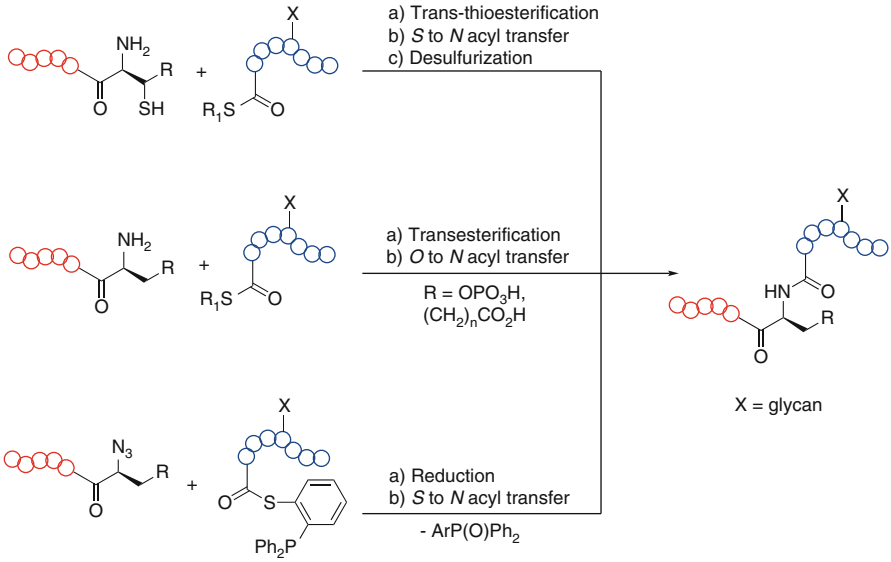
other one bearing a free cysteine at the *N*-terminus (Dawson et al. 1994; Schnolzer and Kent 1992). The reaction mechanism is shown in Scheme 19.

Unlike conventional strategies based on automated solid-phase peptide synthesis (SPPS), which usually rely on long linear reaction sequences and protecting group manipulations, the benefits arising from a convergent total synthesis approach that uses unprotected (glyco-)peptide fragments make NCL a leading methodology for the preparation of glycoconjugates.

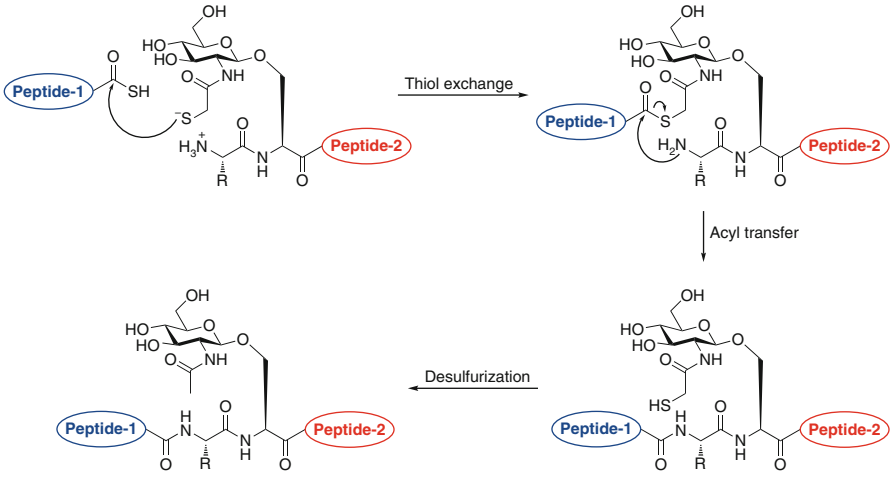
The first examples of NCL-mediated glycoprotein synthesis were reported in 2008 (Yamamoto et al. 2008; Becker et al. 2008). Firstly, a glycan was linked to an amino acid, followed by incorporation into a polypeptide by SPPS. Finally, the resulting glycopeptide chain was coupled via NCL with another peptide sequence, allowing for a fast and chemoselective chain elongation.

This protocol has been studied in detail, and many other types of chemical ligations have been reported in the literature (Payne and Wong 2010). Relevant examples are ligation involving thiol-free moieties such as phosphates (of phosphoserine or phosphothreonine), aspartate or glutamate residues (Thomas et al. 2011), and azides (Scheme 20) (Nilsson et al. 2003).

In addition, a protocol developed by Wong and coworkers, the so-called sugar-assisted chemical ligation, allows for a traceless ligation using thiol-containing glycosyl auxiliaries, which is particularly relevant for the preparation of glycopeptide fragments. It is based on the ligation promoted by β-2-(thioacetamide)-glucosamine-*O*-serine, β-2-(thioacetamide)-glucosamine-*O*-threonine, and β-2-(thioacetamide)-glucosamine-*N*-asparagine residues, which represent favored handles for subsequent (chemo)enzymatic attachment of more complex glycan epitopes for vaccine preparation (Scheme 21) (Brik et al. 2006).



Scheme 20 Different chemical ligation strategies



Scheme 21 Mechanism of the sugar-assisted chemical ligation

3.2 Site-Selective Protein Modification

A complementary protocol to the stepwise insertion of glycosylated amino acid building blocks in the early stages of NCL-like approaches is the site-selective protein modification.

The key aspect is the presence of a bioorthogonal functionality, commonly named "tag," at a specific point in the protein, that allows for a late-stage homogenous glycosylation (Chalker et al. 2011a; Gamblin et al. 2009). The tagging can be obtained either by site-selective protein modification or by selective protein tagging. The former approach involves site-specific chemical modification under mild conditions of natural residues, such as cysteine, its elimination product, and dehydroalanine, which are well suited for thiol-ene reaction and Michael addition (Bernardes et al. 2008; Lin et al. 2008; Chalker et al. 2011b). Even more interesting is the selective protein-tagging approach. This methodology relies on the insertion of nonnatural amino acids (UAAs) into proteins by genetically reprogramming the translation cascade in *E. coli*. Translation has a great intrinsic capacity to be adapted to accommodate new building blocks, since the relationship between the template (mRNA) and the product (polypeptide) is defined by the genetic code, which utilizes aminoacyl-tRNA adapters to establish the map between mRNA and the protein sequence.

The use of modified aminoacyl-tRNA thus led to the incorporation of UAAs in the expressed protein with excellent consistency (Liu and Schultz 2010). Some of the most representative examples include homoallylglycine for thiol-ene reactions (Floyd et al. 2009); *S*-allyl- or *Se*-allylselenocysteine for cross-metathesis reactions (Lin et al. 2008); azidohomoalanine, suitable for the well-known Cu(I)-catalyzed azide-alkyne cycloaddition (CuAAC) (Boutureira et al. 2010); Staudinger and traceless Staudinger ligations (Loka et al. 2010; Bernardes et al. 2011); and also recent strained alkyne-based Cu-free cycloaddition protocols (Agard et al. 2004). Other important transformations include the use of carbonyl handles, typically employed in oxime bond formation (Hudak et al. 2011); homopropargylglycine and other alkyne handles for CuAAC, thiol-yne reactions (Li et al. 2013); and Sonogashira as well as Suzuki cross-couplings with p-halophenylalanine tags (Fig. 3) (Spicer and Davis 2013).

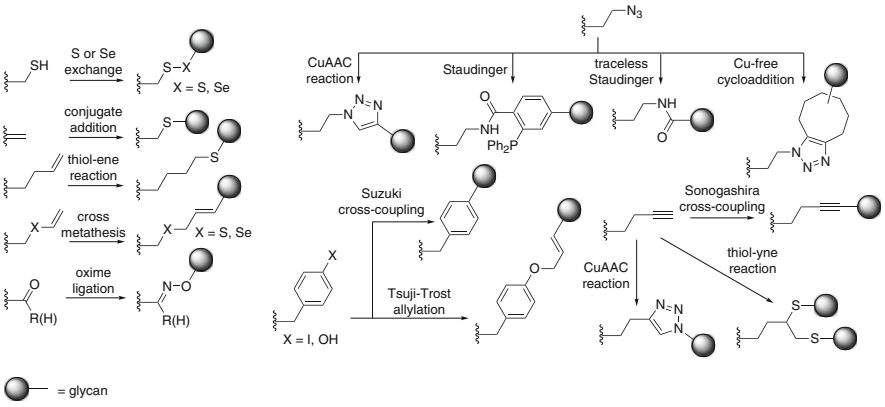


Fig. 3 Significant examples of selective protein-tagging techniques

Excellent orthogonality of different tags permits differentiation of the conjugation sites for multiple presentations of different antigens (van Kasteren et al. 2007).

If needed, the glycan pattern can be extended by sequential addition of further monosaccharide units using a chemoenzymatic approach based on endoglycosidases (Fernandez-Gonzalez et al. 2010).

3.3 Protein Glycan Coupling Technology

The discovery that some bacteria, such as *Campylobacter jejuni*, possess a *N*- or *O*-glycosylation machinery that can modify several proteins opened a new way towards selective glycoconjugation (Nothaft and Szymanski 2010). The key enzyme of this pathway was found to be an oligosaccharyltransferase (OST) named PglB, which demonstrated relaxed glycan specificity and the ability to transfer a number of polysaccharides to acceptor proteins containing the extended glycosylation sequence recognition pattern D/EYNXS/T (where X and Y are any amino acids except proline). When *E. coli* was genetically modified to express the general glycosylation locus, it was established, for the first time, that recombinant glycoproteins could be obtained (Wacker et al. 2002).

These findings were recently translated into a novel approach, named protein glycan coupling technology (PGCT), where selected glycans are coupled to target proteins using an *E. coli* recombinant system to produce an unlimited and readily purified supply of vast combinations of glycoconjugate vaccine candidates. Moreover, in a more advanced vision, both the glycan and protein syntheses could be triggered inside the *E. coli* host, avoiding the long multistep synthesis of the glycan and the need of manipulating pathogenic bacteria for protein isolation (Terra et al. 2012). To this end, the loci encoding the glycan and the target carrier protein (containing the appropriate consensus sequon; otherwise it can be directly engineered (Ihssen et al. 2010)) have to be cloned and expressed in *E. coli*, usually on a suitable plasmid. Finally, the coupling enzyme has to recognize the reducing end of the target glycan in order to transfer it to the protein (Fig. 4).

Although still in its infancy, PGCT is however a very promising technique. Striking examples concern glycoconjugate vaccine candidates obtained by conjugation of *Shigella dysenteriae* O antigen 1 to two different carrier proteins (Ihssen et al. 2010).

3.4 Peptides as T Cell Epitopes

In addition to the abovementioned problems, another important aspect should also be taken into account when designing glycoconjugate vaccines. Due to the presence of diverse T cell epitopes, carrier proteins are highly immunogenic and therefore elicit strong T cell responses, which can overcome that of the saccharide moiety (especially in the case of very short oligosaccharide fragments) causing hapten suppression (Herzenberg and Tokuhisa 1980). The use of a single peptide as a T cell

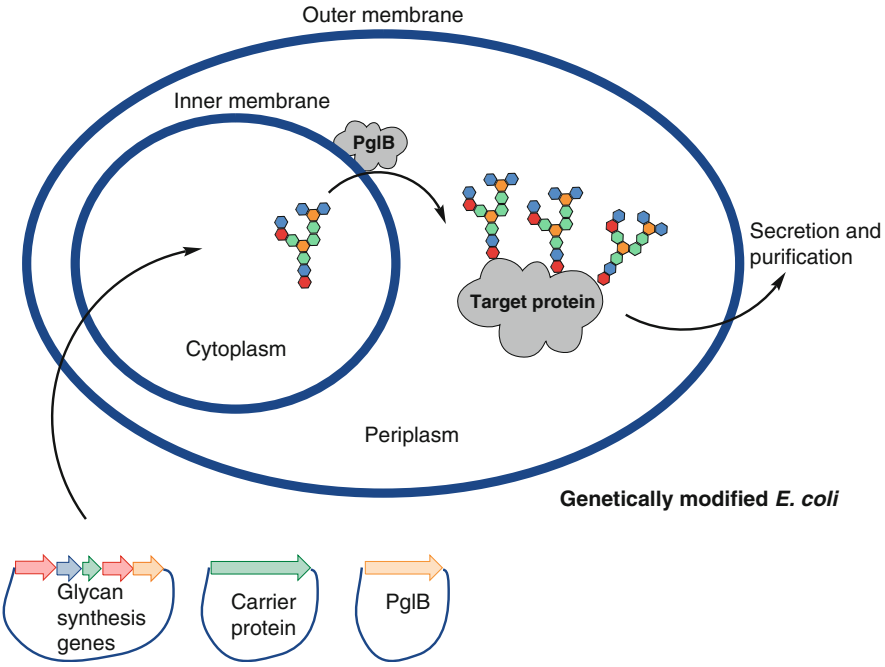

Fig. 4 Protein glycan coupling technology mechanism

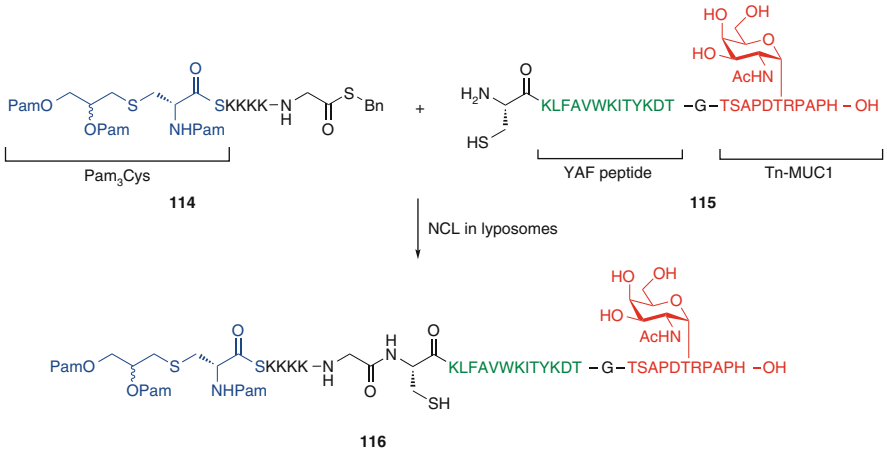
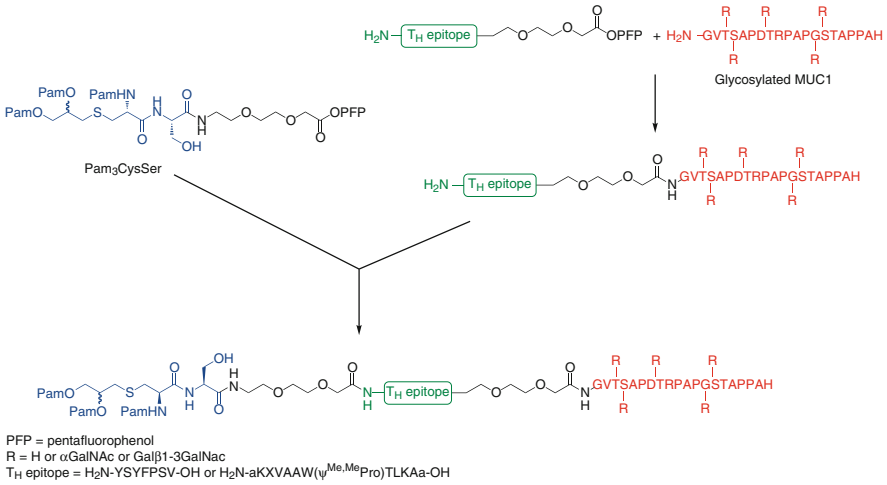
epitope should give rise to a more robust immune response, more specifically directed towards the carbohydrate antigen. To address this issue, over the last decade, a number of computer algorithms that map the locations of MHC-restricted T cell epitopes within proteins of various origins have been developed. As a result, it has been found that some sequence regions of protein antigens might sensitize CD4+ cells (Weber et al. 2009). This finding led to the identification of small and simple T_H peptide epitopes that are chemically defined, easily synthesized by SPPS, and able to generate effective helper T cell responses in humans. Among them, the Pan HLA DR-binding Epitope (PADRE), $OVA_{323–339}$ and YAF peptides, TT heptapeptide, and tridecapeptide from poliovirus are widely used (Panina-Bordignon et al. 1989; Diethelm-Okita et al. 1997, 2000).

Boons recently developed a tricomponent synthetic anticancer vaccine **116** incorporating the Tn antigen (αGalNAc) linked to YAF peptide and also containing the immunoadjuvant Pam_3Cys (Scheme 22) (Ingale et al. 2009).

Other two examples were reported by the Payne group (Wilkinson et al. 2011, 2012). Both are anticancer vaccines containing the Tn and TF (Galβ1-3GalNAc) antigens as carbohydrate epitopes, commonly overexpressed in cancer cells. In both vaccines the B cell epitope is linked to the T cell epitope, tetanus toxoid peptide (YSYFPSV) or PADRE, via an ethylene glycol spacer. The peptide *N*-terminus is connected via the same spacer to the Pam_3Cys moiety terminated with a serine residue. The three building blocks were assembled by means of a pentafluorophenyl



Scheme 22 Synthesis of tricomponent synthetic anticancer vaccine by NCL

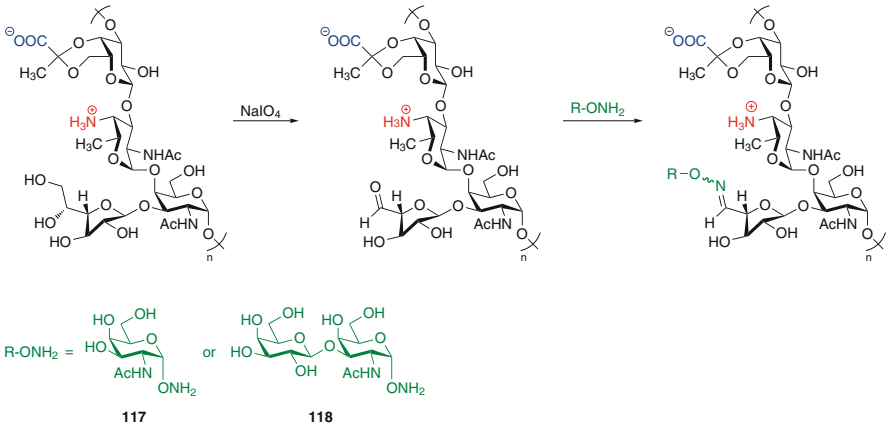


Scheme 23 Synthesis of the three-component anticancer vaccine candidates

ester-mediated condensation (Scheme 23). Mice immunization confirmed the strong adjuvant role of the $Pam_3CysSer$ and the superior immunogenicity of tricomponent vaccines compared to others lacking the T cell epitope.

3.5 Zwitterionic Polysaccharides

Zwitterionic polysaccharides (ZPS) are a class of structurally distinct bacterial polysaccharides that possess a zwitterionic charge motif distributed along the



Scheme 24 Synthesis of the TACA-PSA1 conjugates

chain, within the repeating unit. Typical examples are the Sp1 capsular polysaccharide from *S. pneumoniae* type 1 and capsular polysaccharides A1, A2, and B from *Bacteroides fragilis*. A number of recent reports described the ability of such compounds to behave like traditional T cell-dependent antigens, activating CD4+ T cells both in vitro and in vivo through the traditional MHC-dependent mechanism, without protein conjugation (Cobb and Kasper 2008; Surana and Kasper 2012; Avci et al. 2013; Bloem et al. 2013; Berti and Adamo 2013).

Due to their unique behavior, ZPSs are gaining attention as potential scaffolds for vaccine assembly, acting both as carrier and adjuvant. Andreana and coworkers recently reported the first two examples of entirely carbohydrate vaccine constructs containing the α-aminooxy derivatives of Tn and TF tumor-associated cancer antigens attached to PSA1 polysaccharide (**117** and **118**, Scheme 24) (De Silva et al. 2009, 2012; Bourgault et al. 2014). Immunization studies conducted on the Tn-PSA1 conjugate **117** showed the production of high titers of specific IgG antibodies, even in the absence of any external adjuvants.

4 Fully Synthetic Vaccines

The use of sugars as ligands for protein targeting (such as antibodies) is a challenging task because carbohydrate-protein interactions are typically weak, with dissociation constants in the mM range. In living cells, this issue is circumvented by multivalent receptor-ligand interactions, where multiple ligands interact simultaneously with multimeric receptors inducing an increase of the binding affinities of several orders of magnitude (multivalency effect). When this phenomenon is referred to carbohydrate-receptor interactions, it is commonly named "cluster glycoside effect" (Lundquist and Toone 2002).

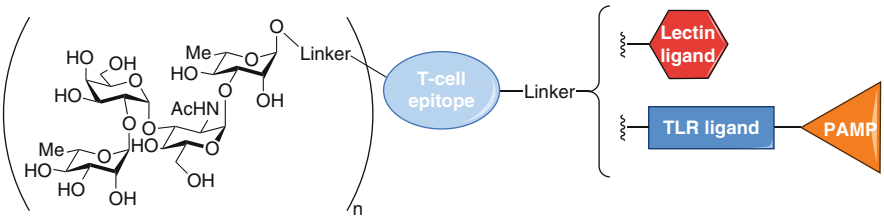


Fig. 5 Composition of fully synthetic vaccines

A major goal pursued by the vaccinology research is to reproduce the multivalency effect into fully synthetic systems using polyfunctional scaffolds capable of displaying multiple copies of carbohydrate antigens and that can be univocally characterized from a chemical point of view (mass and NMR spectroscopy). Under this point of view, the traditional glycoconjugate vaccines can be considered as an example of replication of the cluster glycoside effect, since they contain a large number of carbohydrate antigens exposed on the protein surface that are collectively much more immunogenic than the corresponding monovalent forms.

Fully synthetic vaccines are based on a modular architecture and incorporate into the same molecule different functional units: a synthetic glycan or a multivalent glycocluster, a synthetic T cell epitope, and an adjuvant, such as a ligand of TLR or C-type lectin receptor onto dendritic cell surface. Each of them is synthesized independently and then chemically conjugated in a convergent way, providing total control on the chemical structure (Fig. 5).

During the last years, a wide range of synthetic clustered glycosides has been designed to interfere in an array of biological processes. Among them, glycopeptides (Lee and Lee 1994; Krauss et al. 2007; Ohta et al. 2003; Pujol et al. 2011), glycodendrimers (Chabre and Roy 2010; Andre et al. 2001; Heidecke and Lindhorst 2007; Mintzer et al. 2012; Touaibia and Roy 2007; Turnbull and Stoddart 2002), glycopolymers (Kiessling et al. 2006; Bes et al. 2003; Otsuka et al. 2010; Ponader et al. 2012; Rieger et al. 2007), glyconanoparticles (Marradi et al. 2010; Wang et al. 2011), glycofullerenes (Cecioni et al. 2011; Nierengarten et al. 2010; Compain et al. 2010), glycocalixarenes (Dondoni and Marra 2010; Sansone et al. 2011; Baldini et al. 2007; Cecioni et al. 2009; Andre et al. 2011), and sugar-functionalized carbon nanotubes (Hong et al. 2010) and quantum dots (Kikkeri et al. 2010; Robinson et al. 2005; Yang et al. 2010) were shown to be efficient biomimetics of natural glycoclusters, often reaching low nM activities. This continuously growing topic is well covered by some recently published reviews (Bernardi et al. 2013; Galan et al. 2013; Marradi et al. 2013; Peri 2013; Shiao and Roy 2012; Blanco et al. 2013; Sansone and Casnati 2013). In the following sections, we will focus on systems with different architectures, specifically designed for vaccine developments.

4.1 Dendrimers

Dendrimers are repetitively branched molecules. The name comes from the Greek word δένδρον (dendron), which translates to "tree" (Astruc et al. 2010). Dendritic molecules are characterized by structural perfection: they are monodisperse and usually highly symmetric around the core, adopting a globular three-dimensional morphology. Dendritic molecules can be categorized into low-molecular weight and high-molecular weight species. The first class includes dendrimers and dendrons, while the latter comprises dendronized polymers, hyperbranched polymers, and polymer brushes. Dendrimers can be considered to have three major portions: a core, an inner shell, and an outer shell. In principle, a dendrimer can bear different functionalities in each of these portions to control properties such as solubility, thermal stability, and attachment of compounds for specific applications. Synthetic processes can also precisely control the size and number of branches on the dendrimer. Such molecules can be assembled following two different approaches. In the divergent method, the dendrimer is assembled from a multifunctional core, which is extended outward by a series of reactions. However, each step must be driven to completion in order to avoid mistakes in the dendrimer, which can cause trailing generations (some branches are shorter than others, Fig. 6a). On the other hand, in the convergent methods, dendrimers are built from

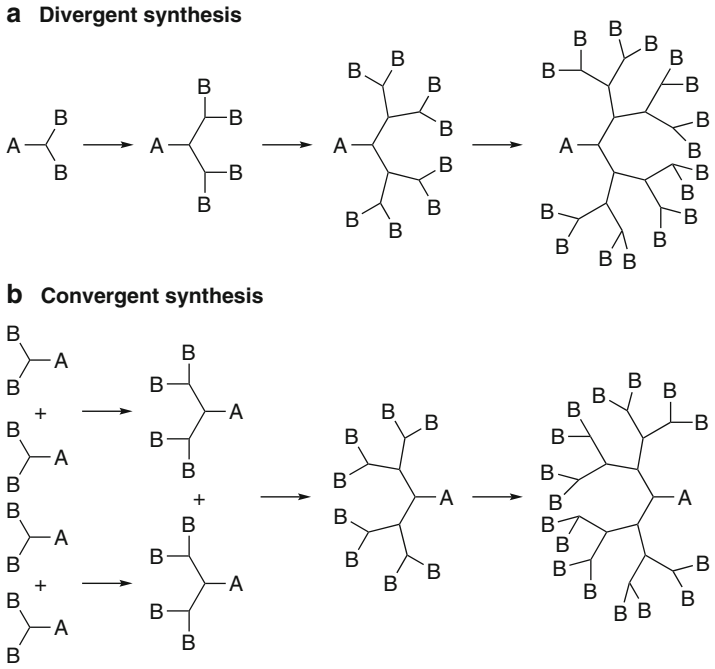

Fig. 6 Outline of convergent and divergent syntheses of dendrimers

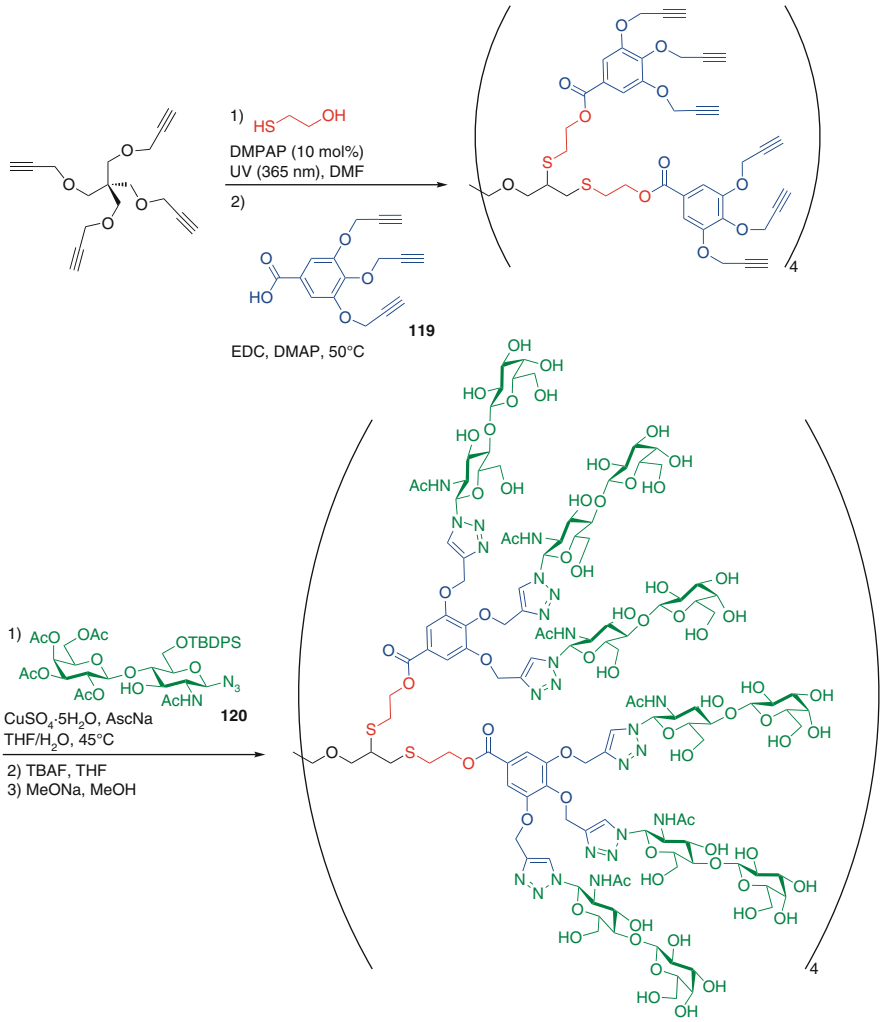
small molecules that end up at the surface of the sphere, and reactions proceed inward to the center core (Fig. 6b). This method makes it much easier to remove impurities and shorter branches. However dendrimers made this way cannot be as large as those made by divergent methods because of crowding due to steric effects around the core.

The possibility to incorporate a huge variety of building blocks containing orthogonal functional groups at each layer allows for the construction of original dendritic architectures that differ in terms of constitution, valency, and peripheral functionalities, exemplified by Roy et al. in a recent paper (Sharma et al. 2014). They proposed a new family of model glycoclusters and glycodendrimers, decorated with *N*-acetyllactosamine (LacNAc) termini, that can be assembled through a divergent original "onion peel strategy." High chemo- and regioselective photolytic thiol-ene coupling (TEC) and thiol-yne coupling (TYC) were used to rapidly and sequentially grow the dendritic architectures and to install a high degree of branching (Dondoni and Marra 2012; Gingras et al. 2013). Further branching (up to 36 valences) was added by EDC-mediated esterifications (or amidations) of polypropargylated dendrons (such as **119**), to which the LacNAc azide derivative **120** was attached by "click chemistry" (Scheme 25). As far as the biological relevance is concerned, LacNAc represents a part of the Lewis^x and Lewis^y tumor-associated carbohydrate antigens (Heimburg-Molinaro et al. 2011), and it is known to possess strong binding affinities towards galectins, a cancer-associated family of proteins (Zhou 2003; Liu and Rabinovich 2005; Salatino et al. 2008; Rabinovich and Toscano 2009). Therefore, a protein binding study was carried out with a model leguminous lectin from *Erythrina cristagalli* agglutinin (ECA). Interestingly, the glycodendrimers exhibited high relative potencies, with an up to 216-fold enhancement in global affinity with respect to the reference monomer.

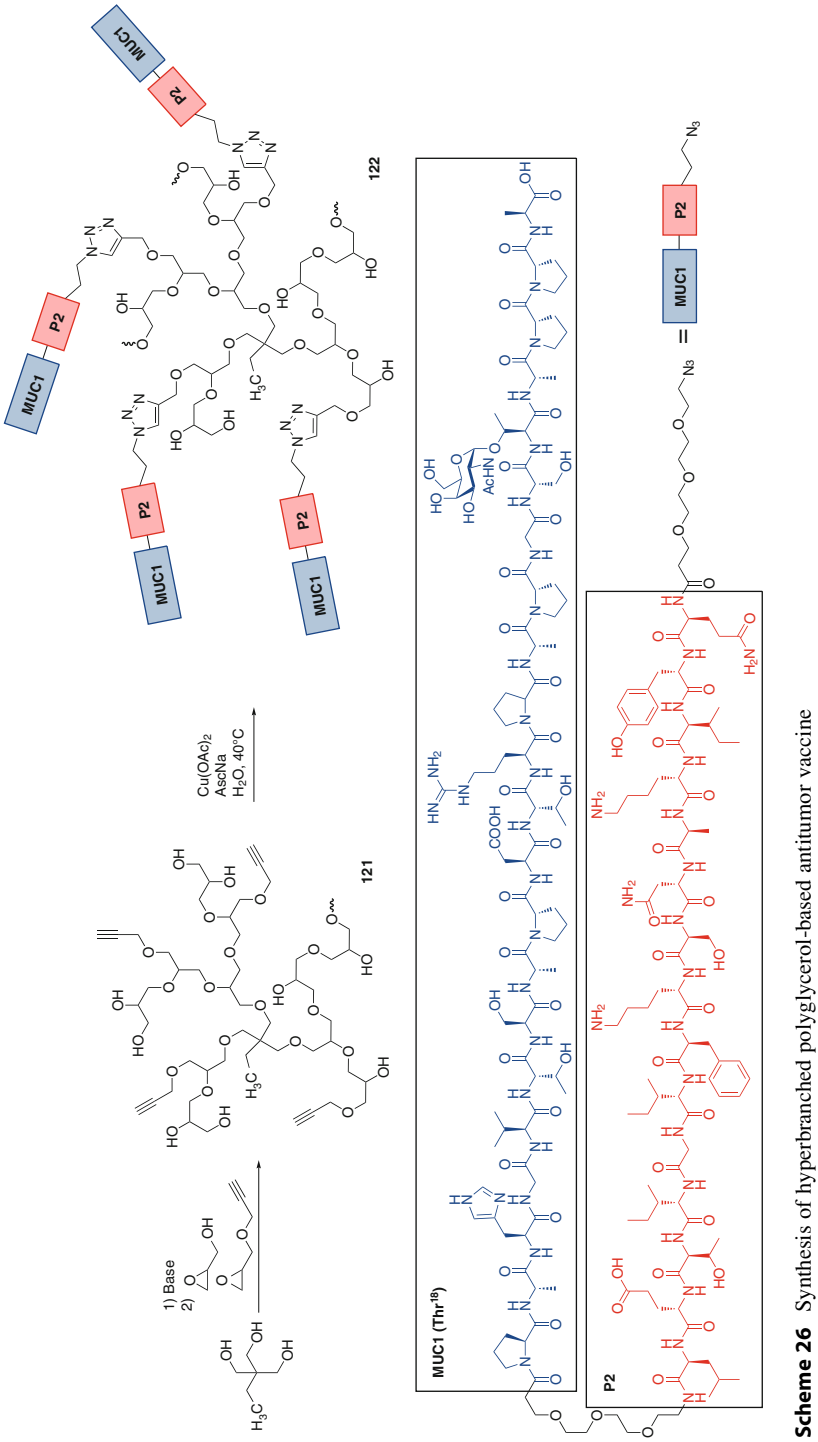
An example of the use of high-molecular weight species was reported by Kunz (Glaffig et al. 2014). The authors employed a water-soluble and readily available polymer, which is the multi-alkyne-functionalized hyperbranched polyglycerol (hbPG) **121**, obtained in a one-step copolymerization of glycidol and its propargyl ether. The scaffold presents a globular shape and a flexible dendrimer-like structure, which allows an optimal antigen presentation to the immune system. Moreover, polyglycerols are suitable as inert carriers for biomedical applications, as they are considered biocompatible and non-immunogenic. A tumor-associated MUC1 glycopeptide combined with the immunostimulating T cell epitope P2 from tetanus toxoid was coupled to the terminal alkyne groups by "click chemistry" (Scheme 26). MUC1 is a tumor-associated glycoprotein member of the mucins family, densely glycosylated high molecular weight proteins implicated in a variety of epithelial cancers. Typical TACAs of mucins include Tn, sTn (NeuAcα2-6GalNAc), and TF, α-*O*-glycosylated to serine/threonine residues in the peptide backbone (Heimburg-Molinaro et al. 2011; Pashov et al. 2011). The resulting construct **122** was shown to induce a strong immune response in mice, raising IgG antibodies able to recognize human breast cancer cells.



Scheme 25 Representative synthesis of LacNAc decorated "onion peel" dendritic structures via an accelerated divergent strategy

4.2 (Cyclo)peptide Scaffolds

Membrane-bound tumor-associated glycoproteins like MUC1 are known to be highly overexpressed on tumor cells. Therefore, they represent an attractive target for anticancer vaccine formulation (Pashov et al. 2011; Beatson et al. 2010). Over the years, considerable efforts have been devoted to the synthesis of glycopeptide assemblies that include either a carrier protein or T cell epitopes in order to induce stronger immunological responses.



Scheme 26 Synthesis of hyperbranched polyglycerol-based antitumor vaccine

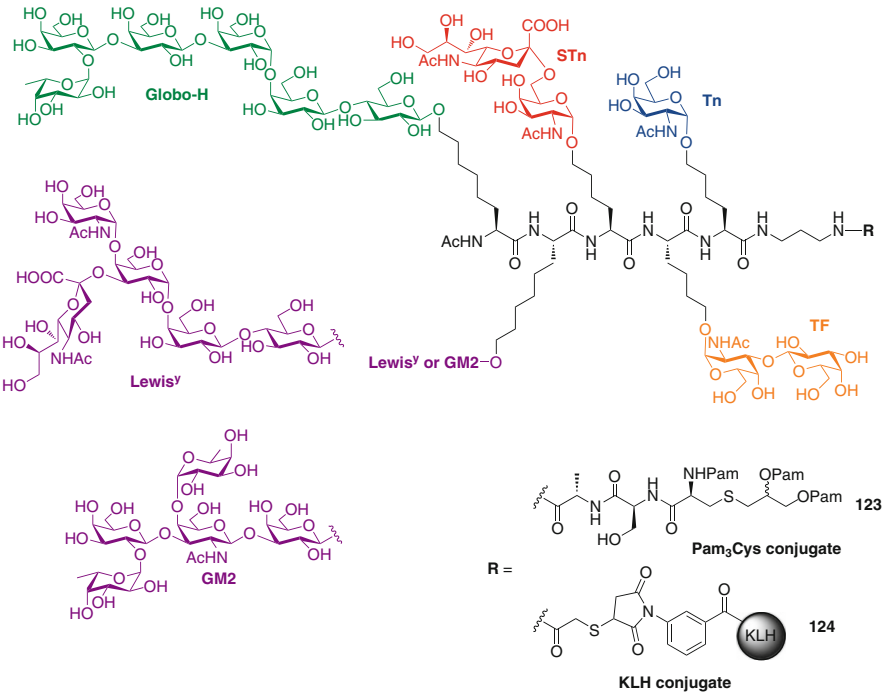


Fig. 7 Structure of the pentavalent vaccine candidates **123** and **124**

The major contribution to this field came from Danishefsky and coworkers. They reported the synthesis and immunological evaluation of several multivalent, fully synthetic, glycopeptide-based antitumor vaccines (Ragupathi et al. 2006). The authors speculated that the combination of several carbohydrate antigens closely associated with a particular cancer type could induce a more robust immune response, decreasing the percentage of tumor cells that can elude an immunological response. The constructs were assembled following a unimolecular multivalent approach, where several distinct TACAs are displayed on a single peptide backbone (Kim and Varki 1997). A sequential assembly of the glycopeptide in order of carbohydrate size, from the smallest (Tn) to the largest and most complex one (Globo H), was performed. The functionalized carbohydrate antigens were prepared either by manipulation of glycal epoxides or sulfonylaziridines, whereas the spacers were built through Horner-Emmons reactions followed by asymmetric hydrogenation or by cross-metathesis (Fig. 7). The results coming from mice immunization point out that the immunological properties of the individual antigens are preserved in the multivalent structures. However, it seems also that the immunogenicity is influenced by the position of the antigen on the peptide backbone. Overall, the antibodies showed significant reactivity with all three cell lines tested (MCF-7, LSC, DU-145). These vaccine candidates are now at the stage of evaluation in clinical trials.

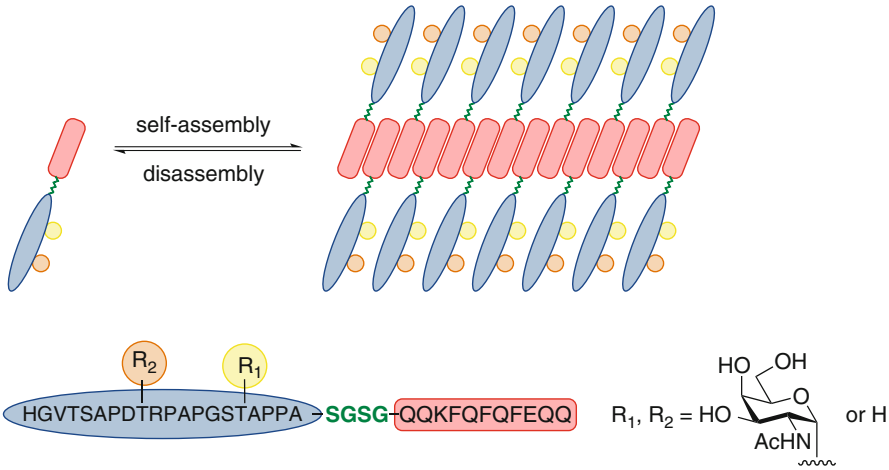

Fig. 8 Structure of self-adjuvanting, self-assembling vaccine candidates with different MUC1 glycosylation pattern

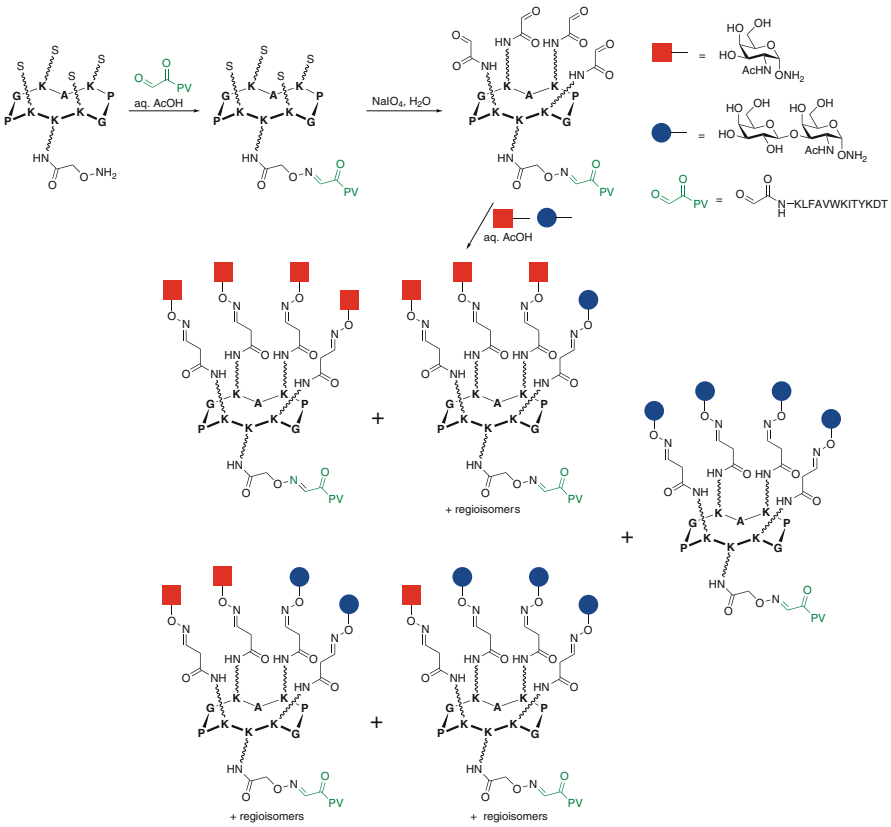
Another exciting approach was reported by the Li team (Huang et al. 2012). They synthesized self-adjuvanting vaccine candidates containing Tn-glycosylated full-length MUC1 VNTR (variable number of tandem repeats) domains (Pashov et al. 2011) conjugated to a self-assembled peptide sequence (Q11 domain, Fig. 8) (Jung et al. 2009). The Q11 domain could aggregate in solution, under mild conditions, into fibers over 200 nm long, thus displaying multivalent B cell epitopes on the fiber surface, and it served both as adjuvant and vaccine carrier (Rudra et al. 2010). Immunological studies revealed the production of high titers of antibodies capable of recognizing human breast tumor cells.

Conversely, the major advantage in the use of small cyclopeptides over linear ones is certainly their locked and rigid conformations that allows for a well-defined spatial orientation of functional groups, thus preventing hindrances between the assembled elements. Up to now, the most widely used architecture is Mutter's Regioselectively Addressable Functionalized Templates (RAFTs), extensively explored by Dumy and Renaudet (Dumy et al. 1995; Renaudet and Dumy 2003; Grigalevicius et al. 2005; Renaudet and Dumy 2008). RAFTs are cyclic decapeptides constrained in an antiparallel β-sheet by two L-proline-glycine β-turns and stabilized by intramolecular hydrogen bonds in solution. They display two functional faces that can be independently functionalized.

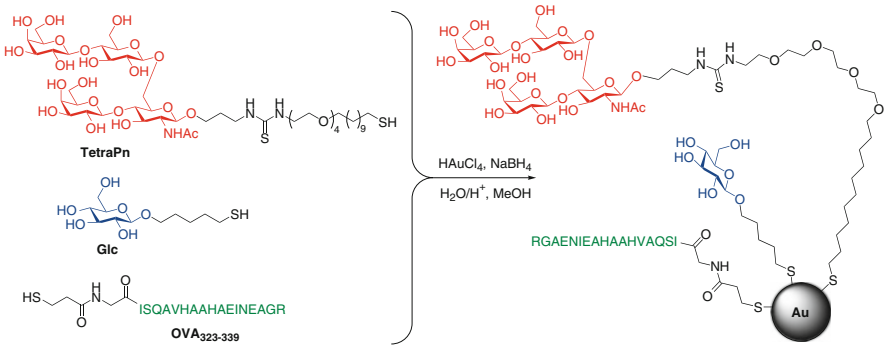
One of the most recent applications of RAFTs was the combination of various TACAs into a modular synthetic vaccine candidate (Fiore et al. 2013). One face of the scaffold was decorated with a mixture of the Tn and the TF carbohydrate antigens, by means of a randomized chemoselective ligation of aminooxy carbohydrates to glyoxoaldehydes anchoring sites under mild conditions. The bottom side was provided with an immunostimulating T cell peptide sequence derived from polio virus type 1 (PV, Scheme 27).



Scheme 27 Chemoselective synthesis of RAFT-based anticancer vaccine candidates

4.3 Gold Nanoparticles

In 2001 the Penadès group reported for the first time the use of gold nanoparticles (GNPs) as scaffolds for the multivalent presentation of biologically relevant oligosaccharides through self-assembled monolayers (SAMs) (de la Fuente et al. 2001). Since then, comprehensive studies have been carried out on the influence of loading, presentation of the ligands (i.e., type and length of the linker), and core size on the interaction with the specific receptor (Marradi et al. 2013; Fallarini et al. 2013; Reynolds et al. 2013; de la Fuente and Penades 2006; Manea et al. 2008). In 2012 the same group reported the first example of a fully synthetic carbohydrate vaccine based on GNPs (Safari et al. 2012). By using the "direct" synthesis, they were able to prepare gold nanoparticles (2 nm average diameter) coated with thiol-ended linkers bearing, respectively, a synthetic tetrasaccharide (the single repeating unit of the *Streptococcus pneumoniae* type 14 capsular polysaccharide), the T cell epitope OVA peptide, and β-D-glucopyranoside in variable



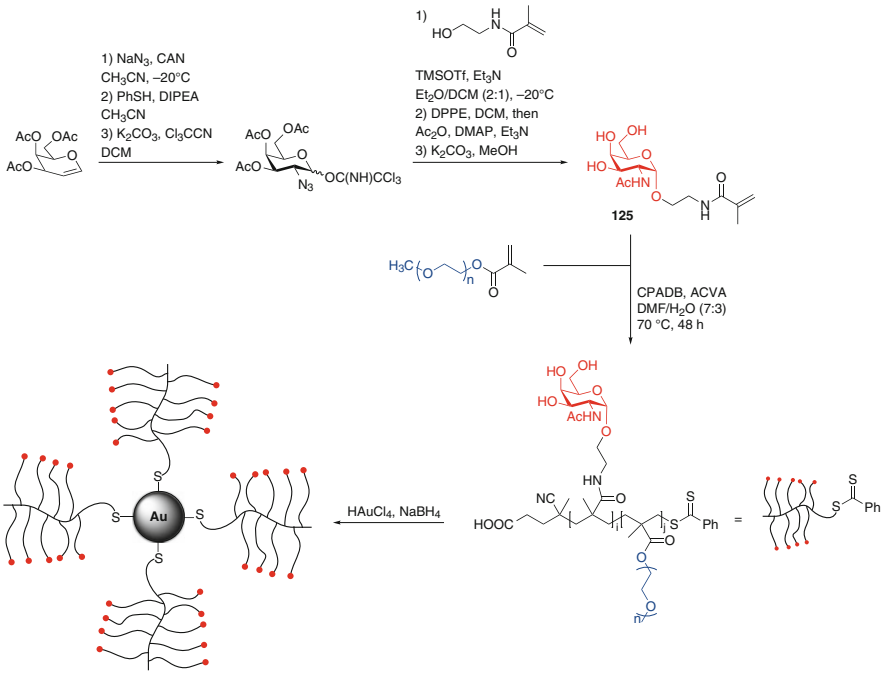
Scheme 28 "Direct" synthesis of sugar-decorated GNPs

ratio (Scheme 28). The authors found out that the molar ratio between the three components and the simultaneous presence of the OVA peptide and the tetrasaccharide antigen were critical for the induction of high titers of specific and functional IgG antibodies.

Another interesting example was reported by Davis group (Parry et al. 2013). The aim of the work was to closely mimic, on gold nanoparticles surface, the overexpression of truncated core 1 mucin-type glycans such as the Tn antigen occurring on the surface of cancer cells. To this end, a glycopolymer displaying multiple copies of the Tn antigen was used to coat and stabilize the surface of GNPs. First of all, a Tn-antigen glycan bearing a polymerizable linker **125** was prepared and then converted by Reversible Addition Fragmentation chain Transfer polymerization technique (RAFT) into various PEG block copolymers with different glycan densities and chain lengths (Scheme 29). Sodium borohydride was finally used to reduce the dithioester end groups of the polymers to thiol and to simultaneously produce GNPs in situ. Immunological studies showed a strong and long-lasting production of antibodies that are selective for the Tn antigen and cross-reactive towards mucin proteins displaying Tn.

4.4 Calixarenes

Calixarenes are a family of cyclic oligomers obtained by the condensation of phenols and formaldehyde (Sansone and Casnati 2013). The even-numbered macrocycles ($n = 4, 6, 8$) are easily obtained using cheap reagents through well-consolidated synthetic procedures and are also commercially available. The odd-numbered homologues ($n = 5, 7, 9$), although known in the literature, are rarely used, as they require more complicated syntheses. The considerable success met by calixarenes, especially calix[4]arenes, as scaffolds for the construction of multivalent ligands can be ascribed to a combination of different factors.



Scheme 29 Preparation of glycopolymer-stabilized GNPs

Among them, the ease to modulate valency, size, structure, and topology of the binding group presentation, together with the possibility to keep them conformationally mobile to exploit an induced-fit binding, or, in contrast, to lock them in a more preorganized specific structure. In fact, while the tetramethoxy and tetraethoxy derivatives are conformationally mobile, the selective introduction of larger groups can lock the macrocycle into one of the four possible conformations. These structures were named by Gutsche as cone, partial cone, 1,3-alternate, and 1,2-alternate (Fig. 9) and are characterized by a remarkably different spatial orientation of the phenolic units.

Functionalization of the calixarene scaffold can be addressed both at the phenolic oxygen atoms (lower rim) and at the para position (with respect to the OH group) on the aromatic nuclei (upper rim), and chains of variable length and containing most of the functional groups used for the glycoconjugation can be introduced.

An interesting example of such an approach is represented by an anticancer vaccine candidate **126** (Geraci et al. 2008). A cone calix[4]arene bearing four Cys-linked tumor-associated Tn antigens at the upper rim was functionalized at the opposite lower rim with the immunoadjuvant Pam_3Cys moiety (Scheme 30). When mice were immunized with the tetravalent calixarene, a fourfold increase in antibody production was observed with respect to a monovalent analogue **127** exposing the same immunoadjuvant but with a single antigen.

5 Conclusions

Infectious diseases have still strong impact on public health, both in industrialized and developing countries, due to their significant health-related costs for clinical treatment. According to the WHO, the most cost-effective strategy for controlling infections caused by pathogenic microorganisms is the vaccination practice, which should confer long-term protective immunity on the population. Carbohydrate-based vaccines, specifically designed to target pathogen-specific cell surface saccharide structures, showed enormous potential benefits for human health. In particular, it has been ascertained that optimal protection of the population, including newborns and young children, elderly, and immunocompromised patients, may be achieved with the administration of glycoconjugate vaccines that convert the T cell-independent immune response typical of plain polysaccharides into a T cell-dependent response, thereby establishing immunological memory.

However, the manufacture of glycoconjugate vaccines based on carbohydrate antigens isolated from their natural sources is a great challenge that may lead to heterogeneous compositions and batch-to-batch variability, thus raising severe issues of quality assurance and potential difficulties for their approval by the licensing authority.

Over the recent years, the synthesis of complex glycans has made significant progress and is becoming a relevant way to provide oligosaccharide antigens with well-defined chemical structure and devoid of bacterial contaminations which could derive from purification of biological materials. This could be a crucial feature to improve batch-to-batch consistency in vaccine manufacturing and to confer a better safety profile. In addition, synthetic oligosaccharides can be valuable tools for epitope recognition, i.e., to identify within the polysaccharide antigen the minimal structural requirements needed to elicit a protective immune response.

However, glycoconjugate constructs containing synthetic oligosaccharides may encounter a problem of low immunogenicity, as the multi-epitope protein carrier could overlook and weaken the immune response against the saccharide antigens. Some of the most innovative approaches that emerged during the last years in the field of vaccinology are therefore based on the concept that a fully competent immune response targeting poorly immunogenic synthetic carbohydrate antigens may be achieved by including in the vaccine setting only those elements strictly required to elicit a robust carbohydrate-specific immune response, devoid of any unnecessary component. Accordingly, there is a growing interest towards new kind of vaccines where the protein carrier is replaced by a synthetic short peptide able to act as a T cell epitope and to enhance the immunogenicity of the carbohydrate antigen. These new constructs include also fully synthetic vaccines exploiting the multivalency effect, where a significant enhancement of the immunogenicity is achieved by display of multiple copies of the oligosaccharide antigen on a suitable polyfunctional scaffold. A variety of scaffolds with different molecular architectures and chemical properties have been developed and applied during the last years, giving rise to new and very promising vaccine candidates that could open a new front line in vaccinology.

Plant Polysaccharides and Their Effects on Cell Adhesion

69

Xianxiang Xu

Contents

Abstract

Cell adhesion mediated by cell adhesion molecules (CAMs) constitutes essential life phenomenon. In inflammation, immunity, infection, tumor, cardiovascular injury, and wound healing, cell adhesion comes into being the basic physiological and pathological process. Intervening with cell adhesion has been the important therapeutic and prophylactic strategies for diseases. Accumulated evidence has indicated that plant polysaccharides especially those exacted from Chinese traditional and herbal medicine (most of plant medicine) displayed various pharmacological effects such as anti-inflammation, antitumor, anti-infection, immunomodulation, cardiovascular protective effects, and so on.

Polysaccharides • Plant medicine • Cell adhesion • Cell adhesion molecule • Inflammation • Immunity • Tumor • Infection • Cardiovascular injury • Wound healing

1 Introduction

Carbohydrates make up important components of biological organisms. They not only provide carbon source and energy for cells but also are a kind of important informational molecules in addition to proteins and nucleic acids. Most glycoproteins are made of N- or O-linked complex sugar residues. Glycosylated proteins were mainly localized extracellularly, including the cell surface and extracellular matrix (ECM) (Bektas and Rubenstein 2011). As for cell adhesion molecules (CAMs) which are glycoproteins (a few glycolipids), carbohydrate chains play key roles in CAM recognition. CAMs have been found to facilitate cell–cell interactions or interactions between cells and ECM. These interactions not only stick cells together in multicellular organisms but also enable CAMs to modulate intracellular signal transduction. Consequently, cell adhesion and signaling by CAMs are involved in a variety of biological processes such as cell proliferation, gene expression, differentiation, apoptosis, and migration. Not surprisingly, CAMs are therefore also implicated in numerous diseases.

Plant medicine can intervene with cell adhesion and regulate CAMs, with different pharmacological effects and modest risk (Spelman et al. 2011). As a kind of active ingredient in plant medicine especially Chinese herbal medicine, polysaccharides have wide sources and low toxicity. Plant polysaccharides exhibit various activities including anti-inflammation, antitumor, immune regulation, anti-infection, cardiovascular protection, etc. Some plant polysaccharides have been developed as drugs applied in clinic, such as Lentinan, *Astragalus* polysaccharide, *Polyporus* polysaccharide, and *Coriolus versicolor* polysaccharide. Polysaccharides are the important material basis of herbal medicine, while their intervention with cell adhesion may be an important function basis of their bioactivities (Figs. 1 and 2).

2 What Is Cell Adhesion?

Cell adhesion is the binding of a cell to another cell, ECM, or a specific surface, which is essential for cell growth and survival and also its communication with other cells. The ability of cells to interact with each other and their surroundings in a coordinated manner depends on multiple adhesive interactions between neighboring cells and their extracellular environment. The process of cell adhesion involves

Fig. 1 *Astragalus membranaceus* (Fisch.) Bunge var. *mongholicus* (Bunge) Hsiao

Fig. 2 *Radix astragali*, a vital qi-reinforcing herb medicine in China

a range of biological events such as three-dimensional reorganization of the cytoskeleton, biochemical reactions in the cell, and changes in molecules on the surface of the cell. The formation and remodeling of cell contacts are basic to cell and tissue structure (Braga and Harwood 2001). As an example, consider the epithelial cells that line the inner and outer surfaces of the human body, including the skin, intestines, airway, and reproductive tract. These cells provide a dramatic example of the different kinds of cell-to-cell junctions. The side surfaces of epithelial cells are tightly linked to those of neighboring cells, forming a sheet that acts as a barrier. Metazoans clearly need cell adhesion to hold cells together, but adhesion does much more than that. Adhesion receptors make transmembrane connections, linking ECM and adjacent cells to the intracellular cytoskeleton, and they also serve as signal transducers. All cells rely on cell signaling to detect and respond to cues in their environment. This process not only promotes the proper functioning of individual cells, but it also allows communication and coordination among groups of cells. Because of cell signaling, tissues have the ability to carry out tasks. Many physiological processes including cell activation, migration, proliferation, and differentiation require direct contact between cells or ECM. Cell adhesion participates in normal biological processes and disease states such as immune processes, leukocyte recirculation, wound healing, infection, tumor, thrombosis, and neurodegenerative disorders.

3 Cell Adhesion Molecules

Most cell adhesion events rely on members of CAMs. The term "CAM" can be traced back to the mid-1970s where it was used to describe molecules forming bonds between cells. According to their structural and functional features, CAMs have been classified into at least four major families: selectins E, P, and L; integrins; cadherins; and members of the immunoglobulin superfamily. More recently, several proteins with enzymatic activity have also been demonstrated to mediate cell adhesion, for instance, receptor protein tyrosine phosphatases, and an increasing number of CAMs have been found not to belong to any of the four protein families mentioned above, for example, neurexins/neuroligins and members of the family of proteins with extracellular leucine-rich repeats.

In addition to targeting cell adhesion to specific extracellular matrix proteins and ligands on adjacent cells, CAMs also act as receptors that interact via their cytoplasmic domain with numerous signaling molecules such as protein kinases and phosphatases. Unlike other adhesion molecules which bind to other proteins, the selectins interact with carbohydrate ligands. Recent work has demonstrated that adhesion molecules play a role in signaling as well. For example, integrins are cell adhesion molecules that have both direct and indirect roles in signaling (Arnaout et al. 2007). CAMs are key mediators in different disease states such as inflammatory disorders, cancer, cardiovascular diseases, autoimmune diseases (e.g., rheumatoid arthritis and type 1 diabetes), and even in the cold (Krieglstein and Granger 2001). In addition, CAMs have been implicated in pathogenic (i.e., bacteria and

virus) infections. The various isoforms of neural cell adhesion molecules (NCAM) play an important role in Alzheimer's disease (AD), which is characterized by a progressive loss of neurons and disturbances in neuronal plasticity and synaptogenesis. Interestingly, senile plaques containing accumulations of amyloid also contain NCAM and other adhesion molecules and may be able to stimulate neuritogenesis in the same microenvironment as degeneration. β-Amyloid may act via the NCAM–FAK/Fyn signal transduction pathway, which is important in apoptosis and inappropriately inducing neuronal death. β-Amyloid has also been shown to disrupt the biosynthesis of HNK-1, a glycoepitope conjugated to NCAM which modulates synaptic plasticity and memory consolidation (Thomas et al. 2005).

4 Cell Adhesion in Disease State

Considering the complicated interactions of blood cells and endothelium involved in many disease processes, abnormality of cell adhesion can lead to both acute and chronic disease states such as inflammation, thrombosis, angiogenesis, atherosclerosis, infection, and cancer metastasis. Within the vascular system, cell adhesion is important for the correct formation, networking, and remodeling of vessels. The semipermeable barrier property of microvascular endothelium is maintained by a layer of endothelial cells. On stimulation, endothelial cells express adhesion molecules that serve as keys that selectively open gateways to platelets, leukocytes, and sickle erythrocytes. Although adhesive junctions in vascular endothelial cells account for the integrity of the vessel wall, they are not to be considered as static molecular structures that function as intercellular glue (Liebner et al. 2006). The adhesive complexes at the endothelium not only provide an anchor point for blood cells to adhere but also transmit forces and biochemical signals (Wu 2005). A common theme in the processes is the need for rapid integrin activation, often initiated by binding of ligands to their cognate G protein-coupled receptors, followed by adhesion strengthening associated with integrin redistribution and outside-in signaling (Fig. 3).

4.1 Platelet Adhesion

Platelet adhesive properties play a well-defined role in hemostasis and thrombosis but also lead to other pathophysiological processes, including inflammation, immune-mediated responses to microbial and viral pathogens, and metastasis. Platelet adhesion and activation is a multistep process involving multiple platelet receptor–ligand interactions. Upon vessel wall injury, circulating platelets are rapidly decelerated by transient interactions between the glycoprotein (GP) Ib-V-IX complex and von Willebrand factor (VWF) bound to collagen. This interaction retains platelets close to the vessel wall and facilitates the contact between GPVI and collagen. The GPVI–collagen interaction induces intracellular

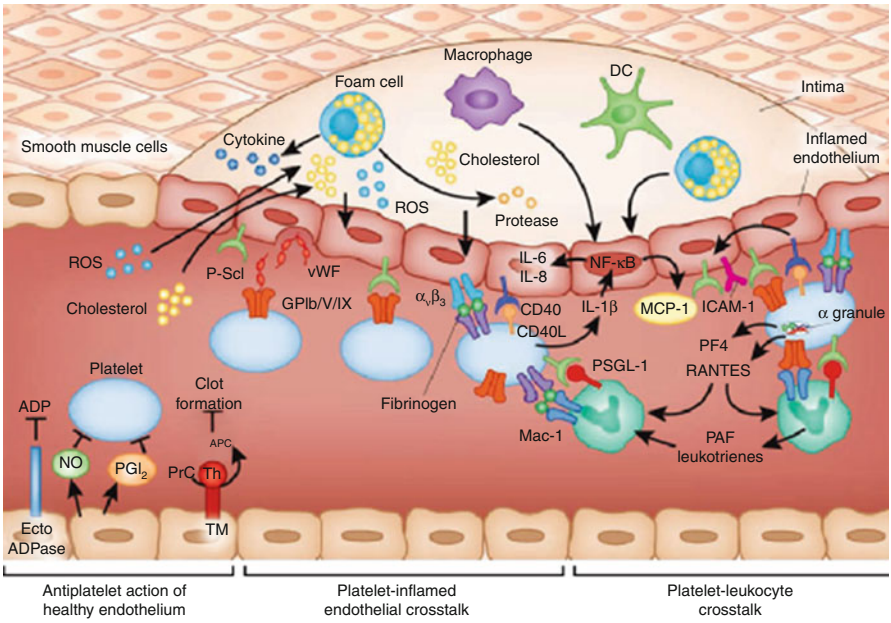

Fig. 3 The complicated interactions of blood cells and endothelium (Jackson 2011)

signaling leading to cellular activation and subsequent synthesis and release of secondary platelet agonists. Together, these events promote a shift of β_1 and β_3 integrins from a low to a high affinity state for their ligands through "inside-out" signaling allowing firm platelet adhesion and aggregation, further contributing to platelet activation through G protein-coupled receptors, inducing complex cellular responses such as release of granule contents and coagulant activity (Nieswandt et al. 2011).

4.2 Leukocyte Adhesion

Leukocytes are an integral component of the host defense system. However, in some disease states, their action may instead be deleterious to the host, and they may cause a significant amount of tissue damage. In inflammatory diseases, such as rheumatoid arthritis, leukocytes cause tissue damage without an apparent initial insult. In order for leukocytes to cause vascular or tissue damage, they must first adhere to the endothelium and then exit the bloodstream to gain access to extravascular tissue. Leukocyte emigration involves adhesion molecules both on the leukocyte and on the endothelial cell surface. Endothelial cells regulate mucosal immune homeostasis, acting as "gatekeepers," controlling leukocyte accumulation in the interstitial compartment. Leukocytes are recruited to the inflamed tissue by sequential adhesive interactions between leukocytes and the endothelium.

Table 1 Leukocyte–endothelial cell adhesion molecules

Adhesion molecule	Primary expression	Major ligands
P-selectin	Endothelial cells, platelets	PSGL-1
E-selectin	Endothelial cells	PSGL-1, ESL-1
L-selectin	Polymorphonuclear leukocytes, monocytes, majority of lymphocytes	CD34, GLYCAM-1
ICAM-1	Endothelial cells, lymphocytes, fibroblasts, other	LFA-1, Mac-1
ICAM-2	Endothelial cells, lymphocytes	LFA-1
ICAM-3	Polymorphonuclear leukocytes, monocytes, lymphocytes	LFA-1, CD11d/CD18
VCAM-1	Endothelial cells	VLA-4
MAdCAM-1	Endothelial cells	α4β7
PECAM-1	Endothelial cells, platelets, polymorphonuclear leukocytes, lymphocytes	PECAM-1
LFA-1	Polymorphonuclear leukocytes, monocytes, lymphocytes, other	ICAM-1, ICAM-2, ICAM-3
Mac-1	Polymorphonuclear leukocytes, monocytes, other	ICAM-1, Factor X, iC3b, fibrinogen
p150/95	Monocytes, polymorphonuclear leukocytes, dendritic cells	ICAM-1, iC3b, fibrinogen
CD11d	Polymorphonuclear leukocytes, lymphocytes, monocytes, specialized macrophages	ICAM-3, VCAM-1
VLA-4	Lymphocytes, monocytes	VCAM-1, fibronectin
VAP-1	Endothelial cells	Unknown
CD44	Lymphocytes, monocytes	Hyaluronan

Under certain conditions they can contribute to host destruction by participation in both acute and chronic immune/inflammatory responses. Leukocyte–endothelial cell adhesion molecules are essential mediators of both immune and inflammatory responses (Table 1) (Bullard 2002).

Much progress has been made in delineating the role of leukocyte–endothelial cell adhesion in the pathogenesis of cardiovascular disease. Adhesive interactions are involved in the pathogenesis of cardiovascular disease, regulating thrombus formation, facilitating leukocyte infiltration, mediating the migration and proliferation of smooth muscle cells, and enabling the deposition of fibrotic tissue. The magnitude of leukocyte–endothelial cell adhesion is determined by an array of factors including: the expression of adhesion molecules on the surfaces of leukocytes and endothelial cells, the inflammatory mediators which are secreted by activated leukocytes and endothelial cells, and the homodynamic forces resident within the blood vessels. They form a complex communication network (Eppihimer 1998). The multistep process of leukocyte recruitment illustrates how the coordinated and regulated expression of structurally and functionally distinct families of CAM can elicit a highly reproducible vascular response to inflammation. Selectins mediate the initial, low-affinity leukocyte–endothelial cell interaction that is

manifested as leukocyte rolling. This transient binding results in further leukocyte activation and subsequent firm adhesion and transendothelial migration of leukocytes, both of which are mediated by interactions between members of the integrin and immunoglobulin superfamily of CAM. This CAM-regulated process of leukocyte recruitment often results in endothelial cell dysfunction, which can be manifested as either impaired endothelium-dependent vasorelaxation in arterioles, excess fluid filtration in capillaries, and enhanced protein extravasation in venules. Consequently, CAMs have been implicated in a variety of vascular disorders (e.g., ischemia/reperfusion, atherosclerosis, allograft dysfunction, and vasculitis), and an enhanced expression of these CAMs has been invoked to explain the exaggerated microvascular dysfunction associated with some of the risk factors (hypertension, hypercholesterolemia, diabetes) for cardiovascular disease (Krieglstein and Granger 2001). The prevalence of cardiovascular disease in diabetic nephropathy patients is high and is a major cause of morbidity and mortality. The cell adhesion molecules, ICAM-1 and VCAM-1, are raised in both cardiovascular disease and diabetic nephropathy, with levels increasing in stepwise fashion with increasing kidney disease (Wu et al. 2005).

Leukocyte adhesion and platelet adhesion may be influenced by each other. For instance, adherent platelets, platelet-derived microparticles, and platelet-released substances, such as platelet-derived growth factor (PDGF), platelet factor 4, and thromboxane A_2 (TXA_2), may enhance leukocyte rolling and adhesion to the vessel wall. Conversely, platelet activation may be influenced by leukocyte adhesion and leukocyte-released mediators (Li et al. 2000). A key adhesion molecule implicated in platelet interaction with leukocytes is P-selectin, of which counterpart on leukocytes is known as P-selectin glycoprotein ligand-1 (PSGL-1) (McGregor et al. 2006).

4.3 Cancer Cell Adhesion

Cancer progression is a multistep process in which some adhesion molecules play a pivotal role in the development of recurrent, invasive, and distant metastasis. One critical step in tumor metastasis is tumor cell adhesion to the endothelium forming the microvessel wall. Cancer cells, especially the highly metastatic types, are believed to have enhanced adhesion ability that often facilitates the migration of the cells to establish new tumors in the body. Circulating cancer cells have been shown to extravasate to a secondary site using a process similar to inflammatory cells. The interaction of cancer and endothelial cells is considered not only to determine the physical site of metastasis but also to provide the necessary anchorage to facilitate tumor cell extravasation (Iiizumi et al. 2007). This process, shared by inflammatory cells and cancer cells, may partially explain the link between inflammation and tumorigenesis.

Multiple and diverse cell adhesion molecules take part in intercellular and cell–extracellular matrix interactions of cancer. During cancer metastasis, the formation of platelet–tumor cell aggregates in the circulation facilitates immune

evasion and the microvascular arrest of cancer cells at distant sites (Borsig 2008). Cancer cells can escape T-cell immunity by overexpressing the vascular cell adhesion molecule-1 (VCAM-1) (Wu 2007). The most studied ligands for CAMs expressed on cancer cells, sialyl Lewis (a/x) antigens, are shown to be involved in adhesion to endothelial cells by binding to E-selectin. In addition to participating in tumor invasiveness and metastasis, adhesion molecules regulate or significantly contribute to a variety of functions including signal transduction, cell growth, differentiation, site-specific gene expression, morphogenesis, immunologic function, cell motility, wound healing, and inflammation (Okegawa et al. 2004).

4.4 Red Cell Adhesion

Red cells express a large number of cell adhesion molecules at their surface. A subset of these molecules has been reported to play a role in pathological situations such as sickle cell disease, malaria, diabetes mellitus, and other vascular disorders and contribute to the clinical manifestations of these diseases by mediating abnormal RBC adhesion to the vascular endothelium (El Nemer et al. 2014). Among multiple pathologies associated with sickle cell disease, sickle red cell–endothelial cell interaction has been implicated as a potential initiating mechanism in vaso-occlusive events that characterize this disease. Sickle erythrocytes strongly adhere to endothelium by specific interactions between cell receptors and plasma proteins, such as thrombospondin, von Willebrand factor, fibrinogen, and fibronectin (Kaul 2008).

4.5 Bacteria and Virus Adhesion

Adhesion of enteric, oral, and respiratory bacteria is required for colonization and for subsequent development of disease. Moreover, bacteria assume a significantly greater resistance to clearance by normal cleansing mechanisms and to killing by normal immune factors, bacteriolytic enzymes, and antibiotics when they are adherent to surfaces and subsequent biofilm formation. Thus, the adherent state is advantageous for bacterial survival (Gu and Ren 2014). The alarming increase in drug-resistant bacteria makes a search for novel means of fighting bacterial infections imperative. Therefore, prevention of adhesion at an early stage following the exposure of the host to pathogens should prevent the disease. An attractive approach is the use of agents that interfere with the ability of the bacteria to adhere to tissues of the host, since such adhesion is one of the initial stages of the infectious process. Because anti-adhesive agents are not bactericidal, the propagation and spread of resistant strains is much less likely to occur than as a result of exposure to bactericidal agents, such as antibiotics (Ofek et al. 2003).

Viruses also have adhesion molecules required for viral binding to host cells. For example, influenza virus has a hemagglutinin on its surface that is required for recognition of the sugar sialic acid on host cell surface molecules. Since the

beginning of the HIV epidemic, endothelial function has been investigated in HIV-positive patients and was seen to be impaired to varying degrees. ECs lining liver sinusoids, human umbilical veins, bone marrow stroma, or brain microvessels have been shown to be variably permissive for HIV infection. Entry of virus into ECs may occur in different ways, such as via CD4 antigen, galactosylceramide receptors, or chemokine receptors. HIV has an adhesion molecule termed gp120 that binds to its ligand CD4, which is expressed on lymphocytes. The adhesive molecule-mediated interactions between ECs and leukocytes have been interpreted as a "Trojan horse" mechanism by which infected leukocytes cross the endothelial barrier and gain entry into extravascular tissue, where HIV replication may occur. Endothelial activation may also occur either by cytokines secreted in response to mononuclear or adventitial cell activation by HIV virus or by the effects of gp120 and HIV-associated protein Tat on endothelium. Endothelium could be activated either directly by HIV virus or by a leukocyte-mediated inflammatory cascade triggered by HIV infection (de Gaetano et al. 2004). Circulating (c) forms of the molecules have been used as monitors of disease progression. The levels of cICAMs and cVCAM-1 are increased during HIV infection. Serum cCAM-1 and cICAM-2 in HIV infection could be additional markers to discriminate between asymptomatic and progressor patients (Galea et al. 1997).

5 Anti-adhesion Therapies

Advances in our knowledge of cell adhesion mechanisms point to new therapeutic drugs capable of interfering with abnormality of cell adhesion. Much of the attention has been focused on inhibitors of adhesion molecules due to their crucial roles in pathological processes involving cell adhesion. The effects of many anti-inflammatory drugs can be ascribed, in part, to inhibition of the expression of CAMs. However, in the search for more selective and potent drugs for clinically important diseases such as multiple sclerosis, asthma, rheumatoid arthritis, inflammatory bowel disease, allergies, and atherosclerosis, direct inhibition of the function of CAMs has attracted increasing interest (Ulbrich et al. 2003). The first adhesion antagonists, anti-glycoprotein IIb/IIIa monoclonal antibody, have been tested in randomized trials as an adjunct to percutaneous transluminal coronary angioplasty. While considerably, progress in the development of orally available antagonists has been slower and more problematic than envisioned (Simmons 2005).

In fact, some old agents like aspirin and heparin have been used in treating diseases correlated with cell adhesion for many years in clinical practices. Experimental researches indicated they processed evident anti-adhesion activities. Aspirin can inhibit T-cell adhesion to and transmigration through endothelium by preventing integrin activation induced by contact with endothelial cells. The infusion of aspirin into healthy volunteers induced downregulation of L-selectin on circulating T cells (Gerli et al. 2001). Aspirin also inhibits the adhesion of T cells to IL-1beta-activated smooth muscle cells by reducing NF-kappaB activity

and decreasing expression of ICAM-1 and VCAM-1 and may prevent the development of atherosclerosis (Yotsui et al. 2007). The polysaccharides of animal origin, heparin, have been shown to interfere with selectins. Parnaparin, a low molecular weight heparin (LMWH), prevents P-selectin-dependent platelet-polymorphonuclear (PMN) aggregate formation and PMN leukocyte activation (Maugeri et al. 2007). Non-anticoagulant heparin prepared by chemical modifications exhibited strong anti-P-selectin and anti-L-selectin activity and more and inhibited cell adhesion in vivo (Xie et al. 2000).

6 The Polysaccharides Intervening with Cell Adhesion in Inflammation

Selectin-mediated leukocyte initial attachment and rolling over vessel endothelial surface are crucial steps for inflammatory responses. P-selectin is a promising target for anti-inflammation therapeutic strategy. Fucoidan is a natural polysaccharide extracted from brown seaweeds with anti-inflammatory and anti-oxidative effects. The anti-inflammatory effect of fucoidan related to its capacity to interact with the selectin or scavenger receptor on the cell membrane (Cui et al. 2008). Three water-soluble polysaccharide fractions (PPS-1, PPS-2, and PPS-3) were isolated from the roots of *Physalis alkekengi*. Among the polysaccharide fractions, PPS-2 could effectively block the interaction between P-selectin and its native ligand (Tong et al. 2011). The purified polysaccharides of ginkgo biloba leaves (PGBL) could effectively inhibit the acute inflammation in mice and interfere with the adhesion of HL-60 cells or neutrophils to P-selectin in static conditions, as well as the adhesion of neutrophils to Chinese hamster ovary cells expressing human P-selectin and human umbilical vein endothelial cells in flow conditions (Fei et al. 2008).

A pectic polysaccharide named comaruman (CP) was extracted from the aerial part of *Comarum palustre*. CP fractions obtained with acidic hydrolysis inhibit spontaneous and phorbol-12-myristate-13-acetate-activated adhesion of peritoneal leukocytes in vitro (Popov et al. 2005a). The polysaccharides isolated from Golden needle (GNP) mushroom possessed strong anti-inflammatory activity in burned rats and could significantly decreased ICAM-1 in serum and colon of normal and burned rats (Wu et al. 2010). The anti-adhesive activity of polysaccharides from the red alga *Lithothamnion muelleri* (Hapalidiaceae) was assayed by visualizing lipopolysaccharide-induced leukocyte rolling. The intravenous injection of fractions B1a and B1b in mice reduced leukocyte rolling by approximately 90 % (Soares et al. 2012). *Porphyra vietnamensis* possesses potential immunomodulatory activity. An isolated polysaccharide fraction evoked an increase in the percent of neutrophil adhesion to nylon fibers (Bhatia et al. 2013). Extracts of the vine-like plant *Tripterygium wilfordii* (TW) have been widely used in China as an immunosuppressant and anti-inflammatory drug for the treatments of rheumatoid arthritis, lupus erythematosus, and other inflammatory disorders. The lipopolysaccharide (LPS)-mediated stimulatory effects of tumor necrosis factor-alpha (TNF-alpha) cytokine production and cell adhesion molecule (CD11c, CD18, CD14, CD54)

expression in human monocytic THP-1 cells were modulated by treatments of the TW extracts. The TW polysaccharide moiety exhibited more profound immunosuppressive properties than the aqueous and ethanol extract (Luk et al. 2000). The pectic polysaccharide named bergenan BC was obtained using extraction of the green leaves of Siberian tea *Bergenia crassifolia* (L.) Fritsch. Bergenan BC was found to increase the spontaneous adhesion of peritoneal leukocytes and failed to influence adhesion stimulated by PMA or adhesion of peritoneal leukocytes incubated in the presence of EDTA. Thus, bergenan was shown to possess immunostimulating activity in relation to DTH response in vivo and phagocytic activity in vitro (Popov et al. 2005b). EA.hy926 cell cultures were used as an established bronchopulmonary dysplasia (BPD) cell model. *Astragalus* polysaccharide (APS) retards the inflammatory response by hyperoxia, as shown by the reduced expression of ICAM-1 (Huang et al. 2013).

7 The Polysaccharides Intervening with Cell Adhesion in Immunity

Tricholoma matsutake is well-known mushroom in Asian country. The immunomodulatory effect of *T. matsutake*-derived polysaccharide fraction (TmC-2) was evaluated using functional activation models of macrophages, monocytes, and splenic lymphocytes. TmC-2 stimulated CD29-mediated cell–cell or cell–fibronectin adhesions in monocytes, while CD43-mediated cell adhesion was downregulated (Byeon et al. 2009). *Coriolus versicolor* polysaccharide (PSK) is a plant polysaccharide widely used for cancer immunotherapy. It is considered that its antitumor effect is derived from its immunomodulating activity on the tumor-bearing host. ICAM-1 was expressed on human KATO-3 gastric cells but not on Colo205. The expression of ICAM-1 was enhanced by treatment with PSK (Iguchi et al. 2001). *Astragalus* heteropolysaccharides (AHPS) is obtained from the dried roots of *Astragalus membranaceus* (Fisch.) Bunge var. *mongholicus* (Bunge) Hsiao. Its therapeutic effects were observed on erythrocyte immune adherence function in mice with adjuvant-induced arthritis (AA). AHPS significantly improved the primary and secondary local or systemic symptoms of the mice with AA. AHPS could significantly increase the number of complement receptor 1 (CR1, CD35) on erythrocyte, improve the elimination of circulation immune complex (CIC) in the peripheral blood, and reduce the deposition of IC in joint synovium (Yang et al. 2009).

8 The Polysaccharides Intervening with Cell Adhesion in Tumor

Ganoderma lucidum has been widely used as a miraculous herb for health promotion, especially by cancer patients. It has been known that *G. lucidum* affects cancer cell activities. Polysaccharides isolated from *G. lucidum* fruiting bodies grown on

logs of wood exhibited the greatest inhibitory activity on cell adhesion. Purified polysaccharides also inhibited cell adhesion to various matrix molecules. The polysaccharide interacted with cell surface proteins. Specially, β_1-integrin expression was greatly reduced (Wu et al. 2006). *Ganoderma lucidum* polysaccharides peptide (Gl-PP) could suppress invasion of human lung carcinoma cells in vitro (PG cell). Pretreated with Gl-PP, PG cell motility was inhibited significantly. PG cell adhesion was also inhibited (Cao et al. 2007).

One low molecular weight polysaccharide (LMW-ABP) was isolated from the fruiting bodies of *Agaricus blazei* Murill. LMW-ABP could effectively inhibit adhesion of HT-29 cells to human umbilical vein endothelial cells (HUVECs) in static conditions, as well as downregulating the expression of both α-1,3-fucosyltransferase-VII (FucT-VII) and sialyl Lewis X (sLex). The results suggested that LMW-ABP could suppress the metastasizing capacity of cancer cells through interfering with the interaction between E-selectin and sLex (Liu et al. 2010). The acidic polysaccharide (PL) from *Phellinus linteus* markedly inhibit melanoma cell metastasis in mice and directly inhibit cancer cell adhesion to and invasion through the extracellular matrix, but it has no direct effect on cancer cell growth (Han et al. 2006a). The pectic polysaccharide (angelan) of *Angelica gigas* Nakai directly inhibited cancer cell adhesion and invasion through the extracellular matrix, in addition to activating the immune functions of B cells and macrophages. Angelan can inhibit tumor growth and metastasis by stimulating host immunity and directly inhibiting cancer cell adhesion (Han et al. 2006b). An acidic polysaccharide (CPPA) from the roots of *Codonopsis pilosula* induced a potent inhibitory effect on the invasion and migration potential of human epithelial ovarian cancer HO-8910 cells in vitro. Moreover, the CD44 expression on the HO-8910 cells was also attenuated by CPPA treatment (Xin et al. 2012). T739 cells were treated with a combination of *Polyporus* polysaccharide (PPS) and Bacillus Calmette–Guerin (BCG). The expression of genes associated with the NF-κB signaling pathway such as ICAM-1 was downregulated (Wei et al. 2011).

9 The Polysaccharides Intervening with Cell Adhesion in Infection

Anti-adhesive compounds are potential prophylactic tools in alternative treatment regimes against bacterial infection, as bacterial adhesion is commonly mediated by carbohydrate–protein interactions between surface adhesions of microorganisms and the host cell. The use of exogenous polyvalent, high-molecular carbohydrates, and tannin-like plant-derived compounds should antagonize the adhesive interaction. High molecular weight polysaccharides from black currant seeds (*Ribes nigrum* L.) inhibit adhesion of *Helicobacter pylori* to human gastric mucosa (Lengsfeld et al. 2004). High-molecular glycosylated compounds (polysaccharides and glycoproteins) from the immature fruits of the okra plant, *Abelmoschus esculentus* (L.) Moench,, were shown to have a strong in vitro anti-adhesive activity against *Helicobacter pylori*, leading to an inhibition of the binding to mucosal

epithelia from human stomach in situ. In an in vitro adhesion model with fluorescent-labeled *C. jejuni*, the isolate okra polysaccharides strongly inhibited the microbial adhesion to colonic tissue (Lengsfeld et al. 2007). The acidic polysaccharide fraction APS-F2 from Aloe vera did not reveal an inhibitory effect on the growth of *H. pylori* or cell viability but could reduce the count of *H. pylori* attached to MKN45 cells. In addition, APS-F2 was shown to have a potent anti-adhesive effect against *Escherichia coli* (Xu et al. 2010). Aqueous extract of *Glycyrrhiza glabra* L. (Fabaceae) significantly inhibited the adhesion of *Helicobacter pylori* to human stomach tissue. This effect was related to the polysaccharides isolated from the extract, with one purified acidic fraction as main active polymer. Purified polysaccharides did not exhibit direct cytotoxic effects against *Helicobacter pylori* and did not influence hemagglutination. Additionally raw polysaccharides from *Glycyrrhiza glabra* were shown to have strong anti-adhesive effects against *Porphyromonas gingivalis* (Wittschier and Faller 2009).

A range of carbohydrates and carbohydrate- and proanthocyanidin-enriched plant extracts were screened for potential anti-adhesive effects against *Helicobacter pylori*, *Campylobacter jejuni*, *Porphyromonas gingivalis*, and *Candida albicans* in different in situ assays on primary tissue. The adhesion of *H. pylori* on human stomach tissue was effectively blocked by glucuronic acid-enriched polysaccharides from immature okra fruits (*Abelmoschus esculentus*). These compounds also had strong in vitro effects against *C. jejuni* but were ineffective in an in vivo study in infected chicken broilers due to metabolism in the gastrointestinal system. Polysaccharides from *Glycyrrhiza glabra*, also enriched with glucuronic acid, showed strong anti-adhesive properties against *H. pylori* and *P. gingivalis* (Wittschier et al. 2007). An acidic polysaccharide CS-F2 from *Camellia sinensis* might exert a selective anti-adhesive effect against certain pathogenic bacteria, most notably *Helicobacter pylori*, *Propionibacterium acnes*, and Staphylococcus aureus, while exerting no effects against beneficial and commensal bacteria including *Lactobacillus acidophilus*, *Escherichia coli*, or *Staphylococcus epidermidis*. CS-F2 showed marked inhibitory activity against the pathogen-mediated hemagglutination (Lee et al. 2006).

A polysaccharide with high uronic acid content from the roots of *Panax ginseng* was found to inhibit the ability of *Porphyromonas gingivalis* to agglutinate erythrocytes. This polysaccharide showed a strong inhibitory activity, but treatment with pectinase resulted in non-inhibitory hydrolyzed products. In contrast, the inhibition by the acidic polysaccharide from the leaves of *Artemisia capillaris* was negligible. The carbohydrate composition of the two polysaccharides indicated that the anti-adhesive activity may be correlated with glucuronic acid content, one of the components of glycosaminoglycans. Low molecular weight heparin and sucrose octasulfate revealed stronger inhibitory effects on bacterial binding than the acidic polysaccharide from *P. ginseng* (Lee et al. 2004). Lentinan, a mushroom polysaccharide, isolated from *Lentinus edodes* (shiitake mushroom) was sulfated in dimethyl sulfoxide to obtain a water-soluble derivative coded as LS. Then, two polysaccharide-based polyelectrolytes, polyanionic lentinan sulfate (LS) and polycationic chitosan (CS), were alternatively deposited onto the surfaces of

polyurethane (PU) via layer-by-layer (LbL) assembly technique. Polyurethane (PU) modified by polysaccharide-based multilayers showed antibacterial activity against *Pseudomonas aeruginosa*. The number of adherent platelets on the surface modified by five bilayers (LS as topmost layer) was reduced. The tests of L-929 cells indicated that LbL-modified PU surfaces had better cytocompatibility than unmodified PU (Wang et al. 2012).

10 The Polysaccharides Intervening with Cell Adhesion in Cardiovascular Injury

A polysaccharide from brown algae decreased polymorphonucleated leukocytes (PMNs) sticking to autologous rabbit aortae. The fucan sulfate could be a heparin substitute endowed with antithrombotic and anti-inflammatory activities, devoid of the problems caused to heparin by its animal origin, i.e., possible prion protein contamination (Trento et al. 2001). *Astragalus* polysaccharide effectively alleviates ischemia–reperfusion injury (IRI) of cardiac muscle. Human cardiac microvascular endothelial cells (HCMECs) were used to validate the protective effects of astragalus under an IRI scheme simulated through hypoxia/reoxygenation in vitro. *Astragalus* polysaccharide inhibited the cohesion between HCMECs and polymorphonuclear leukocyte (PMN) during IRI through the downregulation of p38 MAPK signaling and the reduction of cohesive molecule expression in HCMECs (Zhu et al. 2013).

11 The Polysaccharides Intervening with Cell Adhesion in Wound Healing

The fresh leaves and juice of *Sedum telephium* L. are used as wound-healing promoters. Cell adhesion represents a primary event in wound repair and in tissue homeostasis. Total *Sedum* juice strongly inhibited human fibroblast (MRC5) cell adhesion to laminin and fibronectin (EC50 = 1.03 +/− 0.12 mg/mL). This anti-adhesive feature was concentrated mainly in the two polysaccharide fractions (EC50 values comprised between 0.09 and 0.44 mg/mL). The flavonol fractions did not seem to contribute to this effect. The results confirmed that natural polysaccharides, with chemical structures different from heparin, were able to interfere with integrin-mediated cell behavior, and they contributed to the outstanding effects of *Sedum* juice and to the role of polysaccharides in cell–matrix interaction (Raimondi et al. 2000). The natural polysaccharide extracted from tamarind seed (xyloglucan or tamarind seed polysaccharide, TSP) exerted a positive influence on human conjunctival cell adhesion to laminin. TSP slightly but significantly increased corneal wound healing rate. The ability of the polysaccharide to promote corneal wound healing might depend on its influence on the integrin recognition system (Burgalassi et al. 2000). Xylan, a natural polysaccharide, was electrospun along with polyvinyl alcohol (PVA) to produce xylan/PVA nanofibers for skin

tissue engineering. The natural biodegradable xylan/PVA nanofibrous scaffolds have good potential for fibroblast adhesion, proliferation, and cell–matrix interactions relevant for skin tissue regeneration (Krishnan et al. 2012).

12 Discussion

With the increasing awareness of the roles of cell adhesion in the pathological process, anti-adhesion become an effective strategy for the prevention and treatment of diseases. Compared with protein–protein interactions, the knowledge on interactions between proteins and carbohydrates is still inadequate. How heparin effect on cell adhesion was previously reviewed (Xu and Dai 2010). Although as a classic anticoagulant drugs, heparin shows more and more its non-anticoagulant effects such as anti-inflammation, antitumor, and anti-infection in recent years. Additionally, other non-anticoagulant heparins and heparin derivatives can interfere with cell adhesion among various cells. The anti-adhesion characteristics of heparin may be many of its pharmacological action mechanism. Notably, the chemical components of heparin are impure polysaccharides extracted from animals, with "multiple components and multiple targets" which are similar to plant polysaccharides. Therefore, focusing on cell adhesion, application of glycobiology in polysaccharide research is expected to reveal the therapeutic mechanism of plant polysaccharides in disease processes.

Polysaccharides from *Aloe vera* and Oral Ulcerations

70

Kanokporn Bhalang and Kevin Tompkins

Contents

Abstract

Aloe vera is a locally grown herbal plant. *Aloe vera* has historically been used to treat skin wounds. Investigations have discovered that *Aloe vera* can increase the number of fibroblasts, which play a key role in wound healing. The active ingredient in *Aloe vera* gel is acemannan. Acemannan is a polysaccharide located within the protoplast of the *Aloe vera* parenchyma cells. Acemannan is composed of β-(1 → 4)-acetylated polymannose chains. Acemannan has been reported to accelerate oral wound healing in animal studies. Recurrent aphthous ulcerations are common painful oral mucosal ulcers that affect the quality of life of patients. Clinically, acemannan is effective in reducing both ulcer size and associated pain. Patients reported that they were mostly satisfied with acemannan treatment compared to standard topical steroid treatment. Thus, acemannan can be used for the treatment of recurrent aphthous ulceration.

Aloe vera • Acemannan • Oral ulcer • Aphthous

1 Introduction

Recurrent aphthous ulceration (RAU) is a lesion commonly found in the oral cavity, causing pain and discomfort in patients. Currently, there is no curative management of RAU available. The treatment of choice for these lesions is topical steroid application (Porter et al. 1998; Barrons 2001). Because of the possible adverse effects from steroid use, herbal medicines are very attractive as an alternative for use in treating RAU.

Several natural products have been investigated for the promotion of wound healing. *Aloe vera (Aloe barbadensis* Miller*)* has long been used to treat various skin conditions such as cuts and burns (Reynolds and Dweck 1999). *Aloe vera* has been demonstrated to stimulate dermal wound healing in rats by increasing collagen and glycosaminoglycan synthesis (Chithra et al. 1998a, b). *Aloe vera*'s beneficial properties may be attributed to the polysaccharides present in the inner gel of the leaf, especially β-(1 → 4)-acetylated polymannose, also known as acemannan (Reynolds and Dweck 1999; Femenia et al. 1993). Acemannan has been reported to increase oral epithelial and fibroblast cell proliferation through the activation of growth factors (Jettanacheawchankit et al. 2009). Animal experiments also confirmed the effect of acemannan in accelerating oral wound healing (Jettanacheawchankit et al. 2009). In a clinical study, it was found that acemannan had an immediate effect in relieving pain symptoms from RAU (Bhalang et al. 2013).

1.1 *Aloe vera*

There have been many studies investigating herbal plants used in traditional medicine. *Aloe vera (Aloe barbadensis* Miller*)* (Fig. 1) is a succulent plant that develops a compartment for water storage in the leaves to survive in the dry season. *Aloe vera* has been used since ancient Rome for treating burns and has been utilized widely in the cosmetic and medical industry in many types of products such as shampoo and herbal drinks. Because it can be easily grown in several climates, it is a good candidate to be commercially produced (Reynolds and Dweck 1999; Hamman 2008).

Extracts from *Aloe vera* can be divided into two parts, *Aloe vera* sap and *Aloe vera* gel. The bitter yellow sap is from the leaf, while the clear and colorless gel extract is from the inner leaf. The sap consists of anthraquinones such as emodin and aloe-emodin. Because its phenol content can irritate the skin, the sap has not commonly been developed for human use. The inner part of the leaf in which water is held in the form of a viscous mucin is a clear tissue that consists of large thin-walled parenchyma cells (Hamman 2008; Vogler and Ernst 1999).

Fig. 1 *Aloe vera* plants at the Faculty of Dentistry, Chulalongkorn University, Bangkok, Thailand

Aloe vera gel extract is composed of water, carbohydrates, proteins, vitamins, minerals, and sterols. Water is the main component (99 %) of the gel. Carbohydrates in the form of polysaccharides are the second most prevalent component of the gel. The carbohydrates can be divided into two main types: glucomannan and acemannan. Other sugars such as galactose, xylose, arabinose, rhamnose, cellulose, and pentose are also found in the gel. Protein is mostly found as glycoproteins, such as lectins, aloctin A, and aloctin B. The vitamins present in the gel are provitamin A, riboflavin, thiamine, niacin, and ascorbic acid. Potassium, sodium, and manganese are the most commonly found minerals in the gel extracts (Hamman 2008). The evidence for the medicinal effects of *Aloe vera* has historically been anecdotal. However, a number of studies investigating the use of *Aloe vera* in wound healing and other processes have been conducted, and the results are summarized as follows:

(a) *Aloe vera* has been demonstrated to stimulate dermal wound healing in rats by increasing collagen and glycosaminoglycan synthesis (Chithra et al. 1998a, b). *Aloe vera* can also help reduce skin irritation from ultraviolet rays (Strickland et al. 1994). Wound healing both on the skin and on the oral mucosa was accelerated by *Aloe vera*. *Aloe vera* accelerated the migration of epithelial cells into the wound area, increased the number of endothelial cells and new blood vessels, and stimulated the number of fibroblasts and collagen fibers in forming granulation tissue to fill the wound (Jettanacheawchankit et al. 2009).
(b) *Aloe vera* has immunomodulatory activity (Im et al. 2010; Seongwon and Myung-Hee 2003) and anti-inflammatory effects (Vazquez et al. 1996). These effects occur through the activation of macrophages and the suppression of mast cell migration to the injury and by inhibiting the enzyme cyclooxygenase, which controls the synthesis of prostaglandin E2, an important mediator in the occurrence of pain and inflammation.

(c) *Aloe vera* has antimicrobial effects against several bacteria strains and fungi (Im et al. 2010; Nejatzadeh-Barandozi 2013). These effects are exerted by enhancing the release of cytokines, including interleukin (IL), interferon (IFN), granulocyte/monocyte-colony-stimulating factor (GM-CSF), and tumor necrosis factor (TNF) (Talmadge et al. 2004).
(d) *Aloe vera* solution reduced the blood sugar level of diabetic rats (Okyar et al. 2001). This solution also significantly lowered the levels of blood glucose, cholesterol, triglycerides, and blood pressure of diabetic patients (Choudhary et al. 2014). Other reported effects of *Aloe vera* are the reduction of gastric ulcers (Mahattanadul 1996) and thyroid hormone levels (Kar et al. 2002).
(e) *Aloe vera* has also been studied for its use in dentistry. *Aloe vera* has been investigated as supplemental root canal filling material in primary teeth (Kriplani et al. 2013) and recommended as a suitable storage media for avulsed teeth (Badakhsh et al. 2014).

2 Acemannan: A Polysaccharide from *Aloe vera*

Polysaccharides are readily found in nature, plants, animals, and bacteria. The diversity and complexity of polysaccharides is based on the multiple monosaccharide linkage forms available (1 → 2, →3, →4, →5, or → 6), being in either the α or β confirmation, and the presence of chains branching from the main backbone (Hamman 2008). The *Aloe vera* leaf pulp contains multiple polysaccharides that differ in their location in the pulp (Fig. 2).

The major polysaccharide present in the inner gel of the *Aloe vera* leaf is acemannan (β-(1 → 4)-acetylated polymannose). Acemannan, also known commercially as carrysin, is produced by specialized cells known as leucoplasts (Hamman 2008; Lex 2012). Acemannan has a backbone chain of mannose that is acetylated at the C-2 and C-3 positions with a 1:1 mannose monomer/acetyl ratio. Acemannan contains side chains that are mainly composed of galactose attached at the mannose C-6 position (Hamman 2008). The molecular weight of acemannan ranges from 30 to 40 kDa (Lex 2012). A ratio of 1:3 (glucose/mannose) is commonly found in the repeating units. However, other ratios have also been reported, and these discrepancies could stem from differences among species or from sample processing (Hamman 2008).

When the linkage between the monomers in acemannan was analyzed, it was demonstrated that acemannan has a single-chain backbone of β-(1 → 4) mannose with β-(1 → 4) glucose inserted into the backbone with α-(1 → 6) galactose branching from the backbone (Fig. 3) (Talmadge et al. 2004). The manner in which acemannan is processed and handled can affect its structure and possibly its bioactivity. Acemannan loses mannosyl residues when dehydration was performed. Deacetylation and reduction of galactosyl residues were also detected (Femenia et al. 2003). The loss of galactosyl and acetyl residues may influence the interactions between mannose chains and change their binding capacity.

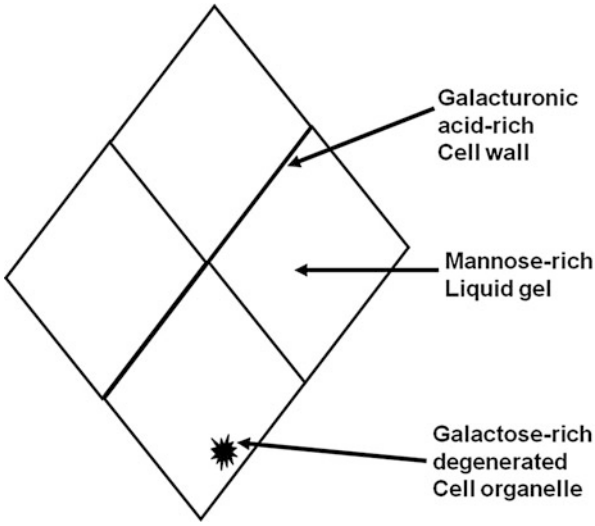

Fig. 2 Schematic of the distribution of the polysaccharides in the *Aloe vera* pulp

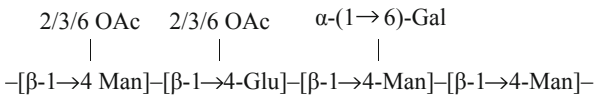

Fig. 3 Diagram of the molecular structure of acemannan

Because acemannan consists of long polymer chains, it must be broken down to facilitate cellular uptake while passing through the gastrointestinal system. The epithelial cells lining the gastrointestinal system have mannose-specific receptors, and when taken orally, acemannan can be detected in the blood within 90 min (Moreira and Filho 2008; Lex 2012). A study using orally administered 14C-labeled acemannan showed that 72 h after administration, 86.4 % of the radioactivity could be found in CO_2 and 2.2 % was found in the urine and feces, suggesting that the majority of orally administered acemannan is absorbed and metabolized. Thus after 72 h, 11.4 % of acemannan is stored in the mannose pool or efficiently used in the body. Detoxification and synthesis of glycoproteins and oligosaccharides occurs mainly in the liver. Reflecting acemannan's role in immunomodulation, the spleen and thymus are other sites of acemannan uptake (Lex 2012).

Many of the beneficial effects of *Aloe vera* derive from the effects of acemannan. Acemannan is known to have immunomodulatory activity both in vivo and in vitro. The immunoaugmenting activity of acemannan appears to be mediated through macrophage activation. Acemannan induces multiple macrophage functions including recognition of foreign antigens and removal of microorganisms. Part of the macrophage inducing effect of acemannan may be because mannose is rarely present as the terminal moiety in polysaccharides in humans, although it is

commonly so on those of microorganisms (Lex 2012). Thus, human macrophages will recognize the terminal mannose of acemannan as foreign and activate the immune system. Macrophage activation also results in the production of inflammatory cytokines such as IL-6 and tumor necrosis factor α (TNF-α) (Zhang and Tizard 1996).

Acemannan's anti-inflammatory effects occur by blocking the generation of histamine and bradykinin and inhibiting bradykinin activity, eicosanoid formation, and PMM leukocyte infiltration (Lex 2012). Acemannan has also been shown to have anticancer activity and has received approval for use in the treatment of fibrosarcoma in cats and dogs. The anticancer effects of acemannan occur by activating local macrophages and stimulating an immune response to the cancer cells (Lex 2012).

Acemannan was investigated for its use in treating dental pathologies such as periodontal disease or dental pulp exposure. It was found that acemannan induced the expression of bone-formation-associated proteins in both the periodontal ligament and dental pulp fibroblasts (Boonyagul et al. 2014). Acemannan also stimulated the mRNA expression of dentin sialophosphoprotein and dentin matrix protein 1, which are involved in the differentiation of the odontoblast cells that produce the dentin of the tooth (Jittapiromsak et al. 2010). When used on exposed pulp tissue, acemannan increased pulpal fibroblast number, alkaline phosphatase activity, and expression of dentin sialoprotein (Lardungdee et al. 2008). A retrospective study in the use of acemannan-containing patches on the reduction of alveolar osteitis following tooth extraction indicated that the acemannan-treated patients had a significantly reduced incidence of dry socket compared to the typical gelfoam treatment (Poor et al. 2002). In that study, smokers had twice the rate of dry socket compared to nonsmokers; however, no acemannan-treated smokers experienced dry socket. Furthermore, Acemannan has also been used as denture adhesive (Tello et al. 1998).

3 Toxicity and Side Effects

The direct cytotoxicity of acemannan to target cells was investigated, and acemannan was not found to be cytotoxic to these cells at any dose evaluated (Womble and Helderman 1992). When acemannan was administered as a solution to mice, rats, or dogs, there were no significant signs of toxicity and none of the animals died. Because of the immune-stimulating activity of acemannan, an accumulation of macrophages and monocytes without subsequent inflammatory reaction was found in the lungs, liver, and spleen of the animals. These findings were not considered adverse effects (Fogleman et al. 1992a). Investigations using rats or dogs determined that none of the animals had any adverse effects when administered up to 2,000 mg/kg for up to 6 months (Fogleman et al. 1992b). Importantly, no human subjects experienced undesirable reactions to the use

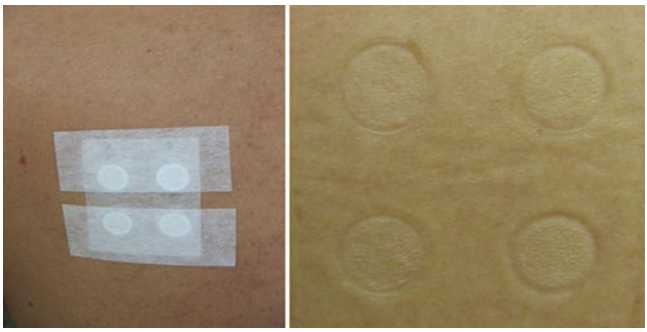

Fig. 4 Skin patch test of 0.5 % acemannan in Carbopol at the Faculty of Dentistry, Chulalongkorn University, Bangkok, Thailand. (*left*) Upper back of a patient with test and control materials in Finn Chambers. (*right*) After 24 h, the patch was removed revealing no allergic reaction

of acemannan either extraorally (Fig. 4) or intraorally (Bhalang et al. 2013; Poor et al. 2002). In addition, there were no local or systemic side effects of acemannan when used on normal oral mucosa (Bhalang et al. 2013).

4 In Vitro Studies

Early investigations of acemannan concentrated on its effects on cells in vitro. It was found that acemannan acts as an important immunoenhancer by increasing the lymphocytic response to alloantigens (Womble and Helderman 1998). Furthermore, the immunomodulatory activities of acemannan were effected through macrophages by increasing nitric oxide synthase mRNA expression in these cells (Ramamoorthy et al. 1996). Acemannan was also found to stimulate macrophage cytokine production and nitric oxide release (Zhang and Tizard 1996).

Acemannan significantly increased periodontal ligament cell proliferation; expression of vascular endothelial growth factor, bone morphogenetic protein 2, and type I collagen mRNA; alkaline phosphatase activity; and mineral deposition when compared with the untreated control group in vitro (Boonyagul et al. 2014). In addition, a study has established the antiviral potential of acemannan in vitro (Kahlon et al. 1991a), and it was shown that acemannan combined with azidothymidine and acyclovir acts synergistically to inhibit the replication of human immunodeficiency virus and herpes simplex virus, respectively (Kahlon et al. 1991b).

A study investigating the ability of acemannan in inhibiting adherence of *Pseudomonas aeruginosa* to cultures of human lung epithelial cells found that the binding of either mucoid or non-mucoid bacteria was inhibited by acemannan (Azghani et al. 1995). In addition, the preexposure of macrophages to acemannan resulted in 38 % killing of *Candida albicans* by these cells compared with 0–5 % killing in the control group (Stuart et al. 1997).

5 Animal Studies

The majority of the studies of the in vivo effects of acemannan were mostly performed in animals, with the results summarized as follows:

(a) Animal experiments on wound healing showed that acemannan accelerated oral wound healing. When used on rat oral wounds, increased levels of proliferating cell nuclear antigen, keratinocyte growth factor-1, vascular endothelial growth factor, and type I collagen were found (Jettanacheawchankit et al. 2009). Furthermore, when used as a wound dressing gel, acemannan reduced acute radiation-induced skin reactions in mice (Roberts and Travis 1995).
(b) It was hypothesized that acemannan could function as a bioactive molecule inducing bone formation by stimulating stem cell proliferation, differentiation into osteoblasts, and extracellular matrix synthesis. Thus, acemannan could be a candidate natural material for bone regeneration (Boonyagul et al. 2014). Indeed, in a study using canines, acemannan significantly accelerated new alveolar bone, cementum, and periodontal ligament formation in class II furcation defects (Chantarawaratit et al. 2014).
(c) Studies of feline virus infection found that administration of acemannan to clinically symptomatic cats significantly improved both the quality of life and the survival rate, demonstrating its antiviral effect (Sheets et al. 1991; Yates et al. 1992).
(d) Acemannan has demonstrated anticancer effects. When acemannan was administered intraperitoneally to mice into which murine sarcoma cells had been subcutaneously implanted, it was found that 40 % of the animals treated with acemannan at the time of tumor cell implantation survived. The tumors in the acemannan-treated animals showed vascular congestion, polymorphonuclear leukocyte infiltration, and central necrosing foci with peripheral fibrosis. The results suggested that acemannan initiated an immune attack on the cancer cells, necrosis, and regression of implanted sarcomas in mice (Peng et al. 1991). Studies in canines and felines with fibrosarcomas and other neoplasms also revealed comparable results (King et al. 1995; Harris et al. 1991).
(e) For the treatment of oral ulcers, an animal study has shown that intentional palatal wounds in rats treated with Carbopol® containing 0.5 % acemannan had significantly better healing compared to that of animals receiving normal saline and 0.1 % triamcinolone acetonide. Thus, acemannan can have a marked effect on the oral wound healing process, possibly through the induction of fibroblast proliferation (Jettanacheawchankit et al. 2009).

6 Oral Ulcerations

There are several kinds of oral ulcerations. The most commonly found ulceration in the oral cavity is recurrent aphthous ulceration (RAU) (Graykowski et al. 1966; Vincent and Lilly 1992). The name “aphthous” is derived from the Greek “aptha”

Fig. 5 Minor recurrent aphthous ulcerations on a patient's left lateral tongue

meaning ulcer. RAU is mostly found on nonkeratinized oral mucosa. RAU is present most commonly in young adults and the frequency of developing the ulcers reduces with age. RAU is painful and affects the quality of life of patients experiencing the ulcers. The incidence rate of RAU is 46.7 % and is detected more frequently in females than in males (Scully et al. 2003; Krisdapong et al. 2012).

RAU is a small, round or oval, well-defined ulcer with a yellowish gray center consisting of necrotic tissue. The ulcer commonly has an erythematous border and is found on the oral mucosa of movable tissues such the tongue and the lining mucosa on the cheek and inner side of the lip (Cooke 1969).

RAU is classified into three subtypes: minor aphthous ulcers, major aphthous ulcers, and herpetiform ulcers, based on the size and number of ulcerations. Minor RAU (MiRAU) (Fig. 5) is the most common type affecting approximately 80 % of RAU patients. Patients with MiRAU typically present with 1–5 ulcers per episode, with each ulcer varying in size from 3 to 10 mm. These ulcers normally resolve in 4–14 days without scarring (Femiano et al. 2007). Major aphthous and herpetiform ulcers are less common. Major aphthous ulcers are larger than 1 cm in diameter and quite painful, lasting up to 6 weeks with scarring. Herpetiform ulcers are very small in size (2–3 mm) and can number up to one hundred. Many of these small ulcers commonly coalesce to form larger irregularly shaped ulcers. These lesions differ from herpetic ulcers in that they do not contain virus and are not preceded by vesicle formation (Preeti et al. 2011).

The etiology of RAU has not been clearly identified. However, associations between RAU and immunological disorders have been reported (Lewkowicz et al. 2011). It was proposed that there is a relationship between cell-immediate immune response and RAU. Patients with RAU have been described as having increased numbers of blood CD8+ T lymphocytes and decreased CD4+ T lymphocytes (Pedersen et al. 1989). Furthermore, RAU patients demonstrated higher levels of T-cell receptor γδ cells, which are involved in antibody-dependent cell-mediated cytotoxicity (Pedersen and Ryder 1994). Cytotoxic T lymphocytes play a major role

in destroying epithelial cells, resulting in oral ulceration. The ulcerative phase is marked by an increase of CD8+ cytotoxic cells; however, during healing, these are replaced by CD4+ cells (Savage et al. 1985).

There are also associations between the occurrence of RAU and the levels of several cytokines such as tumor necrosis factor alpha and interleukin 2. There appears to be a genetic component to RAU, with 40 % of patients reporting a family history and a high correlation in identical twins (Sircus et al. 1957; Miller et al. 1977). In addition, there are several predisposing factors suspected of stimulating the onset of RAU. These factors include anxiety; hormonal imbalance; nutritional deficiency such as iron, folate, vitamin B, and zinc; gastrointestinal disorders such as Crohn's disease, ulcerative colitis, and celiac disease; and systemic diseases such as Behcet's disease, Reiter's syndrome, Sweet's syndrome, and cyclic neutrophilia (Jurge et al. 2006). Furthermore, sensitivity to certain medications, diets, or substances such as beta blockers, nonsteroidal anti-inflammatory medicines, alendronate, chocolate, coffee, peanuts, grains, cheese, strawberry, sodium lauryl sulfate, food dye, and preservatives may be involved in RAU development (Jurge et al. 2006). Interestingly, another stimulant for the development of RAU is smoking cessation. RAU develops on nonkeratinized oral mucosa, and smoking results in increased mucosal keratinization, which may serve as a barrier against both trauma and bacteria (Shapiro et al. 1970). Furthermore, nicotine reduces the expression of TNF-α and IL-1 and IL-6 (Floto and Smith 2003).

There is presently no known curative management of RAU available. Most current treatments are palliative and aim to reduce the pain and inflammation resulting from the ulcers. The treatments of choice for RAU are steroid medications in the forms of pastes or gels to be used topically on the lesion. Commonly used steroid medications are triamcinolone acetonide, betamethasone valerate, fluocinonide, fluocinolone acetonide, clobetasol propionate, and dexamethasone elixir (Barrons 2001). Topical steroids are very effective in the treatment of RAU but do not prevent the reoccurrence of the ulcers. The most important side effect of topical steroids is local fungal infection. Other treatments for RAU include antimicrobial agents, topical analgesics, immunosuppressive agents, anti-inflammatory agents, and laser therapy (Barrons 2001). Because steroid treatment has the potential for the development of secondary oral candidiasis over long-term use, herbal medicines have been considered as an alternative treatment.

7 Acemannan and Oral Ulcerations

To evaluate the use of acemannan in the treatment of oral ulcerations, a double-blind clinical study compared three groups of subjects with MiRAU treated with 0.1 % triamcinolone acetonide (topical steroid), 0.5 % acemannan in Carbopol® 934P NF, or pure Carbopol® 934P NF for 7 days (Bhalang et al. 2013).

Four aspects of treatment success were measured in this study: ulcer size reduction, pain control, symptom control, and satisfaction. Although acemannan

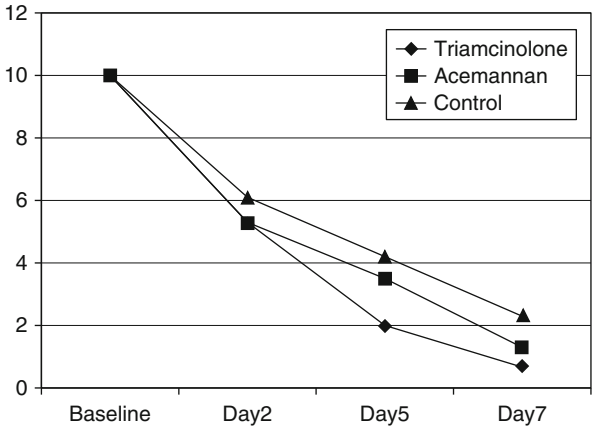

Fig. 6 Comparison of symptom relief rating between the groups receiving 0.1 % triamcinolone acetonide (topical steroid), 0.5 % acemannan in Carbopol® 934P NF, or pure Carbopol® 934P NF. Patients were asked to rate the symptom relief as compared to the level before treatment if the baseline level was 10

treatment did not result in a reduction in ulcer size to the same extent as did 0.1 % triamcinolone acetonide, the difference was not significant. Wound healing is composed of overlapping phases of inflammation, reepithelialization and dermal connective tissue growth, and tissue remodeling. An in vitro study indicated that acemannan stimulated gingival fibroblast proliferation, the expression of VEGF, an angiogenic factor, and collagen type I, all of which contribute to the formation of the granulation tissue in wound healing (Jettanacheawchankit et al. 2009). In addition, this study found increased fibroblast expression of keratinocyte growth factor, which is involved in wound reepithelialization. These findings likely explain the increased wound healing by acemannan found in the clinical RAU study.

When ulcer pain ratings were compared between the three groups, they found that acemannan had a more immediate effect in relieving pain symptoms. Acemannan has been shown to inhibit the formation of bradykinin and to have other anti-inflammatory effects (Lex 2012), which may account for this finding. The subjects were asked on follow-up if the medication used had relieved their symptoms, and at day 5, the subjects who received 0.1 % triamcinolone acetonide felt their symptoms were mostly relieved, followed by acemannan, and then control (Fig. 6). Post hoc tests revealed that the 0.1 % triamcinolone acetonide group experienced significantly greater aphthous ulcer symptom relief compared to the acemannan group at day 5 and the control group at days 5 and 7. Notably, the subjects were significantly more satisfied with 0.1 % triamcinolone acetonide and acemannan treatment compared to control, and there was no difference in satisfaction levels between subjects receiving 0.5 % acemannan and 0.1 % triamcinolone acetonide at day 7. Subjects who received all three treatments at different time points reported that they were mostly satisfied with acemannan treatment compared to standard topical steroid treatment. This indicates that acemannan is a suitable alternative to steroid medication in the treatment of RAU.

8 Conclusion

Acemannan is effective in reducing RAU ulcer size and pain. Patients were mostly satisfied mostly with acemannan treatment when compared to topical steroid and control. Thus, acemannan can be used for the treatment of RAU.

Natural Polysaccharides from Mushrooms: Antinociceptive and Anti-inflammatory Properties

71

Fhernanda Ribeiro Smiderle, Andrea Caroline Ruthes, and Marcello Iacomini

Contents

Abstract

Mushrooms have been used in traditional Chinese medicine or as functional foods in Japan and other Asian countries. They have received increasing attention from the researchers for the use in food and pharmaceutical fields. Nowadays there is an increasing public interest in the mushroom constituents for discovering new drugs or lead compounds. A number of bioactive compounds, especially polysaccharides, have been isolated from mushrooms. These bioactive components have become popular sources of natural antioxidative, antitumor, antiviral, antimicrobial, and immunomodulatory agents, and more recently polysaccharides have been explored about their effects against nociception and inflammation. Although there are many studies showing interesting results, more research is necessary to explore such potential. From the results obtained till now, the present chapter explores the antinociceptive and anti-inflammatory bioactivity of natural polysaccharides from mushrooms and

1 Introduction

For millennia, mushrooms have been valued as edible and medicinal, especially taking into account their use in the folk medicine of the Western world and in traditional medicine of the Orient. Consequently, nowadays mushrooms have been widely evaluated for their nutritional value and acceptability as well as for their pharmacological properties. Although there are limited direct human intervention trials, there is a rapidly growing volume of in vitro and in vivo animal trials describing a range of possible health benefits attributed to mushrooms, including immunomodulatory, antitumor, and antimicrobial properties, among others (Wasser 2002; Zhang et al. 2007). Nevertheless, mushrooms represent a vast and currently untapped source for researchers, only 10 % (approximately 15,000–22,000 named species) are known by scientists (Hawksworth 2001; Kirk et al. 2008; Mueller and Schmit 2007).

A great variety of active molecules have been obtained from mushrooms and identified; among them, the polysaccharides have been the subject of intense research, taking into view its high potential for application in different sectors. Polysaccharides can be isolated from fruiting bodies, mycelia, and culture media, released as exopolysaccharides (Smith et al. 2003; Wasser 2002, 2010; Zhang et al. 2007), which deserve attention, since this class of molecules make up a vast and yet largely unexploited source of powerfully new pharmaceutical products.

The fungal polysaccharides and polysaccharide-protein complexes have been mainly investigated by presenting a variety of biological responses, such as antitumor, antioxidative, and immune stimulatory activities and more recently antinociceptive and anti-inflammatory effects (Baggio et al. 2010; Carbonero et al. 2008a; Novak and Vetvicka 2008; Ruthes et al. 2013a; Smiderle et al. 2008a). The therapeutic application seems to depend on chemical structure and spatial conformation of each macromolecule, and small structural differences of each polymer can result in peculiar features for new biotechnological applications (Wasser 2010).

Several polysaccharides have been isolated from mushrooms, the most studied are structurally different β-D-glucans (Carbonero et al. 2006; Rowan et al. 2003; Ruthes et al. 2013b; Smiderle et al. 2008a), besides xyloglucan (Moradali et al. 2007), xylomannan (Smiderle et al. 2006), and heterogalactans, which may contain *O*-methyl groups or a variety of side chains (Wasser 2002; Zhang et al. 2007) including manogalactans (Jakovljevic et al. 1998; Rosado et al. 2003; Smiderle et al. 2008b; Zhang et al. 2013), fucogalactans (Fan et al. 2006; Komura et al. 2010; Mizuno et al. 2000; Ruthes et al. 2012, 2013a; Zhang et al. 2006), and

fucomannogalactans (Alquini et al. 2004; Carbonero et al. 2008; Cho et al. 1998, 2011; Smiderle et al. 2006; Ruthes et al. 2013c).

Recent studies concerned to anti-inflammatory and antinociceptive effects evaluated the potential of crude extracts or isolated polysaccharides such as glucans, fucogalactans, fucomannogalactans, and mannogalactans isolated from different mushroom species such as *Agaricus brasiliensis* and *Agaricus bisporus* var. *hortensis* (Komura et al. 2010), *Agaricus bisporus* (Ruthes et al. 2012, 2013a), *Amanita muscaria* (Ruthes et al. 2013c), *Caripia montagnei* (Castro et al. 2014; Queiroz et al. 2010), *Flammulina velutipes* (Wu et al. 2010), *Geastrum saccatum* (Dore et al. 2007), *Inonotus obliquus* (Ma et al. 2013), *Lactarius rufus* (Ruthes et al. 2013b), *Lentinus edodes* (Carbonero et al. 2008), *Pleurotus pulmonarius* (Smiderle et al. 2008b), and *Rhodotorula mucilaginosa* (Valasques-Junior et al. 2014).

Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage. It typically involves a noxious stimulus or experience that activate nociceptors in the body's tissues, which deliver signals to the central nervous system, where they are processed and generate multiple responses. It could be divided into two main categories: acute and chronic pain. Acute or nociceptive pain involves the motor neurons of the central nervous system. It is mediated by nociceptors on A-δ and C fibers. Chronic pain, however, is considered a disease process itself. There are two types of chronic pain, the inflammatory nociceptive pain and the neuropathic pain. Inflammatory nociceptive pain is associated with tissue damage and the resulting inflammatory process, while neuropathic pain is produced by damage to the neurons in the peripheral and central nervous systems and involves sensitization of these systems (Campbell and Meyer 2006).

On the other hand, inflammation itself is a host defense mechanism to eliminate invading pathogens and to initiate healing process. Uncontrolled or overproduction of inflammatory products can lead to injury of host cells, chronic inflammation, chronic diseases, and also neoplastic transformation (Mantovani et al. 2008). During inflammatory process, the inflammatory biomarkers are highly produced such as reactive oxygen species (ROS), reactive nitrogen species (RNS), tumor necrosis factor-α (TNF-α), interleukin (IL)-1, IL-6, and cyclooxygenase (COX)-2.

Therefore, taking steps to ease inflammation is an effective means of interfering with the process of pain sensitization. This is why drugs like acetaminophen and ibuprofen, which are anti-inflammatory, relieve pain. Unfortunately, though these drugs and others like them are very effective for reducing inflammation and pain, they often cause side effects, which compromise their long-term risk versus benefit profile.

A variety of natural anti-inflammatory compounds are able to target inflammation by reducing the synthesis of inflammatory mediators or modulating inflammatory pathways. Natural polysaccharides from mushrooms represent a source of natural compounds able to target inflammation and alleviate nociception showing promising results in recent studies.

Thus, the aim of the present text is to explore the antinociceptive and anti-inflammatory bioactivity of natural polysaccharides from mushrooms and review their mechanism of action, toxicity, bioavailability, and metabolism, besides describing other biological activities and the already done clinical trials.

2 Bioactivity

Regarding the anti-inflammatory and antinociceptive properties of mushroom polysaccharides, it is possible to infer that such polymers have shown pronounced therapeutic effects by experiments performed in vitro and in vivo (Chang et al. 2013; Kim et al. 2007; Komura et al. 2010; Queiroz et al. 2010; Ruthes et al. 2013c).

Although inflammation is a normal host response to repair tissue damage provoked by external stimuli, chronic inflammation can induce the host to develop various diseases, including cancer (Li et al. 2014; Wu et al. 2014). The assessment of anti-inflammatory compounds is in continuous update, and besides the evident immunomodulatory properties of mushroom polysaccharides, it was observed that they can also act against inflammation (Castro et al. 2014; Fangkrathok et al. 2013; Wu et al. 2010). In vitro analysis showed that neutral and sulfated polysaccharides extracted from *Armillariella mellea* inhibited the secretion of TNF-α and IL-6 by RAW 264.7 macrophages when stimulated with lipopolysaccharide (Chang et al. 2013). As some in vivo examples, an extract from *Caripia montagnei* containing 98.7 ± 3.3 % of carbohydrates, which was 63.3 ± 4.1 % composed of β-D-glucans, was tested (Castro et al. 2014; Queiroz et al. 2010). The extract reduced the inflammatory infiltrate produced by thioglycolate-induced peritonitis by 75.5 ± 5.2 % when administered to mice; furthermore, a decrease in cytokine production was observed (Queiroz et al. 2010). In rats, the same extract inhibited the carrageenan-induced paw edema by 90.7 ± 3.5 % (Castro et al. 2014). Another polysaccharide extract containing glucose, mannose, and xylose, obtained from *Flammulina velutipes*, was administered to burned rats. The treatment showed an anti-inflammatory effect by the reduction of ICAM-1 concentrations and MPO activity and by the increase of the anti-inflammatory cytokine IL-10 in the serum (Wu et al. 2010).

Purified polysaccharides have also demonstrated strong anti-inflammatory activity. A fucomannogalactan and a β-D-glucan isolated from *Amanita muscaria* were effective against the inflammatory pain of formalin-induced nociception in mice (Ruthes et al. 2013c). The nociception and inflammation can be evaluated in mice/rats by a well-established approach which consists in the injection of formalin, and the nociception can be observed in two distinct phases: neurogenic pain (early phase) and inflammatory pain (late phase) (Tjolsen et al. 1992). This method is an alternative for the problems encountered to evaluate the nociception because there are several limitations in the use of human patients to assess pain mechanisms and pathways. Therefore, in vitro studies and research on animals are more frequently used; however, they do not eliminate another limitation: the investigator can only

speculate on the experience of the animal and must instead use secondary behavioral indicators to infer pain (Hogan 2002).

Homopolysaccharides, as β-D-glucans isolated from *L. rufus* and *P. pulmonarius*, were tested in mice using the formalin-induced nociception method (Tjolsen et al. 1992). In both studies, a slight inhibition of the neurogenic pain (early phase) at the higher doses (30 mg kg^{-1}) was observed , while the greater analgesic effect was observed on the late phase (inflammatory pain) at the same or lower doses (Ruthes et al. 2013b; Smiderle et al. 2008a). These studies showed that the analgesic effect demonstrated by the mushroom β-D-glucans is probably related to an anti-inflammatory action, being similar to that of nonsteroidal anti-inflammatory drugs. The strong analgesic effect of the β-D-glucan isolated from *P. pulmonarius* was confirmed by other methods as nociception is induced by glutamate, capsaicin, cinnamaldehyde, menthol, and acidified saline (Baggio et al. 2010, 2012).

Heteropolysaccharides isolated from *L. edodes*, *Agaricus* spp., and *P. pulmonarius* have also demonstrated an analgesic effect. The abdominal constriction caused by the intraperitoneal injection of acetic acid was inhibited in mice that received the heteropolysaccharide injections 30 min before. A fucomannogalactan from *L. edodes* (Carbonero et al. 2008), two different fucogalactans from *Agaricus* spp. (Komura et al. 2010), and a mannogalactan from *P. pulmonarius* (Smiderle et al. 2008b) were tested. Comparing these studies, it can be suggested that the bioactivity of the polysaccharide is closely related to its chemical structure, because these four compounds exhibited different effects, and although these polymers present the same main chain structure [α-D-Gal*p*-(1→6)-linked], they presented different branching degrees and substitutions, as fucose, mannose, galactose, and methyl groups. Furthermore, two of them have also diminished the leukocyte migration and the peritoneal capillary permeability, showing a pronounced anti-inflammatory activity (Carbonero et al. 2008; Komura et al. 2010).

There is a variety of methods to study nociception responses in animals, although, as cited previously, the results may be subjective and based on observations on the animal behavior. Taking into account that the analgesic properties of mushroom polysaccharides are closely related to anti-inflammatory effects, it is strongly recommended to evaluate both bioactivities to determine their mechanism of action.

3 Mechanism of Action

It is well established that a lot of known and tested polysaccharides isolated from various natural sources, particularly from mushrooms, occupy a notorious position in turn of their biological potential. This fact should possibly be due to their very low or absent toxicity.

The benefits of mushroom compounds on different clinical conditions have attracted the interest of the scientific community in the last decade in order to understand the molecular mechanisms responsible for their actions.

β-D-Glucans are undoubtedly the most exploited polysaccharide structures by researchers, regarding the elucidation of their chemical structure and their probable biological potential and mechanisms of action. Despite long-term interest and research, the mechanism of how β-D-glucans affect health remained a mystery for a long time. Only in the last decade, extensive research has helped to reveal the effects that β-D-glucans have on the immune system. However, little is known about the mechanisms of action of β-D-glucans or other polysaccharide structures in relation to the antinociceptive and anti-inflammatory effects. The probable mechanisms of action of mushroom natural polysaccharides on nociception and inflammation studied to date will be given in the following.

The pain sensation acts as a warning device that alerts an organism to the presence of damaging stimuli. Although acute pain has a protective role as a warning system (Julius and Basbaum 2001), chronic pain, as neuropathic pain, is produced by dysfunction or damage to the peripheral or central nervous system (Somers and Clemente 2009; Zimmermann 2001). Frequently, tissue damage leads to the activation of nociceptors through the release of diverse chemical mediators such as excitatory amino acids, protons, peptides, lipids, and cytokines, which act on specific receptors and ion channels to various signal transduction cascades (Sawynok 2003).

Smiderle et al. (2008a) demonstrated that GL, a (1→3, 1→6)-linked β-D-glucan isolated from *P. pulmonarius*, inhibits abdominal contractions induced by acetic acid with a concomitant reduction of leukocyte migration to the peritoneal cavity and plasmatic extravasation. It was also shown that GL inhibits both the first and second phases of formalin-induced licking (Smiderle et al. 2008a). Acetic acid and formalin are thought to act through the release of endogenous inflammatory mediators such as bradykinins, glutamate, SP, prostanoids, and cytokines (TNF-α, IL-1β, and IL-8), which stimulate primary sensory neurons (Collier et al. 1968; Ikeda et al. 2001; Ribeiro et al. 2000; Vinegar et al. 1979). Thus, these previous findings suggest that the possible antinociceptive action of GL could be due to the inhibition of the release of endogenous mediators (i.e., glutamate, TNF-α, or IL-1β).

Baggio et al. (2010), extending their findings on GL possible mechanisms of action, investigated more evidence concerning the participation of the glutamatergic system on antinociception caused by GL. Glutamate is a major excitatory neurotransmitter involved in the transmission of nociceptive signals. Furthermore, the nociceptive neurons activated by glutamate may release several inflammatory mediators and neuropeptides that could also be involved on nociceptive transmission both in the central and peripheral nervous system (Fundytus 2001; Millan 1999). GL effectively inhibits the nociceptive response induced by the intraplantar injection of glutamate into the mouse hind paw. The nociceptive response induced by glutamate, which acts through the glutamate receptors, is present in the peripheral, spinal, and supraspinal sites of action (Beirith et al. 2002). So, GL antinociception may arise from the inhibition of ionotropic or metabotropic glutamate receptors. Furthermore, animals were intraperitoneally treated, and GL showed to inhibit the nociceptive response caused by NMDA, AMPA, and kainate. However, GL did not inhibit the nociceptive response induced

by intrathecal injection of trans-ACPD, a nonselective metabotropic glutamate receptor agonist. The potency of GL to inhibit ionotropic glutamate receptor-induced nociception is important because ionotropic glutamate receptors are involved in several pain conditions (Bleakman et al. 2006). Moreover, there is evidence indicating the interaction of substance P (SP) and glutamate at the spinal level. Behavioral changes observed after spinal administration of SP are potentiated by the coadministration of NMDA and kainite (Mjellem-Joly et al. 1991, 1992). In turn GL does not reduce the nociceptive response induced by the intrathecal injection of SP. These observations suggest that the antinociceptive action of GL could be regulated by ionotropic glutamate receptor pathways that modulate nociceptive transmission at the spine (Baggio et al. 2010).

The proinflammatory cytokines are also involved in the modulation of nociceptive processes, and the ability of cytokines, such as TNF-α and IL-1β, to induce nociceptive behavior when administered intrathecally has been attributed to the induction of glutamate and SP release from nerve terminals (Choi et al. 2003; Tadano et al. 1999). For this reason, the effect of GL against the TNF-α- and IL-1β-induced nociceptive responses in mice was evaluated. Authors demonstrated that the treatment of animals with GL inhibits the nociceptive response induced by IL-1β, suggesting the inhibitory activity of GL on events triggered by IL-1β (Baggio et al. 2010). The glutamatergic system and proinflammatory cytokine pathways play important roles in acute pain. Likewise, the glutamatergic system and proinflammatory cytokines, such as IL-1β and TNF-α, participate in the establishment or maintenance of chronic pain (Sawynok 2003; Zimmermann 2001). The next step of the study was to use an experimental model of mononeuropathy produced by partial sciatic nerve ligation (PSNL) in mice, which mimics important symptoms observed in patients with peripheral neuropathy and is used in behavioral research (Paszcuk et al. 2007).

Peripheral nerve injury is often accompanied by transient local inflammation, which probably contributes to the instigation of neuropathic pain. Several inflammatory mediators, such as prostaglandin E2 (PGE2), bradykinin, nerve growth factor, histamine, serotonin, IL-1β, TNF-α, ATP, glutamate, endothelin-1, and various chemokines, can be released from damaged axons or Schwann cells or from satellite cells, mast cells, and infiltrating leukocytes (Ji and Strichartz 2004). Interestingly, the results demonstrated that GL significantly reverses mechanical allodynia caused by PSNL (Baggio et al. 2010). Moreover, the anti-allodynic response caused by GL was not susceptible to tolerance. This conclusion is based on data showing that (1) the withdrawal of GL was followed by complete return to baseline allodynia and (2) the intraperitoneal treatment with GL twice a day produced very similar and pronounced anti-allodynic effects. This finding allowed authors to infer that the anti-allodynic effect of GL involves the inhibition of the glutamatergic system, ionotropic glutamate receptors, and the proinflammatory cytokine IL-1β (Baggio et al. 2010).

Finally, the open-field test was used to exclude the possibility that the antinociceptive action of GL could be related to nonspecific disturbances in the locomotor activity of the animals. Authors observed that at doses that have

antinociceptive action, GL did not alter the motor performance of mice (Baggio et al. 2010). In this regard, it has been reported that several drugs that antagonize glutamate receptors produce significant disturbances in locomotor activity (Jordan et al. 2008).

Collectively, the results of Baggio et al.'s (2010) research confirm the data about the antinociceptive properties of GL on acute or chronic pain. It was demonstrated that systemic treatment with GL provides a pronounced inhibition of acute nociceptive responses induced by chemicals (EEAs, SP, and proinflammatory cytokines). Furthermore, prolonged systemic treatment of animals with GL is effective in preventing persistent mechanical allodynia caused by partial sciatic nerve ligation in mice.

A better understanding of the mode of action of GL would enhance the potential therapeutic interest on this naturally occurring β-D-glucan. Several ion channels play an essential role in the ability of nociceptors (C and A fibers) to detect and discriminate noxious thermal, mechanical, and chemical stimuli and convey this sensory information to second-order nociceptive neurons of the dorsal horn of the spinal cord (McCleskey and Gold 1999). GL effectively inhibited nociceptive responses induced by intraplantar injections of capsaicin or cinnamaldehyde, which are highly selective activators/agonists of TRPV1 and TRPA1 channels, respectively, as well as menthol (a preferential TRPM8 channel agonist that can also activate TRPA1 channels at higher concentrations) or acidified saline (which activates TRPV1 and ASIC channels) (Baggio et al. 2012). This study confirmed that the nociceptive responses elicited by capsaicin, cinnamaldehyde, and acidified saline were extensively inhibited by prior treatment with antagonists of their respective specific or preferential targets, i.e., ruthenium red (TRPV1), camphor (TRPA1), and amiloride (ASIC). Due to the lack of a suitable selective antagonist, authors were unable to determine if responses to menthol resulted from activation of TRPM8 channels (Baggio et al. 2012). In addition, the potency of GL in inhibiting cinnamaldehyde-induced nociception is in excellent agreement with that previously observed in the model of formalin-induced hind paw nociception (Smiderle et al. 2008a), especially considering that formalin is an activator of TRPA1 channels (McNamara et al. 2007). These results strengthen considerably the evidence that GL is an effective analgesic in rodents (Baggio et al. 2012). However, it appears most unlikely that GL induces antinociception by selectively antagonizing the binding of capsaicin, cinnamaldehyde, menthol, or protons to their respective target channels, which was supported by the no alteration of nociceptive responses when the GL was coadministered with these activators/agonists (Baggio et al. 2012). It was demonstrated that capsaicin, stimulating TRPV1 receptor, mediates the release of several neurotransmitters, including glutamate; besides, menthol (TRPM8 agonist) and allyl isothiocyanate (TRPA1 agonist) enhance spontaneous glutamatergic synaptic transmission onto lamina II neurons in spinal cord slices (Baccei et al. 2003; Kosugi et al. 2007; Medvedeva et al. 2008). Indeed, it was previously demonstrated by the same research group that GL inhibited the nociceptive responses induced by injection of intrathecal excitatory amino acids (Baggio et al. 2010), suggesting that the GL effect seems to be partially related to

the inhibition of glutamate release in the dorsal horn after peripheral stimulation of TRPs (Baggio et al. 2012). It was also shown that GL effectively inhibited nociceptive responses to intraplantar injection of PMA, a direct activator of PKC (Ferreira et al. 2008). Given the extensive evidence implicating PKC in signaling mechanisms leading to nociception and hyperalgesia (Souza et al. 2002), Baggio et al. (2012) hypothesized that this could constitute a potentially relevant target for the antinociceptive action of GL. In this regard, using Western blot analysis, they obtained ex vivo evidence that intraplantar PMA injection clearly promoted the translocation of PKC from the cytosolic to the membrane-enriched fractions of hind paw skin homogenates, as would be expected of a PKC activator (Ferreira et al. 2008). More importantly, prior i.p. treatment of the animal with GL, at a dose promoting effective analgesia, fully prevented this PMA-induced PKC translocation (Baggio et al. 2012). In addition, authors found that GF109203X, a selective PKC inhibitor (Ferreira et al. 2008), inhibited nociceptive responses induced by i.pl. injection of capsaicin and menthol (Baggio et al. 2012). However, unlike GL, GF109203X did not influence responses induced by either cinnamaldehyde or acidified saline (Baggio et al. 2012). As the phosphorylation of TRPV1 by PKC sensitizes this channel to activation by capsaicin (Bhave et al. 2003), blockade of this process by GL might account for the analgesic effect of GL (and GF109203X) against capsaicin-induced nociception (Baggio et al. 2012). Nonetheless, this does not appear to be a plausible explanation for its inhibitory effects on nociception induced by menthol, cinnamaldehyde, or protons (i.e., acidified saline), as PKC actually dephosphorylates and downregulates TRPM8 channels (Premkumar et al. 2005), does not contribute to the sensitization of TRPA1 channels (Wang et al. 2008), and appears to phosphorylate and sensitize only ASIC channels containing ASIC2 subunits (Baron et al. 2002; Deval et al. 2004), which are poorly expressed by DRG neurons (Ugawa et al. 2004). It is interesting to note, however, that the antinociceptive profile of action of GF109203X (i.e., more effective against responses induced by menthol than capsaicin and inactive against cinnamaldehyde or acidified saline) was remarkably similar to that of GL, which displayed an ID_{50} against nociception triggered by menthol that was 42-, 72-, and 156-fold lower than those obtained against responses induced by capsaicin, cinnamaldehyde, and acidified saline, respectively (Baggio et al. 2012). Therefore, the collected evidence strongly suggests that the antinociceptive effects of GL are associated, at least to a significant extent, to the inhibition of PKC activation (Baggio et al. 2012).

In conclusion, Baggio et al. (2012) demonstrated that GL, a naturally occurring β-D-glucan from *P. pulmonarius*, displays pronounced systemic antinociceptive properties in chemical models of nociception models in mice. The mechanisms underlying GL-induced antinociception appear to involve inhibition of PKC. It remains to be determined if GL also has other potentially relevant targets for its antinociceptive actions and if it is a selective inhibitor of PKC or can also block activity of other PKC isoforms.

The research using GL showed to be the deeper study regarding the mechanism of action of a natural mushroom polysaccharide on nociception and inflammation

published till now (Baggio et al. 2010, 2012). Other researches evaluating the potential of D-glucans or heteropolysaccharides, especially heterogalactans as antinociceptive and anti-inflammatory compounds, just make suggestions for possible mechanisms of actions.

Smiderle et al. (2008b) demonstrated that a mannogalactan (MG) from *P. pulmonarius* and indomethacin gave rise to a similar analgesic effect, while the inflammatory response, characterized by leukocyte infiltration and peritoneal capillary permeability, was inhibited by dexamethasone and indomethacin, but not MG. Such results could indicate that MG showed an antinociceptive action, independent of an anti-inflammatory activity, in the acetic acid-induced writhing test. The mechanism by which MG produces antinociception still remains unclear, but the inhibition of cytokine proinflammatory release or glutamate in the cerebrospinal fluid increase seems to explain, at least in part, its analgesic effects.

Studying some structural different heterogalactans from *L. edodes* (Carbonero et al. 2008), *A. brasiliensis* and *A. bisporus* var. *hortensis* (Komura et al. 2010), *A. bisporus* (Ruthes et al. 2012, 2013a), *Lactarius rufus* (Ruthes et al. 2012), and *Amanita muscaria* (Ruthes et al. 2013c), it was demonstrated that tested polysaccharide fractions have significant antinociceptive and anti-inflammatory properties using the model of abdominal constrictions induced by acetic acid (Carbonero et al. 2008; Komura et al. 2010) which, additionally, involves endogenous inflammatory mediators or the formalin-induced pain model in mice (Ruthes et al. 2012, 2013a).

The formalin test is a satisfactory and comprehensive model for evaluating the antinociceptive activity of drugs. The intraplantar injection of formalin activates nociceptive nerve terminals and produces neurogenic pain, whereas inflammatory pain is mediated by a combination of peripheral input and spinal cord sensitization (Hunskaar and Hole 1987; Tjolsen et al. 1992). Moreover, it has been demonstrated that the intraplantar injection of formalin in rodents increases the spinal levels of excitatory amino acids, PGE2, nitric oxide, tachykinin, and kinins, among other peptides (Malmberg and Yaksh 1995; Santos and Calixto 1997; Santos et al. 1998; Tjolsen et al. 1992). Experimental data indicate that formalin predominantly evokes activity in C-fiber peroxidase (Tjolsen et al. 1992), although A fibers are thought to be responsible for fast nociceptive transmission in the first phase of the pain response (Julius and Basbaum 2001). It is notable that the nociception produced by formalin (neurogenic phase) is quite resistant to the majority of NSAIDs, such as acetylsalicylic acid, indomethacin, paracetamol, and diclofenac. However, these drugs can dose-dependently attenuate the inflammatory phase of formalin-induced licking (Hunskaar and Hole 1987; Malmberg and Yaksh 1992; Santos et al. 1998).

Ruthes et al. (2013a) also examined the effects of *A. bisporus* fucogalactan (EFP-*Ab*) on iNOS and COX-2 expression in the ileum of septic mice by immunoblotting. EFP-*Ab* decreased both iNOS and COX-2 expression by 53 % and 54 %, respectively. Dexamethasone also affected both iNOS and COX-2 expression, reducing by 74.5 % and 71.4 %, respectively. These results strongly confirmed the anti-inflammatory activity of EFP-*Ab*.

The enzymes iNOS and COX-2 are both upper expressed during proinflammatory events including sepsis. The iNOS (inducible nitric oxide

synthase), once expressed, produces high amounts of NO over long periods of time, which causes cellular damage. It is also associated with the septic shock, considered the main cause of mortality among the septic patients (Landry and Oliver 2001). Compounds that inhibit iNOS expression or iNOS activity have anti-inflammatory properties (Tinker and Wallace 2006). In turn, COX-2 is the inducible isoform of the cyclooxygenase enzyme that catalyzes the production of inflammatory prostanoids. Systemic COX-2 is increasingly recognized as an important player in sepsis-induced inflammation. In fact, COX-2-deficient mice are protected from sepsis-induced inflammation and death (Ejima et al. 2003).

The inflammatory response is induced by various agents, resulting in tissue damage and triggering immune activities (Castro et al. 2014). These responses can be enhanced by a cyclic process, promoting angiogenesis-inducing effects, such as facilitation of tumor growth and metastasis. The inflammatory process exposes the body to prolonged levels of ROS, leading to the accumulation of oxidative damage in tissues (Ferguson 2010). A class of receptors linked to the regulation of inflammation and angiogenesis are peroxisome proliferator-activated receptors (PPAR), which regulate expression in many genes, including COX-2, nitric oxide synthase, and vascular endothelial growth factor (VEGF), among others (Dupont et al. 2008). Angiogenesis also stimulates the growth and development of tumor cells. This is considered a step in cancer therapy, where the study of angiogenesis inhibitors is of great importance (Pitt et al. 2004). Inflammation also exposes the body to prolonged levels of ROS, causing an accumulation of oxidative damage in tissues. Prooxidant compounds are part of the immune response against pathogens (Costantini and Møller 2009).

Nitric oxide, a short-lived free radical produced by enzyme nitric oxide synthase (NOS), acts as an effector of vasodilatation in the inflammatory process. It is converted to a reactive nitrogen species, such as peroxynitrite, by reacting with superoxide and/or oxygen (Luca and Olefsky 2008). Inhibition of these reactive oxygen species is important in reducing inflammation. Several authors suggest that receptors activated by peroxisome proliferators (PPARs) act as modulators of inflammation both in vivo and in vitro (Castro et al. 2014). However, the mechanisms of this process are still unclear. Moreover, research on paw edema inhibition has demonstrated that the activation of PPAR receptors may also contribute to antiangiogenic action of its ligands (agonists), which, once activated, inhibit angiogenesis through the modulation of cytokines (Keshamouni et al. 2005; Queiroz et al. 2010). The search for antioxidant compounds, inhibitors of inflammation and angiogenesis, is of great medical importance due to their potential as potent suppressors of tumor proliferation, among others (Dong and Yao 2008).

Inflammation and angiogenesis are two dependent processes regulated by macrophages. These produce a series of potent angiogenic factors, such as the vascular endothelial growth factor (Farges et al. 2006; Wang et al. 2009). Although inflammation and the action of free radicals are correlated, studies remain scarce in the literature regarding mechanisms of action combining the processes of oxidation, inflammation, angiogenesis, and tumorigenesis. Castro et al. (2014) demonstrated that polysaccharides from *Caripia montagnei*, rich in D-glucans, have important

anti-inflammatory properties, indicating strong pharmacological potential for these polysaccharides. The findings suggest that these polysaccharides can act by a COX pathway and through PPAR to inhibit MPO and iNOS. The antiangiogenic extract of *C. montagnei*, rich in β-D-glucans, does not occur as demonstrated via VEGF, but by a different pathway. Authors affirm in their previous research which showed that this polysaccharide inhibits NF-κB (Queiroz et al. 2010). Furthermore, they suggest that this polysaccharide's potential antitumor, antiagiogenic, and COX-2 inhibitor effects are due to its inhibitory actions on COX-2 and free radicals (Castro et al. 2014).

Other way to evaluate the anti-inflammatory potential of polysaccharides is the intrapleural administration of carrageenan, which implies the induction of an inflammatory process with increased neutrophil and mononuclear leukocyte number (Ke et al. 2009). The inflammation in the respiratory pathway induces histamine, thromboxane A2, leukotrienes, cytokines, and nitric oxide release (Wang et al. 2009).

The anti-inflammatory effect of D-glucans from *Geastrum saccatum* extract on carrageenan-induced pleurisy was studied by Dore et al. (2007). The results have revealed synergistic interaction between iNOS or COX inhibitors and glucan extract, which have led the authors to suggest that the anti-inflammatory effect of glucan extract from *G. saccatum* is mediated by inhibition of both NOS and COX (Dore et al. 2007).

Up to date, there is a lack of information regarding the mechanisms by which the mushroom polysaccharides exhibit anti-inflammatory and antinociceptive effects. More research on this field is required to clarify how these macromolecules act on the living organisms.

4 Toxicity

Considering that mushrooms are consumed as food, medicine, and, more recently, dietary supplements, it is important to determine their toxicity (Cheung 2013; Hardy 2008). Usually, the commercially available mushrooms present no or low toxicity; however, the great number of species requires a careful evaluation on their edibility and poisonous characteristics, considering that some of them were not described yet (Wasser 2011).

In vitro assays are frequently performed to determine the cytotoxicity of mushroom extracts, before continuing with further investigations on their medicinal properties. It was observed that aqueous extracts from mushrooms *Ganoderma lucidum*, *Lignosus rhinocerotis*, *Pleurotus giganteus*, and *Grifola frondosa* showed absence of embryotoxic or neurotoxic effects when incubated with mouse embryonic fibroblast (BALB/3T3) and mouse neuroblastoma (N2a) cells. The same was observed for ethanol extracts obtained from *Cordyceps militaris* (Phan et al. 2013). Furthermore, a species from Taiwan, *Antrodia cinnamomea*, presented hepatoprotective effect, including anti-hepatitis, anti-hepatocarcinoma, and anti-alcoholism both in vitro and in vivo, showing that no hepatotoxicity was exhibited (Yue et al. 2013).

Regarding the consumption of mushrooms by humans, some adverse effects were observed on patients that received a treatment containing chemotherapy (tegafur/uracil) plus mushroom PSK, a protein-bound polysaccharide extracted from the basidiomycete *Coriolus versicolor*. It was observed that 15.1 % of patients had grade 1 or 2 hematological or gastrointestinal toxicity, although no grade 3 or 4 toxicity was observed. Symptoms of gastrointestinal toxicity were loss of appetite, nausea, vomiting, diarrhea, and stomatitis, while the hematological problems were hepatotoxic, neurotoxic, and dermatological effects. However, it was not proven that the PSK was the responsible for such dysfunctions (Ohwada et al. 2004).

A case of a 17-year-old male that suffered from a systemic anaphylactic episode was reported. The patient presented the anaphylactic reaction during exercise 50 min after the ingestion of mushrooms cooked with wine in a restaurant. Investigations on this case showed that an immunologic cross-reaction between the mushroom and other fungus from environment might have occurred, although it was not proven that the edible mushroom presented any toxicity by itself (Carrapatoso and Bartolome 2013).

The main problems concerning mushroom toxicity rely on their ability of absorbing pollutants from the environment. Mushrooms can be efficiently used as mycoremediation tools because they are able to degrade or bioconvert wastes/pollutants by their enzymatic machinery; however, they can also absorb these compounds, such as arsenic, lead, cadmium, mercury, copper, zinc, iron, nickel, and even ^{137}Cs (Firenzuoli et al. 2008; Hardy 2008; Kulshreshtha et al. 2014). Therefore, high levels of toxic compounds may offset whatever health benefits that a diet rich in mushrooms or mushroom supplements can provide. This shows the importance of cultivate mushrooms in a "clean" environment free of heavy metals and other pollutants.

5 Bioavailability and Metabolism

Although there are a lot of studies pointing to the beneficial health effects of mushrooms, there are few studies evaluating the absorption and pharmacokinetics of mushroom compounds (Rice and Adams 2005). Besides, the β-D-glucans are not the only bioactive compounds of mushrooms, and there are other nutrients that should be considered as possible biological active agents, such as proteins, triterpenes, phenolics, sterols, nucleosides, and mannitol (Cheung 2013; Ng and Wang 2005; Roupas et al. 2012). The main studies performed in vitro or in vivo use the whole milled mushrooms or hot water and/or alcoholic extracts, which are composed by hundreds of compounds in different proportions, making impossible to study their benefit individually. The main protocols required to obtain claims from national and international food agencies (e.g., ANSES and ESFA) are strongly modeled on the pharmacological approaches developed for drugs that aim to test the effect of a single molecule. These approaches are not compatible to assess supplements and nutraceutical foods such as mushroom extracts, considering that it

is not known whether the bioactive effects are caused by a single component or are a result of a synergistic impact from several ingredients (Fardet and Rock 2014; Wasser 2011).

From the published data, it is possible to infer that the oral administration of mushroom β-D-glucan extracts may be the best via, because these polysaccharides are not digested by the animal or human enzymes, passing almost intact through the digestive tract. In the intestines, the β-D-glucans can be absorbed by the M cells located among the epithelial cells and get in contact with macrophages of the gut-associated lymphatic tissue (GALT) (Aouadi et al. 2009; Bouike et al. 2011; Rice and Adams 2005). Once in contact with immune cells, the β-D-glucans bind to membrane receptors as dectin-1, complement receptor 3, scavenger receptor, and Toll-like receptors, initiating the immunological responses (Aouadi et al. 2009; Chen and Seviour 2007; Rice and Adams 2005; Underhill 2003).

The main concern is that mushrooms are composed by different β-D-glucans, which present linear or branched structures, and they are not completely purified for the analysis of biological effects or even bioavailability. It is required to have more studies on this field to determine which component(s) is (are) responsible for the therapeutic effects of mushrooms and also to evaluate if the mushroom capsules/extracts on the food supplement market are really effective, considering their bioavailability.

6 Other Biological Activities

In addition to the antinociceptive and anti-inflammatory effects already mentioned, mushroom polysaccharides, specially β-D-glucans, have been shown to have other numerous biological effects. The most studied are surely their effects as immunomodulators and in cancer therapy.

Polysaccharides are the best known and most potent mushroom-derived substances with antitumor and immunomodulating properties. Although the process of isolation, structural characterization, and antitumor activity of mushroom polysaccharides have been extensively investigated in the past three decades, the relationship between the antitumor activity and the chemical composition as well as the high-order structure of their active components is still not well established.

Antitumor effects, primarily in human cell lines, have been reported from polysaccharides extracted from various mushrooms. The polysaccharides generally belong to the β-D-glucan family and appear to exert their anti-tumorigenic effects via enhancement of cellular immunity. The antitumor action of polysaccharides is mediated through a thymus-dependent immune mechanism, stimulating the immune system via effects on NK cells, macrophages, monocytes, neutrophils, and dendritic cells and via T cells and their cytokine production.

Cytokines in turn activate adaptive immunity through the promotion of B cells for antibodies production and stimulation of T-cell differentiation to T helper (Th) 1

and Th2 cells, which mediate cell and humoral immunities, respectively (Borchers et al. 2008). Based on their high molecular weight, mushroom polysaccharides are not able to penetrate the immune cells to activate them directly. The stimulation mechanism of polysaccharides involves different cell receptors such as dectin-1, complement receptor 3 (CR3), lactosylceramide (LacCer), and Toll-like receptor (TLR) 2. Thus, the effectiveness of polysaccharide immunomodulatory effects is governed by their binding affinity to immune cell receptors (Chen and Seviour 2007).

Immune-active compounds isolated from more than 30 medicinal mushroom species have demonstrated antitumor activity in animal treatments. However, only a few have been tested for their anticancer potential in humans, mainly β-D-glucans or β-D-glucan-protein complexes. The main clinical studies proving the cancer inhibitory effects have been done showing the inhibitory effects caused by polysaccharides isolated from *Lentinus edodes* (Jeff et al. 2013a, b; Mizuno 1997; Yu et al. 2009), *Grifola frondosa* (Adachi et al. 1994; Cun et al. 1994; Mizuno 1997; Zhuang et al. 1994), *Schizophyllum commune* (Zhang et al. 2013), *Ganoderma lucidum* (Mizuno 1997; Wang et al. 2002), *Trametes versicolor* (Chow et al. 2003), *Inonotus obliquus* (Fan et al. 2012; Kim et al. 2005a, 2006; Mizuno et al. 1999), *Phellinus linteus* (Han et al. 1999; Kim et al. 2004; Li et al. 2004, 2013), *Flammulina velutipes* (Leung et al. 1997; Yang et al. 2012; Zeng 1990), and *Cordyceps sinensis* (Leung et al. 2009; Nie et al. 2013), among others (Zhang et al. 2007; Zong et al. 2012).

Five polysaccharide constituents from mushrooms have shown significant anticancer efficacy against several human cancers in clinical trials as biological response modifiers, including lentinan from *Lentinus edodes*, D-fraction from *Grifola frondosa*, schizophyllan from *Schizophyllum commune*, and polysaccharide-K (PSK) and polysaccharide peptide (PSP) from *Trametes versicolor* (Wasser 2002). Such polymers have been developed with clinical and commercial purposes.

Other biological activities presented by natural polysaccharides from mushrooms are the antioxidant, radical scavenging, cardiovascular, antihypercholesterolemic, antiviral, antibacterial, antiparasitic, antifungal, detoxification, hepatoprotective, and antidiabetic effects (Dai et al. 2009; Gao et al. 2002, 2003, 2004; Ichinohe et al. 2010; Rowan et al. 2003; Sullivan et al. 2006; Wasser 2010; Zhang et al. 2007).

The antioxidative activity of polysaccharides is attributed to their ability to scavenge free radicals, their reduction property and ability to chelate Fe^{2+} ions, lipid peroxidation inhibition, erythrocyte hemolysis, and the increase of activities in eukaryotic as well as in prokaryotic cells of enzymes that take part in antioxidative processes, such as SOD, CAT, and GPx (Guo et al. 2009; Liu et al. 2010; Lo et al. 2011; Ping et al. 2009; Tseng et al. 2008). In some researches, besides the increase in the enzyme activity, antioxidative properties are also attributed to the property of polysaccharides to induce an increase expression of antioxidative enzymes, such as SOD and GPx (Jia et al. 2009).

The ability of polysaccharides to scavenge free radicals depends on its size and may be conditioned by the presence of hydrogen from specific, certain monosaccharide units, and the type of their binding in side branches of the main chain.

The most studied mushroom regarding the antioxidant potential of its polysaccharides was *L. edodes*, especially lentinan (Liu et al. 2014). Polysaccharide fractions from *Agaricus bisporus*, *Agaricus brasiliensis*, *Ganoderma lucidum*, and *Phellinus linteus* also presented antioxidant effects and are shown to be composed mainly by D-glucans (Kozarski et al. 2011).

Some animal studies, using both normal and diabetic animals, have demonstrated a hypoglycemic effect of mushrooms and mushroom components. This effect appears to be mediated via mushroom polysaccharides, possibly both α- and β-D-glucans, via a direct interaction with insulin receptors on target tissues, although the mechanism remains to be confirmed (Hsu et al. 2007; Kim et al. 2010; Roupas et al. 2012; Vetvicka and Novak 2011).

Aqueous extracts of various mushrooms – *Agaricus blazei* (Kim et al. 2005), *G. lucidum* (Seto et al. 2009), *P. pulmonarius* (Badole et al. 2006), *G. frondosa* (Cui et al. 2009), and *Coprinus comatus* (Han and Liu 2009) – have been shown to possess hypoglycemic activity and antihyperglycemic activity against diabetes-inducing compounds in obese and diabetic animal models. However, the consistency between the effects of the mushroom extracts in diabetic animal models and the preliminary data from human trials, which mirror decreases in plasma glucose, blood pressure, and cholesterol and triglyceride concentrations, strengthen the level of evidence for anti-diabetogenic effects of the studied mushrooms and their extracts.

Mushrooms and mushroom components have been reported to have an innumerable positive health benefits, mainly on the basis of in vitro and in vivo animal trials. However, the majority of these effects are indirect, being caused probably due to a stimulation or modulation of natural cellular immunity. Mushrooms and mushroom components exert many of their positive effects on health via a balance of T helper cells, the induction of interferon-gamma and certain interleukins, or NO-mediated mechanisms. Many of these immunomodulating effects are due to the polysaccharide content of mushrooms, either from β-D-glucans or from polysaccharide-protein complexes (Roupas et al. 2012).

Unfortunately, most studies are made with crude polysaccharide extracts, thus not allowing the knowledge of the component responsible for such effects. There is a lack of information regarding the relation between the polysaccharide structure and its biological effect.

A wide range of biologically active polysaccharides could be found among mushrooms, and their practical application is dependent not only on their unique properties but also on biotechnological availability. Isolation and purification of polysaccharides from mushroom material are relatively simple and straightforward. Once a molecule of interest is found and characterized and have its biological application confirmed, mycelia formed by growing pure cultures in submerged conditions are of constant composition and appear as the best technique for obtaining consistent and safe mushroom products (Reshetnikov et al. 2001; Wasser 2011).

7 Clinical Trials

The human clinical trials performed with mushrooms and mushroom extracts up to date evaluated mainly their anticancer properties, considering that mushroom compounds are immunoceuticals. β-D-Glucan extracts from *L. edodes* and *S. commune* are used in traditional medicine for cancer treatment in Japan since 1980, although little was published about their effects in humans (Akramien et al. 2007; Kidd 2000). The human trials carried out to date have primarily been smaller observational studies, or studies without appropriate placebo or other matched controls, and therefore larger, double-blind, placebo controlled human studies are required before clear effects on human health outcomes can be substantiated (Roupas et al. 2012).

Scientific publications about some clinical trials were released from 1976 to 1999 and the more recent publications date from 2004 to 2011. The investigators carried out their studies mainly in hospitals of Japan, China, and Korea, where the mushrooms have been used for many years as traditional medicine for treating various diseases (Abrams et al. 2011; Ahn et al. 2004; Kidd 2000; Ohwada et al. 2006). However, these fungi are not recognized as medicine in Occidental countries yet, and significant questions still arise about their safety, standardization, regulation, efficacy, and mechanism of action (Deng et al. 2009; Wasser 2011).

One of the trials evaluated a mushroom extract of *A. blazei Murill* Kyowa (ABMK) that was administered (three packs/day) to gynecological cancer patients undergoing chemotherapy for 3 weeks. The natural killer cell activity was significantly higher in the ABMK-treated group as compared with non-treated placebo group. Besides, the chemotherapy-associated side effects (appetite, alopecia, emotional stability, and general weakness) were reduced by the ABMK treatment, and the welfare of patients was improved. However, no significant difference in lymphokine-activated killer cell and monocyte activities was observed (Ahn et al. 2004).

Patients that presented advanced lung cancer received 1,800 mg of Ganopoly, three times daily before meals for 12 weeks, totalizing 5,400 mg day^{-1}. Each capsule of Ganopoly contained 600 mg of hot water extract of *G. lucidum*, with 25 % (wt/wt) crude polysaccharides. In the 30 cancer patients who completed the trial, treatment with Ganopoly did not significantly alter the mean mitogenic reactivity to phytohemagglutinin; mean counts of CD3, CD4, CD8, and CD56; mean plasma concentrations of IL-2, IL-6, and interferon (IFN)-γ; or natural killer cell activity in the patients, but the results were significantly variable. The data obtained of this study suggested that subgroups of cancer patients might be responsive to Ganopoly in combination with chemotherapy/radiotherapy; therefore, this trial was not conclusive (Gao et al. 2005).

P. ostreatus was also used, although, in this trial, the aim was to assess the safety and efficacy of the mushroom in reducing the lipid levels of patients with HIV undergoing antiretroviral treatment (ART). During the study, patients received packets of freeze-dried *P. ostreatus* (15 g day^{-1}) to be administered orally

for 8 weeks. Lipid levels of the patients were drawn every 2 weeks, and it was concluded that the mushroom did not lower non-HDL cholesterol in that patients (Abrams et al. 2011).

One of the most studied mushrooms as human therapeutics is *C. versicolor* from which was isolated two polysaccharide peptides or proteoglycans, named PSK and PSP. The latter was coadministered with *Salvia miltiorrhiza* to treat nasopharyngeal carcinoma and breast cancer patients. For the nasopharyngeal carcinoma (NPC) study, 27 patients histologically proven NPC were recruited to take PSP (3.6 g day^{-1}) plus *S. miltiorrhiza* (1.4 g day^{-1}) in the form of 12 combination capsules or placebo for 16 weeks. The normal decrease of T lymphocyte count in NPC patients was alleviated by the treatment with the PSP + *S. miltiorrhiza* (Bao et al. 2006). On the other trial, 82 patients with breast cancer were recruited to take PSP (50 mg kg^{-1} body weight) plus *S. miltiorrhiza* (20 mg kg^{-1} body weight) capsules every day for a total of 6 months. The investigators observed that the absolute counts of T helper lymphocytes (CD4+), the ratio of T helper (CD4+)/T suppressor and cytotoxic lymphocytes (CD8+), and the counts of B lymphocytes were significantly elevated in patients with breast cancer after receiving the treatment (Wong et al. 2005).

PSK was also evaluated about its effects on patients at stage II or III colorectal cancer, and the authors observed that the administration of 3 g of PSK plus chemotherapy reduced the recurrence of cancer, decreased the mean serum immunosuppressive acidic protein (IAP) level, and increased the mean population of natural killer cells (Ohwada et al. 2004, 2006).

There are plenty of studies using milled mushroom capsules and others evaluating the effects of mushroom extracts, although none of them investigated the isolated compounds as the bioactive β-D-glucans, for example. More standardization of the production of these extracts is required, and also the clinical trials should be carefully designed to guarantee the analysis of the data, the efficacy of the treatment, and the mechanism of action of the bioactive compound(s). The clinical trials available up to date are not conclusive to develop new natural drugs. Besides, other parameters such as anti-inflammatory and antinociceptive effects were not assessed in humans yet.

8 Conclusion

The above information, compiled after careful revision of the research on mushroom polysaccharides, has shown the importance of such macromolecules for the treatment of many health problems, including inflammation and nociception.

It was observed that fungal polysaccharides and polysaccharide-protein complexes have been mainly investigated by presenting a variety of biological responses, such as antitumor, antioxidative, and immune stimulatory activities and more recently antinociceptive and anti-inflammatory effects. The therapeutic application of these polymers seems to be closely related to their chemical structures and tridimensional conformations, showing the great importance of the

chemical analysis to determine the fine structure of each polysaccharide. Some researchers noticed that small differences in the polymer structure may exhibit different effects, when the antinociceptive and anti-inflammatory properties were tested. Besides, it was observed that the analgesic effect of some polysaccharides may be related to their capacity of blocking the production or release of proinflammatory molecules and PKC activity. However, the mechanism of action behind the antinociceptive and anti-inflammatory effects of these polymers is still under discussion and requires further studies.

The development of the research on this field on the last decades has provided plenty of data regarding the medicinal benefits of mushroom polysaccharides, although there are some limitations that must be transcended. The main studies are still based on the crude polysaccharide extracts, making difficult to define which compound is the responsible for the bioactivity. There are no standard procedures on the preparation of the extracts, and there are fewer authors who isolated the molecules for their assessments. Furthermore, the clinical trials and toxicity assays have primarily been smaller observational studies or studies without appropriate placebo or other matched controls, and therefore, larger, double-blind, placebo controlled human studies are required before clear effects on human health outcomes can be substantiated.

With the advances of biotechnological tools, the fungus polysaccharides can be obtained not only from the fruiting bodies, but from the cultured mycelia or culture medium. Therefore, the research on this field has a promising future, with the possibility of finding and producing natural medicines with lower or no side effects, and great benefits. But the first step is to improve the clinical analysis and provide clear information about the medicinal properties of mushroom polysaccharides.

Acknowledgments The authors would like to thank the following Brazilian funding agencies – CAPES (Coordenação de Aperfeiçoamento de Pessoal de Nível Superior), CNPq (Conselho Nacional de Desenvolvimento Científico e Tecnológico), and Fundação Araucária – for their financial support.

Abstract

Polysaccharides (PS) are one of the major classes of carbohydrate biomolecule found within living system. Current knowledge built on scientific rationale and anecdotal evidence over the years acknowledge therapeutic and health benefit effects of bioactive polysaccharides and PS- protein complex from medicinal mushrooms and botanical sources. Medicinal PS is also acknowledged as "biological response modifiers" – substances that stimulate the body's response to infection and disease. In related context of cancer therapy, efficacy of bioactive PS has been documented in preclinical models and found to reduce tumor growth and prolong survival by immune stimulation, apoptosis, and cell

cycle arrest. The immunomodulating activity by PS includes activation of macrophage(s), natural killer (NK) cells, lymphocyte activated killer (LAK) cells, dendritic cells, tumor-infiltrating lymphocytes, and stimulated release of various cytokines including interferons, tumor necrosis factor, interleukins, and colony-stimulating factors by specific receptor-mediated (Toll-like receptor, dectin-1 and CR3) induction of gene expression. Many of the investigated PS from mushrooms and botanicals have proceeded to pharmaceutical-grade GMP products such as lentinan, schizophyllan/sizofiran/sonifilan, Krestin (polysaccharide-K), GanoPoly, astragalan, GCS-100, and PectaSol, with low toxicity and potent antitumor activity. In countries such as Japan, China, and Korea, pharmaceutical-grade bioactive PS have been introduced as an adjuvant alongside standard radio- and chemotherapy in cancer treatment. This chapter presents a succinct overview of some select bioactive PS derived from Basidiomycetes class of mushrooms (lentinan from *Lentinus edodes*, Krestin from *Coriolus versicolor*, schizophyllan from *Schizophyllum commune*, and *Ganoderma* sps) and few other botanical herbs (*Angelica sinensis, Astragalus membranaceus, Panax ginseng*, pectins, and modified citrus pectin) citing instances of preclinical test results and clinical efficacy outcome signifying their anticancer perspective either as monotherapy or combination therapy for future implementation either as chemopreventive or therapeutic regimen in clinic.

Keywords

Polysaccharide • β-glucan • Lentinan • *Schizophyllan* • Krestin • Astragalan • Modified citrus pectin • *Angelica* • Ginsan • *Ganoderma*

1 Introduction

Cancer singularly represents a class of disease characterized by feature of uncontrolled division of abnormal cells and their dissemination to other parts of body through blood and lymphatic systems. Despite innovations in early detection and prevention strategies, cancer continues as a threat to public health in developing and developed countries. According to American Cancer Society, a total of 1,658,370 new cancer cases and 589,430 cancer deaths are projected to occur in the USA in 2015 (Siegel et al. 2015). Further, complying to International Agency of Cancer (IARC) and World Health Organization (WHO) estimates, by 2030 above 25 million new incidences of cancer cases with estimated 11 million deaths worldwide are anticipated. This underscores current efforts in existing cancer control knowledge and strategies across all segments of population in finding a cure for this deadly menace. Research has shown that up to two-thirds of cancer deaths are caused by smoking, physical inactivity, and poor dietary choices and can be prevented by adopting smart lifestyle and early detection and prevention.

In recent years, non-starchy polysaccharide (PS) macromolecules and PS-protein complexes from botanical and microbiological sources have attracted the attention of researchers as an important class of bioactive products.

Numerous studies based on pharmacology have demonstrated their potency in preventive and therapeutic effects alongside chemotherapy towards a variety of diseases including cancer (Zong et al. 2012; Lemieszek and Rzeski 2012). Emerging evidence indicates that PS fractions are associated with modulation of a variety of biological effects including hematopoietic, antitumor, antioxidant, antidiabetic, radioprotective and as immune stimulant signifying a wide spectrum of clinical applications of PS along with relatively low toxicity (Schepetkin and Quinn 2006; Ramberg et al. 2010). Unlike human and mammalian cells, botanical PS occur as structural constituent of cell wall and accordingly basic procedure for their extraction involves breaking the cell wall under controlled conditions such as pH and temperature thereby avoiding undesirable alterations in their configuration and structural features. Thus, the simple and economical hot water extraction (with short period of heating temperature) followed by concentration under decompression conditions continues as a preferential scientifically validated and classical method for the extraction of PS from botanical sources. Further purification prior to preclinical testing usually involves a combination of techniques such as ethanol precipitation, fractional precipitation, ion-exchange chromatography, gel filtration, and affinity chromatography (Wasser 2002). Additional characterization of the purified polysaccharides product for physiochemical and structural features is pursued based on molecular weight, monosaccharide composition and their sequence, configuration and position of glycosidic linkages, type and polymerization degree of branch, spatial configuration, particle size, solubility, rheological properties, etc. (Jin et al. 2011; Nie and Xie 2011). This chapter presents a succinct overview and objective appraisal of evidences focusing primarily on published preclinical data and ongoing clinical trials in context of cancer prevention and therapy. Figure 1 depicts the chemical structures of various PS from different sources included in the text.

2 General Mechanism of Antitumor Action of Polysaccharides

Evidences collected till date for beneficial activity of polysaccharides from different biological origins reveal antitumor action mainly by two mechanisms against tumor cells: (a) a broad spectrum immune-enhancing activity predominantly by activation of the immune system response of host with relative low accompanying toxicity and (b) indirect inhibition of tumor growth and apoptosis of tumor cells.

2.1 Indirect Actions of Polysaccharides in Immunological Functioning

Even though few PS have been scrupulously investigated, results thus far point to noteworthy effect of PS in the regulation of immune response. Essentially, plant polysaccharides are considered as biological response modifiers and being not

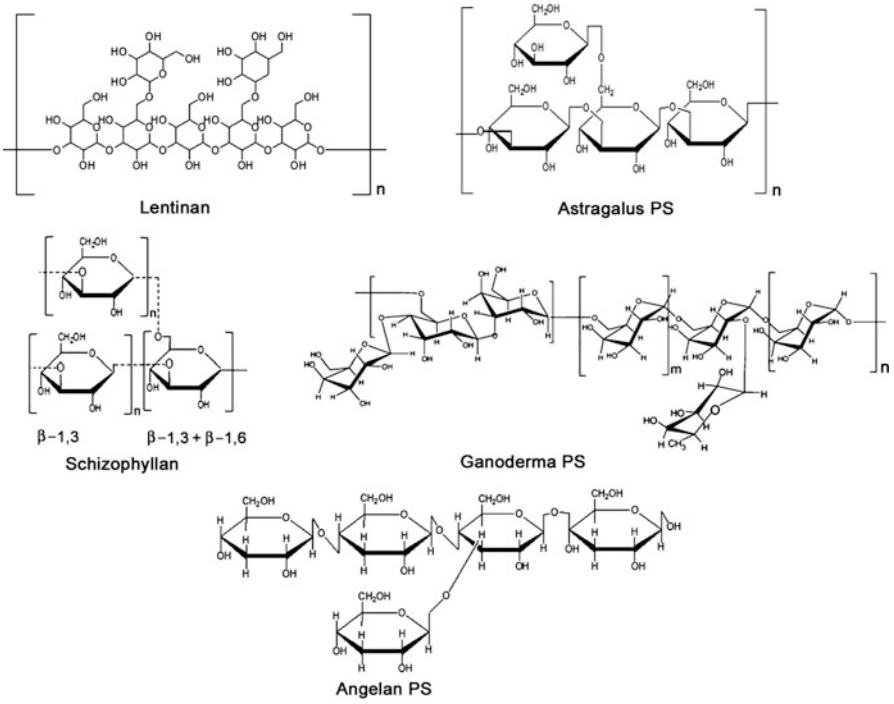

Fig. 1 Chemical structures of various PS from different botanical sources as included in text

synthesized by humans are recognized by the immune system as foreign molecules eliciting immunological response addressed by the innate and the adaptive immune system (Fig. 2).

Emerging evidence from studies on immune modulation have led to an important conclusion that PS with evolutionary conserved structural features do not attack cancer cells directly, but invoke antitumor effects mainly by potentiating the cellular and humoral component of the host immune system and repressing the production of immunosuppressive cytokines (Volman et al. 2008). A broad spectrum possibility of immune-potentiation by PS include the ability to stimulate T-cell generation and potentiate the induction of different types of antitumor effector cells such as cytotoxic T cells, NK cells, macrophages, and dendritic cells (DC). NK cells are frontline defenses in cancer prevention and circulate in blood to lyse cancer and virus-infected cells. Macrophages together with neutrophils are key participants in innate immune response and produce cytokines and local immunomodulators which act to activate adaptive immunity which involves both B and T cells. B cells produce antibodies to mediate humoral immunity, whereas T cells induce cell-mediated immunity. The activation of macrophages by PS is thought to be mediated primarily by the recognition of PS polymers by specific receptors as discussed in the following section. Another element of the adaptive immune system reactive to PS is dendritic cells (DCs) derived from monocytes; these cells present antigens to T cells and therefore

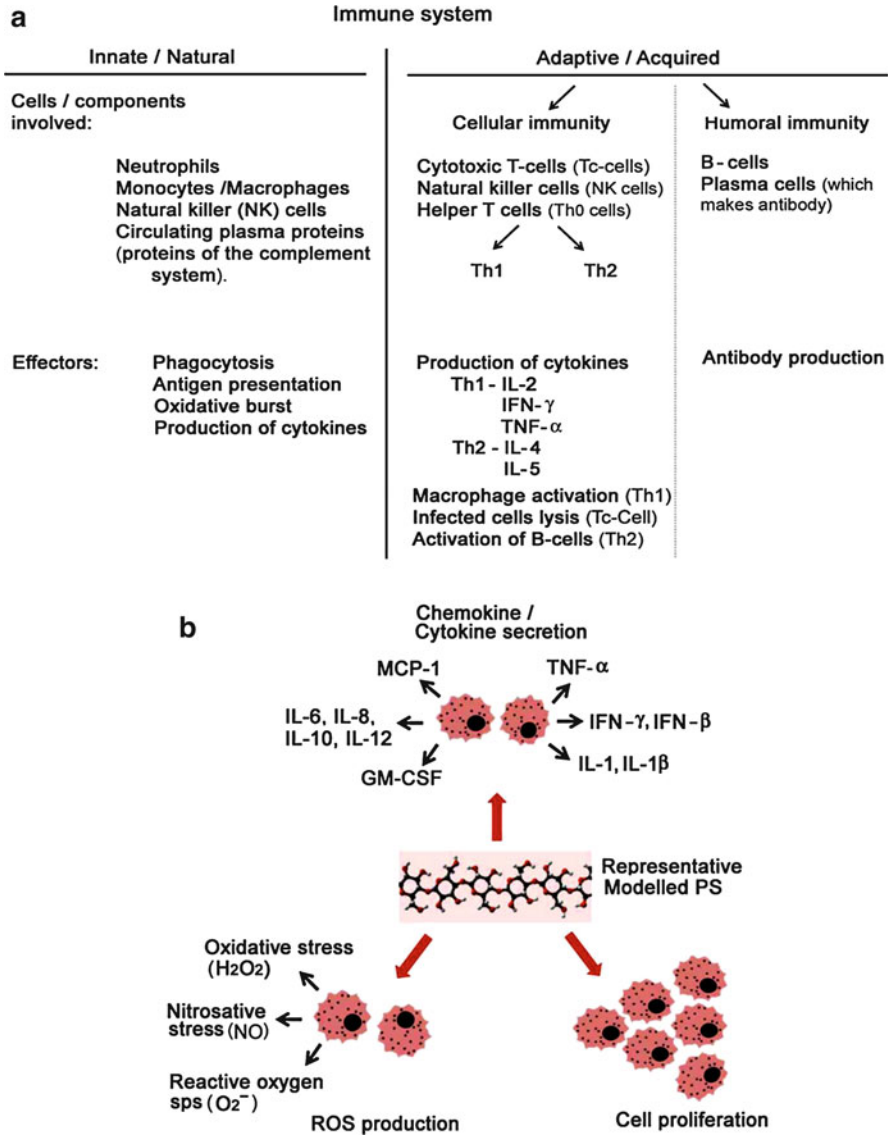

Fig. 2 Overview of immunological response (**a**), and macrophage response to polysaccharides (**b**)

are considered important in the initiation of antitumor T cell response. Crude Ps isolated from *Angelica dahurica* activates DC to produce cytokines and costimulatory molecules to increase all-T cell activation (Kim et al. 2013). Accordingly, an intact thymus (T-cell component) is a precondition for antitumor action of polysaccharides; this has been verified in studies indicating abrogation of antitumor effects of PS in neonatally thymectomized mice and also after administration of

antilymphocyte serum (Maeda et al. 1971). In phase II and phase III clinical trial in China, mushroom polysaccharides PSK and PSP significantly enhanced the immune status in 70–97 % of patients with cancers of the stomach, esophagus, lung, ovary, and cervix. In these studies reported, the investigated mushroom polysaccharides were well tolerated and compatible with chemotherapy and radiotherapy and concur with an increase number of immune cells and infiltration of dendritic and cytotoxic T cell into tumors. In preclinical animal model, the antitumor dose of polysaccharide SNL-P1a from *Solanum nigrum* showed a protective effect on thymus tissue of tumor-bearing mice, whereas the thymus of control mice was damaged seriously because of the tumor ambush (Li et al. 2007). It has been reported that the addition of PS into cell cultures increases proliferation of T cells augmenting the cytotoxic activity of T lymphocytes. Furthermore, PS from 35 different plant sps have shown to increase macrophage cytotoxic activity against tumor cells following in vitro and in vivo treatment of PS by increasing reactive oxygen species (ROS) and nitric oxide (NO) production and enhancing secretion of cytokines and chemokines, such as TNF-α, interleukin (IL)-1β, IL-6, IL-8, IL12, and IFN-γ (Schepetkin and Quinn 2006). Additionally, several lines of evidence suggest that besides macrophage activating effects of Ps, they also affect macrophage hematopoiesis. A high MW polysaccharide isolated from *Salicornia herbacea* and polysaccharide fraction from fu-ling (*Poria cocos*) used in traditional oriental remedies against cancer induce differentiation of monocytic cells into macrophages (Chen and Chang 2004; Im et al. 2006).

2.1.1 Polysaccharides and Cell Signaling in Immunological Context

Noteworthy insight from mechanistic analysis reveals that several well-researched plant PS signals a distinct signal transduction pathway resulting in induction and secretion of cytokines and other paracrine factors supposedly critical for potentiation of innate immunity. Accumulating evidence point that many effect of PS are at least in part mediated through NF-κB and IRF (interferon regulatory factor) family of transcription factors and MAPK signaling. Polysaccharide polymers are primarily recognized during the initial phase of the immune response by specific receptors collectively referred to as pattern recognition receptors (PRRs). These receptors have a carbohydrate recognition domain (CRD) in their extracellular carboxy-terminal domain which recognizes PS as a pathogen-associated molecular pattern (PAMP) during the initial phase of immune activation. Specifically, the major receptors to which botanical PS and glycoproteins bind and implicated in signaling are Toll-like receptor 4 (TLR4), complement receptor 3 (CR3), dectin-1, and CD14 (Fig. 3).

Dectin-1 Receptor and Signaling

Dectin-1 is the major functional receptor for fungal β-1,3-glucans on cells of the myeloid lineage, namely, macrophage and dendritic cells (DC), initiating cytokine-related antitumor biological effects of β-glucans. It is a transmembrane protein with lectin-like carbohydrate recognition domain (CRD) connected by a stalk to the transmembrane region, followed by a cytoplasmic tail containing an immunoreceptor tyrosine-based activation motif (ITAM). After ligand binding, receptor engagement

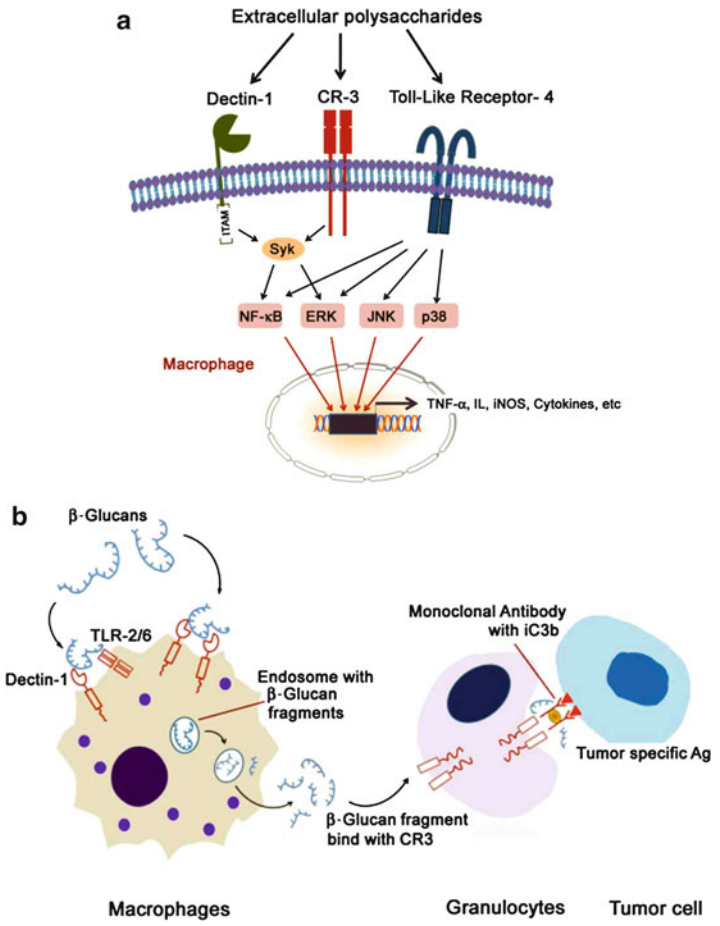

Fig. 3 Schematic model illustrating signaling pathways activated by polysaccharides (**a**) and CR-3 receptor mediated tumor cell lysis (**b**)

leads to tyrosine phosphorylation by Src family kinases and the phosphorylated sequences provide docking sites for Syk kinases. Syk is then activated through intervening phosphorylated substrates (SLP76 and PKC isoform) and induces the CARD9-Bcl10-MALT1 complex. This complex mediates the downstream activation of NF-κB and production of pro-inflammatory cytokines (IL-2, IL-10, and TNFα) (Grunebach et al. 2002). It is known that MAPK-ERK also participates in dectin-1 downstream signaling. In addition to activation of immune response, binding of dectin-1 with ligand induces its own signaling including response such as ROS production (Dennehy and Brown 2007). Dectin-1-mediated signaling is involved among many in SPG-mediated antitumor activity for sarcoma 180 cell growth in mice (Ikeda et al. 2007) and benefit to enhance immunological surveillance system during treatment in combination with irradiation.

Toll-Like Receptor-4 (TLR-4) Signaling

TLR-4 are critical signaling component of innate immune response and mainly expressed on monocytes, macrophages, dendritic cells, and B cells (Leung et al. 2006). These receptors are predominantly activated by BRM-associated molecular pattern and characterized by an extracellular N-terminal leucine-rich-repeat (LRR) domain, a single transmembrane domain, and a cytoplasmic C-terminal intracellular TIR (Toll/IL-1 receptor) domain (Tang and Wang 2010). PS from *Ganoderma lucidum*, *Sparassis crispa*, *Angelica gigas*, and *Phellinus linteus* activate dendritic cells through TLR4 (Kim et al. 2011a). TLR signaling is mediated by two types of pathways, the myeloid differentiation primary-response gene 88 (MyD88)-dependent and (MyD88)-independent (TRIF) pathway. Upon binding with ligand, TLR4 recruit adaptor proteins and activate both the MyD88- and TRIF-dependent signaling pathways leading to common coordinated downstream activation of MAP kinase and activation of interferon regulatory factors (IRF-3 and IRF-7) that leads to production of IFN-β and NF-κB. Together these acts to regulate phenotypic and functional maturation of DC upregulate costimulatory molecules and pro-inflammatory cytokines (IL-1β, IL-6, IL-8, TNF-α) as well as reactive nitrogen and oxygen products that drive events such as recruiting leucocytes, activating APCs, and initiating adaptive immune response (Kawai and Akira 2006).

CR3 Receptor and Signaling

The CR3 receptor is a transmembrane heterodimer protein of integrin superfamily and composed of a α-subunit (CD11b) and β-chain (CD18) domains having binding site for β-glucans located within the C-terminus of CD11b domain. It is expressed mainly on neutrophils, monocytes, and NK cells, but not macrophages (Ross 2000), and associated with adhesion to the extracellular matrix and functions in addition to phagocytosis. As no β-glucan is synthesized by humans, binding of β-glucan to ligand-binding domain of the receptor prime activates the iC3b pathway causing tumor cytotoxicity as depicted in Fig. 3.

2.2 Direct Action of Polysaccharides: Apoptosis and Cell Cycle Arrest

In addition to the aforementioned accepted dogma of antitumor effect of PS resulting from enhancement of host immunity, emerging evidence citing induction of cancer cell death by activation of apoptotic pathways as another mechanism for inhibition of tumor growth has gained attention. An increasing number of reports confirm that PS or their complexes can induce apoptosis with likelihood of therapeutic implication in the future for use in cancer regression as well as in prevention strategies. In general terms, apoptotic pathways have been divided into two categories: the extrinsic pathway and the intrinsic pathway. The extrinsic pathway begins outside the cell being initiated by

proapoptotic ligands (FasL, TNF, and TRAIL) binding to cell surface receptors (Fas, TNF receptor, and TRAIL receptor); ligand binding causes receptors to cluster and form death-inducing signaling complex (DISC) which next adopt and activate membrane-proximal caspases (caspase-8 and caspase-3). The intrinsic pathway initiated from within the cell requires disruption of the mitochondrial membrane and efflux of small mitochondrial proteins, such as cytochrome c (cyt c) and calcium into the cytosol. Once cyt c is in the cytosol, it binds to Apaf-1 and gives rise to activated caspase-9, and caspase-3. Subsequently, active caspase-3 mediates inhibition of caspase-activated DNase (ICAD) and cleaves the substrate protein poly(ADP-ribose) polymerase (PARP) to cause DNA fragmentation, cell dysfunction, and elimination of cancer cells. Further evidence suggests that Bcl-2 family proteins composed of both antiapoptotic (Bcl-2 and Bcl-xL) and proapoptotic members (Bax, Bak, and Bim) are important regulators of the mitochondrial apoptotic pathway and ensure cell survival. Thus, reduction in expression of Bcl-2 and conversely upregulation of Bax encourages apoptotic response to antitumor PS. In addition, tumor suppressor p53 has been identified as an effector of apoptosis signals, and upregulation of p53 has been recorded as suppressing the survival of tumor cells. The antitumor effect of most natural chemopreventive agents has been reported to be associated with induction of apoptosis.

Bioactive PS such as lentinan from *Lentinus edodes* and PS-K/PS-P from *Coriolus versicolor* and *Ganoderma lucidum* PS from Basidiomycetes family are associated with apoptotic efficacies, in addition to boosting of the immune system as basis for their cytotoxic effect against different types of tumor cells in vitro and in vivo. PSG-1, a novel bioactive PS from *Ganoderma atrum*, exhibit no significant effect on cell proliferation but markedly suppresses tumor growth of colon cancer cells on tumor-bearing mice by apoptosis induction via mitochondria-mediated apoptotic pathway (Zhang et al. 2014). Intriguingly, PS from another *Ganoderma* sps (*G lucidum*) reportedly induces apoptosis in colon cancer cells by activating Fas-mediated caspase-dependent apoptosis (Liang et al. 2014). The antitumor effects of fucoidan, a sulfated PS found in brown algae, are mediated via both the death receptor- and mitochondria-mediated apoptotic pathways (Kim et al. 2010). Furthermore, fucoidan PS increases the levels of activated caspase-8, caspase-9, and caspase-3 and cleaves PARP along with Bak and truncate Bid proteins and additionally increases the levels of tumor necrosis factor-related apoptosis-inducing ligand (TRAIL), Fas, and death receptor-5 protein suggesting its usefulness in cancer prevention and use as a therapeutic adjuvant (Kim et al. 2010). Another instance is novel PS isolated from *Angelica sinensis* named ASP-1d, which inhibits tumor growth in nude mice and induces apoptosis of cervical cancer HeLa cells through mechanism involving intrinsic apoptotic pathway (Cao et al. 2010a). The antitumor effects of ulvan PS in EAC-bearing mice have been recorded as being mediated by downregulation of antiapoptotic protein Bcl-2 and upregulation of proapoptotic and cell cycle arrest protein p53 (Ahmed and Ahmed 2014).

3 Antitumor Polysaccharides of Clinical Interest from Basidiomycetes Class

The Basidiomycetes class of fungal family compendium comprises edible mushrooms with dual medicinal and nutritional values. Conventionally, edible mushrooms have been categorized as macrofungus with a fleshy aerial umbrella-shaped fruiting body called carpophore/myocarp growing from spacious underground mycelia (hyphae). Unlike plants, both the fruiting body and mycelia lacks chlorophyll and contains low fat levels, but a wide range of beneficial compounds (high amounts of proteins and essential amino acids and dietary fibers) impacting human health such as anti-inflammatory, antitumor, cholesterol-lowering properties, and most importantly immunomodulatory effects have been reported (Wasser 2002; Patel and Goyal 2012). Of particular significance with regard to mushrooms of Basidiomycetes class is the presence of biologically active polysaccharide biomolecules in fruiting bodies, cultured mycelium, and culture broth affecting human health. Researchers in Japan found that enokitake mushroom producers had lower cancer rates than the rest of the population. A survey conducted among mushroom workers in the Nagao Prefecture in Japan inferred that regular eating of medicinal mushrooms was associated with lower death rate from cancer than for other people in the prefecture (Ikekawa 2001). Another case-control study published compared the diets of 1,009 women diagnosed with breast cancer with healthy women. Compared to nonconsumers of mushrooms, women who consumed at least 10 g of fresh mushrooms per day had a breast cancer risk of only 36 %. The risk for those who consumed at least 4 g of dried mushrooms per day was 53 % (Zhang et al. 2009). A similar case-control study involving 362 women with breast cancer also found a strong association between mushroom consumption and decreased risk of breast cancer in postmenopausal, but not premenopausal, women (Hong et al. 2008).

Notwithstanding much debate, mushroom polysaccharide and polysaccharide-protein complex are generally considered as biological response modifiers, so the immune system is stimulated by their presence in a way, leading to inhibition of tumor growth. At cellular and molecular level, these include the activation of macrophages, T lymphocytes, and natural killer cells (NK), which are able to secrete inflammatory mediators and cytokines such as the tumor necrosis factor α (TNF-α), γ interferon (IFN-γ), and interleukin (IL-1β), IL-6, IL-8, and IL-12, among others. However, some of the effects owing to direct cytotoxic action cannot be ruled out.

3.1 Lentinan

As a representative purified bioactive polysaccharide fraction derived from mycelium of one of the most widely edible Shitake mushroom – *Lentinus edodes*, lentinan has been approved for clinical use in cancer treatment in Far East oriental countries. First evidence of a mechanistically focused anticancer effects associated with lentinan intake was proposed by Chihara et al. confirming in vivo administration of lentinan with growth inhibition of sarcoma 180 cancer cells transplanted in

CD-1/CD mice (Chihara et al. 1969, 1970). Subsequent studies captivated attention for use of lentinan as stimulant of host immune response by activating and increasing the number of various types of immune cells (such as T cells, natural killer cells, and macrophages). In multiple clinical trials, addition of lentinan to standard cancer therapies augmented sensitivity of tumor cells towards therapy resulting in reducing recurrence along with improved quality of life and patient's survival. The efficacy of lentinan has been investigated both in preclinical and in clinical subjects for its role mainly as therapeutic adjuvant for treatment of advanced gastrointestinal (GI) malignancies such as gastric, pancreatic, colorectal, and hepatocellular carcinoma as described in the following sections. Essentially, the addition of lentinan have been estimated to be safe, with results from multiple studies pointing to a profound reduction in recognizable effect of chemotherapeutic drug-related adverse effects in recurrent and metastatic conditions along with improvement in quality of life and patient's survival. Unfortunately, well designed, large-scale randomized studies in Western setup are lacking to establish the role of lentinan as a useful adjunct to cancer treatment. Large overdoses of lentinan, above the specified clinical dose, may cause immune suppression without any immune-potentiating effect. Otherwise, side effects are few, except for skin rashes that clear up shortly after discontinuing the extract.

As resolved from basic understanding of its chemical structure, lentinan contains a branched chain molecule with a backbone of 1,3β-D-glucan and side chains of β1,3- and β1,3-D-glucose residues and exists in form of triple helix structure in aqueous solution sustained by inter- and intramolecular hydrogen bonds. The retention of triple helix structure is vital for desired antitumor efficacy of lentinan since once the triple helix is broken into single random coils, it loses antitumor activity (Zhang et al. 2011). Additionally, chemical modifications such as sulfation reportedly enhance the efficacy of lentinan, especially against viral diseases including inhibition of HIV viral replication, and thus lentinan have also been exploited as vaccine (Yoshida et al. 1988; Guo et al. 2009).

A great deal of preclinical research linking animal models and human clinical studies confirms the antitumor efficacy of lentinan and its competency in preventing viral and chemical carcinogenesis. The antitumor and antimetastatic activity of lentinan has been reviewed by Chihara et al. and acknowledged to be host-mediated T cell-oriented adjuvant (Chihara et al. 1987). Lentinan elicits an increased production of various kinds of bioactive serum factors associated with immunity and inflammation such as IL-1, CSF, IL-3, vascular dilation inducer, and acute-phase protein induction by the direct action on macrophages or indirectly via lentinan-stimulated T cells resulting in the induction of many immunobiological changes in the host.

In 1985, lentinan injection was approved as therapeutic adjuvant for treatment of certain cancer in Japan and China, and the effect of lentinan in gastric cancer treatment has recently been reviewed (Ina et al. 2013). Lentinan has been evaluated in combination with other agents as well singularly for treatment of patients with advanced or recurrent gastric or colorectal cancer. Results of phase III study of lentinan in combination with chemotherapeutic agents such as 5FU + mitomycin C

or tegafur on patients with advanced or recurrent (GI) cancer reveal that lentinan confer a significant life-span prolongation effect and a higher survival rate especially in combination with tegafur in gastric cancer patients (Taguchi et al. 1985). In a multi-institutional randomized prospective protocol, comprising patients with advanced unresectable gastric cancer and recurrent diseases, the effect of lentinan on patients administered tegafur and cisplatin (control group), and patients administered lentinan, tegafur, and cisplatin (lentinan group), was performed. Addition of lentinan was found to prolong survival and improved quality of life in combination with chemotherapeutic agents (Nakano et al. 1999). Another multicenter chemoimmunotherapy trial using S-1 combined with lentinan benefited patients with unresectable or recurrent gastric cancer with high QOL and prolonged NC period within window of acceptable toxicity (Nimura et al. 2006). Trastuzumab, an antibody against HER2/neu growth factor receptor, has been used for the treatment of gastric and breast cancer in combination with cytotoxic chemotherapeutic agents. Lentinan has been appreciated exerting a synergistic action with anticancer monoclonal antibodies to activate complement systems through the mechanism of antibody-dependent cellular cytotoxicity and complement-dependent cytotoxicity (Ina et al. 2013). There are also reports mentioning higher overall response rates with addition of lentinan to conventional regimens in esophageal and hepatocellular carcinomas (Wang et al. 2012; Yang et al. 2008). Recently, superfine dispersed lentinan – an oral formulation – has become available with seemingly QOL improvement and prognosis in patients with advanced gastric, colorectal, pancreatic, and hepatocellular cancer, although many of the comparison arms in these trials did not utilize standard Western chemotherapy regimens (Yoshino et al. 2010; Hazama et al. 2009; Isoda et al. 2009; Shimizu et al. 2009).

The clinical safety of lentinan administration for patients with advanced or recurrent breast cancer with bilateral oophorectomy (Ox) and adrenalectomy (Ax) and its efficacy as judged by prolongation of life span and antitumor effect has been established. Improvement in prognosis was observed in lentinan-treated patients, compared with the control (Kosaka et al. 1982). Another related extension of this study evaluated lentinan posttreatment with endocrine therapy to patients undergoing surgical therapy (adrenalectomy and oophorectomy) for recurring breast tumor patients. It has been noted that lentinan injection following surgical therapy (Ax + Ox) resulted in a much greater regression of tumor growth than that obtained by surgery alone, but not after tamoxifen therapy. Immunohistochemistry of resected tumor tissue confirmed that lentinan-surgical therapy results in marked atrophy of tumors as well as intense infiltration of T cells, B cells, and macrophages into the stroma around the tumor. Blood prolactin level was also found greatly reduced by lentinan injection (Kosaka et al. 1987).

3.2 Schizophyllan

It is a natural nonionic, water-soluble exopolysaccharide produced using strains of the wood-rotting, filamentous basidiomycete *Schizophyllum commune* commonly

known as split gill mushroom. Schizophyllan (SPG) consists of a linear chain of β-D-(1,3)-glucopyranosyl backbone with single β-D-(1,6)-glucopyranosyl side chains at approximately every third monomer of the main β-1,3-chain (Fig. 1) and dissolves in water as a rigid rodlike triple helix molecule. SPG has been approved for clinical use in Japan and thus commercially produced by several Japanese pharmaceutical companies. It has been reported to be active as biological response modifier and nonspecific stimulator of immune system. Its physicochemical properties, bioactivities, and other developments regarding its application have recently been reviewed and accessible (Zhang et al. 2013). Scientific understanding in context for a mechanistic basis for SPG-associated antitumor effects conclude that aqueous solution of SPG potentiates host-mediated antitumor activity which corroborate with increased overall survival of patients with tumors.

Assembling the reported antitumor studies in preclinical models reveals antitumor activity of SPG against both the solid and ascites forms of sarcoma 180, as well as against the solid form only of sarcoma 37, Ehrlich sarcoma, Yoshida sarcoma, and Lewis lung carcinoma (Wasser 2002). The survival of sarcoma 180 xenografts was not affected by pretreatment with SPG, while pre- and posttreatment with SPG resulted in increased survival. The underlying antitumor events following SPG treatment in these models have been shown being associated with increased cellular immunity by enhanced generation of T lymphocytes and augmented increased production of cytokines – interleukin-2 and interferon-γ – by the peripheral blood mononuclear cells that results in ~95 % tumor inhibition (Matsuo et al. 1982); the antitumor activity of SPG diminishes in thymectomized mice indicating antitumor actions of SPG is T cell mediated (Borchers et al. 1999). In chemically induced breast carcinomas, SPG inhibits tumor incidence along with decrease cell proliferation in tumor tissue (Mansour et al. 2012), while in rat ovarian adenocarcinoma, SPG administration augmented the antitumor effect of cisplatin as inferred from reduced tumor size and improved survival rate in SPG alone and combination arm together with infiltrative increase in cytotoxic T lymphocytes; clinical antitumor effect was also amplified by induction of IL-2 receptor expression and increased NK cell activity (Sugiyama et al. 1995; Hoshino et al. 1993) In ovarian cancer patients undergoing chemotherapy, SPG has been found useful against myelosuppression by chemotherapy (Hoshino et al. 1996).

SPG potentiates photodynamic therapy of squamous cell carcinoma-bearing mice revealing three times increase in tumor cure rate when PDT was preceded by the SPG therapy (Krosl and Korbelik 1994). Schizophyllan pretreatment also prolonged the survival time of B16 melanoma-bearing mice when treated with fractionated X-rays and reestablished mitosis of bone-marrow cells previously suppressed by anticancer drug treatment (Takai et al. 1994). The effect of SPG on lung metastases, immune reactions in tumor tissue, and the survival time of mice bearing transplanted Lewis lung cancer cells subjected to X-rays has been promising (Inomata et al. 1996). SPG reduced the number of lung metastases and prolonged the life span of the mice, these effects being independent of radiation. The addition of SPG to radiation increases both the macrophage infiltration and T-lymphocyte infiltration in the local tumor and the lung nodules (Inomata et al. 1996).

In a previously reported randomized controlled clinical study of 367 patients with recurrent and inoperable gastric cancer, response to conventional chemotherapy – tegafur or mitomycin and 5-fluorouracil – was found increased by SPG, along with significant prolongation of life span without serious side effects but without any significant influence on tumor size (Furue et al. 1985). SPG has been shown to extend the survival time of patients with head and neck cancers by augmenting the accelerated recovery of cellular immunity compromised by radiation, chemotherapy, and surgical procedure. SPG enhances the immune functioning of the regional lymph nodes in patients, as revealed by increased IL-2 production and cytotoxic activities of effector cells (NK, LAK) and increased helper T lymphocytes (CD4+) in the tumor-uninvolved lymph nodes (Kimura et al. 1994; Kano et al. 1996). Subsequently, in a phase II randomized controlled trial, the clinical efficacy and tolerability of SPG in combination with standard chemotherapy in cohort of patients with locally advanced head and neck squamous cell carcinoma revealed no significant difference in overall response rate, although a higher number of complete responses (CR) was registered in Arm A (SPG associated with chemotherapy) verses Arm B (treatment with chemotherapy regimen alone) (Mantovani et al. 1997).

Sizofiran is a potent biologic response modifier in augmenting immune function of regional lymph nodes in patients with cervical cancer (Shimizu et al. 1991, 1992). Further, in one randomized controlled study of SPG in combination with radiotherapy, this polysaccharide molecule significantly prolonged the overall survival time and time to recurrence of stage II but not stage III cancer (Okamura et al. 1989). Later, another study reported higher complete response rate among stage II and III patients than the control group along with rapid significant recovery of decreased lymphocyte counts due to radiotherapy (Noda et al. 1992). In a prospective, randomized clinical trial involving 312 patients treated with surgery, radiotherapy, chemotherapy (fluorouracil), and SPG in various combinations, it is reported that patients treated with SPG survived significantly longer than those who did not receive SPG (Miyazaki et al. 1995). A prospective randomized control trial at https://clinicaltrials.gov is currently recruiting participants [T01926821] for a study evaluating the impact of sonifilan on the quality of life in patients with cervical cancer during radiation or chemoradiotherapy. The primary endpoint of this study is to evaluate QOL, while secondary endpoint relates to complications and treatment effect of sonifilan. Proposed in this study is a dose of 20 mg of sonifilan twice per week for 8 weeks.

3.3 Krestin

Is a protein-bound polysaccharide (PSK; Krestin®) isolated and purified from the cultured mycelium of a nonedible traditional medicinal mushroom *Coriolus versicolor* of Basidiomycetes family (strain: CM-101). It has an average MW of 9.4×10^4, and its major sugar moiety is glucan having a main chain β1-4 bond and a side chain β1-3 as well as β1-6 bond that binds to a protein moiety through *O*- or *N*-glycoside bond (Tsukagoshi et al. 1984). PSK has been shown to regress tumors and

nonspecific immunomodulatory activity is considered the principal mechanism of action of this agent (Tsukagoshi et al. 1984). Specifically, PSK improves host immune competence by either inhibiting the production or neutralizing immunosuppressive substances that are increased in cancer. Secondly, PSK activates immune cells such as lymphocytes, either directly or by regulating the production of various cytokines. Thirdly, PSK acts directly on cancer cells. These mechanisms support the clinical effectiveness of PSK in suppressing cancer relapse (Maehara et al. 2012).

Many basic studies reported in preclinical models show signs of preventive effect of PSK on chemical carcinogen-induced, radiation-induced, and spontaneously developing cancers, suppressing pulmonary metastasis of methylcholanthrene-induced sarcomas, human prostate cancer metastasis, and lymphatic metastasis of mouse leukemia P388 and prolonging survival period in various spontaneously developing metastasis models. In murine models of metastasis, PSK has been shown to suppress the metastasis of rat hepatoma AH60C, mouse colon cancer cells, and mouse leukemia RL (Kobayashi et al. 1995). Decades of numerous clinical trials have shown that the administration of PSK in conjunction with other pharmaceutical drugs escalates the effectiveness of chemotherapy and survival in patients suffering from lung, breast, gastric, colon, liver, and prostate cancer. PSK has been used both orally and intravenously, and in one reported clinical study with a median follow-up of 82 months, there were no significant differences in the 5-year disease-free survival (73 % vs. 55 %) and overall survival (77 % vs. 66 %) between oral chemo-immunotherapy (CITX) versus intravenous CITX in locally advanced gastric cancer patients (Ahn et al. 2013). Other reported clinical trials comprising PSK and chemotherapeutic agents, including fluoropyrimidines (Sakai et al. 2008), UFT (tegafur/uracil) (Ohwada et al. 2006; Yoshitani and Takashima 2009), S-1(tegafur/gimeracil/oteracil) (Kono et al. 2008), or FOLFOX4 (5-fluorouracil/folinic acid/oxaliplatin) (Shibata et al. 2011) all demonstrate favorable long-term prognosis along with reduction in risk of recurrence and extension in survival rates of patients with gastric and colorectal cancer. The effectiveness of PSK as an adjuvant therapy has been a subject to evaluation mainly during postoperative period, by comparing chemotherapy + PSK with chemotherapy alone, and validates that chemotherapy + PSK improve survival in patients with curatively resected gastric cancer (Oba et al. 2007). For advanced colorectal cancers prognosis of surgical treatment is poor and postoperative adjuvant therapy is considered essential. In Japan, multiple multicenter randomized control trial evaluated the efficacy of PSK as postoperative adjuvant therapy for colorectal cancer with oral 5-fluorouracil or oral UFT (tegafur/uracil) or intravenous mitomycin C, compared with surgery alone, and concluded significantly better overall survival (OS) and disease-free survival (DFS) (Torisu et al. 1990; Ito et al. 2004; Ohwada et al. 2004). Since aberrant Wnt-β-catenin signaling is a common phenomenon in colon cancer, a study comprising 44 % patients of colon cancer with diffuse nuclear accumulation of β-catenin activation underwent adjuvant immunochemotherapy protocol [5-fluorouracil plus PSK vs. chemotherapy with 5-fluorouracil alone]. The study outcome exposed significantly improved recurrence-free survival, cancer death survival, and overall survival rates compared with patients receiving chemotherapy alone (Yamashita et al. 2007).

It is not yet known whether vaccine therapy and trastuzumab is more effective when given with or without polysaccharide-K in treating breast cancer (https://clinicaltrials.gov). To address this, a joint collaborative study between University of Washington, National Cancer Inst. (NCI), and National Center for Complementary and Alternative Medicine (NCCAM) is currently recruiting participants for phase I/II randomized study of combination immunotherapy with or without polysaccharide Krestin (PSK®) concurrent with a HER2 ICD peptide-based vaccine and trastuzumab in patients with stage IV breast cancer [NCT Number NCT01922921 at https://clinicaltrials.gov].

Since radiotherapy is generally associated with reducing immune function, preoperative PSK therapy administered to patients reveals improved immune functioning as inferred from the significant increase of NK cell count in peripheral blood and cytotoxic T-cell counts in the peri-tumoral and normal mucosa, along with significant decrease of serum immunosuppressive acidic protein levels noted in the PSK group (Sadahiro et al. 2010). It is also interesting to note that in patients, PSK partially prevents apoptosis of circulating T cells induced by anticancer drug S-1 (Kono et al. 2008).

Other site-specific solid tumors including breast, esophageal and in lung cancer patients the benefit of PSK inclusion in adjuvant setting has been consistently demonstrated in clinical trials. A large trial on patients with breast cancer undergoing curative resection followed by adjuvant therapies with PSK had a better 10-year survival rate of 81 % compared to 64 % in the group using chemotherapy alone (Iino et al. 1995). Similarly, the beneficial effect of PSK supplementation was confirmed in prospective multicenter studies on patients diagnosed with esophageal cancer showing significantly better 5-year survival compared to patients without PSK supplementation (Ogoshi et al. 1995a, b). Patients diagnosed as stage III lung cancer and continuing with PSK treatment (cycle of 2 weeks on and 2 weeks off) after the cessation of radiotherapy had better prognosis than those with stage I and II of the disease but without access to PSK supplementation therapy (Ke et al. 1999).

3.4 *Ganoderma lucidum*

This woody basidiomycete rot fungus commonly referred as "linghzi" and touted in traditional Chinese medicine as a remedy for promoting longevity and preserving human vitality. It has also been overvalued for use as an antitumor medication and known to have anti-inflammatory and antidiabetic effects as well (Sliva 2004; Xu et al. 2011a). The anticancer effects of *Ganoderma* sps is associated with diversified chemical constituents extracted from the fruiting body, mycelium, and spores and includes a wide variety of bioactive compounds such as triterpenes and polysaccharides and other minor constituents such as amino acids, lignin, phenols, sterols, and vitamins (Yuen and Gohel 2005). Biologically active compound originally isolated and purified from *G. lucidum* was a fucose-containing polysaccharide fraction (F3) from water-soluble extract. Most linghzi isolated polysaccharides are heteropolymeric macromolecules having MW ranging between 4×10^5 and

1×10^6 Da containing xylose, mannose, galactose, and fucose in different conformations including 1 → 3-, 1 → 4-, and 1 → 6-linked β- and α-D (or L)-substitutions (Bao et al. 2002). Upon further characterization of different polysaccharide fractions, only branched glucan conformation consisting of (1 → 3)-, (1 → 4)-, and (1 → 6)-β-D linkages has been noted to have strong antitumor activity and better oral absorption compared to other polysaccharide fractions in *G. lucidum* (Miyazaki and Nishijima 1981). Further investigation uncovered that the antitumor activity of β-D-glucans is mainly localized at the branched (1 → 3) chain which binds to complement receptor type 3 and prompts a series of molecular pathways such as NF-κB, mitogen-activated protein kinase (MAPK), and protein kinase C (PKC), which converge and activate the host immune system stimulating immune cell proliferation and cytokine production (Ooi and Liu 2000; Lee and Hong 2011; Ren et al. 2012). The polysaccharide compounds from *G. lucidum* has been suggested to be carcinostatic and reportedly highly suppressive to tumor cell proliferation by boosting host immune functions resulting in the production of cytokines that activate anticancer activities of immune cells rather than direct cytotoxic effect (Kao et al. 2013; Wang et al. 1997). This underlying pathway of cellular action invokes the stimulation of macrophages, maturation and function of dendritic cells, natural killer (NK) cells, cytotoxic T lymphocytes (CTL), and cytokine-induced killer cell (CIK) function and activities along with immune-enhancing secretory products, such as reactive nitrogen and oxygen intermediates and a range of cytokines, for instance, IL-1β, IL-6, TNF-α, and IFN-γ (Wang et al. 1997). Corollary to this hypothesis, *Ganoderma* polysaccharides have been reported to enhance the function of immunologic effector cells in immune-suppressed mice (Zhu et al. 2007). In Adriamycin (ADM)-resistant leukemic (K562/ADM) cell line, *Ganoderma* polysaccharide was effective in reversing multidrug resistance (MDR) through downregulation of the expression of MDR-1 and MDR-associated protein-1 (MRP-1) (Li et al. 2008a). In human lung cancer cells, the addition of this polysaccharide was found effective in inhibiting induction of vascular endothelial growth factor (VEGF) along with inhibition of growth of vascular endothelial cells and thus seems effective as an anti-angiogenic molecule as well (Cao and Lin 2006).

In clinical setup, two randomized trials investigated the effect of GanoPoly® (*G. lucidum* polysaccharide) on the immune functions in advanced-stage cancer patients (Gao et al. 2003a). A total of 34 advanced-stage cancer patients were included and treated with 1,800 mg of GanoPoly® three times daily orally before meals for 12 weeks. The tumors were mainly from lung, breast, liver colon, prostate, bladder, and brain and GanoPoly® was the only anticancer agent administered during the 12-week study period. Another study evaluated the effect of GanoPoly® on 68 lung cancer patients revealing improvement in quality of life in ~65 % of patients. Of clinical interest was a significant increase of total T cells and NK cells along with slight increase of CD4/CD8 ratios in treatment arm compared to placebo (Gao et al. 2003b). Recently, Sun et al. reported *G. lucidum* polysaccharide could antagonize and potentially reverse immune-suppressive effects of lung cancer patient derived plasma-induced suppression of lymphocyte function

and activation (Sun et al. 2014a). Such reversal of immunosuppression by *Ganoderma* polysaccharide treatment suggests the potential of this polysaccharide in cancer therapy (Sun et al. 2014a).

4 Polysaccharides of Clinical Interest from Botanicals in Preclinical and Clinical Models of Cancer

PS component of some medicinally important terrestrial plants with anecdotal anticancer effect has been isolated and characterized. A few select important ones are discussed below.

4.1 *Astragalus* Polysaccharide

Astragalus membranaceus (Fisch.) Bunge (AM), Maxim of the Leguminosae family, is a traditional Chinese medicinal herb. The dried root of AM (known as Huang qi in Chinese) with a sweet warm taste has been acknowledged as a promising complimentary medication for cardiovascular diseases, antiviral infection, diuretic, antidiabetic nephropathy, and antioxidative damage prevention. Using modern analytical techniques major bioactive constituents of the roots of AM have been identified as flavonoids, polysaccharides (astragalan), saponins, and amino acids. Among various component functional fractions, polysaccharides have emerged as an important class receiving much attention for a variety of biological activities such as antitumor, immune modulation, hypoglycemic, and other related beneficial effects of *Astragalus*. Chemical structure characterization by NMR spectroscopy of a homogenous bioactive polysaccharide (APS) obtained by hot water extraction of sliced root of *Astragalus* followed by purification on DEAE-cellulose and Sephacryl-S400 columns detected structure of the polysaccharide being composed of repeating (1 → 4)-linked dextran backbone with a (1 → 6)-linked branch every ten residues as shown in Fig. 1.

APS have been found associated with antioxidant activity including scavenging of hydroxyl radical (·OH) and hydrogen peroxide (H_2O_2) and chelating effect on transition metals such as ferrous iron (Fe^{2+}); the latter can facilitate the generation of ROS. The high chelating capacity of APS against Fe^{2+} could be an important approach in retarding metal-catalyzed oxidation since ferrous ions are the most effective prooxidants in biological systems. ROS such as superoxide anion ($O_2^{\cdot -}$), hydroxyl radical, and hydrogen peroxide are generated ubiquitously as part of normal cellular physiological process, and their involvement in the pathogenesis of certain human diseases including cancer, cardiovascular diseases, and other aging-associated health problems is well recognized. Thus, the antioxidant effect of APS as free radical scavenger suggests it might be a potentially useful agent to reduce adverse effects of oxidative stress. Recent reports have pointed association between *Astragalus* and symptom relief including improvement in organs function in severe heart and liver diseases (Ma and Guan 2005).

From cancer therapeutic viewpoint, application of *Astragalus* polysaccharide in cancer immunotherapy seems promising. An increasing number of experiments both in vivo and in vitro have shown that *Astragalus* polysaccharide can enhance the body's natural defense mechanism including immunorestorative effect by stimulating phagocytic activity of macrophages (Wang 1989; Yang et al. 2013). Mechanistically, *Astragalus* polysaccharide enforces anticancer effects at least partly via improving immune responses of host organism through modulation of cytokine production such as increase IL-1α, IL-2, IL-6, TNF-α, and the levels of IFN-gamma and significantly decreasing IL-10 and TGF-β levels as deduced from the analysis of tumor-bearing mice treated with *Astragalus* polysaccharide (Yang et al. 2013; Tian et al. 2012a; Sun et al. 2014b). *Astragalus* polysaccharide also downregulate the expression of cyclooxygenase-2 (Liu et al. 2014).

Rui et al. demonstrated antitumor efficacy of oral *Astragalus* polysaccharide treatment to mice bearing B16F10 xenograft tumors. Additionally, moderate to strong antitumor effect was observed following single intraperitoneal treatment with CD-40 gene siRNA plasmid to *Astragalus* polysaccharide-treated mice; the effect being confirmed with decreasing CD-40 cell surface marker (Zhu et al. 2011). *Astragalus* polysaccharides as a therapeutic adjunct along with Adriamycin (AMD) chemotherapy have shown promising results in tumor models along with restoration of AMD-induced immunosuppression (Li et al. 2008b); in another study, it was shown to enhance sensitivity of chemotherapy drugs such as cyclophosphamide, Adriamycin, 5-fluorouracil, cisplatin, etoposide, and vincristine in Adriamycin-resistant cell line by pharmacologically inhibiting P-glycoprotein efflux pump function (Tian et al. 2012b). A recent report reveals that *Astragalus* polysaccharides ameliorate doxorubicin-induced cardiac dysfunction in cancer patients by a mechanism involving suppression of oxidative stress and apoptosis by regulating the PI3k/Akt and p38MAPK pathways (Cao et al. 2014). In advanced small cell lung carcinoma patients undergoing vinorelbine and cisplatin chemotherapy, APS injection integrated with chemotherapy showed increased tumor response, stable improvement in performance status including QOL and survival, and reduced toxicity towards chemotherapy dose (Guo et al. 2012; McCulloch et al. 2006).

4.2 *Angelica*

The dried roots of genus *Angelica* of Umbelliferae family are a source of many oriental drugs in Korea, Japan, and China and include mainly all-purpose women's medicinal herbs such as *Angelica sinensis* Diels, *Angelica acutiloba* Kitagawa, *Angelica dahurica*, and *Angelica officinale* Koch. Phytochemical investigations point attention to polysaccharides as principle constituent associated with many of the reported bioactivities such as anti-inflammatory, antimutagenic, antimicrobial, antitumor, and antioxidant and as immunotherapeutic biological response modifier (Kim et al. 1991; Xu et al. 2011b; Sarker and Nahar 2004). Additional pharmacological activity of *Angelica* polysaccharides on hematopoiesis, blood coagulation, and platelet aggregation and its protective effect on hepatic injury

have also been documented (Ye et al. 2001; Yang et al. 2002). Based on chemical and instrumental analysis till date, 36 polysaccharides have been identified from the root of *A sinensis* (RAS); an overview of their primary structural features such as monosaccharide composition and MW has been compiled and published recently by Jin et.al. (2012). Most polysaccharides isolated from *Angelica* sps are heteropolysaccharides, with constituent units identified as comprising of fucose, galactose, glucose, arabinose, rhamnose, arabinose, mannose, and xylose. A neutral polysaccharide (ASP1) and two acidic polysaccharides (ASP2 and ASP3) have been separated from RAS by hot water extraction (Chen et al. 2013). A pectic polysaccharide – angelan (MW 10 kDa) – was purified from the root and cell culture of *A. gigas* Nakai and chemically characterized being composed of arabinose, galactose, and galacturonic acid and inorganic compounds (Ca^{2+} and Mg^{2+}) but does not contain glucose (Ahn et al. 1996, 1998).

From a therapeutic viewpoint, Cao et al. evaluated the antitumor activity of several different kinds of PS from *A sinensis*. A novel arabinoglucan heteropolysaccharide – APS-1d (MW 5.1×10^3 Da) – purified from *A. sinensis* significantly inhibited proliferation of two representative human solid cancer cell lines (cervical cancer HeLa cells and lung carcinoma A549 cells) by apoptosis primarily involving the activation of the intrinsic mitochondrial pathway. In addition, APS-1d inhibited in a dose-responsive manner the growth of HeLa cell xenograft tumors in nude mice through apoptosis, and also suppressed the growth of transplanted sarcoma 180 (S180) by a mechanism suggestive of activation of immune response of host (Cao et al. 2006, 2010a; Ooi and Liu 2000). Furthermore, three acidic homogenous polysaccharides (APS-3a, APS-3b, and APS-3c) from *A. sinensis* were successfully isolated and purified and their antitumor efficacy appraised (Cao et al. 2010b). Of the three APS, only two – APS-3b and APS-3c – could significantly inhibit the growth of S180 tumors and increase life spans of S180 tumor-bearing mice, whereas APS-3a had no significant effect. Mechanistically, the antitumor effects were found associated with enhancement of some immunological parameters as was evident from concentration-dependent proliferation of the splenocytes in concurrence with the upregulation of IFN-γ, IL-2, and IL-6 mRNA expressions and production of NO and TNF-α in peritoneal macrophages (Cao et al. 2010b).

Shang et al. previously isolated total polysaccharide (AP-0) and its subconstituents (AP-1, AP-2, and AP-3) from fresh roots of *A. sinensis* (Oliv.) by ethanol and multi-precipitation after boiling water extraction and carried an assessment of the antitumor efficacy of total polysaccharide (AP-0) on three in vivo murine tumor models (sarcoma 180, leukemia L1210, and Ehrlich ascites cancer (EAC)). Additionally, the in vitro inhibitory effects of AP-0 and its subconstituents (AP-1, AP-2, and AP-3) on invasion and metastasis of human hepatocellular carcinoma cells (HHCC) into Matrigel reconstituted basement membrane were also evaluated (Shang et al. 2003). From transplantation experiments it is worth to note the influence of AP-0 fraction on the thymus of mice, although the effect was not strong enough to inhibit the growth of S180 tumor, but instead this fraction was effective in inhibiting the production of ascitic fluid and prolonging life of mice bearing L1210 leukemic cells. Collectively, these results of in vivo experiments

suggest that AP-0 has antitumor effect on murine ascitic tumors (EAC and L1210) and affects the thymus of mice bearing S180 tumor. Reference to invasion and migration proficiency on HCC, AP-0, and its subconstituent AP-2 had significant inhibitory effect on the invasion of HHCC into the Matrigel with inhibition rate up to 68 %. Furthermore, AP-0, AP-1, and AP-3 could partially inhibit the chemotactic migration abilities of HHCC cells. Cumulatively, these results are suggestive that polysaccharides from *A. sinensis* exhibit antitumor effects on experimental tumor models in vivo and inhibitory effects on invasion and metastasis in vitro.

Of interest to human health, contemporary investigations by Jiang et al. on the modulatory effect of *A. sinensis* PS and Tai Chi exercise on oxidative injury in middle-aged women subjects revealed reduced oxidative stress and improved blood lipid metabolism; it was shown that antioxidant activities such as superoxide dismutase, catalase, and glutathione peroxidase in the *A. sinensis* PS-treated group were significantly elevated while lipid peroxidation products were found reduced compared to control group (Juan et al. 2009). Survey on the federal website https://clinicaltrials.gov/ flag two studies currently recruiting participants – NCT01720550 and NCT01720563 – using PG2® (PhytoHealth Corp; *Astragalus* polysaccharide 250 and *Astragalus* polysaccharide 500 mg in saline) in cancer patients. The objective of NCT01720550 study is to evaluate the efficacy and safety of different doses of PG2 treatment for relieving fatigue among advanced cancer patients who are under standard palliative care (SPC) at hospice setting and have no further curative options available. NCT01720563 is a phase II double-blind and randomized trial comparing concurrent chemoradiotherapy plus PG2 injection versus concurrent chemoradiotherapy (cisplatin/tegafur plus uracil (UFT)/leucovorin) every 2 weeks plus placebo in advanced pharyngeal or laryngeal squamous cell carcinoma. No study results of these trials have been posted yet.

Radiotherapy is an alternate treatment modality frequently used in cancer treatment but unfortunately is associated with non-targeted adverse effects especially in hematopoietic and reproductive organs. Contextually, pectic PS – ASP3 isolated from *A. sinensis* – exhibited significant radioprotection to mice exposed to a ^{60}Co source of irradiation (Sun et al. 2005, 2009). ASP-3 pretreatment for 7 days demonstrates a protective effect on peripheral lymphocytes against not only apoptotic effect of irradiation, but had significant impact on formation of micronucleus within polychromatic erythrocytes in bone-marrow and sperm aberration, enhances transformation rates of spleen lymphocyte, and improves endurance of the body against radiation. Other emerging studies reveal multimodal therapeutic effect of *A. sinensis* polysaccharide (ASP) combined with cytarabine (Ara-C) in leukemia treatment. ASP combined with Ara-C inhibited proliferation of human acute myeloid (AML) cell line KG1α in vitro by blocking cells in the Go-G1 phase of the cell cycle (Xu et al. 2014). Intraperitoneal injections of ASP + Ara-C in human leukemia NOD/SCID mouse model induced by implanting K562 human leukemic cells alleviate liver damage and pathological changes as shown by improved liver function test and improvement in antioxidant enzyme status in the liver of treated mice along with decreased inflammation of hepatocytes. Of greater interest was the observation that diffuse leukemic cell infiltration into the liver lobules was

significantly reduced along with remarkable increase in the number of apoptotic cells (Zhu et al. 2014). The effect of APS in inducing differentiation of erythroleukemia cells (K562) towards erythrocyte and granulocyte series has been documented (Zheng and Wang 2002). Other studies report the efficacy of ASP as representing an important agent in leukemia stem cell-targeted therapy by a mechanism inducing senescence of human AML stem and progenitor cells by telomere end attrition and by repressing telomerase activity (Liu et al. 2013). Collectively, these preclinical findings hold promise for ASP in hematological malignancies. Angelan exhibited features of tumor growth inhibition and metastasis by stimulating host immune functioning of B cells and macrophages and also directly inhibited cancer cell adhesion; it significantly prolonged the survival of melanoma B16F10 cell-implanted mice and reduced the frequency of pulmonary metastasis of B16F10 melanoma (Han et al. 2006). A further extension to this study incorporating the combined treatment of angelan and doxorubicin (a cytotoxic anticancer agent) shows greater effectiveness in the inhibition of tumor growth and metastasis than either compound alone by a mechanism involving direct inhibition of cancer cell adhesion and invasion through the extracellular matrix in addition to activating the immune functions of B cells and macrophages (Han et al. 2006).

4.3 *Ginseng*

The roots of *Panax* herb of Araliaceae family have been in use for centuries because of assumingly many therapeutic effects. It has been reported to have neuroprotective (Nah 2014), antidiabetic (Kim et al. 2011b; Uzayisenga et al. 2014), and cardiovascular effects (Lee and Kim 2014) and in addition perceived to improve cancer treatment (Chen et al. 2014). Although it is not approved by the Food and Drug Administration in the USA, it remains as one of the most frequently purchased herbal supplement in the USA, whereas in Asian countries and Western Europe, it is commonly used as adjuvant for cancer therapy (Qi et al. 2010; Vogler et al. 1999). The use and benefit of ginseng by cancer patients appears to be well accepted because of reported improvement in clinical outcome and its potential to reduce the adverse effects of chemo- and radiotherapy. Of greater interest in the use of this drug relates to its associated chemopreventive action as deduced from epidemiological studies revealing that subjects with ginseng intake had significantly lower risk of recurrence of cancer compared to nonusers of this supplement (Choi 2008; Shin et al. 2000; Yun and Choi 1995). Two species of ginseng with their roots as preferred source for multi-action compound isolation have been largely focused for anticancer properties, i.e., Asian (*Panax ginseng* CA Meyer) and American (*Panax quinquefolius*) ginseng. Their roots contain various bioactive components including 20 different ginsenosides, polysaccharides, flavonoids, and poly-acetylene alcohols, among which ginsenosides and polysaccharides appear to be responsible for a spectrum of biological activities including immunomodulation, antioxidation, and anticancer effects (Nag et al. 2012; King and Murphy 2010).

Ginseng polysaccharides naturally occur as admixture of structurally and functionally different compounds with yet unclear structure-activity relationship. According to published results, water-soluble ginseng root polysaccharides constitute ~10–15 % of dry weight and these hydrophilic macromolecules are heterogenous, being formed from complex chains of monosaccharides, such as L-arabinose, D-galactose, L-rhamnose, D-galacturonic acid, D-glucuronic acid, and D-galactosyl residues linked together through glycosidic bonds with molecular weights ranging from 3.5 to 2,000 kDa (Azike et al. 2015). The monosaccharide composition of American ginseng root polysaccharides (AGRPS) has been ascribed to contain glucose, galactose, arabinose, rhamnose, and galacturonic acid (Lui et al. 2012). Using a multistep procedure, Cheng et al. fractionated and characterized the heterogenous fractions of ginseng polysaccharides that enabled their group to study and compare the effects of individual components. Accordingly, eluting ginseng polysaccharides on a preparative DEAE-cellulose column yield an acidic population (20 %) and a neutral polysaccharide population (80 %) (Cheng et al. 2011). Neutral polysaccharide fraction of ginseng mainly contains starch-like glucans with no antiproliferative effect on cancer cell, while the acidic fraction is found composed mainly of two types of polysaccharides – the HG-rich pectins and the arabinogalactans. Further bioassay studies revealed that HG-rich pectins, but not arabinogalactans, contain the active component of ginseng polysaccharides that inhibits cell proliferation possibly by G2/M phase arrest of cell cycle. Further, high temperature treatment of HG-rich pectins revealed an improved growth inhibition of colon cancer cells by inducing apoptosis in addition to cell cycle arrest (Cheng et al. 2011). Conceivably, steam treatment might generate or enrich specific structural element that are responsible for the apoptotic activity akin to temperature-modified citrus pectin becoming effective in inducing apoptosis of human cancer cells, while its intact counterpart remains ineffective (Jackson et al. 2007). Ginsan, an acidic ginseng polysaccharide fraction, has been shown to reduce the incidence of benzo(a)pyrene-induced primary lung tumors in mice and the pulmonary metastasis of B16F10 melanoma cells (Lee et al. 1997; Shin et al. 2002). RGAP, another acidic polysaccharide isolated from red ginseng, inhibits the growth of lung carcinoma 3LL, sarcoma 180, and adenocarcinoma JC and enhances the antitumor effects of paclitaxel (Shin et al. 2004a, b). The results from a 14-week randomized, placebo-controlled, double-blind clinical trial evaluating efficacy and safety of ginseng polysaccharide extract (Y75®) registered at https://clinicaltrials.gov/ [NCT 02161198] have recently been published. Interestingly, Y75 significantly enhanced NK cell cytotoxic activity, phagocytic activity of peripheral blood cells, and serum level of TNF-α after treatment. Additionally, administration of Y75 is well tolerated without treatment-related adverse events or alteration of complete blood cell count or blood chemistry over the entire study period (Cho et al. 2014).

4.4 Pectins and Modified Citrus Pectin

Pectins are natural cell wall component representing a family of complex polysaccharides containing galacturonic acid residues and in addition containing galactose,

rhamnose, and arabinose with occasional glucose, mannose, and glucuronic acid residues whose content and linkages vary in pectin from different sources. Thus, centering on the content of sugar residues and linkages along with accompanying structural domains, pectins have been organized into few different types as homogalacturonan, type I rhamnogalacturonan, type II rhamnogalacturonan, xylogalacturonan, apiogalacturonan, arabino-galacturonan, and galactan (Perez et al. 2003). An important feature of pectins is their capability to form gels in the presence of Ca^{++} or sugar and acid and usually resistant to digestion by human intestinal enzymes. Typical levels of pectin as food additive are between 0.5 % and 1 % which is almost equivalent to the amount obtained from consumption of fresh fruit. Accumulating evidence suggests pectins play an important role in prevention of cancer and metastasis. Interestingly, pectin polysaccharides usually have low toxicity and are resistant to digestion by human intestinal enzymes and thus could be of significance in the inhibition of colon cancer in humans. The introduction of pectin into the diet of experimental animals considerably inhibited the development of chemical carcinogen-induced precancerous lesions in colonic mucosa of rats and significantly suppressed the growth of transplantable EMT6 breast carcinoma, TLT liver tumor, and Ehrlich adenocarcinoma (Taper et al. 1997; Taper and Roberfroid 1999; Khotimchenko et al. 2007) and prevented dissemination of B16F1 melanoma cells into the lungs of mice (Platt and Raz 1992). Apple pectins are reportedly effective in significantly reducing the frequency and the number of tumor foci induced by the chemical carcinogen azoxymethane and dimethylhydrazine in the colon of rats and transgenic mice bearing the human transgenes – *c-Ha-ras* (Ohno et al. 2000; Ohkami et al. 1995). The effect of rhamnogalacturonan I pectin from potato and ginseng pectin on HT-29 colon cancer cells inhibited the proliferation of tumor cells by inducing significant G2/M cell cycle arrest associated with downregulation of cyclin B1 and cyclin-dependent kinase 1 expression (Cheng et al. 2011, 2013).

Citrus pectins are acidic water-soluble polysaccharide obtained from the skin and pulp of citrus fruits. Citrus pectin modified under the effects of high pH and temperature – modified citrus pectin (MCP) – has emerged as a promising agent affecting metastatic dissemination of various cancers. It retains structural elements present in the citrus pectin, including the homogalacturonan, rhamnogalacturonan I, and rhamnogalacturonan II domains and the side chains. MCP has been shown in laboratory to be effective either in vitro or in vivo or both against prostate carcinoma (Pienta et al. 1995; Hsieh and Wu 1995; Glinskii et al. 2005), colon carcinoma (Hayashi et al. 2000; Nangia-Makker et al. 2002), breast carcinoma (Glinskii et al. 2005; Nangia-Makker et al. 2002; Sathisha et al. 2007), melanoma (Platt and Raz 1992; Inohara and Raz 1994), multiple myeloma (Chauhan et al. 2005), and hemangiosarcoma (Johnson et al. 2007). MCP is speculated to affect metastasis in part by its ability to inhibit the prometastatic regulatory protein galectin-3, a β-galactoside-binding protein related to tumor cell adhesion, motility, and metastatic properties; it inhibits cell migration and metastatic spread (Inohara and Raz 1994). Citrus pectin is ineffective in controlling proliferation in cells that are deficient in the expression β-galactosidase (Bergman et al. 2010). MCP inhibits the development of metastatic deposits of human breast carcinoma cells in the lungs and prostate

carcinoma in the bones (Glinskii et al. 2005). The effect of citrus pectin on cytokine production by human peripheral blood mononuclear cells has been cited showing a dose-dependent inhibition of the pro-inflammatory cytokine IL-1β secretion and a dose-dependent increased secretion of the anti-inflammatory cytokines IL-1ra and IL-10 testifying immunomodulatory response in human PBMC (Salman et al. 2008). As further extension to these findings, the ability of MCP to induce activation of human blood lymphocyte subsets like T, B, and NK cells has been reported including the activation of functional NK cells against K562 leukemic cells (Ramachandran et al. 2011).

There are data indicating that addition of therapeutic regimens in Gal-3-expressing malignancies could increase the sensitivity of cancer cells to cytostatic and cytotoxic chemotherapeutic agents. Contextually, MCP has shown to significantly increase the sensitivity of multiple myeloma cells to dexamethasone (Chauhan et al. 2005) and hemangiosarcoma cells to doxorubicin-induced apoptosis (Johnson et al. 2007). Increased sensitivity of malignant cells to various other chemotherapeutic agents such as cisplatin, staurosporine, etoposide, and oxaliplatin enhancing response to apoptosis has also been recorded and published (Glinsky and Raz 2009).

GCS-100 is a polysaccharide derived from citrus pectin and currently undergoing evaluation in several disease conditions including chronic kidney disease, liver disease, and cancer immunotherapy. GCS-100 has shown to induce apoptosis in various multiple myeloma cell lines, including those resistant to dexamethasone, melphalan, or doxorubicin. The findings were also recapitulated in purified patient multiple myeloma cells. Specifically, GCS-100 decreased viability of bortezomib/PS-341-resistant multiple myeloma patient cells, and when combined with dexamethasone, GCS-100 induced an additive anti-multiple myeloma cytotoxicity (Chauhan et al. 2005).

Clinical investigation emerging from a phase II study report the tolerability and effect of modified citrus pectin (marketed under the commercial name "PectaSol" (Econugenics, Santa Rosa, CA)) in 13 men with prostate cancer. A statistically significant enhancement of PSA doubling time index was noted in seven out of ten patients after taking MCP for 12 months compared to the baseline before initiation of MCP therapy validating "proof of concept" theme indicative of slowing down of cancer progression with accompanying possible extension of the expected lifetime of patients (Guess et al. 2003).

5 Polysaccharides from Other Plants in Preclinical Models of Cancer Therapy

In recent years different parts of many other terrestrial plants are undergoing thorough investigation with a premise to identify promising PS components in disease curability including cancer. Accordingly, a rich collection of PS showing activity against cancer has emerged with limited clinical data. Due to limited constrain it is not possible to describe an in-depth detail of PS isolation and characterization. A preview of PS from other plant sources with anticancer effects has been summarized in Table 1 incorporating tumor cells investigated,

Table 1 Anticancer polysaccharides obtained from plants (Adapted from Zong et al. (2012))

Sources	Tumor models	Effects
Aconitum coreanum	H22 tumor cells in vitro and in vivo	Inhibited tumor growth, induced cell cycle arrest
Actinidia eriantha	S180- and H22-bearing mice	Inhibited tumor growth, improved immune responses
Anemone raddeana	H22-bearing mice	Inhibited tumor growth, improved immune responses
Asparagus officinalis	BEL-7404 and HeLa cells	Inhibited cell proliferation
Black currant	Ehrlich carcinoma in mice	Inhibited tumor growth
Brassica napus L.	S180- and B16-bearing mice	Inhibited tumor growth, improved immunofunction and leukogenic actions
Boschniakia rossica	S180-bearing mice	Inhibited tumor growth, presented synergistic effects with 5-FU
Buckwheat	THP-1 cells	Inhibited cell proliferation, induced cell differentiation and maturity
Cactus pear fruit	S180-bearing mice	Inhibited tumor growth, promoted apoptosis and immune responses
Camellia oleifera Abel.	S180-bearing mice	Inhibited tumor growth
Codonopsis pilosula	H22-bearing mice	Inhibited tumor growth, activated immune system
Curcuma kwangsiensis	CNE-2 cells	Inhibited cell proliferation, induced cell apoptosis
Dahlia tubers γ-inulin	B16BL6-, MCA205-, and FsaR-bearing mice	Enhanced effect of photodynamic therapy, reduced recurrence rates of tumor
Dendrobium nobile Lindl	HL-60 cells, S180-bearing mice	Inhibited tumor growth
Dimocarpus longan Lour.	S180-bearing mice	Inhibited tumor growth, stimulated immune system
Gastrodia elata Bl.	PANC-1 cells	Inhibited cell proliferation
Ginkgo biloba sarcotesta	U937 cells	Inhibited cell proliferation
Gynostemma pentaphyllum Makino	Hep-G2 cells and HeLa cells	Inhibited cell proliferation, induced cell cycle arrested
Hedysarum polybotrys	Hep-G2 and MGC-803 cells	Inhibited cell proliferation
Lycium barbarum	MGC-803, BIU87, SGC-7901, SW480, and Caco-2 cells	Inhibited cell proliferation, induced cell cycle arrested
Melia toosendan Sieb. Et Zucc	BGC-823 cells	Inhibited cell proliferation
Ornithogalum caudatum Ait	K562 cells, S180-bearing mice	Inhibited tumor growth
Orostachys japonicus	HT-29 cells	Inhibited cell growth, induced cell apoptosis and cell cycle arrested

(*continued*)

Table 1 (continued)

Sources	Tumor models	Effects
Passiflora edulis	S180-bearing mice	Inhibited tumor growth
Patrinia scabra Bunge	U14-bearing mice	Inhibited tumor growth, induced cell apoptosis and cell cycle arrest
Phaseolus vulgaris L.	HT-29 cells	Upregulated SIAH1, PRKCA, and MSH2 genes, downregulated CHEK1 and GADD45A genes
Prunella vulgaris L.	Lewis lung carcinoma mice model	Inhibited tumor growth, enhanced immune function
Pulsatilla chinensis	C6-bearing mice	Inhibited tumor growth, prolonged survival
Punica granatum	MCF-7 and K562 cells	Inhibited cell proliferation
Safflower	S180- and LA795-bearing mice	Inhibited tumor growth, enhanced the cytotoxicity of immunocytes
Schisandra chinensis leaf	L5178Y-bearing mice	Inhibited tumor growth, enhanced functions of immune system
Sweet potato	K562 and Hca-F cells	Inhibited tumor cells fissiparity
Taxus yunnanensis	HeLa, HT1080 cells	Inhibited cell growth
Tea leaf	H22-bearing rats	Inhibited tumor growth, decreased microvessel density in tumor, regulated immune function
Tea plant flower	S180-bearing mice	Inhibited tumor growth, prolonged the mice survival day, regulated immune function
Tea seeds	K562 cells	Inhibited cell proliferation
Thuja occidentalis	B16F-10 bearing mice	Stimulated cell-mediated immune system, decreased pro-inflammatory cytokines, inhibited metastasis of tumor
Ziziphus jujuba	Melanoma cells	Inhibited cell proliferation, induced cell apoptosis

source of PS, and their effect on tumor cells. Isolation and evaluation of anticancer PS from terrestrial and underground plant parts is becoming an active area of research.

6 Conclusion

From the above-described narrative, there appears a strong "proof of concept" in support of PS ability to augment conventional cancer therapy. However, their translational input into clinics as monotherapy is taken with skepticism in the field of Western medicine, except for their general use as immune-stimulating agents. This is because of a general lack of integration with modern biomedical advancements relating to proficiency testing. More rigorous nonrandomized clinical control trials are warranted with GMP standard single agent before PS becomes a realm in the field of cancer control strategy. Some initiative in this direction has

been initiated by the National Cancer Institute, USA. Nevertheless, the safety profile of PS, especially medicinal mushrooms, makes them attractive candidates for the development of chemopreventive agents. Unlike Basidiomycetes, PS from terrestrial herbs with potent promise need to be developed into GMP standard single agent and need to undergo rigorous evaluation for relevant comprehensive toxicity data and safety profile in preclinical and clinical models and identify potential adverse effect. Moreover, there exists severe deficiency regarding data relating to bioavailability, pharmacokinetics, and pharmacogenomics of PS. With recent developments in the availability of genetically modified murine models of diseases, it is imperative to evaluate the efficacy and safety profile of GMP standard PS in such models that closely mimic human situation recapitulating sequential stages of tumor initiation, promotion, and progression. Although some molecular targets of PS have been identified such as IL-6, IL-1β, TNFα, and others, in silico analysis and molecular modeling will further enhance the current state of knowledge and develop novel analogs with much greater potency. Together, this will strengthen our understanding towards an endeavor to convince oncologists and federal authorities in accepting this novel class of compound to complement along with modern medicine to prolong survival and improve QOL of cancer patients.

Contents

Abstract

Research with natural products is an alternative, which includes several bioproducts from bacteria, plant, animal, insect, and marine organisms. Such bioproducts include polysaccharides, proteins, dietary fibers, and many other biomolecules. Studies on fungus have attracted considerable interest for its application in the pharmaceutical and food industry. The anti-inflammatory potential of polysaccharides from the fungus *Scleroderma nitidum* Berk. and their possible action mechanism were studied. The effect of these polymers on the inflammatory process was tested using the carrageenan- and histamine-induced paw edema model and the sodium thioglycolate- and zymosan-induced models. The polysaccharides from *S. nitidum* were effective in reducing edema and cell infiltrate in both inflammation models tested. Nitric oxide, a mediator in the inflammatory process, also showed a low reduction. Analysis of pro- and anti-inflammatory cytokines showed that in the groups treated with polysaccharides from *S. nitidum,* there was an increase in cytokines such as IL-1ra, IL-10, and MIP-1β concomitant with the decrease in 17INF-γ and IL-2. The influence of polysaccharides on the modulation of the

expression of nuclear factor κB showed that this compound reduced the expression of NF-κB by up to 64 %. This suggests that NF-κB modulation also explains the anti-inflammatory effect of polysaccharides from the fungus *S. nitidum.*

1 Introduction

The growing study of microorganisms such as fungi, algae, and bacteria is due to their essential importance in the different food chains and the possibility of commercial application in different areas such as nutrition and human and animal health. Mushrooms are used in the treatment of waste water, in energy production, and in the production of compounds of interest to food, chemical, and pharmaceutical industries, among others (Kirk et al. 2001).

The cell wall of fungi provides both protective and aggressive functions. It is protective, as it acts as an initial barrier that is in contact with hostile environments encountered by the fungus (Latgé 2007; Bowman and Free 2006). For a long time the cell wall was considered as an inert exoskeleton, but this wall is now seen as a dynamic structure that is continuously changing as a result of the modification of culture conditions and environmental stresses. Edible mushrooms are widely consumed due to their flavor, nutritional value, and texture (Cheung and Lee 2000; Giavasis 2014). They are also believed to have therapeutic properties in relation to cancer, heart disease, viral infection, cholesterol levels, and hypertension, which are attributed to dietary fiber, mainly chitin, the polysaccharide making up the cell walls (Wasser and Weiss 1999; Ofodile et al. 2005a). Mushrooms also contain considerable amounts of proteins. Amino acids occurring in the greatest quantities are alanine, asparagine, glycine, and glutamine (Akindahunsi and Oyetayo 2006; Manzi et al. 1999). Furthermore, the fungi are rich in polysaccharides.

The composition of nutrients in fungi differs from fungi to fungi. Breene (1990) analyzed the percentage composition of the fungus *Lentinus edodes* and observed that it is composed of 24.6 % proteins and 44 % carbohydrates. The fungi *Caripia montagnei* was found to be composed mainly of carbohydrates (63.3 %) and lipids (21.4 %). The lipid content in this fungus was considerably higher than that reported by Demiate and Shibata 2003, who found 0.89 % of lipids in the fungus *Agaricus blazei*. The chemical analyses carried out in this study show that the aqueous extract of *Caripia montagnei* is composed mainly of polysaccharides (98.7 %) and low protein content (1.3 %), in addition to being composed basically of glucose units (Queiroz et al. 2010). This result differs from those of other studies conducted in our laboratory. Dore et al. 2007 analyzed the fungus G*eastrum saccatum* and observed that it is composed of a large amount of carbohydrates (84 %) containing glucose and traces of galactose. The presence of protein in the extract may imply glucan-protein complexes (Wang et al. 1996; Gonzaga et al. 2009), which could be fundamental for

Table 1 Chemical components of the fruiting body of *Scleroderma nitidum* "in nature"

Fungi	Carbohydrates (%)	Proteins (%)	Lipids (%)	Moisture (%)	Fibers (%)
S. nitidum	35.31	3.59	1.86	33. 69	25.61

the action of glucans (Dore et al. 2007). The chemical composition is variable with the extraction, fungi species, and maturity of species. The chemical analyses conducted after obtaining polysaccharides from the extract of fungus *S. nitidum* fractionated with ethanol showed high carbohydrate content (94.71 %), low protein content (5.29 %), and no sulfate (Nascimento et al. 2012). The acid hydrolysis of polysaccharides by 2 M HCl showed the presence of glucose, galactose, mannose, and xylose, which were detected by HPLC analysis and found to be present in a molar ratio of 1: 0.4: 0.6: 0.2, respectively (Table 1).

The polysaccharides are natural biomolecules found in all living organisms and are a group of the most abundant and important compounds in the biosphere (Glazer and Nikaido 1995). These polymers are composed of monosaccharide units joined by glycosidic linkages that differ from each other in unity and degree of branching, the type of connections between them, and the length of their chains, with different compositions and functions, being classified as homopolymers or heteropolymers (Pazur 1994). These glucose polymers are widely distributed in nature and classified according to the type of glycosidic linkage [α,β] of the main chain. The β glucans are the predominant form found in fungi. In the cell walls of fungi, these polymers are normally linked to proteins, lipids, and other carbohydrates such as mannan (Williams 1997).

Fungal polysaccharides, belonging to the extracellular cell wall, have been investigated for a variety of biological defense responses, such as antitumor, anti-inflammatory, and immunomodulatory activities (Wasser 2002; Kiho et al. 1993). The exopolysaccharides are defined as extracellular polysaccharides produced by bacteria and some fungi (Kang et al. 1979). In yeast, exopolysaccharides constitute a major proportion of the biomass, accounting for over 75 % of the constituent polysaccharides of the hyphal wall. About these polysaccharides, the glucans are the most abundant in the cell walls of fungi which helps to maintain the optimum pH for ligninolytic enzymes, besides preventing dehydration hyphae and regulating the concentration of extracellular glucose (Gutiérrez et al. 1996).

Polysaccharides derived from mushrooms have been considered an important class of bioactive compounds, and their anti-inflammatory potential has been widely studied (Dore et al. 2007; Carbonero et al. 2008; Smiderle et al. 2008; Seviour et al. 1992). Glucans are widely distributed in nature and could be α, β, or totally β. The β-glucans are the predominant form found in fungi. In cell walls of fungi, these polymers are normally linked to proteins, lipids, and other carbohydrates such as mannans (Williams 1997). Regarding these polysaccharides, the glucans are the most abundant in the cell walls of fungi (Fig. 1), helping to maintain the optimum pH for ligninolytic enzymes, in addition to preventing dehydration hyphae and regulating the concentration of extracellular glucose (Gutiérrez et al. 1996).

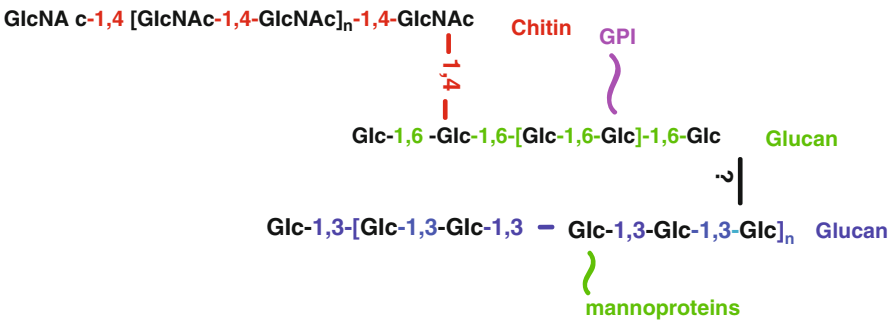

Fig. 1 Schematic representation of cell wall components and their linkages. GPI cell wall proteins, linkages in colors (Adapted from Guillaume and Bussey (2014))

β-glucans have both beneficial and deleterious effects. Zymosan is a crude glucan from yeast (*Saccharomyces cerevisiae*) and is used in the research on the acute inflammatory response. Several studies have demonstrated that zymosan induced arthritis, inflammation, and septic shock in rats (Chittaragi et al. 1998; Paiva et al. 2011). There are several glucans with variable structure. However, this glucan shows various biological activities related to inflammatory responses.

Several glucans are highly branched with linkages 1,3/1,6 being at the cell surface. However, form 1,3-linear of glucans is linked to chitin (Fig. 2). This contains a -1,4-acetyl-glucosamine homopolymer. However, their microfibrils are homopolymer similar to cellulose (β-1,4 glucose), enforcing the strength of the cell walls (Wessels 1990; Carbonero et al. 2008). Chitins are responsible for maintaining the shape, strength, and integrity of the cell structure. The production of chitosan from fungal mycelia has many advantages over crustacean chitosan such as the degree of acetylation, molecular weight, viscosity, and charge distribution of the fungal chitosan (Vetter 2007; Guo et al. 2007a, b). Chitosan from fungal mycelia has also been shown to be more stable than crustacean chitosan. Some investigators reported that chitin and chitosan induce analgesia (Okamoto et al. 2002).

Lentinan, a β-(1→)-glucan produced by *Lentinus edodes*, increases the body's resistance against infection by parasites and its sulfated form has been shown to exhibit potent anti-HIV action (Battle et al. 1998). The botryosphaeran exopolysaccharides produced by the ascomycete fungus *Botryosphaeria rhodina* is considered useful in immunotherapies (Barbosa et al. 2003). Among other examples of biologically active polysaccharides, the D-type β-glucan (1→3) and β-(1→3, 1→6) proved to be potent compounds, as well as being effective against syngeneic, allogeneic, and autologous tumors. Lentinan and schizophyllan, two fungal glucans β-(1→3, 1→6), have become clinically relevant as immunoadjuvants in cancer therapy in Japan. These glucans, non-cytotoxic, supposedly express their antitumor effect by stimulation of the immune host. It is believed that the action occurs mainly by T cell activation helper cells, such as natural killer and cytotoxic macrophages, as well as by an increase in cytotoxic T cells (Gomaa et al. 1992; Zhang and Cheung et al. 2002; Chen and Seviour 2007). Glucans β-(1→3) modulate the immune

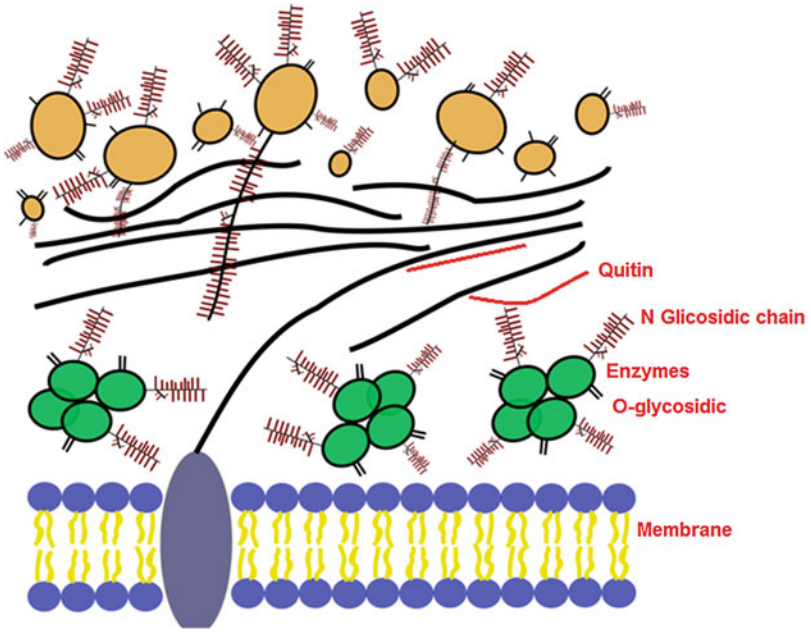

Fig. 2 Cell walls of fungi (Adapted from Seviour et al. (1992))

system by activating macrophages through binding of the polymer to the specific receptors of these cells (Williams 1997; Young et al. 2001). Subsequently was observed that insoluble glucan extracted from the inner cell wall of the fungus *Saccharomyces cerevisiae,* when administered intraperitoneally in mice in an abdominal sepsis model, improved survival by inducing protection against the formation of bacterial colonies in the peritoneal liquid with an increase in leukocyte migration (Freitas et al. 2006; Lesage and Bussey 2006).

In vivo studies have suggested that β-glucans of different molecular weights can directly activate leukocytes and stimulate phagocytic, cytotoxic, and antimicrobial activities, including the production of reactive oxygen and nitrogen intermediates. These carbohydrates can also stimulate the production of proinflammatory mediators and cytokines such as IL-8, IL-1 β, IL- 6, and TNF-α (Rice et al. 2004; William et al. 1997).

2 Occurrence/Sources of Mushroom

The world's largest mushroom producers are the United States, France, Germany, Netherlands, China, and Japan and the main consumers may be seconded to Germany, Netherlands, Japan, and China (Moda et al. 2005). The fungi have a biodiversity found in Brazil that accounts for 15–20 % of the total biodiversity worldwide and is considered a source of biologically active compounds with

Fig. 3 *Scleroderma* genus Pers: Fr (Gasteromycetes, Sclerodermatales)

enormous potential as a source of new drugs (Barreiro and Fraga 1999). In contrast, consumption of mushrooms in Brazil is small compared to that of European and Asian peoples and is restricted to certain ethnic groups or larger cultural and economic statuses (Dias et al. 2004).

Mushrooms have been well studied because of their potential biotechnological importance. A number of mushroom-based compounds with pharmacological potential can be mentioned, such as triterpenes, lectins (Koyama et al. 2002), and polysaccharides (Carbonerro et al. 2008). Among the various polysaccharides isolated from Basidiomycetes are glucans, heterogalactans, and heteromanans (Schepetkin and Quinn 2006).

Scleroderma genus Pers.:Fr. (Gasteromycetes, Sclerodermatales), *Scleroderma nitidum,,* or *Veligaster nitidus* (Berk),name proposed by Guzman and Tapia, contains 25 ectomycorrhizal species (Fig. 3). *Scleroderma nitidum* was collected in Mata da Estrela, Rio Grande do Norte, Brazil. Guzmán and Ovrebo 2000 have included species commonly known as "earth balls," distributed worldwide (Kirk et al. 2001). At least 5,000 species of fungi are involved in ectomycorrhizal associations, usually with a high degree of specificity (Raven et al. 2001). The ectomycorrhizae are mostly formed by basidiomycetes, including many kinds of mushrooms. Although this genus, *Scleroderma,* contains poisonous species, the species have been investigated for their anti-inflammatory and hemostatic properties (Guzmán and Ovrebo 2000; Liu 1984; Nascimento et al. 2012).

Scleroderma nitidum (Fig. 1) has basidiomata yellowish brown subglobose, 1.5–3 cm diameter. Peridium, 4–5 mm thick when fresh, verrucous surface, dark brown, evenly spread over the surface is irregular dehiscence; hyphae hyaline, 10–18 × 6–12 μm. Gleba powdery, olive gray. Dark brown basidiospores, globose, equinulados, 11–12 mM diameter.

3 Biotechnological Approaches

Mushroom is highly nutritious containing all the classes of food. Using biotechnological approaches, they can not only be domesticated but also cultivated in large quantity and be available all season.

Several in vitro and in vivo mechanisms are related to the anti-inflammatory activity of polysaccharides and extracts rich in fungal polysaccharides. Among these mechanisms are cyclooxygenase inhibition (Hong et al. 2004), inhibition or decrease in cytokine levels (Kim et al. 2003), and inhibition of inflammatory cell recruitment (Dore et al. 2007). Clinical evidence of the antitumoral effect of mushroom was verified in commercial polysaccharides such as lentinan, krestin, and schizophyllan, but some other polysaccharides also showed good activities (Mizuno 1999; Zaidman et al. 2005). Their activity was also good when associated with chemotherapy. Research has demonstrated that mushrooms do not affect tumoral cells, as their action is to stimulate cells of immune response Akramiene et al. (2007).

Mushrooms are rich in vitamins, amino acids, and minerals, besides being significantly involved in human detoxification processes that have also an important role to play in reducing blood cholesterol (Oyetavo and Oyetavo 2009; Jeong et al. 2010). Edible mushrooms are of low calorie with very low fat and are highly nutritive as good quality proteins (Naumann et al. 2006; Oyetayo et al. 2007). Therefore, they are the delight of the diabetics (Kiho et al. 1993; Gray and Flatt 1998; Zhang et al. 2006; Lo et al. 2006).

Several mushrooms have antibacterial properties (Sutherland 1998). The antibacterial activity test of the *Caripia montagnei* extract showed that it did not have an effect on gram-positive or gram-negative bacteria at the three concentrations tested (Queiroz et al. 2010). Although the genus *Scleroderma* includes poisonous fungi, they have been studied for their anti-inflammatory and homeostatic properties (Guzman 1970). This result differs from that found by Smania et al. 2007, who studied the Brazilian fungus *Ganoderma australe* and observed the presence of activity against fungi, as well as against gram-positive and gram-negative bacteria. Research conducted with extracts of four species of *Ganoderma* (*Ganoderma colossum, G. resinaceum, G. lucidum,* and *G. boninense*) of Nigeria has demonstrated that these have microbicides activities and were active against *Pseudomonas syringae* and *Bacillus subtilis* (Ofodile et al. 2005b).

4 Phytochemical Screening

The phytochemical screening of the mushroom extract revealed the presence of alkaloids, saponins, steroids, phlobatannins, flavonoids, and anthraquinones. Extract of Scleroderma with different solvents was subjected to phytochemical analysis for secondary metabolites. In mushroom extracts, these metabolites were found to contain steroids, saponins, glycosides, fibers, and phenols (Cheung and Lee 2000). The qualitative phytochemical screening of *Scleroderma bermudense* has revealed the presence of various secondary metabolites of therapeutic importance, namely, steroids, saponins, phenols, glycosides, and flavonoids, but the absence of alkaloids, tannins, and terpenoids (Chittaragi et al. 2013).

Aqueous extraction is one of the most widely used techniques in scientific studies (Barbisan et al. 2002; Bellini et al. 2006; Giacomini and Eira 2003; Lavi et al. 2006). Its efficiency in obtaining polysaccharides and the low cost may be the main reasons for its wide use. Most complex carbohydrates are technically water insoluble but do form gels to varying degrees when mixed with water. *Scleroderma nitidum* showed polysaccharides partially soluble in water.

The chemical analyses conducted after obtaining polysaccharides from the fungus *S. nitidum* revealed very high carbohydrate content, low protein content, and no sulfate. The polysaccharide of this mushroom was submitted to acid hydrolysis by HCL and showed the presence of glucose, galactose, mannose, and xylose, which were detected by HPLC analysis and found to be present in a molar ratio of 1:0.4:0.6 :0.2, respectively. This polysaccharide is heterogenous like other polysaccharides of mushroom. Also found in *Ganoderma applanatum* mushroom is the monomer composition of polysaccharides containing glucose, galactose, mannose, and arabinose (Lee et al. 2007).

Many biological functions have been attributed to polysaccharides from fungi and much has been investigated with respect to their pharmacological potential (Novak and Vetvicka 2008). Many have Reid et al. (2009) been reported in the literature as having therapeutic properties, for example, members of the genus *Cordyceps*, which have antitumor, anti-metastatic, immunomodulatory, antioxidant, anti-inflammatory, microbicide, hypoglycemic, and hypolipidemic activities (Naumann et al. 2006; Zhang et al. 2006).

In addition, three cell receptor β-glucans have been identified: CR3, dectin-1, and lactosylceramide (Zimmerman et al. 1998; Ross et al. 1999; Brown and Gordon 2001, 2003). The CR3 are responsible for various cellular receptor activities in vitro and in vivo, stimulating the secretion of cytokines (TNF-α, IFN-α, IFN-γ, and IL-6) in NK cells, especially in the presence of pathogens (Ross et al. 1999). Dectin-1 is a receptor on cells of the monocytes and macrophages, has an exogenous ligand for binding polysaccharides and other co-stimulatory signals for T cell activation. Studies have shown that these cellular receptors and the lactosylceramide recognize β-glucans, particularly with the structure of type β-(1→3) and β-(1→6), and lymphocytes (Zimmerman et al. 1998; Brown and Gordon 2003; Stier et al. 2014).

The phytochemical screening of the mushroom extract revealed the presence of alkaloids, saponins, steroids, phlobatannins, flavonoids, and anthraquinones

(Adebayo et al. 2012). Extract of Scleroderma with solvents different was subjected to phytochemical analysis for secondary metabolites. In mushroom extracts this metabolites were found to contain steroids, saponins, glycosides, flavonoids, and phenols. The qualitative phytochemical screening of *Scleroderma bermudense* has revealed the presence of various secondary metabolites of therapeutic importance, namely, steroids, saponins, phenols, glycosides, and flavonoids, whereas absence of alkaloids, tannins, and terpenoids (Chittaragi et al. 2013).

Aqueous extraction is one of the most widely used techniques in scientific studies (Barbisan et al. 2002; Bellini et al. 2006; Giacomini and Eira 2003; Lavi et al. 2006). Its efficiency in obtaining polysaccharides and the low cost may be the main reasons for its wide use. Most complex carbohydrates are technically water insoluble; they do form gels to varying degrees when mixed with water. *Scleroderma nitidum* showed polysaccharides partially soluble in water.

Many activities have been reported in the literature as having therapeutic properties, for example, the genus *Cordyceps* which have antitumor effects, antimetastatic, immunomodulatory, antioxidants (Fu and Shieh 2002), anti-inflammatories, microbicide, hypoglycemic, and hypolipidemic (Kim et al. 2005; Badole et al. 2006; De et al. 2012).

The chemical analyses conducted after obtaining polysaccharides from the fungus *S. nitidum* showed very high carbohydrate content, low protein content, and no sulfate content. The polysaccharide of this mushroom submitted the acid hydrolysis by HCL and showed the presence of glucose, galactose, mannose, and xylose that were detected by HPLC analysis and found to be present in a molar ratio of 1:0.4:0.6:0.2, respectively. This polysaccharide is heterogenous as other polysaccharides of mushroom. *Ganoderma applanatum*, is a mushroom whose composition of polysaccharides contain sugars as glucose, galactose, mannose, and arabinose (Lee et al. 2007).

Many biological functions have been attributed to polysaccharide from fungi and much has been investigated with respect to their pharmacological potential (Lindequist et al. 2005). Three cells receptors β-glucans were proposed and were identified: CR3, dectin-1, and lactosylceramide (Zimmerman et al. 1998; Ross et al. 1999; Brown and Gordon 2003). The CR3 are responsible for various cellular receptor activities in vitro and in vivo, stimulating the secretion of cytokines (TNF-α, IFN- α, IFN- γ, and IL-6) in NK cells, especially in the presence of pathogens (Ross et al. 1999). Dectin-1 is a receptor on dectin-1 type on cells of the monocytes and macrophages has an exogenous ligand for binding polysaccharides and other co-stimulatory signals for T cell (Brown 2006). Fungal β-1,3-glucans can be recognized by a number of receptors apart from Dectin-1, such as CR3, lactosylceramide, and scavenger receptors. Studies have shown that these cellular receptors and the lactosylceramide and also lymphocytes recognize β-glucans, particularly with the structure types β-(1→) and β-(1→6) Dectin-1 and complement receptor 3 (CR3) pathways leading to NF-κB activation and cytokine production (Zimmerman et al. 1998; Brown and Gordon 2003). There are evidence that the antitumural and immunomodulatory effects of glucans fungal and in particulate β-glucans, despite their large size occurr pathway these receptors (Barbayar et al. 2012; Volman and Ramakers 2008).

The study of natural products derived of mushrooms and other bioactive compound of plants offers many perspectives for the development of new effective and safe immunomodulation agents. Polysaccharides derived from mushrooms have been considered an important class of bioactive compounds, and their anti-inflammatory potential has been widely studied (Dore et al. 2007; Carbonero et al. 2008; Smiderle et al. 2008).

5 *S. nitidum* and Their Effect on Inflammation

Inflammation is a complex event that consists of recognizing the lesion stimulus and the consequent attempt at restoring the damaged tissue (Nathan 2002; Medzhitov 2010). This involves a series of cellular and vascular events (Nussler and Billiar 1993; Rocha and Silva 1978). In inflammatory reactions, nitric oxide derived from cells stimulated by the action of cytokines promotes changes in the vascular permeability of the inflamed tissue (Barnes and Karin 1997; Winter et al. 1962). Adverse conditions, adverse conditions induce inflammation triggering the recruitment of leukocytes and plasma proteins to the affected tissue site (Medzhitov 2008). Macrophages and monocytes are proinflammatory cells that respond to invading pathogens by releasing proinflammatory mediators, as tumor necrosis factor-α (TNF-α), interleukin-6 (IL-6), interleukin-12 (IL-12), cyclooxygenase-2 (COX-2), and nitric oxide (NO) (Lawrence et al. 2002).

Acute inflammation is essentially mediated by exudate formation and leukocyte migration. Innumerable studies have proven the potential of polysaccharides extracted from fungi in reducing leukocyte migration to the inflammation sites. To confirm the anti-inflammatory potential of fungal polysaccharides, the aim of this study, we tested their effect in models of plantar edema induced by carrageenan and histamine and of peritonitis induced by sodium thioglycolate and zymosan (Cui et al.; Nascimento et al. 2012).

The inflammatory process of the extract of *S. nitidum*, rich in polysaccharides, was assessed in *Wistar* rats. Polysaccharides of this mushroom reduced carrageenan-induced paw edema at the inflammatory peak (second hour) with major reduction at the end of the fourth hour. In the histamine-induced paw edema, all the doses of polysaccharides (10–50 mg/kg) were efficient in reducing the edema. The greatest reduction observed occurred in the second hour, where the effect exceeded that obtained with L-NAME. At the end of the fourth hour, all the groups treated with the different doses of polysaccharides did not exhibit edema (Nascimento et al. 2012).

We observed that histological examinations demonstrated that the animals sensitized only with histamine, a positive control, exhibited intense cell infiltrate, characteristic of the inflammatory reaction. However, those that received only saline solution (negative control) showed an absence of inflammatory reaction. It was also observed that the animals treated with polysaccharides from the fungus *S. nitidum* (10, 30, and 50 mg/kg) showed a significant decrease in PMN cell recruitment at the inflammation site.

To check if the polysaccharides were capable of potentiating drug action, two drugs were used for this assay: L-NAME and diclofenac. Diclofenac is a COX 1 and 2 inhibitor, whereas L-NAME is a competitive inhibitor of arginine that promotes a decrease in the enzymatic activity of the iNOS (Bogle et al. 1992). Polysaccharides of *S. nitidum*, when tested at low doses and applied jointly with diclofenac, exceeded the action of this drug by around 10 %. However, the polysaccharides showed no significant differences when L-NAME was applied. The data demonstrate that these fungal polysaccharides may act synergically with other inflammatory drugs, potentiating their effect.

Nitric oxide (NO) is important in the physiological and biochemistry aspects including cell to cell communication in the nervous system and brain (Davies et al. 1995), as well as functioning in the immune system (Ignarro 2009). Its synthesis occurs by actions of enzyme called nitric oxide synthase (NOS). Three distinct isoforms of NOS are known to exist; two were originally described as constitutive and one inducible (Moncada et al. 1997; Nussler and Billiar 1993). Expression of enzymes (iNOS) is regulated, positively and negatively, by mediators present during infection and inflammation. The iNOS enzymes induction occur by lipopolysaccharide (LPS), interferon-y, interleukin (IL)-10, and tumor necrosis factor (TNF)-α. The expression of these enzymes may be increased by combinations of TNFα and interferon-γ, via the transcription factor NF-κB (Sato et al. 2003).

Nitric oxide in most body fluids is rapidly metabolized to stable products such as nitrite and nitrate. According to the results obtained in the sodium thioglycolate-induced model, the polysaccharides from the fungus *Scleroderma nitidum* showed a reduction of around 32.4 % in NO_2/NO_3 content. However, in the zymosan-induced peritonitis model, no significant reduction in NO_2/NO_3 levels was observed.

Polysaccharides of *S. nitidium*, rich in glucose, had no toxic effect at the doses tested. Such glucans showed an effect on cytokine expression. We observed a twofold and threefold increase in the release of anti-inflammatory cytokines IL-1ra and IL-10, respectively, in the groups treated with polysaccharides when compared with the positive control. A significant decrease (75 %) was also observed in IFN-γ levels as well as a slight reduction in IL-2 and MIP-1β levels of 22 % and 29 %, respectively, in the groups treated with the different polysaccharide doses. In addition, the effect of polysaccharides was not dose dependent.

The nuclear factor κB (NF-κB), an important transcription factor in the progression of inflammation, is related to gene activation in many of the mediators involved in the inflammatory response, such as TNF-α, IL-1β, and iNOS (Barnes and Karin 1997; Ben-Neriah and Schmidt-Supprian 2007). NF-κB exists in the cytoplasm in an inactive form associated with regulatory proteins (κB). NF-κB is clearly one of the most important regulators of proinflammatory gene expression (Fig. 4). This nuclear factor kappa B plays a principal role in the induction of eosinophilia in allergic airway inflammation, gastritis, arthritis, and other inflammatory diseases.

Nuclear factor kB activation is a critical event in inflammation. NF-kB activation is related to gene activation for many cytokines, chemokines, and adhesion molecules. This experiment was conducted to determine whether the polysaccharides from the fungus *Scleroderma nitidum* are capable of modulating

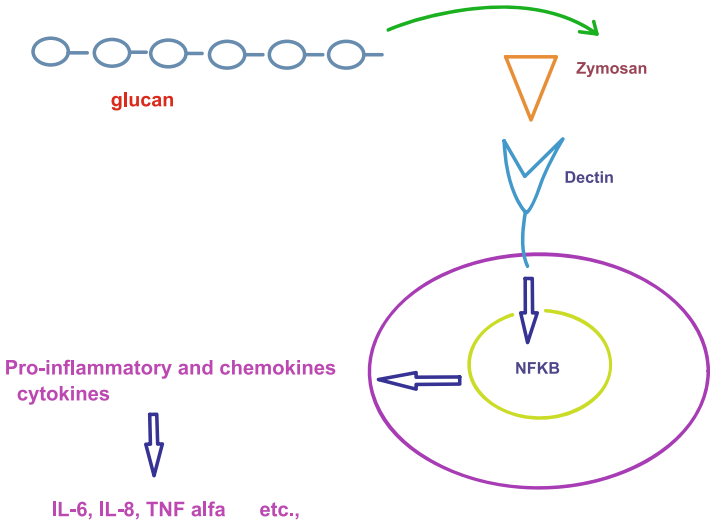

Fig. 4 Effect of zymosan in cell

NF-κB expression. According to the results obtained, the dose that had the best effect was 30 mg/kg, reducing NF-κB expression by 63 ± 8 %, whereas doses of 50 and 100 mg/kg reduced it by only 30 ± 1 %. Thus, it can be observed that all the fungal polysaccharide doses tested significantly reduced nuclear factor NF-kB expression (Fig. 4c).

During the inflammatory process, monocytes are recruited for parenchyma tissue, where they are activated to become cells with a phagocytic function, that is, macrophages. These cells can release inflammatory cytokines, free radicals, and nitric oxide, which can mediate the tissue lesion related to inflammatory response (Almeida et al. 1980; Gordon 2001; Hermann et al. 2001; Fu and Shieh 2002). Studies on mushrooms with medicinal potential have been conducted to discover compounds that can positively or negatively modulate the immunological system. The significant reduction of edema observed in the rats treated with polysaccharides from the fungus *Scleroderma nitidum* can be observed in two plantar edema models, suggesting their anti-inflammatory effect (Nascimento et al. 2012)

Macrophage activation via the classic pathway leads to the secretion of nitric oxide and proinflammatory cytokines, whereas activation via the alternative pathway leads to the release of anti-inflammatory cytokines (Gordon 2003). The polysaccharides from the fungus (glucans) *Scleroderma nitidum* did reduce INF-γ levels in the peritoneal wash of the mice. Furthermore, we observed a reduction in the levels of IL-2, a cytokine that stimulates T cell proliferation (Malek and Bayer 2004). The macrophage inflammatory protein 1 beta (MIP-1β) is a chemokine that induces chemotaxis and T cell adhesion (Tanaka et al. 1993). The MIP-1β levels were found to be reduced after treatment with polysaccharides from *Scleroderma nitidum*. IL-1ra can inhibit the proinflammatory effects of IL-1 (Dinarello 1992, 1994). Polysaccharides from the fungus *Scleroderma nitidum* caused a threefold

increase in IL-1ra levels in the peritoneal wash of mice with zymosan-induced peritonitis. In the present study a substantial increase in IL-10 levels was also found.

The increase in anti-inflammatory cytokine levels concomitant with the decrease in proinflammatory cytokine release is a plausible explanation for the anti-inflammatory activity of polysaccharides extracted from the fungus *Scleroderma nitidum.* Given that polysaccharides from the fungus *Scleroderma nitidum* were capable of decreasing nitric oxide levels and modulating cytokine expression, we decided to assess a possible action mechanism to explain their biological effects. Thus, an assay was conducted to determine the expression of transcription factor NF-kB. In the groups treated with polysaccharides from the fungus *Scleroderma nitidum,* a significant reduction in NF-κB expression was observed, showing that the polysaccharides could modulate nitric oxide and cytokine levels through the regulation of NF-κB expression. This fact may explain the anti-inflammatory effect of these polysaccharides.

6 Conclusion

The macrophage inflammatory protein 1 beta (MIP-1β) is a chemokine that induces chemotaxis and adhesion of T cells. Levels of MIP-1β were found to be reduced after treatment with polysaccharides of *Scleroderma nitidum*. The increased levels of inflammatory cytokines concomitant with decreased release of proinflammatory cytokines suggest an explanation for the anti-inflammatory activity of polysaccharides extracted from fungus *Scleroderma nitidum*. As the polysaccharides of the fungus *Scleroderma nitidum* were able to decrease the levels of nitric oxide and modulate cytokine expression, we decided to evaluate a possible mechanism of action to explain their biological effects. Thus, a test was performed to verify the expression of the transcriptional factor κB (NF-kB). In the groups treated with the polysaccharides of the fungus *Scleroderma nitidum,* a significant reduction of the expression of NF-kB was observed, indicating that the polysaccharides could act by modulating the levels of nitric oxide and cytokines by regulating the expression of NF-kB. This fact could explain the anti-inflammatory effect of these polysaccharides. Knowing the importance of evaluating the cytotoxicitys of a compound.
