No part of it may be reproduced, stored in a retrieval system, or transmitted in any form or by any means, electronic, mechanical, photocopying, recording, or otherwise, without the prior written permission of the publisher.

Chapter 21, "The Older Adult" by Jeffrey Englander, David X. Cifu, and Trinh Tran, is an updated version of the chapter that originally appeared in the book, *Rehabilitation of the Adult and Child with Traumatic Brain Injury, Third Edition*, edited by M. Rosenthal, E.R. Griffith, J.S. Kreutzer, and B. Pentland, published by F.A. Davis in 1999.

Medicine is an ever-changing science undergoing continual development. Research and clinical experience are continually expanding our knowledge, in particular our knowledge of proper treatment and drug therapy. The authors, editors, and publisher have made every effort to ensure that all information in this book is in accordance with the state of knowledge at the time of production of the book.

Nevertheless, this does not imply or express any guarantee or responsibility on the part of the authors, editors, or publisher with respect to any dosage instructions and forms of application stated in the book. Every reader should examine carefully the package inserts accompanying each drug and check—if necessary, in consultation with a physician or specialist—whether the dosage schedules mentioned therein or the contraindications stated by the manufacturer differ from the statements made in this book. Such examination is particularly important with drugs that are either rarely used or have been newly released on the market. Every dosage schedule or every form of application used is entirely at the reader's own risk and responsibility. The editors and publisher welcome any reader to report to the publisher any discrepancies or inaccuracies noticed.

# Acknowledgments

The three of us wish to thank all the contributors who agreed to take time to author chapters and share their expertise with the readers of this textbook. We hope that readers will be pleased with the quality and diversity of the various medical, rehabilitative, and other specialists who enabled this book to come to fruition. We believe the scope and multidisciplinary nature of this textbook add important dimensions to its overall value as a primary resource to you, the practitioner.

We would also like to thank the individuals at Demos Medical Publishing for their patience with this project. A special thanks to Dr. Diana Schneider for her leadership as well as her willingness to compromise. Additionally, we thank Craig Percy and Edith Barry who were essential along with other Demos staff in seeing this text come to completion.

Lastly, we would like to dedicate this book to all individuals with brain injuries, their families, and the professionals who are committed to serve and assist them in such a way as to optimize their potential to work, play, and love once again.

NZ, DK, RZ

As chief editor of this textbook, I would like to thank my co-editors, Dr. Douglas Katz of HealthSouth Brain-tree Rehabilitation Hospital and Boston University, Department of Neurology, and Dr. Ross Zafonte of University of Pittsburgh, Department of Physical Medicine and Rehabilitation, for their knowledge, patience, and expertise in assisting with the editing (and writing)

of this rather enormous undertaking. I know that each gentleman entered into the project never anticipating the tremendous amount of work and time that would ultimately be required. That said, I would like to thank each of you for your commitment to the project and your willingness to see it through.

I would like to personally thank a number of individuals who have served as professional role models in my career. One such individual is Dr. Henry H. Stonnington under whom I initially trained. He needs to be mentioned as a major guiding force for my decision to enter into the field of brain injury medicine and rehabilitation. I am deeply grateful to Dr. Stonnington for sharing his vision regarding brain injury care. I am also grateful for Dr. Stonnington's major contributions to the field, including founding the International Association for the Study of Traumatic Brain Injury which eventually merged with the International Brain Injury Association of which I currently serve as Chairperson. He was also the founder of the first major journal in the field of brain injury rehabilitation, *Brain Injury* (Taylor & Francis, London). I would also be remiss to not include Dr. Sheldon Berrol and Dr. Catherine Bontke, both now deceased, and Dr. Lawrence Horn as significant professional role models in molding my career goals and practice philosophy.

On a more personal note I would like to thank my beautiful and understanding wife, Lisa Nava Marcelle Zasler, for her love, vitality, and family values, and in particular her patience with regard to my level of professional commitment to my work. Without her as a

stabilizing and energizing force in my life, I would certainly not have the ability to sustain such a level of professional motivation. I must also recognize my three beautiful children— Maia, Anya, and Aaron, who light up every single day of my life and make the world a much brighter place to live in. It is with great hope that by the time these children are adults, we will be much further along in assuring that individuals with brain injury and their families do not incur the type of sorrow, grief, lack of knowledge and/or resources, as well as long-term adverse consequences that so many of our patients today must often and unfortunately experience. I also hope that my brother Jonathan would be proud of my accomplishments, both personally and professionally. Most importantly, I want to thank my parents, Moshe and Joyce Zasler, who have always encouraged me to pursue my dreams and stood by me through “thick and thin.” Thanks for being the best.

NZ

I also thank my co-editors, especially Dr. Nathan Zasler for setting high standards and keeping us moving forward and on target during this ambitious project. I would also like to acknowledge all those who have taught, influenced, supported, inspired, and collaborated with me throughout my career, especially my teachers, neurorehabilitation fellows, colleagues and fellow staff at Braintree Rehabilitation Hospital and Boston University. In particular, I would like to mention: Michael P. Alexander, MD, my

mentor and colleague, who continues to serve as a teacher and role model for me; Virginia Mills, MS, PT, who, as a colleague, friend, and leader, has inspired me and taught me much about brain injury rehabilitation and how to do it right; T. Joy DePiero, MD, my neurorehabilitation partner at Braintree Rehabilitation Hospital, who has been an exceptional colleague, source of knowledge, and support over the last 20 years; my patients and their families who have taught me and inspired me so much over the years; and most importantly, my wonderful family: my wife Kim, my children Rachel and Daniel, and my parents Carol (1924–2004) and Warner, who have been a never-ending source of love and support during my time-consuming professional career.

DK

I would like to express my gratitude to my late parents, Albert and Grace. They instilled in me a desire to continually improve and to always maintain a sense of curiosity. My sincere appreciation goes toward my mentors, too numerous to mention, because they have helped shape my views and focus my enthusiasm throughout the years. To my wife, Cheryl, and son, Alexander, who have given their time to this and many other projects. I am struck by their patience and caring. Most of all, for this project I would like to acknowledge the people with brain injury whom I have had the opportunity to serve. We have grown and learned together, and we will continue to do so.

# Preface

*Brain Injury Medicine: Principles and Practice* is designed as a comprehensive text for all clinicians dealing with the assessment, management, and rehabilitation of patients with traumatic brain injury (TBI) from “coma to community.” This book examines numerous aspects of brain injury with perspectives from an internationally respected group of authors, who include both “in the trenches” practitioners as well as researchers. We hope that this text will serve as a “go-to reference” for clinical practitioners to use in day-to-day practice, students and trainees learning about TBI, and other professionals who need to learn more about TBI and its management.

The text opens with a description of the clinical continuum of care and the natural history of TBI, followed by perspectives on rehabilitative care in the United States and other countries, with discussions on training and research. Public health issues are discussed with chapters on epidemiology and prevention. The effects of trauma and recovery on the brain are described in chapters on pathophysiology, brain plasticity, and treatments that may influence neural recovery. Readers will learn up-to-date information on technologies to assess TBI, including structural and functional neuroimaging

and electrophysiologic techniques. A series of chapters covers prognosis and outcome, including life-expectancy.

The bulk of the text deals with clinical care of patients with TBI—across the continuum of care, at different levels of severity, and among different age groups. There are discussions of the full gamut of medical assessment and management of neurologic, medical, physical, cognitive, and behavioral problems resulting from TBI. Given the biopsychosocial nature of TBI and its consequences, there are also chapters on the psychological, neuropsychological, psychosocial, ethical, and medicolegal aspects of this condition.

Ultimately, the 66 chapters in this comprehensive text will provide readers with a full complement of medical and interdisciplinary rehabilitation perspectives on the assessment and management of persons with mild to severe TBI. It is hoped that this text brings together knowledge, experience, and evidence-based medicine in a manner that will promote further cross-disciplinary practice and research in the field of TBI. Most of all, we hope that this book will result in individuals with TBI receiving timely and accurate assessments and appropriate management to optimize their outcomes as well as the quality of their lives and those who care for them.

# Foreword

We are what our brains allow us to be. A traumatic brain injury (TBI) changes a person as an individual and has an impact on the ability to interact with his or her environment. The neurorehabilitation of persons who have had a traumatic brain injury requires an extraordinarily diverse knowledge base and expertise in order to optimize both neurological and functional outcome and minimize medical, as well as psychosocial, morbidity. In an ideal scenario, the neurorehabilitationist facilitates maximal community independence, patient self-reliance, and community re-integration relative to work, leisure, and social interactions while maintaining psychoemotional health.

TBI may cause changes that affect cognition, behavior, language, somatic function, and neuromedical status. Such an injury can have a negative impact on the complex biopsychosocial relationships that we all have in our environment. Brain injury, in and of itself, can create additional and unexpected problems depending upon the age of the individual at the time of injury. Sometimes, these problems may not be readily apparent early after an injury, but may instead develop later, as the child “grows into” brain injury problems. The neurorehabilitation process should ideally start in the intensive care unit and continue through optimal community reintegration and medical stabilization. For some patients, this stage never comes, and chronic care is therefore necessary.

The neuromedical and rehabilitative management of TBI demands a vast knowledge of a multiplicity of fields including neurophysiology, neuroanatomy, neuropathology, neurology, neuropharmacology, neuropsychiatry,

physiatry, psychology, neuropsychology, orthopedics, nursing, therapy specialties including occupational therapy, physical therapy, speech language pathology, and therapeutic recreation, among others. Based on extensive experience over the years, an interdisciplinary team approach clearly facilitates optimal neurorehabilitation. In order to optimize this process, all clinicians on the team must have a good understanding of how to optimize the efficacy of this treatment model and coordinate care in a manner that is most cost-efficient relative to achieving optimal functional outcomes.

Persons with TBI need to have a continuum of programs available in order to facilitate continuity of care and optimize their outcomes. The specific approaches may differ across the continuum of care, as might the medically indicated clinicians. Each of these stages potentially requires a different and evolving knowledge. Adequate appreciation of clinical nuances is paramount in being able to judge, document, and predict recovery and future neurorehabilitative needs. Functional gains can continue for years, even well after neurologic plateaus are reached. Even in scenarios where one finds that patients have functionally plateaued, there may still be opportunities to manipulate the environment and/or provide new treatment methodologies to further optimize quality-of-life and functional status.

Given the complexities in the medical management of this patient population and the need for a functional, holistic approach that utilizes a biopsychosocial model of care, clinicians need a source of information that brings together the myriad medical and allied health specialties

involved in understanding TBI care and rehabilitation. This is the importance of *Brain Injury Medicine: Principles and Practice*. This book will provide readers with the most recent information and methodologies to facilitate clinical practice and optimize patient functional outcomes. The text provides the knowledge necessary to understand what is happening at various stages of recovery following TBI and, more importantly, what needs to be done during each stage. It is an excellent resource for both clinicians and non-clinicians alike. Medical physicians involved in neurorehabilitation, such as physiatrists or neurologists, as well as other rehabilitation team members, will find this book an invaluable resource. Physicians who deal with TBI in a non-neurorehabilitation context

will certainly benefit from understanding brain injury from the perspective provided by this text, which will further facilitate use of rehabilitation resources in their own community. It is an outstanding and comprehensive book that can serve as the “bible” for each member of a team working with a TBI patient, allowing each of them to understand the reasons behind the decisions of their fellow team members.

We are what our brains allow us to be. The neurorehabilitation professional needs to have a standard by which to understand and advise patients, family members, fellow professionals, and payors regarding TBI-related issues. This book will significantly enable each professional to have access to this vast fund of knowledge.

Centers for Disease Control and Prevention  
Atlanta, Georgia  
*Chapter 6: The Epidemiology of TBI: Implications for  
Public Health*

**John D. Corrigan, PhD**

Professor  
Department of Physical Medicine and Rehabilitation  
The Ohio State University College of Medicine  
Columbus, Ohio  
*Chapter 59: The Treatment of Substance Abuse in  
Persons with TBI*

**Linda Creasey, RD, CNSD**

Clinical Nutrition Supervisor  
Food and Nutrition Services  
Medical College of Virginia  
Virginia Commonwealth University  
Richmond, Virginia  
*Chapter 36: Gastrointestinal and Nutritional Issues*

**Numa Dancause, PT, PhD**

Post-Doctorate Fellow  
Department of Neurology  
University of Rochester  
Rochester, New York  
*Chapter 49: Neuroscientific Basis for Occupational  
and Physical Therapy Interventions*

**Alan M. Davis, MD, PhD**

Assistant Professor  
Department of Physical Medicine and Rehabilitation  
University of Utah School of Medicine  
Salt Lake City, Utah  
*Chapter 57: Complementary and Alternative Medicine*

**Steven M. Day, PhD**

Senior Researcher  
Life Expectancy Project  
San Francisco, California  
*Chapter 17: Life Expectancy*

**Richard L. Delmonico, PhD**

Chief, Neuropsychology  
Kaiser Foundation Rehabilitation Center  
Vallejo, California  
Associate Clinical Professor  
University of California, Davis  
School of Medicine  
Davis, California  
*Chapter 37: Sexuality, Reproduction, and  
Neuroendocrine Disorders Following TBI*

**Pedro Diaz-Marchan, MD**

Associate Professor of Radiology  
Associate Chair for Education  
Program Director, Diagnostic Radiology Residency  
Program Director, Neuroradiology Fellowship  
Baylor College of Medicine  
Chief of Neuroradiology  
Ben Taub General Hospital  
Houston, Texas  
*Chapter 11: Static Neuroimaging in the Evaluation  
of TBI*

**Marcel P.J.M. Dijkers, PhD**

Associate Professor  
Department of Rehabilitation Medicine  
Mount Sinai School of Medicine  
New York, New York  
*Chapter 16: Functional Assessment in TBI  
Rehabilitation*

**C. Edward Dixon, PhD**

Director, Brain Trauma Research Center  
 Professor, Departments of Neurological Surgery,  
 Critical Care Medicine, Neurobiology,  
 and Physical Medicine and Rehabilitation  
 University of Pittsburgh School of Medicine  
 Pittsburgh, Pennsylvania

*Chapter 10: Advances in Innovative Therapies to  
 Enhance Neural Recovery*

**Victor G. Dostrow, MD**

Service Chief  
 Department of Neurology  
 Mississippi State Hospital  
 Whitfield, Mississippi  
 Clinical Associate Professor  
 Department of Neurology  
 University of Mississippi Medical Center  
 Clinical Assistant Professor  
 Department of Psychiatry  
 University of Mississippi Medical Center  
 Adjunct Associate Professor  
 Department of Pharmacy Practice  
 University of Mississippi School of Pharmacy  
 Jackson, Mississippi

*Chapter 26: Post-Traumatic Seizures and Epilepsy*

**Elie P. Elovic, MD**

Director, Traumatic Brain Injury Lab  
 Kessler Medical Rehabilitation Research and Education  
 Corporation  
 Associate Professor  
 Department of Physical Medicine and Rehabilitation  
 University of Medicine and Dentistry of New Jersey  
 New Jersey Medical School  
 West Orange, New Jersey

*Chapter 7: Primary Prevention*

*Chapter 31: Fatigue: Assessment and Treatment*

**Jeffrey Englander, MD**

Vice Chair and Director of Brain Injury Rehabilitation  
 Co-Director, NIDRR TBI Model System of Care,  
 Northern California  
 Santa Clara Valley Medical Center  
 San Jose, California

*Chapter 21: The Older Adult*

**Paul J. Eslinger, PhD**

Professor  
 Departments of Neurology, Neural and Behavioral  
 Sciences,  
 Pediatrics and Radiology  
 Pennsylvania State University, College of Medicine and  
 Milton S. Hershey Medical Center  
 University Hospital Rehabilitation Center  
 Hershey, Pennsylvania

*Chapter 42: Cognitive Impairments After TBI*

**Alberto Esquenazi, MD**

Director, Gait and Motion Analysis Laboratory  
 Co-Director, Neuroorthopedic Program MossRehab  
 Elkins Park, Pennsylvania

*Chapter 35: Assessing and Treating Muscle Overactivity  
 in the Upper Motoneuron Syndrome*

**Jonathan L. Fellus, MD**

Assistant Clinical Professor  
 Department of Neurosciences  
 University of Medicine and Dentistry of New Jersey  
 New Jersey Medical School  
 Newark, New Jersey  
 Director of Brain Injury Services  
 Kessler Institute for Rehabilitation  
 West Orange, New Jersey

*Chapter 31: Fatigue: Assessment and Treatment*

**Lisa P. Fugate, MD, MSPH**

Assistant Professor  
 Department of Physical Medicine and Rehabilitation  
 The Ohio State University College of Medicine  
 Columbus, Ohio

*Chapter 19: Assessment, Early Rehabilitation  
 Intervention, and Tertiary Prevention*

**Michael Gaetz, PhD**

Professor  
 UCFV Concussion Management Program  
 Kinesiology and Physical Education  
 University College of the Fraser Valley  
 Abbotsford, British Columbia  
 Canada

*Chapter 22: Mild TBI*

*Chapter 24: Sport-Related Concussion*

**Joseph T. Giacino, PhD**

Associate Director of Neuropsychology  
 JFK Johnson Rehabilitation Institute  
 New Jersey Neuroscience Institute  
 Edison, New Jersey

*Chapter 25: Assessment and Rehabilitative  
 Management of Individuals with Disorders of  
 Consciousness*

**Daniel D. Gottlieb, OD**

Director  
 Gottlieb Vision Group  
 Stone Mountain, Georgia

*Chapter 29: Evaluating and Treating Visual Dysfunction*

**Brian Greenwald, MD**

Assistant Professor  
 Department of Rehabilitation Medicine  
 Mount Sinai School of Medicine  
 New York, New York

*Chapter 16: Functional Assessment in TBI  
 Rehabilitation*

**Zeev Groswasser, MD, MPH**  
 Head  
 Department of Brain Injury Rehabilitation  
 Loewenstein Rehabilitation Hospital  
 Ra'anana, Israel  
 Professor  
 Sackler Faculty of Medicine  
 Tel Aviv University  
 Tel Aviv, Israel  
*Chapter 3: International Perspectives on TBI  
 Rehabilitation*

**Flora M. Hammond, MD**  
 Brain Injury Program Director  
 Research Director  
 Department of Physical Medicine and Rehabilitation  
 Carolinas Rehabilitation  
 Charlotte, North Carolina  
*Chapter 30: Cranial Nerve Disorders*

**L. Anne Hayman, MD**  
 Private Practice  
 Department of Radiology  
 Medical Clinic of Houston LLP  
 Houston, Texas  
*Chapter 11: Static Neuroimaging in the Evaluation of  
 Traumatic Brain Injury*

**Jeffrey S. Hecht, MD**  
 Associate Professor and Chief  
 Division of Surgical Rehabilitation  
 Department of Surgery  
 University of Tennessee Graduate School of Medicine  
 Medical Director  
 The Rehabilitation Center at Baptist Hospital  
 Medical Director  
 St. Mary's RehabCare Center  
 Knoxville, Tennessee  
*Chapter 55: Nutraceuticals*  
*Chapter 57: Complementary and Alternative Medicine*

**Lawrence J. Horn, MD**  
 Professor  
 Department of Physical Medicine and Rehabilitation  
 Wayne State University School of Medicine  
 Medical Director  
 Traumatic Brain Injury Program  
 Rehabilitation Institute of Michigan  
 Detroit, Michigan  
*Chapter 38: Post-Traumatic Pain Disorders: Medical  
 Assessment and Management*

**Grant L. Iverson, PhD, RPsych**  
 Professor  
 Department of Psychiatry  
 University of British Columbia  
 Coordinator of Psychology and Neuropsychology  
 Services  
 Neuropsychiatry Program  
 Riverview Hospital  
 Vancouver, British Columbia  
 Canada  
*Chapter 22: Mild TBI*  
*Chapter 23: Post-Concussive Disorder*  
*Chapter 24: Sport-Related Concussion*

**Jack I. Jallo, MD, PhD**  
 Associate Professor  
 Department of Neurosurgery  
 Temple University School of Medicine  
 Philadelphia, Pennsylvania  
*Chapter 18: TBI: Pathology, Pathophysiology, Acute  
 Care and Surgical Management, Critical Care  
 Principles and Outcomes*

**Joseph Jankovic, MD**  
 Professor of Neurology  
 Director, Parkinson's Disease Center and Movement  
 Disorders Clinic  
 Department of Neurology  
 Baylor College of Medicine  
 Houston, Texas  
*Chapter 27: Movement Disorders After TBI*

**Larry W. Jenkins, PhD**  
 Associate Professor  
 Department of Neurosurgery  
 University of Pittsburgh School of Medicine  
 Pittsburgh, Pennsylvania  
*Chapter 8: Traumatic Brain Injury: Pathobiology*

**Robert L. Karol, PhD**  
 Director  
 Department of Psychology and Neuropsychology  
 Program Director  
 Brain Injury Services  
 Bethesda Hospital  
 St. Paul, Minnesota  
*Chapter 44: Principles of Behavioral Analysis and  
 Modification*

**Douglas I. Katz, MD**

Associate Professor  
 Department of Neurology  
 Boston University School of Medicine  
 Boston, Massachusetts  
 Medical Director  
 Brain Injury Programs  
 Healthsouth Braintree Rehabilitation Hospital  
 Braintree, Massachusetts  
*Chapter 1: Clinical Continuum of Care and Natural History*  
*Chapter 25: Assessment and Rehabilitative Management of Individuals with Disorders of Consciousness*

**Mary Ann E. Keenan, MD**

Professor and Vice Chair of Graduate Medical Education  
 Chief, Neuro-Orthopedics Program  
 University of Pennsylvania Health System  
 Department of Orthopedic Surgery  
 Philadelphia, Pennsylvania  
*Chapter 35: Assessing and Treating Muscle Overactivity in the Upper Motoneuron Syndrome*

**Ofer Keren, MD**

Director of Rehabilitation Department  
 Alyn Hospital  
 Pediatric and Adolescent Rehabilitation Center  
 Jerusalem, Israel  
 Professor  
 Sackler Faculty of Medicine  
 Tel Aviv University  
 Tel Aviv, Israel  
*Chapter 3: International Perspectives on TBI Rehabilitation*

**Donald F. Kirby, MD**

Professor of Medicine, Psychiatry, Biochemistry and Molecular Physics  
 Chief, Section of Nutrition  
 Medical College of Virginia  
 Virginia Commonwealth University  
 Richmond, Virginia  
*Chapter 36: Gastrointestinal and Nutritional Issues*

**Kristi L. Kirschner, MD**

Coleman Foundation Chair in Rehabilitation Medicine  
 Director, Donnelley Family Disability Ethics Program  
 Rehabilitation Institute of Chicago  
 Associate Professor  
 Departments of Physical Medicine and Rehabilitation and Medical Humanities and Bioethics  
 Northwestern University Feinberg School of Medicine  
 Chicago, Illinois  
*Chapter 65: Decision-Making Capacity After TBI: Clinical Assessment and Ethical Implications*

**Anthony E. Kline, PhD**

Assistant Professor  
 Departments of Physical Medicine and Rehabilitation and Psychology  
 Associate Director of Rehabilitation Research  
 Safar Center for Resuscitation Research  
 University of Pittsburgh School of Medicine  
 Pittsburgh, Pennsylvania  
*Chapter 10: Advances in Innovative Therapies to Enhance Neural Recovery*

**Sally Kneipp, PhD**

Director, Community Skills Program  
 Counseling and Rehabilitation, Inc.  
 Wyomissing, Pennsylvania  
 Counseling and Rehabilitation of New Jersey, Inc.  
 Marlton, New Jersey  
*Chapter 58: Community Re-entry Issues and Long-Term Care*

**Patrick M. Kochanek, MD**

Professor and Vice Chairman  
 Department of Critical Care Medicine  
 Director, Safar Center for Resuscitation Research  
 University of Pittsburgh School of Medicine  
 Pittsburgh, Pennsylvania  
*Chapter 8: TBI: Pathobiology*

**Mary Jean Kotch MSN, CRRN-A**

Clinical Nurse Specialist  
 Kaiser Foundation Rehabilitation Center and Hospital  
 Vallejo, California  
*Chapter 37: Sexuality, Reproduction, and Neuroendocrine Disorders Following TBI*

**Sunil Kothari, MD**

Associate Director  
 Brain Injury and Stroke Program  
 The Institute for Rehabilitation and Research  
 Assistant Professor  
 Department of Rehabilitation Medicine  
 Baylor College of Medicine  
 Houston, Texas  
*Chapter 14: Prognosis After Severe Traumatic Brain Injury: A Practical, Evidence-Based Approach*  
*Chapter 57: Complementary and Alternative Medicine*  
*Chapter 65: Decision-Making Capacity After TBI: Clinical Assessment and Ethical Implications*

**Joachim K. Krauss, MD**

Professor of Neurosurgery  
 Director and Chairman  
 Department of Neurosurgery  
 Medical University, MHH  
 Hannover, Germany  
*Chapter 27: Movement Disorders After TBI*

**Jeffrey S. Kreutzer, PhD, ABPP**  
Professor  
Departments of Physical Medicine and Rehabilitation,  
Neurosurgery, and Psychiatry  
Virginia Commonwealth University School of Medicine  
Richmond, Virginia  
*Chapter 43: Neuropsychological Assessment and  
Treatment of TBI*

**Rael T. Lange, PhD**  
Research Scientist (Neuropsychology)  
Department of Research  
Riverview Hospital  
Coquitlam, British Columbia  
Canada  
*Chapter 22: Mild TBI*  
*Chapter 23: Post-Concussive Disorder*

**Eun Ha Lee, MD, PhD**  
Research Fellow and Clinical Coordinator  
Stanford University School of Medicine  
Physical Medicine and Rehabilitation Service  
VA Palo Alto Health Care System  
Palo Alto, California  
*Chapter 13: Electrophysiologic Assessment Techniques:  
Evoked Potentials and Electroencephalography*

**Henry L. Lew, MD, PhD**  
Clinical Associate Professor  
Stanford University School of Medicine  
Physical Medicine and Rehabilitation Service  
VA Palo Alto Health Care System  
Palo Alto, California  
*Chapter 13: Electrophysiologic Assessment Techniques:  
Evoked Potentials and Electroencephalography*

**Lee A. Livingston, PsyD**  
Clinical Psychologist and Instructor  
Department of Physical Medicine and Rehabilitation  
Virginia Commonwealth University School of Medicine  
Richmond, Virginia  
*Chapter 43: Neuropsychological Assessment and  
Treatment of TBI*

**Lisa A. Lombard, MD**  
Assistant Professor  
Medical Director, Traumatic Brain Injury Rehabilitation  
Department of Physical Medicine and Rehabilitation  
University of Pittsburgh School of Medicine  
Pittsburgh, Pennsylvania  
*Chapter 54: Neuropharmacology: A Rehabilitation  
Perspective*

**Jerilyn A. Logemann, PhD**  
Ralph and Jean Sundin Professor  
Communication Sciences and Disorders  
Northwestern University  
Evanston, Illinois  
*Chapter 47: Evaluation and Treatment of Swallowing  
Problems After TBI*

**David F. Long, MD**  
Brain Injury Program Director  
Bryn Mawr Rehabilitation Hospital  
Malvern, Pennsylvania  
*Chapter 33: Diagnosis and Management of Late  
Intracranial Complications of TBI*

**Mark R. Lovell, PhD**  
Director  
UPMC Sports Medicine Concussion Program  
Associate Professor of Orthopedics  
Division of Sports Medicine  
University of Pittsburgh Medical Center  
Pittsburgh, Pennsylvania  
*Chapter 24: Sport-Related Concussion*

**Michael F. Martelli, PhD**  
Director, Rehabilitation Neuropsychology  
Concussion Care Centre of Virginia, Ltd.  
and Tree of Life Services, Inc.  
Glen Allen, Virginia  
Medical College of Virginia  
Virginia Commonwealth University School of Medicine  
Richmond, Virginia  
*Chapter 38: Post-Traumatic Pain Disorders: Medical  
Assessment and Management*  
*Chapter 39: Psychological Approaches to  
Comprehensive Pain Assessment and Management  
Following TBI*  
*Chapter 63: Ethical Issues in Clinicolegal Practice*  
*Chapter 64: Assessment of Response Bias in Clinical  
and Forensic Evaluations of Impairment  
Following TBI*

**Brent E. Masel, MD**  
President and Medical Director  
Transitional Learning Center at Galveston  
Galveston, Texas  
*Chapter 30: Cranial Nerve Disorders*

**Nathaniel H. Mayer, MD**  
Emeritus Professor of Physical Medicine and  
Rehabilitation  
Temple University School of Medicine  
Philadelphia, Pennsylvania  
Director, Drucker Brain Injury Center and Motor  
Control Analysis Laboratory  
MossRehab Einstein at Elkins Park  
Elkins Park, Pennsylvania  
*Chapter 35: Assessing and Treating Muscle Overactivity  
in the Upper Motoneuron Syndrome*

**Thomas W. McAllister, MD**  
Professor of Psychiatry  
Director of Neuropsychiatry  
Department of Psychiatry  
Dartmouth Medical School  
Lebanon, New Hampshire  
*Chapter 45: Neuropsychiatric Aspects of TBI*

**James T. McDeavitt, MD**  
Senior Vice President  
Division of Education and Research  
Carolinas HealthCare System  
Charlotte, North Carolina  
*Chapter 20: TBI: A Pediatric Perspective*

**Jacinta M. McElligott, MD**  
Director of Rehabilitation  
National Rehabilitation Hospital  
Dun Laoghaire  
Co. Dublin, Ireland  
*Chapter 57: Complementary and Alternative Medicine*

**Robin McNeny, BS, OTR/L**  
Manager  
Inpatient Occupational Therapy and Therapeutic  
Recreation  
Occupational and Physical Therapy Department  
Virginia Commonwealth University  
Medical College of Virginia Hospitals Medical Center  
Richmond, Virginia  
*Chapter 51: Therapy for Activities of Daily Living:  
Theoretical and Practical Perspectives*

**Jay M. Meythaler, MD, JD**  
Chairman and Professor  
Department of Physical Medicine and Rehabilitation  
Wayne State University  
Specialist and Chief  
Department of Physical Medicine and Rehabilitation  
Detroit Medical Center  
Detroit, Michigan  
*Chapter 54: Neuropharmacology: A Rehabilitation  
Perspective*

**Denise Morales, MD**  
Attending Physician  
Department of Physical Medicine and Rehabilitation  
Kaiser Foundation Rehabilitation Center  
Vallejo, California  
*Chapter 11: Static Neuroimaging in the Evaluation  
of TBI*

**John A. Muenz, Jr., MD**  
Private Practice  
Physical Medicine and Rehabilitation, Family Medicine  
Associate Professor  
Departments of Family Medicine, Orthopaedics, and  
Neurology  
University of Florida—Jacksonville  
Jacksonville, Florida  
*Chapter 57: Complementary and Alternative  
Medicine*

**Bruce E. Murdoch, PhD, DSc**  
Professor  
Head School of Health and Rehabilitation Sciences  
The University of Queensland  
St. Lucia, Brisbane  
Australia  
*Chapter 46: Assessment and Treatment of Speech and  
Language Disorders in TBI*

**W. Jerry Mysiw, MD**  
Associate Professor  
Bert C. Wiley Chair and Vice Chair  
Department of Physical Medicine and Rehabilitation  
The Ohio State University College of Medicine  
Columbus, Ohio  
*Chapter 19: Assessment, Early Rehabilitation  
Intervention, and Tertiary Prevention*

**Elena Napolitano, MD**  
Attending Physiatrist  
Department of Physical Medicine and Rehabilitation  
Shore Rehabilitation Institute  
Brick, New Jersey  
*Chapter 7: Primary Prevention*

**Christine A. Nelson, PhD, OTR**  
Clinical Coordinator  
Centro de Desarrollo  
Cuernavaca, Mexico  
*Chapter 29: Evaluating and Treating Visual  
Dysfunction*

**Maureen R. Nelson, MD**  
Director, Pediatric Rehabilitation Services  
Carolinas Rehabilitation  
Physical Medicine and Rehabilitation  
Charlotte, North Carolina  
Clinical Associate Professor  
Department of Physical Medicine and Rehabilitation  
University of North Carolina  
Chapel Hill, North Carolina  
*Chapter 20: TBI: A Pediatric Perspective*

**Keith Nicholson, PhD**

Psychologist  
Comprehensive Pain Program  
The Toronto Western Hospital  
University of Toronto  
Toronto, Ontario  
Canada

*Chapter 38: Post-Traumatic Pain Disorders: Medical Assessment and Management*

*Chapter 39: Psychological Approaches to Comprehensive Pain Assessment and Management following TBI*

*Chapter 64: Assessment of Response Bias in Clinical and Forensic Evaluations of Impairment Following TBI*

**Randolph J. Nudo, PhD**

Professor  
Department of Molecular and Integrative Physiology  
Director, Landon Center on Aging  
The University of Kansas Medical Center  
Kansas City, Kansas

*Chapter 49: Neuroscientific Basis for Occupational and Physical Therapy Interventions*

**Kelly A. Ojdana, MS**

Researcher  
Life Expectancy Project  
San Francisco, California  
*Chapter 17: Life Expectancy*

**William V. Padula, OD**

Director  
Padula Institute of Vision Rehabilitation  
Guilford, Connecticut  
Adjunct Faculty  
Pennsylvania College of Optometry  
Elkins Park, Pennsylvania  
Chairperson, National Academy of Practice in Optometry (NAPO)  
Founding President (Emeritus), Neuro-Optometric Rehabilitation Association (NORA)

*Chapter 29: Evaluating and Treating Visual Dysfunction*

**Steven S. L. Pan, MD**

Research Fellow  
Stanford University School of Medicine  
Physical Medicine and Rehabilitation Service  
VA Palo Alto Health Care System  
Palo Alto, California  
*Chapter 13: Electrophysiologic Assessment Techniques: Evoked Potentials and Electroencephalography*

**Amish R. Patel, DO**

Resident  
Department of Physical Medicine and Rehabilitation  
Medical College of Ohio  
Toledo, Ohio  
*Chapter 32: Sleep Disturbances: Epidemiology, Assessment, and Treatment*

**Thomas Politzer, OD**

Private Practice  
Golden, Colorado  
*Chapter 29: Evaluating and Treating Visual Dysfunction*

**Jeffrey Radecki, MD**

Department of Physical Medicine and Rehabilitation  
New York-Presbyterian  
The University Hospital of Columbia and Cornell  
New York, New York

*Chapter 7: Primary Prevention*

**Cara Camiolo Reddy, MD**

Traumatic Brain Injury Fellow and Clinical Instructor  
Department of Physical Medicine and Rehabilitation  
University of Pittsburgh School of Medicine  
Pittsburgh, Pennsylvania

*Chapter 54: Neuropharmacology: A Rehabilitation Perspective*

**Joseph H. Ricker, PhD**

Associate Professor  
Department of Physical Medicine and Rehabilitation  
University of Pittsburgh School of Medicine  
Pittsburgh, Pennsylvania

*Chapter 12: Functional Neuroimaging of TBI*

**Allen J. Rubin, MD**

The Center for Neuropsychiatry, LLC  
Marlton, New Jersey  
Adjunct Associate Professor of Clinical Psychiatry  
Drexel University School of Medicine  
Philadelphia, Pennsylvania

*Chapter 58: Community Re-entry Issues and Long-Term Care*

**Michael Ruckenstein, MD**

Associate Professor  
Residency Program Director  
Department of Otorhinolaryngology, Head and Neck Surgery  
Hospital of the University of Pennsylvania

Philadelphia, Pennsylvania

*Chapter 28: Balance and Dizziness*

**M. Elizabeth Sandel, MD**

Chief, Physical Medicine and Rehabilitation  
Napa Solano Service Area  
Director, Research and Training  
Kaiser Foundation Rehabilitation Center  
Vallejo, California  
Clinical Professor

Department of Physical Medicine and Rehabilitation  
University of California, Davis, School of Medicine  
Davis, California

*Chapter 37: Sexuality, Reproduction, and Neuroendocrine Disorders Following TBI*

**Angelle M. Sander, PhD**

Assistant Professor and Neuropsychologist  
Department of Physical Medicine and Rehabilitation  
Baylor College of Medicine/Harris County Hospital  
District

Associate Director  
Brain Injury Research Center at The Institute for  
Rehabilitation and Research  
Houston, Texas

*Chapter 60: A Cognitive-Behavioral Intervention for  
Family Members of Persons with TBI*

**Joanne Scandale, PhD, CRC, CCM, LMHC**

Program Director of Vocational Services  
Department of Rehabilitation  
Hutchings Psychiatric Center  
Syracuse, New York

*Chapter 4: Training and Certification of Care  
Providers for Persons Sustaining TBI*

**Nicholas D. Schiff, MD**

Associate Professor  
Department of Neurology and Neuroscience  
Weill Medical College of Cornell University  
New York, New York

*Chapter 25: Assessment and Rehabilitative Management  
of Individuals with Disorders of Consciousness*

**Anbesaw Selassie, DrPH**

Associate Professor of Epidemiology  
Department of Biostatistics, Bioinformatics, and  
Epidemiology  
Medical University of South Carolina  
Charleston, Carolina

*Chapter 6: The Epidemiology of TBI: Implications for  
Public Health*

**Robert M. Shavelle, PhD, MBA**

Technical Director  
Life Expectancy Project  
San Francisco, California

*Chapter 17: Life Expectancy*

**Neil T. Shepard, PhD**

Professor  
Department of Special Education and Communication  
Disorders

University of Nebraska, Lincoln  
Lincoln, Nebraska

*Chapter 28: Balance and Dizziness*

**Jonathan M. Silver, MD**

Clinical Professor of Psychiatry  
New York University School of Medicine  
New York, New York

*Chapter 52: Pharmacotherapy of Neuropsychiatric  
Disturbances*

*Chapter 53: Pharmacotherapy of Cognitive Impairment*

**Donald G. Stein, PhD**

Asa G. Candler Professor  
Department of Emergency Medicine  
Emory University School of Medicine  
Atlanta, Georgia

*Chapter 9: Concepts of CNS Plasticity and Their  
Implications for Understanding Recovery After Brain  
Damage*

**David J. Strauss, PhD**

Director  
Life Expectancy Project  
Emeritus Professor  
University of California  
San Francisco, California

*Chapter 17: Life Expectancy*

**Katherine J. Sullivan, PhD, PT**

Assistant Professor of Clinical Physical Therapy  
Director, Entry-level Doctor of Physical Therapy  
Department of Biokinesiology and Physical Therapy  
University of Southern California  
Los Angeles, California

*Chapter 50: Therapy Interventions for Mobility  
Impairments and Motor Skill Acquisition After TBI*

**Andrew Sumich, MD**

Private Practice  
Physical Medicine and Rehabilitation  
Carolina Neurosurgery and Spine Associates  
Charlotte, North Carolina

*Chapter 20: TBI: A Pediatric Perspective*

**Penelope S. Suter, OD**

Optometrist in Private Practice  
Research Associate  
California State University  
Bakersfield, California

*Chapter 29: Evaluating and Treating Visual  
Dysfunction*

**Pam Targett, MEd**

Rehabilitation Research and Training Center  
Medical College of Virginia  
Virginia Commonwealth University School of Medicine  
Richmond, Virginia

*Chapter 61: Returning to Work Following TBI*

**Laura A. Taylor, PhD**

Licensed Clinical Psychologist  
Village Family Psychiatry  
Richmond, Virginia

*Chapter 43: Neuropsychological Assessment and  
Treatment of TBI*

**Lora L. Thaxton, MD**

Optimal Life Integrative Medicine Pain Center  
Toledo, Ohio  
*Chapter 32: Sleep Disturbances: Epidemiology, Assessment, and Treatment*

**John A. Thomas, OD**

Adjunct Professor  
Pacific University College of Optometry  
Director  
Head Trauma, Vision, Cognitive and Learning Disabilities Center  
Denver, Colorado  
*Chapter 29: Evaluating and Treating Visual Dysfunction*

**David J. Thurman, MD, MPH**

Neuroepidemiologist  
National Center for Chronic Disease Prevention and Health Promotion  
Centers for Disease Control and Prevention  
Atlanta, Georgia  
*Chapter 6: The Epidemiology of TBI: Implications for Public Health*

**Trinh Tran, MD**

Clinical Instructor  
University of California San Francisco School of Medicine  
Laguna Hospital and Rehabilitation Center  
San Francisco, California  
*Chapter 21: The Older Adult*

**Margaret A. Turk, MD**

Professor  
Department of Physical Medicine and Rehabilitation  
Department of Pediatrics  
SUNY Upstate Medical Center  
Syracuse, New York  
*Chapter 4: Training and Certification of Care Providers for Persons Sustaining TBI*

**Vincent Richard Vicci, Jr., OD**

Staff Vision Care Consultant  
Kessler Institute for Rehabilitation  
West Orange, New Jersey  
Staff Vision Care Consultant  
Extended Recovery Unit  
Robert Wood Johnson Rehabilitation Unit  
JFK Memorial Hospital  
Edison, New Jersey  
*Chapter 29: Evaluating and Treating Visual Dysfunction*

**Amy K. Wagner, MD**

Assistant Professor  
Department of Physical Medicine and Rehabilitation  
Associate Director Rehabilitation Research  
Safar Center for Resuscitation Research  
University of Pittsburgh School of Medicine  
Pittsburgh, Pennsylvania  
*Chapter 5: Conducting Research in TBI: Current Concepts and Issues*

**Gary G. Wang, MD**

Director  
Traumatic Brain Injury Program  
Erie County Medical Center  
Buffalo, New York  
*Chapter 56: Traditional Chinese Medicine Theory in the Mechanism and Treatment of TBI*  
*Chapter 57: Complementary and Alternative Medicine*

**Roger O. Weed, PhD, CLCP**

Professor and Coordinator  
Graduate Rehabilitation Counseling Program  
Department of Counseling and Psychological Services  
Georgia State University  
Atlanta, Georgia  
*Chapter 66: Life Care Planning After TBI: Clinical and Forensic Issues*

**Michael West, PhD**

Rehabilitation Research and Training Center  
Medical College of Virginia  
Virginia Commonwealth University School of Medicine  
Richmond, Virginia  
*Chapter 61: Returning to Work Following TBI*

**Paul Wehman, PhD**

Rehabilitation Research and Training Center  
Medical College of Virginia  
Virginia Commonwealth University School of Medicine  
Richmond, Virginia  
*Chapter 61: Returning to Work Following TBI*

**Brooke-Mai Whelan, PhD**

Research Fellow  
Division of Speech Pathology  
School of Health and Rehabilitation Sciences  
The University of Queensland  
St. Lucia, Brisbane  
Australia  
*Chapter 46: Assessment and Treatment of Speech and Language Disorders in TBI*

**Lezheng Wu, MD**

Professor of Ophthalmology  
Zhangshan Ophthalmic Center  
Sun Yat-Sen University  
Guangzhou, Canton  
China

*Chapter 29: Evaluating and Treating Visual  
Dysfunction*

**Stuart A. Yablon, MD**

Director, The Brain Injury Program  
Methodist Rehabilitation Center  
Jackson, Mississippi

*Chapter 26: Post-Traumatic Seizures and Epilepsy*

**Satoko Yasuda, PhD**

Rehabilitation Research and Training Center  
Medical College of Virginia  
Virginia Commonwealth University School of Medicine  
Richmond, Virginia

*Chapter 61: Returning to Work Following TBI*

**Ross D. Zafonte, DO**

Professor and Chair  
Department of Physical Medicine and Rehabilitation  
University of Pittsburgh Medical Center  
Pittsburgh, Pennsylvania

*Chapter 1: Clinical Continuum of Care and Natural  
History*

*Chapter 54: Neuropharmacology: A Rehabilitation  
Perspective*

**Giuseppe Zappalà, MD**

Behavioral Neurology and Cognitive Rehabilitation  
Division of Neurology  
Garibaldi Hospital  
Catania, Italy

*Chapter 42: Cognitive Impairments After TBI*

**Nathan D. Zasler, MD**

CEO and Medical Director

## Clinical Continuum of Care and Natural History

### **SCOPE OF THE PROBLEM AND THE CHARACTERISTICS OF TRAUMATIC BRAIN INJURY**

Systems of care for patients with traumatic brain injury (TBI) must account for the particular characteristics of this disorder. First, TBI is among the most common of serious, disabling neurological disorders. It is a significant problem in all societies. In the United States at least 1.4 million TBIs occur every year, and there are 5.3 million people living with disability from TBI (1–3). (See Thurman et al., Chapter 6, for a full discussion of the epidemiology of TBI). Systems of care must allocate resources for the large number of people who are affected by the disorder.

Second, TBI is largely a younger and older person's disorder (2). Individuals younger than 30, mostly males, make up the largest proportion of those affected. TBI usually impacts people who are in the later stages of adolescent development or in early adulthood. Therefore, TBI typically disrupts important periods of life involving educational and social development, emerging vocational productivity and adult independence, and beginning spousal relationships and family development. Older persons present particular problems related to aging including co-morbidities, slower and less complete recovery, and vulnerability to complications of injury and treatment (4) (see Englander et al., Chapter 21 on "The Older Adult").

Systems of care must address needs that include special educational requirements, independent living, vocational training and supports, and supports for family members.

Third, TBI commonly affects people with preexisting problems such as substance abuse, learning disabilities, behavioral disorders, psychiatric disorders and other risk factors that may make people more prone to injuries. In addition, persons with brain injury are more prone to psychiatric co-morbidities and psychosocial difficulties following injury. Systems of care must consider these pre-injury and post-injury issues with respect to injury prevention, their interactions with the clinical effects of injury and potential detrimental influence on recovery from TBI.

Fourth, the most important and consistent effects of TBI involve cognitive, emotional, and behavioral functioning. Motor and sensory perceptual problems also occur in varying amounts, more likely in those with more severe injuries. Cognitive and behavioral problems present more challenges to the health care system because they are often more difficult to recognize, characterize, and treat than traditional medical and physical problems. Persons with TBI, particularly less severe injuries, may not have any obvious physical markers of the injury, though there may be profound effects on the individual's ability to function, largely resulting from cognitive or behavioral dysfunction. Criteria for medical rehabilitation reimbursement, length of stay, and utilization decisions are

often more focused on motor issues affecting function and less focused on cognitive and behavioral treatment issues. Some insurance payers even exclude coverage for cognitive rehabilitation, although there is evidence to support its efficacy (5, 6) (see Cicerone, Chapter 41 on cognitive rehabilitation). Systems of care must focus on proper assessment and treatment of cognitive and behavioral problems, even though they may not fit the characteristics of medical rehabilitative systems that were originally developed for medical and physical disabilities (see Chapters 41–45).

Fifth, TBI, especially more severe injuries, can have a relatively extended natural history and lifelong effects. Recovery from TBI may be more protracted, over a relative longer portion of the lifespan, than most other acquired injuries or neurological disorders that evolve more quickly or typically affect persons at later stages of life. Thus, systems of care for TBI need to recognize the potentially prolonged recovery timetable. Further, recovery after TBI has a somewhat predictable and characteristic course, with a variety of recognizable cognitive, behavioral, and sensorimotor syndromes at different stages. An appreciation of the natural history of TBI is essential to assessing the individual and to effectively applying treatment and services at different stages of recovery, as well to avoiding treatment that may be unnecessary or ineffective (see discussion on natural history below).

Finally, TBI is a disorder with a wide variety of pathophysiological effects, a range of severities, and a multitude of problems that may occur as the result of injury. Persons with apparently similar injuries may have significant variation in their presentation, course of recovery, response to interventions and ability to return to functioning. Systems of care should have a breadth of treatments and services to address the variety of problems that can occur after TBI, and the flexibility to move persons through the system in different ways depending on their individual needs at different times post-injury.

## THE DEVELOPMENT OF SYSTEMS OF CARE

The provision of a comprehensive continuum of care for persons with TBI is an enormous challenge given the characteristics of TBI outlined above and the wide range of services that should be provided to large numbers of people, over relatively longer periods than most other disorders. The challenge confronts many groups: persons with TBI and their families; clinicians managing the care of the patient with TBI; service providers attempting to provide efficient and effective care; health insurance providers; public and other payers balancing coverage needs with financial pressures; and society at large, making choices about resource allocation and costs. Resources for patients with TBI include: acute and post-acute medical

care; rehabilitative services in the hospital, at home, in the community, and in residential settings; psychosocial services; educational and vocational services; and a variety of other support services.

The development of systems of care for persons with TBI evolved in the 1970s and 1980s. In part, the systems that developed for care of patients with TBI were influenced by systems of care that were developed for those with spinal cord injury (SCI). Prior to development of specific programs for persons with TBI, patients were frequently treated in psychiatric facilities, nursing homes, or more general rehabilitation facilities. The Rehabilitation Services Administration and NIDHR (which was to become NIDRR), which had funded SCI model systems in the early 1970s, also funded two model system projects for TBI in 1978 at Stanford University and New York University (7). The recommendations from these projects helped to promote the development of interdisciplinary, dedicated TBI programs with services across the continuum of recovery. As programs began to develop, the lack of organized planning led to an initiative by the NIDRR under the Department of Education in 1987 to fund five TBI model systems demonstration projects (8). This has expanded to sixteen TBI Model Systems Projects throughout the country in part aimed at gathering information to improve comprehensive systems of care for patients with TBI. The components of these model systems of care includes emergency medical services, acute neurosurgical care, comprehensive rehabilitation services, long-term interdisciplinary follow-up and rehabilitation services, as well as what were termed optional services, including behavior modification programs, home rehabilitation services, case management and community living options (8). A key portion of this program has been longitudinal and project specific based research.

Beginning in the mid-1980s, the Commission on Accreditation of Rehabilitation Facilities (CARF) developed standards for TBI rehabilitative care by establishing specialized accreditation for TBI programs. It now accredits TBI programs in six categories: inpatient, outpatient, home- and community-based, residential, long-term residential, and vocational.

An important development in TBI care was the TBI Act of 1996 passed by Congress to “provide for the conduct of expanded studies and the establishment of innovative programs with respect to traumatic brain injury.” Four provisions of the Act included surveillance and prevention under the CDC; basic and applied research to improve diagnosis, therapeutics and the continuum of clinical care conducted by the NIH; a planning and implementation grant program to the states under the Health Resources and Services Administration (HRSA); and a Consensus Conference conducted by the Center for Medical Rehabilitation and Research at NIH (9). The NIH consensus conference panel addressed the continuum of

care for TBI in their conclusions. The recommendations included that “persons with TBI should have access to rehabilitation services through the entire course of recovery, which may last for many years after the injury” and that “community-based, non-medical services should be components of the extended care and rehabilitation available to persons with TBI” (10).

## REALITIES OF THE MARKETPLACE

Although demonstration projects such as the TBI Model Systems have presented apparently effective systems of care for persons with TBI, the realities of the marketplace in the United States have presented challenges to providing such care and services to all those in need. Corrigan outlined 20 important challenges to meeting the needs of persons with TBI, within the categories of access, availability, appropriateness, and acceptability (9). With regard to access, the problems involve identifying and utilizing services, even if they are available. There may be difficulties accessing information about available resources. Sometimes it is difficult to determine what resources are covered by health insurance, and sometimes coverage is denied even after services are delivered. Families and care providers usually lack roadmaps to guide access to appropriate resources, and points of entry into publicly funded systems may be unclear. Service systems may have artificial barriers created by narrow eligibility criteria. Services are often fragmented and not well coordinated.

Corrigan pointed out a number of availability issues for which the main limiting factor is funding. Health insurance may not cover needed services that are available, or may direct individuals to centers that are less familiar with the care of persons with TBI. Further, lack of payer support may preclude the availability of some services to begin with. Many persons with TBI have no health care funding at all at the time of injury, and present state budget constraints are further threatening the Medicaid program. When available, health insurance typically fully covers acute care, but coverage for rehabilitative care becomes incrementally more difficult across the continuum of care, from inpatient to outpatient to residential and community services. Health insurance coverage also tends to be more restrictive for cognitive and behavioral services as opposed to more traditional physical rehabilitative and medical treatment. In many cases, coverage for services has to shift from private to public sources such as Medicaid and Medicare over the course of recovery because of limits in coverage for longer term care in many policies. Public funding has further restraints on long-term coverage. Several states have developed a system of Medicaid waivers to provide long-term home and community-based services that would otherwise be covered only for institutional settings, such as nursing

homes. The fragmentation and limitations in financing of care and services can create a nightmare of coordination for persons with brain injury, their families, and service providers. Clinicians who coordinate care for persons with brain injury must become aware of the complexities of reimbursement and the array of alternative sources of funding for TBI care and support in their community.

Other issues affecting the availability of services include geographic limitations; lack of transportation; a paucity of appropriate, affordable housing; limitations in resources for behavioral problems in children with special needs; and the long-term needs of persons with TBI (9). Patients with TBI in rural communities have special challenges in finding services within a reasonable distance. Even when available in a nearby area, transport to and from these services can be a major problem, and home services may not be available or sufficiently expert for this population. The ability to provide a full array of services to all age groups within a reasonable proximity, with full funding support, is an enormous challenge that may never be fully satisfied.

The appropriateness of available resources is also a common problem. Sometimes the reason for inappropriate services is dictated by payer constraints. For instance, because the main payer for long-term care services is Medicaid, if waivers to support home and community services are not available, patients with TBI who cannot return home may be placed in nursing homes, even though community-based services may be more appropriate. Even if services are available, programs and professional providers may lack the knowledge and expertise to serve this population. Generalists in a particular discipline or specialty may not have the skills for proper assessment or treatment of the patient with TBI. Accreditation programs such as CARF and the American Academy of Certified Brain Injury Specialists (AACBIS) have attempted to set standards and credentialing to assure appropriateness of programming and expertise. (See also Chapter 4 on training and certification.) Nevertheless, such expertise may simply not be available in some geographic areas or at certain levels of care. Sometimes erroneous services are applied because of this lack of expertise, but at times services may be improperly or needlessly applied even by those with expertise. Inaccurate diagnosis, inappropriate application of treatment at a particular stage of recovery, use of unproven or ineffective treatments, or application of effective treatment to those for whom it would not be of benefit are examples. Use of accurate diagnosis and prognosis is necessary to avoid some of these problems of inappropriate treatment (see below on natural history). Sometimes services are not fully relevant to a person's and family's needs at a particular time or in a particular environment. The acceptability of these services to the goals of the person with TBI and how services promote the persons self-actualization is another challenge to the TBI service marketplace (9).

### ESSENTIAL COMPONENTS OF THE CLINICAL CONTINUUM

The continuum of care for patients with TBI occurs in a variety of settings. Figure 1-1 illustrates the different types of care and how patients may move through these components. The flow through these services may not be linear. Patients may enter or leave the system of care at different points, or reverse directions, based on individual needs or the dictates of the marketplace.

#### Prevention

The earliest aspect of the care continuum involves public health issues prior to injury occurrence. Injury prevention is an essential part of trauma care systems. The TBI Act of 1996 charged the CDC with the responsibility for prevention, in addition to surveillance, to assess factors that increase the risk of TBI and those that are protective. Injury prevention programs generally include three components: programs designed to alter behavior and improve decision-making to increase self-protection; product improvement to minimize the chance of injury or protect the individual

in an accident; and legislation and public policies that require individuals to follow safety guidelines. Prevention of TBI includes a number of efforts such as reducing alcohol-related injuries, preventing falls, preventing violence, promoting safe practices in sports, promoting helmet and seatbelt use, enhancing safe driving practices, and improving vehicle safety. (See Napolitano et al., Chapter 7, for a discussion of primary prevention.)

#### Emergency Medical Services

Since the 1980s, emergency trauma systems have developed throughout the United States and have led to improved survival and recovery (11–13). Mortality for those that reach the hospital has been reduced from nearly 50% to about 25% (13). Regional trauma systems have developed to promote quick evacuation using ground or air transport to level I and level II trauma centers from the field, or from level III and IV trauma centers when necessary for more serious injuries. The level I and II trauma centers have full-time intensive care, imaging, neurosurgical, and other trauma subspecialists. The Brain Trauma Foundation’s (BTF) Guidelines for Prehospital

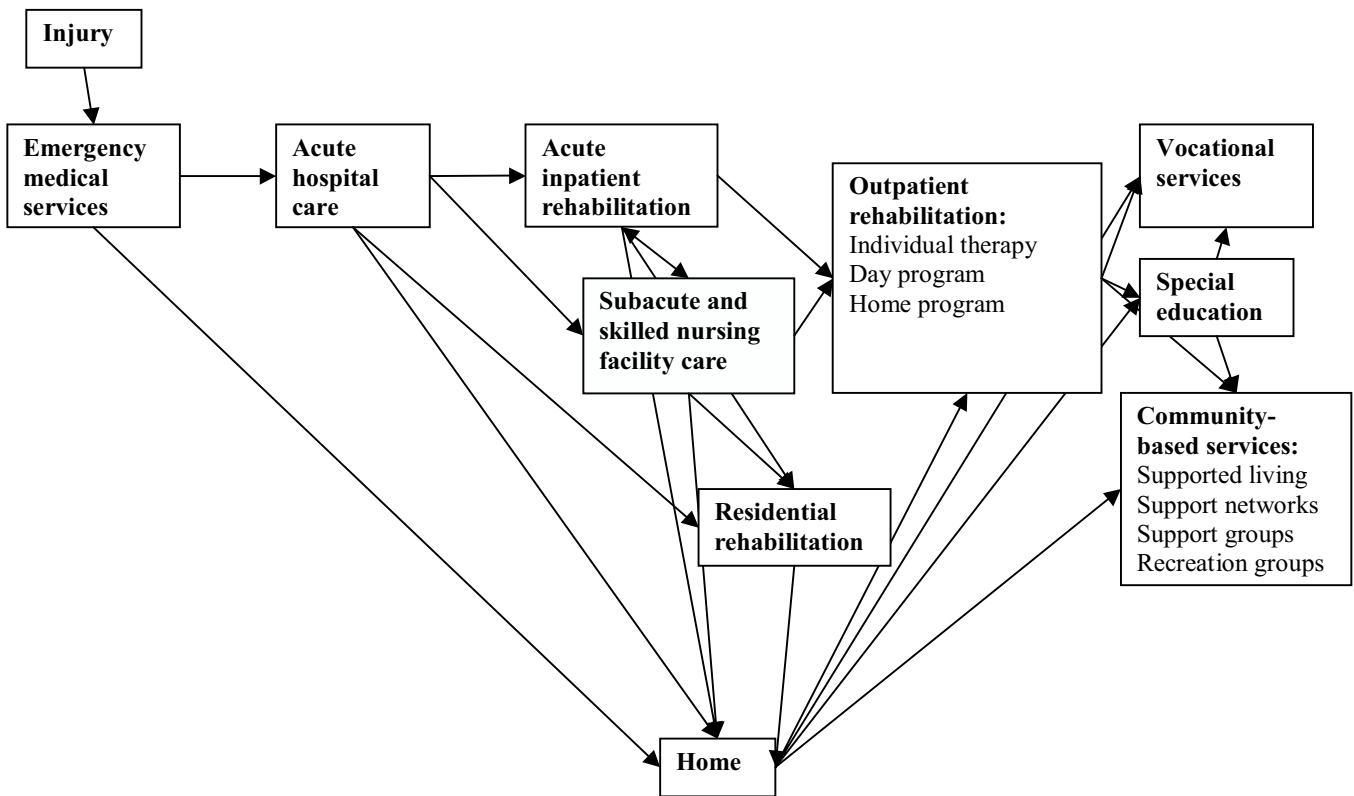

FIGURE 1-1

Usual flow of patients through the clinical continuum of care. Choices of services and direction of flow will be based on severity, stage of recovery, patient’s needs, availability of resources, availability of home and community supports, and constraints of the marketplace

Management of Traumatic Brain Injury have played a role in improving emergency prehospital care (12). Although improved, proper diagnosis, patient education, and referral for appropriate follow-up is still lacking for many patients (14).

### **Acute Hospital Care**

Patients with TBI who are admitted for acute hospital care range from those who need a period of observation to recognize secondary neurological deterioration and neurosurgical complications that may ensue after a delay, to those with co-morbidities that require hospital care, to those with more severe brain injury that requires intensive care management. Acute neurosurgical and intensive care for patients with TBI have improved over the last two decades with better survival and outcomes (15). Evidence-based guidelines for acute TBI care, including the use of intracranial pressure monitoring, have contributed to better outcomes (16–18). (See also Chapters 18 and 19 on acute care.)

Rehabilitation assessment and early rehabilitative interventions should take place a short time after admission, in the acute hospital setting. Subsequent decisions for rehabilitative care are made as the patient progresses toward medical and surgical stability, when the severity of the injury and the clinical rehabilitation needs become more apparent. The pathway toward acute inpatient rehabilitation versus outpatient or subacute care is largely based on injury severity and pace of recovery. Generally, patients with severe injuries (e.g., unconsciousness for a day or more, or post-traumatic amnesia and confusional states of at least days to weeks, or patients with large focal lesions) move to acute inpatient rehabilitation facilities. Constraints related to marketplace issues may affect this decision. For instance, some health care plans will not support admission to inpatient rehabilitation facilities if a patient has few traditional physical rehabilitation needs (e.g., needs little or no help ambulating) even if the patient has profound cognitive and behavioral disturbances related to the injury. Patients with mild injuries generally return home and may need outpatient rehabilitation services. A proportion of patients with moderate injury may benefit from at least a brief inpatient rehabilitation stay, depending on their circumstances. Patients who are slower to recover may require extended care in the acute hospital, or be transferred to subacute or skilled nursing facility (SNF) care instead of inpatient rehabilitation. In many systems such persons may be lost to the follow-up of those with a primary interest in caring for patients with TBI. Strong consideration should be given to transferring such patients to facilities with special expertise in the assessment and care of patients who are unconscious or minimally conscious (usually in acute inpatient rehabilitation or specialized subacute facilities), because these

patients are vulnerable to secondary complications and may have significant potential for further recovery, albeit at a slower pace.

### **Acute Inpatient Rehabilitation**

Acute inpatient rehabilitation may occur on general rehabilitation units or in dedicated brain injury units that are within acute care facilities or part of freestanding rehabilitation hospitals (inpatient rehabilitation facilities or long-term care hospitals). Admission criteria to hospital-based acute inpatient rehabilitation involve the following:

1. an intensity of medical and nursing care needs that requires full-time physician monitoring and specialized rehabilitative nursing expertise;
2. functional deficits that would benefit from a higher level of rehabilitation treatment intensity (usually designated at a minimum duration of 3 hours a day).

Patients are best served in programs dedicated to brain injury care or those with a significant proportion of staff with expertise in managing brain injury. Rehabilitation teams usually include: case managers; physical, occupational, and speech therapy staff; rehabilitation nurses; nursing assistants; psychologists; neuropsychologists; rehabilitation physicians (usually a physiatrist, rehabilitation neurologist, or neuropsychiatrist); primary care physicians; and a variety of other consultant medical specialists. Other disciplines such as social workers, rehabilitation technicians, therapy assistants, behavior specialists, recreation therapists, other subspecialty therapists, chaplains, and attorneys may also contribute to care.

Expertise in managing behavioral problems and assuring patient, family and staff safety is important because patients in agitated confusional states are usually managed at this level of care (see below). Family education to familiarize them with the problems and needs of persons with brain injury is essential at this level of care, especially for those that will transition home from acute inpatient rehabilitation. The decision regarding the next level of care depends on the patient's medical stability, level of dependency, safety, and whether the person's needs can be adequately met at home or requires further institutional care. Patients with severe TBI typically still require some supervision and, perhaps, physical assistance for self-care and mobility when they are ready to be discharged from acute inpatient rehabilitation.

### **Subacute and Skilled Nursing Facility Rehabilitation**

Patients with TBI are usually admitted to this level of care from acute hospital care or acute inpatient rehabilitation. Therapies are provided at a lower level of intensity than in

acute inpatient rehabilitation and the level of medical monitoring is less frequent than acute inpatient rehabilitation. There are many programs at this level that specialize in neurorehabilitation and it is certainly preferable if this level of care occurs in programs with special expertise in brain injury management. Specialized neurobehavioral treatment units in SNFs are available in some areas for patients with more persistent behavioral regulation problems.

As noted above, some SNFs may offer specialized care for patients with TBI with prolonged impairments of consciousness. The availability of specialized subacute and SNF facilities may be limited in some areas because of market constraints. Care for the needs of TBI patients in these settings may be costly, exceeding the usual reimbursement standards for this level of care. Alternative funding sources or variance in reimbursement standards may be necessary to maintain more specialized subacute or SNF care.

Often, SNF level rehabilitation care takes place in more general facilities, and frequently younger patients with TBI are in the minority among an older group of patients with other disorders, such as dementia. Lengths of stay at this level of care varies but usually lasts one or more months; a minority of patients transition to unskilled residential levels of care at the same facilities. A large proportion of patients transition home and may go on to outpatient rehabilitation or other outpatient services.

### **Outpatient Rehabilitation**

Outpatient rehabilitation can take on a number of different forms. Sometimes it consists of individual therapies involving physical, occupational and speech therapists. There may be other available services including psychology, neuropsychology and therapeutic recreation. The team may be led by a case manager, and they may provide other coordinated activities such as group treatments. Usually rehabilitation at this level is less coordinated than inpatient treatment and therapists provide care more autonomously. This type of care may occur in the setting of the home through visiting nurse or other agencies, or on the premises of an acute hospital, a rehabilitation hospital, or an outpatient rehabilitation facility.

A more coordinated form of outpatient rehabilitation may take place in a day program, with a full array of therapies, group treatments and group activities, case management, and regular team meetings to set goals and review progress. More holistic programs may include a psychotherapeutic milieu associated with the therapy programming. These programs are often in naturalistic, community settings and take advantage of this location to set up activities to foster community reentry treatment goals.

The length and intensity of treatment is determined by the patient's needs but is largely constrained by health insurance payer contracts and public funding policies limiting duration of care and range of covered services.

Following outpatient rehabilitation, additional community-based services may be provided.

### **Residential Rehabilitation**

Group residence programs may provide services at various stages after injury. These programs may offer individual therapies and group therapies, as well as resources to foster independent living skills. Residential programs may be aimed at patients recently discharged from acute hospital settings or acute inpatient rehabilitation, or those later in the process of recovery who cannot be in their own home setting, and who require a structured, supervised setting and specialized programming cannot be in their own home setting. There are usually only part-time nursing services and programs may or may not provide physician services. Those states with more generous auto insurance benefits tend to have more extensive residential programs. Staffing includes a mix of professional therapists, other professional disciplines, and lay staff. Patients may progress in levels of independence in these setting and go back home or to other long-term living arrangements, such as supported living (see "Other Community-Based Services" below), after this level of care.

### **Vocational Services**

For most persons with TBI, the return to work is the most important long-term rehabilitation goal and measure of treatment success. Returning to some sort of productive activity is an essential part of societal reintegration and life satisfaction after brain injury and an important part of the continuum of care. In the United States, the states receive federal money to operate vocational rehabilitation programs to provide vocational rehabilitation services to individuals with disabilities. Services support reeducation, training and worksite support services. Even those with severe injuries, who may not qualify for regular marketplace jobs, are eligible for services under this mandate. Supported employment has become one of the important vocational rehabilitation strategies for getting persons with disabilities back to employment in regular work sites. These services are most successful when coordinated with outpatient rehabilitative care and assessments. Many of these programs have been underfunded and it has been a problem to provide the intensive ongoing supports that are necessary to keep some persons with TBI employed. Many states have adopted innovative programs to extend funding using resources such as Medicaid waivers to improve services and employment retention (19).

### **Special Education**

Education services are a necessary component of the continuum of care for children and adolescents with TBI.

TBI became a part of the federal Individuals with Disability Education Act in 1990. This federal law mandates that the education needs of school age children with TBI, among other disabilities, will be provided in the public schools and must include any necessary rehabilitation services. Services should be planned and monitored using an individualized educational program (IEP). Students often transition from inpatient or outpatient rehabilitation to school-based services, sometimes beginning with home tutoring. Ylvisaker and colleagues have made a number of recommendations for assessment, intervention, student support, educator training, family support and system flexibility to better serve the particular educational and rehabilitative needs of students after TBI (20).

### **Other Community-Based Services**

Persons with TBI may require other ongoing care and support after formal rehabilitative care has ended. These home and community-based services are more fragmented and less readily available. Patients who are unable to live independently, and who are not relying on home supervision by family or friends, require supported living environments. Previously, because Medicaid has been the primary funder of long-term care, this meant placement in nursing homes, usually a poor alternative for younger persons with TBI. A growing number of states with Medicaid waiver programs have been able to provide supported living services in the community using such models as supervised group homes, foster homes, and personal care attendants. A number of other models have been developed.

Community support networks and support groups for persons with TBI and their families are important resources. One such support network, the Clubhouse Model, adapted for persons with TBI in the 1980s from the psychiatric community, provides a setting for members and volunteers to participate in social, recreational, and work-related activities. It has been a cost-effective method to promote practical, functional living skills. Support groups for persons with TBI and their families are often sponsored by state chapters of the Brain Injury Association of America (BIAA).

Other necessary community services include provisions for transportation for those who are unable to drive or ride public transportation. Respite care to provide time-off for full-time caretakers of persons with severe disability after TBI is another important need. Legal services, financial and estate planning, mental health services, and treatment of substance abuse must also be considered part of community-based system of care for people with TBI.

### **Case Management**

Fragmentation and lack of coordination of care is one of the major problems in finding and applying proper

services for the individual with TBI. Case managers within institutions and in the community play an essential role in coordinating services. Case managers collaborate with others, including patients, families, providers, and payers to assess, plan, implement, coordinate and monitor services to meet an individual's needs and promote favorable outcomes in a cost-effective manner. In addition to coordinating care within the TBI system, case managers must coordinate treatment in other areas such as chronic pain, mental health and other medical specialty areas. Case managers and life care planners may develop proposals outlining the anticipated lifelong care needs of persons with TBI (see Weed and Berens, Chapter 66, on life care planning).

### **SERVICE DELIVERY IN RELATION TO NATURAL HISTORY OF TBI**

Accurate diagnosis and an appreciation of the natural history of TBI are useful in formulating treatment plans and assuring appropriateness of services along the continuum of care. This effort involves assessing a person's brain injury in the context of pathophysiologic damage, associated clinical neurobehavioral syndromes, stage of recovery and anticipated course of recovery, based on knowledge of brain-behavior relationships and natural history (21). The formulation must also consider interaction with non-injury factors such as age and psychosocial issues, associated injuries, premorbid problems, co-morbidities, and later complications.

This understanding helps in determining where the patient is along the path of recovery and in projecting expectations for subsequent recovery to inform treatment planning with respect to treatment setting, treatment strategies, treatment goals, and length of stay. It may also help avoid unnecessary treatment of problems that may be expected to resolve as part of the natural course of recovery (e.g., post-traumatic amnesia or confusional agitation) or impairments with a poor prognosis that may not recover with direct treatment (e.g., amnesia after extensive, bilateral hippocampal injury or behavior dysregulation after massive bilateral orbital prefrontal and temporal polar damage).

Such an understanding of natural history also helps determine when clinical syndromes do not fit the expected path of recovery, suggesting possible secondary neurological complications (e.g. hydrocephalus, chronic subdural hematomas), the influence of noninjury factors (medical, iatrogenic or psychogenic), or misdiagnosis of injury type and severity. The clinical natural history of TBI can be defined in the context of focal or diffuse neuropathologic events. (See Kochenak et al., Chapter 8, for an extended discussion of TBI neuropathology.) The critical pathophysiologic factors are the type, distribution,

severity, and location of these combined neuropathological events after brain injury.

Although focal and diffuse pathological processes are often intermingled and have common secondary and metabolic consequences, it is useful to consider them separately for the purposes of clinical diagnosis. The precision of diagnosis varies and may be challenging, especially with respect to diffuse and secondary injuries, for which there are as yet no readily available, direct clinical, diagnostic probes.

### Diffuse Injury

Diffuse axonal injury represents the main diffuse pathological process, but it is associated with a host of associated pathophysiological phenomena (see Chapter 8). The natural history of diffuse injury is characterized by a recognizable pattern of stages that occur across the wide spectrum of severity. Injury severity determines the duration of recovery stages and levels of impairment at each stage of recovery. These stages can be combined into three principal phases of recovery from the acute to chronic stages:

1. loss of consciousness (LOC);
2. post-traumatic confusion and amnesia (PTA);
3. post-confusional restoration of cognitive function.

These form the basis for the main indices of clinical severity for TBI. These indices can help project a rough approximations for the time course of recovery and the probabilities for a particular outcome (22–26). The three phases of recovery appear to be proportionally related in patients with diffuse injury; each subsequent phase is typically several-fold longer than the previous one (22). Their proportionality in patients with diffuse injury, although variable, can contribute to predicting the time course of recovery. For instance, there was a predictable relationship between the duration of unconsciousness (LOC) and duration of confusion/PTA in a series of patients with diffuse injury defined by a linear regression model that predicted nearly 60% of the variance —  $PTA (wks) = 0.4 \times LOC (days) + 3.6$  (22). This model was confirmed in a separate cohort of 228 patients (27). Longer PTA was observed in older patients, especially over age 40, or if a focal frontal lesion was present. Predicting PTA may aid rehabilitative treatment planning with respect to length of stay decisions, treatment choices for confusional agitation, and other treatment issues at this stage of recovery.

Patients with the least severe diffuse injuries (mild concussion) evolve through LOC (if complete loss of consciousness occurs at all) in seconds to minutes and through PTA usually in minutes to hours, followed by a post-confusional phase typically lasting days to weeks. In

mild TBI the transition through the earliest stages may be brief, unwitnessed, and difficult to document. Patients with severe TBI may require days to weeks to evolve through LOC, weeks to months to resolve confusion and PTA, and months to years to evolve through the post-confusional residual recovery phase. The course of recovery after severe TBI is among the longest observed after neurological damage. Dynamic changes in neuropsychological functioning have been observed as long as 5 years post-injury (28–31). Some patients with very severe injuries may stall in recovery at some stage in this process (e.g., permanent vegetative state (32) or minimally conscious state (33).

This pattern of recovery has been delineated in stages according to various schemas. The most widely used is the Rancho Los Amigos levels of cognitive functioning (34). (See Table 1-1.) Another schema, first proposed by Alexander (35) and further modified (referred to as the Braintree scale) (21, 36), follows more traditional neurological nomenclature. (See Table 1-2.) As patients progress through these stages the principal defining cognitive limitations evolve from deficits in arousal and consciousness, to basic attention and anterograde amnesia, to higher-level attention, memory, executive functioning, processing speed, insight, and social awareness (37).

The first stage of recovery is *coma*, a state of unconsciousness without spontaneous eye opening. This corresponds to Rancho level I. Patients with diffuse axonal injury are unconscious at the outset, without lucid interval. The depth of coma in the time period shortly after injury, as measured by the Glasgow Coma Scale (GCS), is one of the common markers of injury severity and prognosis.

Almost all persons with severe TBI who survive resume spontaneous eye opening and sleep/wake cycles while still unconscious, a condition termed a *vegetative state* or Rancho level II. Except for the small percentage of very severely injured patients who remain permanently vegetative, evidence of awareness and purposeful behavior resume, often heralded by visual fixation and tracking. The ability to follow commands is the usual convincing

*Rancho Los Amigo Levels of Cognitive Functioning After TBI (34)*

I.	No response
II.	Generalized responses
III.	Localized responses
IV.	Confused – agitated
V.	Confused – inappropriate
VI.	Confused – appropriate
VII.	Automatic – appropriate
VIII.	Purposeful and appropriate

**TABLE 1-2**  
***Braintree Neurologic Stages of Recovery from Diffuse TBI (and corresponding Rancho Los Amigos Scale Levels) [settings of care]***

1. *Coma*: unresponsive, eyes closed, no sign of wakefulness (Rancho 1) [emergency medical services; acute inpatient hospital]
2. *Vegetative state/wakeful unconsciousness*: no cognitive awareness; gross wakefulness, sleep-wake cycles begin (Rancho 2) [acute hospital; acute inpatient rehabilitation; subacute rehabilitation]
3. *Minimally conscious state*: inconsistent, simple purposeful behavior, inconsistent response to commands begin; often mute (Rancho 3) [acute hospital; acute inpatient rehabilitation; subacute rehabilitation]
4. *Confusional state*: interactive communication and appropriate object use begin; amnesic (PTA), severe basic attentional deficits, hypokinetic or agitated, labile behavior; later, more appropriate goal-directed behavior with continuing anterograde amnesia (Rancho 4, 5, partly 6) [acute hospital; acute inpatient rehabilitation]
5. *Post-confusional/emerging independence*: marked by resolution of PTA; cognitive impairments in higher-level attention, memory retrieval and executive functioning; deficits in self-awareness, social awareness, behavioral and emotional regulation; achieving functional independence in daily self care, improving social interaction; developing independence at home (Rancho 6 & partly 7) [acute inpatient rehabilitation; subacute inpatient rehabilitation; outpatient rehabilitation; residential treatment; outpatient day hospital and community reentry]
6. *Social competence/community reentry*: marked by resumption of basic household independence; developing independence in community, household management skills and later returning to academic or vocational pursuits; recovering higher level cognitive abilities (divided attention, cognitive speed, executive functioning), self-awareness, social skills; developing effective adaptation and compensation for residual problems (Rancho 7& 8) [outpatient community reentry programs; community-based services – vocational; special education; supported living services; mental health services]

marker of restored consciousness. Almost all patients with some loss of consciousness will be evaluated and treated by emergency medical services. Those with brief alterations of consciousness (e.g., seconds or minutes) may be discharged home. Patients with more prolonged LOC or more complicated injuries (e.g., focal lesions, other injuries) will likely be admitted for acute inpatient care, often beginning in surgical intensive care units, usually supervised by neurosurgical or surgical trauma specialists.

For patients recovering slowly, cognitive responsiveness may begin erratically and inconsistently, without any reliable interactive communication. This stage may be called a *minimally conscious state* and corresponds to Rancho level III (33). Many patients at this stage will continue in acute medical care settings and some who are slower to recover will transition to rehabilitation facilities, including acute inpatient rehabilitation, subacute rehabilitation, long-term care hospitals or skilled nursing facilities. (See also Chapter 25 on disorders of consciousness.)

When purposeful cognition is unequivocally established, basic attention and new learning remain severely impaired. This clinical condition may be labeled a *confusional state* and corresponds to Rancho levels IV, V, and part of VI. At this stage, patients are often highly distractible, with poorly regulated behavior. They may rapidly escalate to agitated behavior (Rancho IV). Less often, patients may remain in a state of underactivated, hypokinetic, withdrawn behavior. Dense anterograde

amnesia also defines this stage; patients are disoriented, have little or no moment-to-moment episodic recall and display little or no ability to learn new information after even a brief delay (posttraumatic amnesia). As this stage evolves, patients are better able to focus attention and regulate behavior (Rancho V). The end of this stage is characterized by a significant improvement in focused and sustained attention, reliable orientation, and resumption of continuous, day-to-day memory, albeit still somewhat defective (Rancho VI). Patients at this period of recovery are appropriate for care in dedicated TBI units in acute inpatient rehabilitation. Towards the end of this period of recovery, transition to home and outpatient rehabilitation programs should be contemplated. Patients who are transitioning slowly, or who still require significant amounts of supervision and assistance that may not be feasible at home, may require continued institutional treatment, perhaps at a skilled nursing facility or a residential treatment facility. Some may transition to an outpatient day program.

The *post-confusional* stages of recovery are characterized by a gradual improvement in cognitive and behavioral functioning in those with more severe injuries. This phase of recovery may be further broken into stages of *emerging independence*, as patients' cognitive abilities, self-awareness, and insight allow independence in self-care and safe unsupervised activity at home (Rancho level VII), and a stage of *social competence and community reentry*, with restoration of the capacity for independent function in the community or at the higher-level demands

of school or the workplace (Rancho level VIII). Services at these stages of care include outpatient therapies, day programs, community-reentry programs, residential treatment, and a variety of community-based services.

### Focal Injury

Focal cortical contusions, deep cerebral hemorrhages, and extraaxial (subdural and epidural) hemorrhages make up the majority of focal lesions after TBI. The time course of natural history of focal injury resembles that of vascular lesions of other causes, particularly hemorrhagic stroke, but the clinical consequences of focal injury after TBI are characteristic, owing to the predilection of lesions in the anterior and inferior portions of the frontal and temporal lobes. The acute phase involves edema and other early secondary pathophysiological phenomena which are maximal over the first few days post-injury. The resulting effects may include confusion and, perhaps, decreased arousal, especially if a mass effect compromises diencephalic and mesencephalic structures. Otherwise primary focal pathology is not directly associated with loss of consciousness.

As edema and other secondary effects wane over the first three weeks, more specific localizing effects of focal damage become more apparent. Recovery during this subacute phase is maximal over the first 3 months, but improvement may continue at a slower rate over many months. The size and depth of focal lesions, their laterality and the potential for reorganization within the neural networks affected by the damage, all in large part determine the time course and outcome.

Damage to limbic neocortical and heteromodal areas of the frontal and temporal lobes determines the usual effects of focal TBI on cognitive and behavioral functioning. The residual syndromes of prefrontal lesions include alterations in affect and behavior (e.g., disinhibition or apathy) impairment in attention, working memory and memory retrieval, and dysfunctional higher-level cognition (e.g., executive functions, insight, social awareness). Lesions in anterior and inferior temporal areas may also contribute to affective and behavioral disturbances. Larger lesions extending to medial temporal areas may produce specific impairments in memory encoding and retrieval (amnesia). Other localizing temporal syndromes involve extension of lesions into auditory association areas (e.g., aphasia, with left hemisphere lesions) and visual association areas (e.g., visual agnosias, especially with bilateral lesions).

The clinical syndromes associated with focal lesions are often embedded in the evolving effects of diffuse injury, if both types of injury are combined. Particularly with more severe and diffuse injuries, the overall outcome is driven largely by the effects of diffuse rather than focal injury (38). In patients with mild to moderate diffuse injury, large focal lesions may have more influence on recovery (39–41). Characterization of the localizing

syndromes associated with focal lesions may be difficult until unmasked after resolution of post-traumatic confusion. Another difficulty in isolating the effects of focal lesions is that neurobehavioral syndromes may be identical to those related to diffuse injury (e.g., dysexecutive syndrome, behavioral dysregulation) because these same areas, especially their axonal projections, are affected by diffuse pathology (42).

Although the problems may be similar, recovery and prognosis may be different. For instance, features of the frontal lobe syndrome, may be more persistent in patients with frontal contusion (43, 44). Levin et al. (45) observed that although other aspects of recovery were similar, unilateral frontal lesions adversely affect psychosocial outcome in children with TBI compared to those without focal frontal lesions. These aspects of diagnosis and prognosis related to focal lesions should also help inform rehabilitation planning. For example, behavioral regulation problems related to bilateral frontal and temporal focal lesions may be more persistent and thus demand more active early intervention and treatment planning over a longer horizon than similar problems that might occur after diffuse injury, which may be expected to resolve more successfully as the stages of recovery evolve.

### SUMMARY AND CONCLUSIONS

The provision of a continuum of care for persons with TBI is an enormous challenge given the numbers of people affected by the disorder (patients, family members, and others), the potential long-term course of recovery, the possible life-long effects (often beginning at an earlier stage of life), and the wide variety of types of brain damage, clinical effects, and associated problems. Systems of care for TBI involve coordination of numerous services utilizing many disciplines across the range of severities and course of recovery. These services include prevention; emergency, acute, early, and later rehabilitation; vocational, educational, and community support; and long-term care. A number of marketplace factors constrain the full development and availability of components of these systems for persons in need, most notably cost, payer support, and availability of resources. These constraints become progressively restrictive for services and supports beyond the acute treatment period.

An understanding of brain injury, its clinical consequences, associated problems and complications, and natural history of recovery helps in applying proper services for patients along the continuum of care, and helps assure more effective use of resources. Ongoing efforts at fruitful research to determine which interventions are most effective, for whom, and at what periods of time, will be essential to refine the best clinical practices possible along the continuum of care.

## Brain Injury Rehabilitation: Past, Present, and Future?

*George A. Zitnay*

The ways that persons with disabilities have been viewed by society have changed significantly over the years, due mainly to economic, cultural, religious, and scientific influences. In most cultures, both in ancient and in earlier modern times, persons with a disability were negatively valued. Wolf Wolfensburger (1972) noted that historically persons with disability have been viewed as deviant. In ancient Greece and Rome, among Eskimos, and in Nazi Germany infanticide, abandonment, and extermination have been practiced on those perceived as deviant. Even in the United States, the U.S. Supreme Court upheld the states' right to sterilize persons with mental disability. Chief Justice Holmes declared "It is better for all the world, if instead of waiting to execute degenerate offspring for crime, or to let them starve for their imbecility, society can prevent those who are manifestly unfit from continuing their kind. [Three] generations of imbeciles are enough." *Buck v. Bell*, 274 U.S. 200 (1927).

Since earliest colonial times in America, persons with disabilities have been treated as offensive and frightening. Removal from society has been the way these individuals have been dealt with. During the Industrial Revolution, however, a degree of humanitarianism began to creep into the mainstream views of society as the incidence of occupational injuries increased. This was fueled by increasing public awareness about the issues of child labor, poor working conditions, and the large and growing number

of persons sustaining occupational injuries that left them with permanent disability. During World War I, the public concern over the large number of injured soldiers without means of support spurred on the creation of federal rehabilitation policies for military personnel.

Early pioneers in the emerging field of rehabilitation included Thomas Hopkins Galludet, who brought manual communication to Americans with speech and hearing impairments; Louis Braille, who developed a touch system for reading; Dorothea Dix, who championed the creation of asylums (mental hospitals) so that mentally ill persons would not be held in prisons; Edgar James Elms, who founded Goodwill Industries; Fred Albee, who provided rehabilitation services at his Reconstruction Hospital to return veterans with disabilities to useful civilian life; and many others such as Harvey Wilbur, Samuel Gridley Howe, and Jeremiah Milbank (1).

At the close of the nineteenth century, government responsibility to those with disabilities began to emerge. In 1910, the first workers compensation laws were passed because of industrial injuries; the National Defense Act of 1916 created the authority to assist soldiers in reentering civilian life by providing training in agriculture or mechanical arts (2). The Smith–Hughes Act of 1917 provided states with federal funds, to create vocational education programs, and the Soldiers Rehabilitation Act of 1918 authorized the development of vocational rehabilitation to veterans with disabilities. Two years later,

the Act was extended to civilians (2). It was during these times that John Coulter, MD, established the first program in physical medicine at Northwestern University Medical School (1).

The next most significant public policy change occurred as a result of the Depression. With millions of Americans out of work, the Roosevelt Administration enacted the Social Security Act in 1935. The Act addressed the problems of unemployment, old age, poverty, and blindness. It also made vocational rehabilitation a permanent federal program (3).

World War II made a huge difference in the ways in which Americans perceived persons with disability, but also led to the formalization of physical medicine and rehabilitation as a medical specialty. Dr. Howard Kessler was a strong advocate of rehabilitation of veterans. He introduced the concept of a comprehensive medical-social-psychological-vocational approach to disability. It was during this time that Howard Rush, MD, a colonel in the U.S. Air Force, demonstrated the effectiveness of physical medicine with injured pilots. After World War II, when rehabilitation began to falter, Howard Kessler and Howard Rush persisted. The result was that the American Medical Association created a specialty board on physical medicine in 1944 (1).

The post-war expansion saw the growth of the federal government's role in rehabilitation. The Vocational Rehabilitation Amendments of 1954 forged a partnership between public and private organizations, including a federally assisted research program, and the training of professionals to staff public and private rehabilitation programs. The amendments authorized the construction of rehabilitation facilities. During this time, Mary Switzer served as the Federal Director of the Vocational Rehabilitation Department. She led the department until her retirement in 1970 (4).

During the 1960s and 1970s, there was a shift in focus from rehabilitation and disability program expansion to disability rights. Independent living, the concept of normalization, community-based rehabilitation, class action suits, and personal advocacy grew into a movement (5).

Looking back on the history of rehabilitation, we see the emergence of neurorehabilitation of persons with head injury. Howard Rush began providing neurorehabilitation to pilots injured in World War II, and he and Howard Kessler included psychosocial and psychological services as part of a comprehensive rehabilitation program. The early treatment of head injuries was also influenced by the discovery of new drugs. These psychopharmacological discoveries included lithium in 1949, chlorpromazine in 1952, the discovery of the antidepressant properties of iproniazid and imipramine in 1957 and the introduction of chlor-diazepoxide in 1960. Neuropsychiatry began to show interest in patients with neurobehavioral problems following head injury. It wasn't until the 1970s, however, that what

is looked upon as the era of "head injury rehabilitation" began.

Many efforts emerged to address the needs of persons with disability. The Rehabilitation Act of 1973 (29 U.S.C. 780, et. seq.), which focused primarily on vocational rehabilitation, also established the National Council on Disability (NCD), an independent federal agency with 15 members appointed by the president and confirmed by the Senate. The NCD later to recommend to Congress that a civil rights law be enacted that was specific to persons with disability.

The Vietnam War made its mark on the history of disability rehabilitation as better medicine and the use of medevac helicopters resulted in soldiers surviving injuries they had not in earlier times.

One of the markers of the new era in brain injury rehabilitation was the development of the Glasgow Coma Scale and the Glasgow Outcome Scale by Graham Teasdale and Bryan Jennett (Lancet, 1974, 1975). This standardized method for assessing the severity of injury and predicting long-term outcomes following traumatic brain injury helped to make improvements in acute care and pushed brain injury rehabilitation to the forefront. Sheldon Berrol, Leonard Diller, and Yehuda Ben Yishay were pioneers in innovative rehabilitation, treatment, and organized research programs. This marked the beginning of patients being referred to specialized brain injury rehabilitation centers rather than being sent to nursing homes (6). According to Mitchell Rosenthal, this paradigm shift in care of persons with TBI occurred between 1975 and 1997. Soon, for-profit rehabilitation programs sprang up, and within five years (1980–1984) the number of TBI rehabilitation programs grew from approximately 10 to 500 (6). During this same time period the continuum of care expanded substantially to include day treatment, home programs, transitional living, residential care, behavior management, life care planning, vocational rehabilitation, independent living, coma stimulation programs, and support groups. Neuropsychological assessment, cognitive rehabilitation, computers, and other electronic devices for memory, attention, and organization were used in the treatment of many of the sequelae of TBI.

In April 1980, Marilyn and Martin Spivak hosted the first meeting of what was to become the National Head Injury Foundation (NHIF) at their home in Massachusetts. The purpose of the meeting was to discuss forming an organization to serve people who had survived TBI. During that year, a Board of Directors was selected and NHIF was incorporated as a not-for-profit organization. The founding goals have relevance even to this day. The goals of the NHIF were as follows:

- To stimulate public and professional awareness of the problem of head injury—the silent epidemic.

- To make the public aware of the nature and causes of head injury and the necessary steps that need to be taken to prevent them.
- To provide a central clearinghouse for information and resources for individuals with head injury and their families.
- To provide these individuals and their families with necessary information and support during and after crisis.
- To develop a support group network for both individuals with head injury and their families.
- To establish and promote specialized head injury rehabilitation programs.
- To help educate healthcare professionals about the unique needs of individuals with head injury.
- To advocate for increased research funding and more appropriate care for individuals with brain injury.

Later, in 1983 the goal of prevention was added.

It was during this time that the consumer movement in TBI really took hold. The establishment of NHIF chapters across the country helped to fuel this movement. The NHIF moved from Massachusetts to Washington, DC, to begin a new era of expansion. Soon the name was changed to the Brain Injury Association (BIA). While BIA was expanding into research and public policy, George A. Zitnay and Martin B. Foil, Jr., founded a new international organization in 1991. The International Brain Injury Association (IBIA) rapidly grew with the support of the World Health Organization (WHO). IBIA became a leader in multidisciplinary and interdisciplinary training and treatment with the establishment of the World Congress on Brain Injury, which has since been held in Denmark, Spain, Canada, Italy, and Sweden.

During the 1980s, with the increasing interest by professionals in brain injury rehabilitation, the American Congress of Rehabilitation Medicine created the Head Injury Interdisciplinary Special Interest Group (HI-ISIG). In the late 1980s two journals, *Brain Injury* and the *Journal of Head Trauma Rehabilitation*, began publishing, greatly expanding the scientific literature in TBI (6).

The 1980s were a tumultuous time for brain injury rehabilitation. In the early part of the decade, there was a huge increase in the development of for-profit rehabilitation programs aimed at attracting the families of persons with brain injury that had insurance, court settlements, or the ability to pay. Glossy brochures were published. Recruitment techniques included flying in whole families by private jet to visit programs. Facilities looked terrific. And executives were well paid. Some call this the “golden age.” But others, particularly persons with brain injury, called it a time of shame.

In 1985, standards of care for brain injury rehabilitation were adopted by the Commission on Accreditation

of Rehabilitation Facilities (CARF). These standards resulted from the work of the HI-ISIG. A milestone in brain injury rehabilitation was reached in 1987 when the U.S. Department of Education’s National Institute on Disability and Rehabilitation Research funded five traumatic brain injury model systems of care (Thomas, 1988).

The 1980s can now be classified as a period of ups and downs, growth, investigation of fraud, decline, and then re-emergence as the decade closed with a period of downsizing, buyouts, closures, and finally settling into a period during which insurance companies questioned the value of rehabilitation and limited the amount and time for rehabilitation services. Emphasis was placed on home treatment, community-based rehabilitation, day services, independent living, and advocacy. By 2003, additional federal funding had expanded the program to include 16 participating sites throughout the United States.

In 1990, the Americans with Disabilities Act (ADA) was passed and signed into law by President George H. Bush. The Act proclaims that participation in the mainstream of daily life is the right of all Americans and calls for accommodation in housing and public spaces. The ADA was intended to foster independence and integration, affording persons with disability protection from antidiscrimination.

As important as the ADA was for antidiscrimination protection, however, it did not address many of the most pressing needs of persons with brain injury, such as assistance with access to appropriate care and rehabilitation. The ADA acknowledges that it is not so much the disability per se that makes life difficult for a person with a disability, but rather the way society responds to that disability. According to Justin Dart, the ADA seeks to change the status of people with disabilities by expecting a more enlightened attitude toward them. It rejects the long-standing and outmoded view of people with disabilities as being helpless and pitiful, and the primary role of the government as a charitable one—to take care of them through the provision of special programs and services. The ADA asserts that people with disabilities are full citizens who rightfully claim equal access and full participation, and that the role of government is to facilitate and support such claims (9).

The primary requirement of the ADA is the prohibition of discrimination. Antidiscrimination requirements for people with disabilities may be considered to have two central aspects: The first is that of not being treated in a prejudicial manner because of an individual, and often immutable, characteristic that has no bearing on the individual’s skills or capabilities. The second requires paying particular attention to the individual’s characteristics (e.g., race, sex, age or religion) to use the interaction between the individual and society to ameliorate or end the limitation or exclusion to equal access (10).

To focus greater attention on the wide spectrum of needs specific to persons with brain injury, BIA, under the direction of George A. Zitnay and with the help and support of Senator Edward Kennedy (D-MA), Senator Orrin Hatch (R-UT) and Congressman Jim Greenwood (R-PA), began work on writing the Traumatic Brain Injury (TBI) Act. Persons with brain injury provided leadership and input in the creation and passage of the TBI Act, including Sherrie Watson, Jean Ann McLaughlin, Maureen Campbell-Korves, Patsy Cannon, Gary Busey, and Marvel Vena. The TBI Act was signed into law by President Bill Clinton in 1996 (P.L. 104-166).

The TBI Act was the first federal law specifically for persons with brain injury. The law specifically established a federal grant program for states to create TBI Advisory Boards, conduct planning and assess the needs assessments of persons with TBI in order to improve access to services. The law directed the Centers of Disease Control and Prevention (CDC) to perform incidence and prevalence studies and establish educational and public awareness programs. The Act also required the National Institute of Child Health and Human Development of the federal National Institutes of Health to hold a consensus conference on the rehabilitation of persons with TBI. In 1998, an international panel of experts convened a conference, reaching a consensus that more research was needed on TBI rehabilitation.

The reauthorization of the TBI Act in 2000 (P.L. 106-310), included an expansion of the CDC's work with state registries to collect information that would help improve service delivery, expand incidence and prevalence studies to include persons of all ages as well as those in institutional settings and efforts to capture data on mild TBI. The new law also directed states to enhance "community-based service delivery systems that include timely access to comprehensive appropriate services and supports" as well as additional funding for the national Protection and Advocacy Systems to provide legal resources specifically for persons with TBI,

In 1999, the U.S. Supreme Court decision in *Olmstead v. L.C.* (527 U.S. 581), made a significant contribution to the movement toward community-based services. The court found that states are obligated under the ADA to provide appropriate settings for persons with disabilities in the "least restrictive environment." The court also found it to be discriminatory on the basis of disability for the state of Georgia to disallow the plaintiffs (persons with disabilities) to live in state-funded assisted living rather than the mental institution.

By the early part of the twenty-first century, various federal agencies were involved in brain injury research. The breadth of the federal government's commitment to furthering the science of TBI incidence and to improving rehabilitation increased. Federal efforts spanned from

prevention through education under the CDC, to biomechanics research funded by the U.S. Department of Transportation, to battlefield studies and helmet studies by the U.S. Department of Defense, to 6 bench science research centers funded by the National Institute on Neurological Disorders and Stroke at NIH, to a Cooperative Multi Clinical Trials network of 8 sites funded by the National Center on Medical Rehabilitation Research at NIH, and 16 TBI Model Systems of Care funded by the U.S. Department of Education's National Institute on Disability Rehabilitation Research.

Finally, the late 1990s and early 2000s have come to be seen as a period of cost reduction, accountability, managed care, and the closing or merging of many programs in TBI rehabilitation. Length of stay, payment, and reimbursement have become real problems. While states have sought reimbursement solutions through waivers in the federal-state Medicaid program, the Medicare program—as the largest health insurer in the nation—has not kept up with medical advances and civil rights and expectations for recovery in its reimbursements to hospitals, nursing homes, and particularly specialized brain injury facilities.

The move toward empowering persons with disabilities has led to greater expectations for quality of life and consequently, greater efforts at finding innovative rehabilitation techniques and programs. This, combined with a better understanding of how the brain can heal, has helped shape the evolution of TBI rehabilitation.

Outcomes, evidence-based practice guidelines for management of acute care, penetrating head injury, and neurobehavioral sequelae of TBI have been developed by the Neurotrauma Foundation (NTF) and the National Brain Injury Research, Treatment, and Training Foundation (NBIRTT). This is in response to the need for accountability and improvement in quality of life. Currently an international group of rehabilitation specialists under the leadership of NBIRTT is working to create a new assessment tool to measure quality of life for persons with TBI. The QOLIBRI is currently being field-tested and will soon be available for widespread distribution.

To close this historical chapter, it is important to mention that research into new pharmacological agents, stem cells, and proteomics offer new hope for improving outcomes in rehabilitation.

What is the future of rehabilitation? Traditionally, rehabilitation has been a reactive rather than proactive profession. Rehabilitation education and similar activities have been based on past experience, often with little thought given to future needs. There is agreement in rehabilitation that several issues will profoundly affect the future. Those issues include changes in the nature of work in the United States; growing diversity in the workforce;

changes in the nature of disability; advances in rehabilitation and medical technology; and alterations in the nature of strategies of service delivery.

Constant changes in rehabilitation can be predicted with certainty. History suggests that rehabilitation practitioners, especially those working in brain injury, will continue to face budget cutbacks, resulting in staffing shortages, growing caseloads and changes in the structure and function of the rehabilitation system. To respond, the field must become proactive. This will involve networking with other rehabilitation professionals, facilities, agencies and consumers. There is and will continue to be a need to deliver efficient and effective rehabilitation services that can be measured and evaluated. Finally, we must continue to provide for continuous learning and education of professionals, consumers and policy makers.” (14)

## International Perspectives on TBI Rehabilitation

*Zeev Groswasser*  
*Ofer Keren*

### INTRODUCTION

Craniocerebral trauma has been linked historically with assault and war. Treatment of craniocerebral injuries by trephination was first described in the Edwin Smith surgical papyrus and by Hippocratic physicians. Some patients actually survived the trauma of the trephination, but most died. Over the years, the concept of cerebral compression by hemorrhage, originally described by Arabian physicians, gained recognition and eventually led to recognition of the need for decompression. Cushing (1) used meticulous debridement of penetrating brain injuries, which reduced mortality by 50 percent and resulted in a normal life expectancy for survivors. The introduction of antimicrobial and antibiotic agents, and the recognition that rapid intervention by trained neurosurgeons immensely decreased mortality from penetrating craniocerebral trauma, have both resulted in higher survival rates for patients.

Changes in lifestyle during the last century, especially the introduction of automobiles, became a major source for craniocerebral trauma. In motor vehicle accidents (MVA), brain injury is the cause of death in over 70 percent of fatal cases (2).

### THE MODERN ERA OF TBI REHABILITATION

Interest in traumatic brain injury (TBI) has risen greatly since World War II. The number of publications devoted

to what was then called “craniocerebral trauma” saw a threefold increase in the years 1956–1966 (3) and the topic has attracted increasing attention in national and international neurology and neurological surgery conferences. In the United States, the National Institute of Neurological Diseases and Blindness first designated craniocerebral trauma as a major topic of interest in October 1964. This paved the way for one of the first comprehensive conferences for the study of craniocerebral trauma that took place at the University of Chicago in 1966. The planning committee of that conference, chaired by Dr. Caveness, included neurosurgeons, neurologists, physiologists, and engineers, but no psychologists or physicians working in rehabilitation.

The translation from Russian into English of the works of A.K. Luria, *Human Brain and Psychological Processes* published in 1966 (4) and *The Working Brain*, first published in 1973, (5) led to rapid development of the field of neuropsychology, which plays a key role in the assessment and treatment of TBI patients today. In the last 20 years, TBI has become the accepted term for traumatic brain damage, and terms such as “craniocerebral trauma,” used above, have disappeared altogether from the recent literature.

In the last 150 years, the structure/function relationship has provided one of the most intriguing research topics in the neurosciences. The localistic theories that emerged from the early studies of Broca and Wernicke in

the nineteenth century were replaced in the 1930s by the holistic theory. Brain function and organization remained at center of interest, and in recent years current theories stress the dynamic aspects of brain function at the expense of the localistic or holistic approaches. The crucial role of the prefrontal cortex in human behavior has since gained increased recognition in modern neuropsychology. Historical illustrative case reports such as the case of Phineas Gage (first described in 1842) have become common knowledge (6).

Digital diagnostic brain imaging techniques introduced in the early 1970s in the form of computed tomography (CT), followed by magnetic resonance imaging (MRI), and in recent years by fMRI, PET, and SPECT have further promoted interest and research in the structure/function relationship following brain damage.

Tools developed in the field of neuropsychology have enabled a better assessment of cognitive deficits following TBI, which in turn has promoted various intervention processes designed to remedy the patients' cognitive deficits. It has become clear that the recovery processes may take longer than initially thought.

The drive to rehabilitate war veterans, probably driven by the feelings of guilt held by societies, exerted a profound effect on the rehabilitation of TBI patients. The basics of TBI rehabilitation were laid down in post-World War I Germany by K. Goldstein, who designed a center that included—in addition to the hospital—a psychology laboratory, a school, and later a vocational rehabilitation center, all for the purpose of providing comprehensive treatment (7). Goldstein evidently regarded the assessment of residual work potential and the prediction of vocational outcome as parts of the rehabilitation process (7). This type of rehabilitation approach was abolished altogether in 1933 after the Nazi takeover, especially because most of the leading physicians in these centers were Jewish. Goldstein himself left for the United States but did not pursue this line of work, described in his book *After-Effects of Brain Injuries in War*, which was published in 1942 (7). On the one hand, the state of rehabilitation in the United States at that time, and on the other hand the fact that Goldstein's main interest was aphasia and related disorders, created an atmosphere that hindered further progress along the original lines traced by Goldstein. It is noteworthy that the role of memory and attentional deficits as key sequelae influencing outcome following TBI became evident in the years after World War II.

It took almost 40 years for similar ideas regarding TBI rehabilitation to emerge, again because of war. The "Six-Day War" in 1967 and more so the "Yom Kippur War" in 1973 created the need and played the decisive role in the establishment, in December 1973, of the special medical unit devoted to TBI rehabilitation at the Loewenstein Rehabilitation Hospital (LRH) in Israel (8). TBI patients had been treated at LRH since the early

1960s. But it is worth noting that many of these patients were at that time still referred to mental hospitals because of severe behavioral deficits that may have dominated their condition.

The comprehensive model of treatment developed at LRH can be described as "Coma to Community" (Figure 3-1). It is a model of treatment that can be adopted easily by other countries. As a small country, Israel enjoys certain advantages in this respect because one center, located at the geographical center of the country, can serve the entire population. Patients with TBI had been admitted to LRH since the early 1960s, so it was a natural choice as the national center for TBI rehabilitation after the Yom Kippur War. After the war, patients with severe TBI from the civilian population, as well as victims of motor vehicle accidents (MVA) and work accidents, were referred almost exclusively to LRH. TBI patients in Israel have almost universal access to in-patient rehabilitation services. Victims of road accidents are almost always insured, while work accidents and other minor causes of TBI are covered by

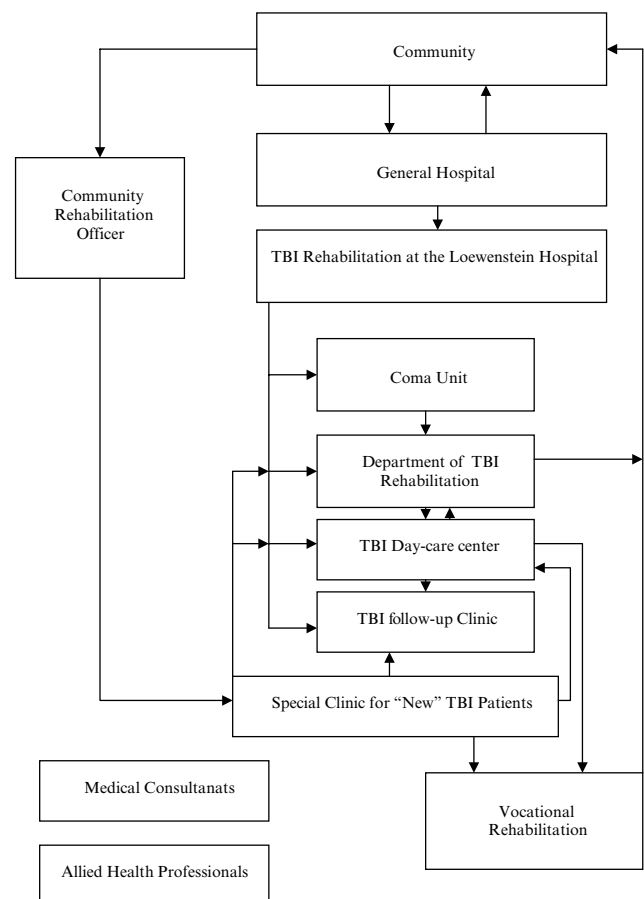

FIGURE 3-1

The LRH comprehensive "Coma to Community" TBI rehabilitation service

the “sick funds.” The establishment of a large rehabilitation center that serves almost all severe TBI patients in Israel has enabled the creation of a critical mass of knowledge regarding treatment and outcome, which was of utmost importance in the early years of modern TBI rehabilitation, before the existence of specialty conferences and journals devoted to this subject.

The LRH “Coma to Community” system provides inpatient rehabilitation facilities for about 220 severe TBI patients a year. The fact that patients are treated in a rehabilitation setting from an early stage has a beneficial effect on outcome (9–11). The out-patient program at LRH ensures continuity of care and prevents misunderstandings that often happen when patients change their place of treatment. The LRH experience suggests that large regional rehabilitation centers for TBI rehabilitation can provide a continuum of care that meets the changing needs of patients and is effective for both patients and healthcare providers. This model helps contain cost while building and maintaining trust with patients and healthcare providers alike.

### Conferences

In the early 1970s, increasing interest in TBI rehabilitation encouraged an international exchange of ideas on this topic, especially because few books or journals were devoted to the subject at that time. The Glasgow Coma Scale (GCS), first published in 1974 by Teasdale and Jennett, exerted a strong influence on research of the effects following TBI by providing a reliable score that could be used to judge the initial severity of injury (12). This made it possible to recruit large numbers of patients for outcome studies, sometimes from several centers, and to compare various methods of treatment (13–15).

Several meetings on TBI research had been organized in the 1960s in the United States, but the first meeting in Europe regarding TBI rehabilitation was organized by Prof. Ö. Höök in Oslo in 1974. Some conferences became annual meetings such as the Williamsburg Annual Meeting and the Braintree Annual Traumatic Head injury Conference. The IX World Congress of Rehabilitation International took place in Israel in 1976. As a result of the involvement of the Loewenstein Rehabilitation Hospital staff, the local scientific committee included in the program a workshop on patients with brain injury. Since then, TBI rehabilitation has become a regular part of most, if not all, international conferences in rehabilitation medicine.

The foundation by Henry H. Stonnington of the International Association for the Study of Traumatic Brain Injury (IASTBI) spearheaded both research and collegial interchange among the international brain injury community. Subsequently, George Zitnay founded the International Brain Injury Association (IBIA). Due to the efforts of Nathan Zasler, Henry Stonnington, and

George Zitnay, these two organizations eventually merged, initially with IBIA becoming the scientific arm of IASTBI. Over time, the IASTBI was simply folded into the IBIA organization, and its members were fully integrated within the latter organization. The IBIA continues to sponsor and plan a biannual international conference devoted to TBI. At these international meetings, experts as well as newcomers to the field meet each other, exchange formal and informal information, and help in the dissemination of information for the benefit of patients with TBI. In countries like the United States, it is not uncommon to have state TBI conferences performing similar functions, but on a smaller, local scale.

### Journals

Research regarding TBI developed along two main lines. The first and more established line dealt with the acute phase. This was pursued primarily by neurosurgeons caring for patients in the early phase. These researchers already had established journals where they could publish their findings. Long-term care, which developed rapidly after the 1970s, posed different questions and research problems. Some peer reviewers described these problems as being of “limited interest,” as described in editorial letters rejecting research findings and manuscripts regarding late sequelae of TBI. This situation led to the creation of special-interest groups such as IASTBI and IBIA, and also to the foundation of journals devoted entirely to TBI studies, such as *Brain Injury* and *The Journal of Head Trauma Rehabilitation*.

Recognition that the number of TBI patients in the community was growing and that rehabilitation techniques could improve a patient’s condition beyond the course of natural recovery, helped to get data regarding TBI published in more general journals in medicine and neurology. In the Editorial of the first issue of *Brain Injury*, in 1987, McKinlay and Pentland wrote: “It is a commonplace that 15 or 20 years ago there was little interest in head injury, and only a small literature addressing the acute and long-term problems it presents. Nowadays there is an extensive literature ranging through epidemiology, pathophysiology, acute management, and rehabilitation, and *Brain Injury* is an expression of that greatly increased interest” (16). Other journals that take an interest in TBI, to mention but a few, are the *Journal of Neurotrauma*, *NeuroRehabilitation*, *Neurorehabilitation & Neural Repair*, and *Neuropsychological Rehabilitation*. The number of citations relevant to traumatic brain injury between the years 1988 and 1998 was 2563 (17).

### Organizations

The increased interest in TBI, the growing number of people working in the field, and the belief that patients with

TBI present problems that are not well understood or treated by the general medical community, have created a genuine need for a “meeting place” for those involved in clinical care of these individuals. Professionals from various countries were involved in the foundation of IASTBI in the mid-1980s. As previously noted, an important role was played by the staff of the Department of Physical Medicine and Rehabilitation, Medical College of Virginia Hospital, Virginia Commonwealth University, from Richmond VA, headed by Henry H. Stonnington, who acted as the first chairperson of IASTBI and was also the first Editor-in-Chief of *Brain Injury* from 1987 to 2000. Subsequently, Jeffrey Kreutzer and Nathan Zasler were named co-editors of this journal.

### **TBI Support Groups**

#### *The Rationale for Support Groups for Post-TBI Patients*

The growing interest in TBI in the medical community, the increased number of patients surviving the acute phase, and the understanding that severe TBI patients need treatment and support far beyond the first few months post-injury, have created a need for information resources. McMorde et al. found that many patients and their families indicated that inadequate information was provided regarding important consequences of TBI such as aftercare, referral resources, and prognosis (18). Areas of greatest informational deficit included post-hospitalization resources and expectations for outcome. Clergy proved to be by far more helpful in these respects to both patients and families than psychiatrists (18).

Starting in the late 1970s and continuing into the early 1980s, the lack of resources for useful information such as books and journals, and the inadequate answers provided by the medical community, led to the foundation of support groups (SG) of patients for persons with TBI, as well as their families. These support groups were started initially by professionals treating such patients and by families of persons with TBI. The goals of such groups were to increase public awareness of the long-term impact of TBI on patients and their families, to stimulate the development of supportive services in the community, and to supply information regarding TBI (19). Peer support has been shown to be a promising approach to enhancing the coping skills of individual TBI patients and their families (20). Moreover, the impact of the cultural gap and feelings of stigma and social isolation have been shown to be universally experienced by TBI patients (21). Attentiveness, friendliness, and guidance on the part of the rehabilitation staff have been shown to have a significant positive impact on the well-being of TBI patients. Family conflicts have commonly deprived patients of familial support (21). A study of Hispanic TBI survivors demonstrated the importance of linguistic and ethnic factors in the implementation of support groups (22).

In many instances, regardless of the severity of TBI, the lives of the injured and their families are changed forever. These changes can produce a “catastrophic reaction.” (11) The impact is often devastating both emotionally and financially. Support groups can be helpful by providing useful information that in many instances may otherwise be gained only by personal experience. This is one reason that individuals trust SGs. Information about the long-term effects of the injury, about available facilities, services, and programs specializing in patients with TBI are shared by these groups. This in turn has led to the establishment of national societies. The SGs are a social reference group, exerting a positive impact on the self-esteem of both TBI patients and their caregivers. The national groups, first in the United States and then in other countries (especially in Western countries), have been able to promote changes that acknowledge the long-term medical and social needs of this special patient population.

The sociopolitical atmosphere following the Vietnam War and the growing awareness regarding both individual and patient rights laid the groundwork for the necessary changes, especially because wounded war veterans and patients with TBI were generally young and had almost normal life expectancies. Understanding that these victims needed care for life helped to promote public awareness of their needs. The fact that most patients with severe TBI had some financial support from insurance companies attracted various organizations (both for and not for profit) to start TBI rehabilitation programs, which resulted in greater availability of such programs in the United States. Almost 700 such programs existed at one time in this country. But in light of the comprehensive “Coma to Community” treatment model set at LRH in Israel, it soon became clear that many of these programs were not able to bring together the critical mass of knowledge and experience needed to provide the long-term (at times life-long) integrative therapeutic milieu needed by TBI patients, and many of these programs survived for only relatively short periods of time.

With the development of electronic means of communication, opportunities for sharing and disseminating information have increased dramatically. Numerous websites can be found today that are operated by TBI SGs, and others contain a variety of sources of information regarding various aspects of TBI. Today, the Internet plays a key role in distributing information. Entering “TBI” in any search engine returns a large number of these sites. SGs are highly developed in the United States, Canada, and the United Kingdom

Support groups quickly understood the lack of public awareness regarding the long-term impact of acquired TBI on individuals, their families, and the community as a whole. This led to consolidation of local SGs into national organizations that are able to exert greater political influence on legislation, healthcare providers such as HMOs, and the insurance industry.

*Structure of Brain Injury Support Groups* Support groups can be nonprofit or for-profit organizations. Large state or national SGs often consist of local SGs. A TBI SG can be organized in different ways, depending on the objectives and composition of its board of directors. Directors may be appointed by the families, by healthcare providers (such as rehabilitation centers and organizations), or by interested parties such as attorneys' offices. In many cases, SGs are composed of all these various sources.

A successful model seems to be one in which all three elements combine into a well-coordinated group in which professionals in TBI rehabilitation (occupational, physical, therapeutic recreational, and speech therapists; vocational counselors; physicians; nurses; and family therapists) take an active role. The activities of individual SGs differ, but they all provide information about post-hospitalization community resources for further individual and family treatment and about vocational and recreational opportunities. Some of these groups have extended their goals and are involved in programs aimed at the prevention of TBI, reducing its overall incidence. TBI survivors are involved in many educational activities of the SGs, in many instances as part of their own rehabilitation program.

*Long-term care for caregivers* Long-term cognitive and especially behavioral changes affect not only the lives of TBI patients but also the lives of those living close to them, most notably that of the caregivers (23). Studies have shown that in many cases anxiety and dissatisfaction at five years post-injury are far more severe than at about three months or one year (24–26). With time, caregivers may need more support than in the early phase, which is often disregarded or neglected by the health providers who focus mainly on treating the patient. TBI programs, however, need to assign a professional staff to provide empathetic and functional help to the patient's caregivers (27). Because this type of intervention can be done for relatively short periods of time, voluntary organizations such as TBI SGs play a key role in providing this service in the later stages of treatment.

Some SGs provide newsletters treating such important subjects as social cognition, learning, and role-modeling processes. Others provide hotlines such as the Head Injury Hotline, which is a nonprofit clearinghouse that was founded by and has been operated by head injury activists since 1985, (28) with a team of consultants that includes individuals with TBI, family members, learning specialists, nurses, paraprofessionals, lawyers, neuropsychologists, and physicians specializing in emergency medicine and neurology. They offer consultations, research assistance, case management services, legal services, and in-service training. Their clientele consists of individuals with brain injuries and their families, U.S. government officials, agency heads, educators, medical and legal professionals,

and social workers. The activities of these groups include multiple and various aspects of TBI and are open to anyone interested.

Some SGs were organized by academic institutions such as Radford University's Waldron College in southwest Virginia, enabling students to take an active role in some of the programs (29). Some SGs have established Clubhouses for survivors of TBI to serve as a bridge between the past and a healing future. For example, the nonprofit program operated by the Long Island Head Injury Association, Inc. (30) provides a place for survivors to participate in meaningful work, and an opportunity to meet and build friendships and ultimately seek gainful employment within the community. Another example is the Jodi House, aimed at providing opportunities for each person to discover new paths to regain autonomy and purposefulness within their community (31).

Virtual support has also been developing in the last years. Examples of such activity can be found at the website of the TBI chat room ([www.tbichat.org](http://www.tbichat.org)) which had an impressive increase of its use from 135,552 visits in 1998 to 554,244 in 2002. Such SGs help those who would enjoy attending SG meetings but are unable to do so because of problems of transportation or distance. A TBI survivor can contact the chat page 24 hours a day, participate in the general chat room, or enter one of several specialized chat rooms such as TBI in children. A chat room has been designed for children with TBI who are under age 17 years, as well as, their care providers and family members (32).

Today the Internet plays a key role in distributing information about resources regarding TBI rehabilitation. SGs have developed as a result of the understanding that patients and their caregivers require prolonged care, beyond what the health care systems and insurance can provide because of financial and knowledge barriers. Unfortunately, these groups are well developed and active only in countries in which rehabilitation medicine has become part and parcel of the routine medical service. It is hoped that other countries will soon recognize the special needs of TBI patients and provide for them. SGs can be instructive in bringing about this much needed change.

## CONCLUDING REMARKS

The understanding and treatment of patients with traumatic brain injury has changed greatly in the last 35 years. As more patients survive the very acute phase and are referred to rehabilitation, the demand for rehabilitation services has been on the rise. Furthermore, recognition that these patients may need treatment and support for the rest of their lives increases the demand for rehabilitation services all over the world. Rational use of resources is a must, and the rapid dissemination of "how-to-do" information

can promote the creation and improvement of TBI rehabilitation services for these individuals and their families, as well as society at large.

The established SGs and the national and international societies devoted to research and treatment of TBI, mostly active in Western countries, should become a source of inspiration for expanding services to these patients elsewhere in the world. Rehabilitation medicine is still one of the branches of medicine to which only a fraction of the people who need it have access. TBI rehabilitation, being more complex and expensive due to the large team needed for comprehensive treatment explains why in many countries these services are in their infancy. Today “how-to” data is becoming increasingly available, but communities and countries have to consider a different allocation of resources to properly implement TBI rehabilitation programs including prevention. Established TBI rehabilitation services are also under considerable financial pressure, which can promote research into more cost-effective prevention as well as treatment solutions. International cooperation in research will be essential in the coming years to achieve an evidence-based foundation for the practice of TBI rehabilitation. Ultimately our goal should be to provide cost-effective treatment that improves outcome, as well as, quality of life.

Joanne Scandale*

### BACKGROUND

An increasing number of individuals have survived traumatic brain injury (TBI) as a result of advances in medical technology, emergency medical procedures, and neurosurgical techniques (1–3). An estimated 5.3 million Americans currently live with disabilities resulting from brain injury. This means that over 2 percent of the American population is living with disabilities caused by TBI (4). Estimates indicate that one million people are treated for head injuries and released from hospitals across the country each year, resulting in 80,000 people experiencing long-term disabilities. TBI is one of the most common childhood injuries (5).

TBI can significantly affect many physical, cognitive, and psychological processes, significantly disrupting the lives of individuals who experience such injuries. Survivors and their families require varying degrees of support along a continuum of disability. Early needs are usually met within the emergency department and/or acute care hospitalization, followed by acute rehabilitation. Medical and health professionals are the primary providers of service, interacting daily with patient and their families. Rehabilitation services are multidisciplinary, and the goals of care and service are restorative. Specialized programs and providers are sought to deliver quality care. Subacute and longer-term post-acute care needs may be very high, and may not always require health professionals. The services

often are provided by different agencies and multiple health professionals, making coordination and continuity of services difficult. Post-acute care often focuses on behavioral plans, daily structure, and developing creative typical tasks. Support aides require communication skills and at least a knowledge base of behavior modification. With an increasing numbers of survivors, there is a greater need for trained and experienced providers for the acute through post-acute continuum.

Families are usually unprepared for their family member's injury, hospital course, and long-term rehabilitation. Changes in the family member are difficult to understand and difficult to deal with, despite educational efforts through rehabilitation programs. Often, these changes have a negative impact on families who then often become the primary caregivers after discharge from the hospital or acute rehabilitation programs (6, 7). Family caregivers of persons with brain injuries report high levels of depression and difficulties coping with the sequelae of brain injury (8–10). Family members are particularly challenged by the altered personalities and behavior changes exhibited by their loved ones (11).

Families may have to adjust their employment and social schedules in order to provide the level of care necessary for their family member with TBI. This may lead to feelings of social isolation, financial burden, and increased levels of stress. Employers, friends, and even family members may not believe that the individual has

sustained a disability, thereby undermining the support necessary to assist him or her in adapting to life with a disability (2). Return to work and other previously held social roles might not be possible following injury, contributing to further disruption and stress within the family. Osberg and colleagues (12) suggest that with the necessary systems of support, family members can avoid some of the psychosocial problems that arise from caring for a family member with TBI.

Clinical practice, programs, and research in traumatic brain injury medicine have grown significantly over the past 35 years. Persons with TBI and their families, however, have reported the service system is “unorganized, uneducated, unresponsive, and uncaring.” (13) A parent of a child with brain injury writes, “Another area of concern is the insufficient numbers of caregivers with training in ways brain injury differs from other neurologically impairing conditions. . . . Until caregivers better understand the cognitive and behavioral changes and learn more effective methods of dealing with deficits resulting from injury to the brain, we’ll still be where we are today” (14). On a national and more general level, the Institute of Medicine (IOM) report, “To Err Is Human: Building a Safer Health System,” notes the importance of communication among multiple providers and the need for standards for training and certification especially regarding safety and prevention of medical errors. At present, however, there exists no formal training or certification for medical health care providers within the field of brain injury medicine. Only recently has there been certification of brain injury care providers, those providing post-acute care within the community.

This chapter will review the state of the field regarding accreditation for programs, as well as training and certification of health care professionals and paraprofessionals providing front-line care and support in the community.

## PROGRAM REVIEW AND ACCREDITATION

An initial attempt at standardizing rehabilitation care and assuring quality care was program evaluation and accreditation through the Commission on Accreditation of Rehabilitation Facilities (CARF). CARF was established in 1966 to ensure quality services for persons with disabilities and others receiving rehabilitation services. Improved safety, value, and quality of care of persons receiving services are a part of their mission. It is an international nonprofit accrediting body that accredits providers for specific services (e.g. behavioral health, employment and community services, medical rehabilitation). CARF standards are developed through leadership panels, advisory committees, focus groups, and field reviews. Persons served are also involved in the development of CARF standards.

The standards for brain injury programs were first offered in 1985, focusing on inpatient rehabilitation programs. Outpatient programs standards for accreditation were obtainable in 1988. Presently, there are standards for a variety of brain injury program services, beginning with inpatient rehabilitation at multiple levels and transitioning to residential and/or vocational services. CARF accredited programs serving persons who have sustained brain injury include over 100 inpatient rehabilitation programs, about 140 outpatient programs, more than 300 residential programs, almost 50 community services programs, and more than 70 vocational programs. Standards cover adult programs and programs for children and youth.

CARF has been responsive to the changing service needs over the last 25 years. As new services developed in the field, the Board of Directors has supported development of new standards. Standards are reviewed and updated on a routine basis. Program standards specifically for brain injury programs have provided some semblance of consistency for certain program elements, and are an initial step in assuring high quality care for persons who have sustained brain injuries.

## MEDICAL AND HEALTH PROFESSIONAL CARE PROVIDERS

Brain injury rehabilitation has been provided for over 35 years in the United States, initially as a part of a larger rehabilitation program, and, increasingly since about the 1980’s, as dedicated programs. Service provision has moved beyond hospitals and clinics, and into residences and communities. Advancements of medical science and vast improvements in medical and surgical care have presaged the growth of knowledge and practice. Patients often require the services of an interdisciplinary treatment team consisting of physicians, physical therapists, occupational therapists, speech language pathologists, rehabilitation counselors, psychologists, and social workers among other professional and paraprofessional staff. Interdisciplinary rehabilitation team members are typically guided by a set of standards of ethical practice for their particular professions (15). Physicians and health care professionals have risen to the challenge to provide high quality care, although subspecialization within disciplines has been acknowledged by acclamation and not certification.

Health professionals require standard training and licensure. Requirements of education and training regarding traumatic brain injury within each discipline now exist, although implementation may be uneven. Health professionals often gain experience by sharing information through team interactions, mentorship, or courses. Training and licensure for professionals does not require specialization in the care of persons who have sustained brain injury. There are no certification programs for

specialization in the care of persons with brain injuries. Most disciplines do not have certification, but rather special interest groups in professional organizations (e.g. speech and language pathology). And where there may be special certification or plans for certification (e.g. physical therapy, psychology, occupational therapy), it is not specific to brain injury medicine or rehabilitation, but to a more general rehabilitation or components of a TBI service need.

The need for training and certification has been recognized increasingly nationally and internationally (16–19). The need to protect the public has been highlighted through the IOM report. The American Board of Medical Specialties (ABMS) has acknowledged this responsibility, and subsequently enacted implementation requirements of each member Board. These require programs of Maintenance of Certification within all represented specialties, and that subspecialty certification be reviewed through a vetted process.

There is a trend to formalize physician training in the management of persons who sustain brain injury. Physical Medicine & Rehabilitation (PM&R) residency programs developed formal training in Brain Injury Medicine during the 1980s and 1990s. A questionnaire survey report of PM&R residents and program directors conducted in 1991 concluded that two-thirds of programs either offer a formal rotation or require residents to participate in a clinical rotation in brain injury medicine (20). The findings of this and other surveys supported a need for more training in brain injury medicine for residents, including additional training sites across the continuum of care (19, 20). Bell and Massagli (19) reported that PM&R residents endorsed the position that a rotation in a skilled nursing unit providing services for individuals with brain injury offered unique clinical experiences. Currently, all PM&R residents must have formal training and competency in brain injury medicine, which is mandated through the Accreditation Council on Graduate Medical Education (ACGME) program requirements. Basic requirements for certification in PM&R include successful completion of an ACGME approved residency in addition to passing written and oral American Board of Physical Medicine & Rehabilitation (ABPMR) examinations. Because PM&R training and examinations require substantive coverage of brain injury medicine, certification in PM&R conveys a basic competence in brain injury medicine (BIM).

Beyond basic competency, there also exist formal (but not ACGME approved) Brain Injury Medicine Fellowships in PM&R. These fellowships and advanced clinical experience at academic and brain injury treatment centers provide the underpinnings for further expertise in BIM. The Brain Injury Special Interest Group (BISIG) of the American Academy of Physical Medicine & Rehabilitation (AAPM&R) supports these efforts. The BISIG

organized the development and writing of curricular materials for brain injury medicine fellowship programs. This material has been utilized by fellowship training program directors and mentors to provide structure and didactic content to fellowship training programs in existence or under development. The document has been updated, most recently in 2003.

Beyond PM&R, a number of other specialties engage in elements of brain injury medicine. Foremost among these are neurology and neurosurgery. These programs are most frequently focused on the immediate acute issues or subsequent co-morbidities (e.g. seizures, increased intracranial pressure). The clinical experience in post acute brain injury medicine is not required. Although some programs support this experience, the focus and intensity is widely variable. In general, the route to significant clinical participation in post acute Brain Injury Medicine is through fellowships, a limited number of which exist. These fellowships are not ACGME approved, nor is training sanctioned by their specialty Boards. Post residency training for neurologists is available in a number of fellowships providing clinical management and diagnostic experience across a variety of neurological diagnoses along with the associated therapy interventions.

None of the aforementioned fellowship programs are accredited through ACGME and there is no formal subspecialty certification in Brain Injury Medicine through ABMS. Therefore physicians who have completed the additional year of study are not formally certified by any ABMS Board.

The American Board of Physical Medicine and Rehabilitation is developing a Brain Injury Medicine subspecialty proposal for ABMS approval. The rationale for establishing this subspecialization is:

- To provide core competency standards of training for the evaluation and treatment of patients with brain injuries;
- To provide a high level of care for patients with acquired brain injury and their families in hospital and outpatient settings, and over the continuum of the process of recovery;
- To provide physicians with brain injury medicine administrative skills for activities such as program development, quality assurance, facilities planning, standards-setting;
- To promote and strengthen research for the advancement of the clinical science of brain injury medicine, including prevention, treatment, and restoration of function and outcomes research;
- To increase the number of expert clinicians, teachers, and investigators dedicated to the care of survivors of brain injury.
- To recognize physicians who have successfully completed additional training in brain injury medicine

programs beyond the primary residency training education in psychiatry or neurology.

- To improve education in brain injury medicine for residents in psychiatry and neurology, residents in other training programs, medical students, practicing physicians, and other medical personnel.
- To generate academic interest in the psychiatric and neurological professional societies.

The formal process requires discussion and vetting through ABMS. The intention of ABPMR is to have an inclusive process with an opportunity for all physicians practicing Brain Injury Medicine to have access to the certification process.

There are many disciplines involved in the ongoing care, medical management, and rehabilitation of persons who have sustained brain injury. Although there are expert clinicians in the field, there is no formal certification for any of the professionals involved. Consumers and their families have made a strong case for the requirement of well trained and certified health care providers in the field of brain injury medicine.

### **COMMUNITY CARERS AND PARAPROFESSIONALS**

Following discharge from the acute or sub-acute setting into the community, many persons with brain injury require ongoing care. Brain injury is a lifelong injury that impacts function across the lifespan. Support needs are typically very high, although social networks generally consist of only family members and service providers (13). Oftentimes, persons with brain injury continue to require the services of a multidisciplinary treatment team. Unfortunately, these services are often spread among several different provider agencies, making coordination and continuity of service a management nightmare.

Unlike the pre-existing community services for persons with mental illness or developmental disabilities, developed in the 1970s as part of deinstitutionalization, community services for persons with brain injury are relatively new. Further, attempts to “fit” persons with brain injury into pre-existing community service models (i.e. those for persons with developmental disabilities or mental illness) have attained limited success toward meeting the needs of persons with TBI. These factors contribute to the serious need for specialized training to meet the various needs of persons with brain injuries, caregivers, and their families.

Post-acute community based brain injury rehabilitation is not only a relatively new field, but is also impacted upon by misconceptions, cultural diversity, and inaccurate knowledge about TBI among community service providers. Many of the individuals who live in the

community today would have likely not survived their injuries 25 years ago (16). The developments in emergency medical procedures, medical technology, and neurosurgical techniques, have sustained the lives of persons with brain injury, as the community services available for them are being established.

There is limited literature discussing the need for formalized training of providers of TBI services. However, the literature that is available speaks to the need for specialized provider training. The individuals who provide care to persons with TBI residing in the community are most often family members and direct care staff. Paid helpers can often lessen the stress placed upon family members, assuming the paid helper understands the nature of the injury and its sequelae.

Research on paid care work as it applies to persons with brain injury is virtually absent from the literature. McCluskey (21) found that agencies needed to increase efforts to train and orient new staff to the types of challenges they would face working with persons with brain injury. She also suggested that persons with brain injuries would benefit from closer contact between professionals and paid caregivers. Given the restrictions funding sources impose on treatment programs for persons with brain injuries there may be limited opportunities for professional intervention, placing greater emphasis on the importance of training care givers to implement activities to improve the functional performance of persons with brain injury (22).

The specific educational need areas that have been identified include several areas integral to the provision of rehabilitation services to persons with brain injury including; treatment of cognitive deficits, family and social issues, behavior modification techniques, and adjustment to brain injury (16, 18). The literature has also differentiated between the types of training and knowledge required by professionals and paraprofessionals and those with direct versus less direct care of the person with brain injury.

A demonstration project through the New York State Department of Health responded to the need for education of care providers and support for this difficult to serve population. Experts in the field of brain injury rehabilitation developed support for persons with brain injury, family members, friends, and community support staff. Additionally, the program offers an “apprentice” aspect that allows caregivers to receive intensive, contextualized training and coaching, enabling them to better serve persons with brain injury. The results of a preliminary cost-effectiveness study of the program (23) suggest that community supports for persons with behavioral issues resulting from TBI can be provided in a cost-effective manner, although recommendations are made for a systematic analysis of quality of life indicators before broader policies and programs are established.

The lifelong sequelae of TBI often exhaust private insurance funding streams early in the rehabilitation process. Therefore, public programs such as Medicaid and Medicare often become the primary sources of payment. Several states have established waiver programs for persons with TBI. These programs offer opportunities for designing integrated service plans for individuals with brain injury who would otherwise require some type of inpatient care. Care needs usually include support for specialists in case coordination and behavior management, not otherwise funded through typical private insurance. New York State's TBI Waiver Program offers long-term support focusing on post-rehabilitative care. The services offered by the waiver program are fashioned to offset several of TBI's sequelae. The services include: Service coordination, home and community support services, non-medical transportation, specialized medical equipment and supplies, home modifications, intensive behavioral supports, community integration counseling, substance abuse counseling, day programs, and independent living skills training. The services are based in a philosophy of individual choice, while accounting for the accompanying realities of needs, health and welfare issues, and budgets. One of the major challenges faced by provider agencies across the state has been the difficulty to attract and retain qualified staff. This may be a result of the lack of understanding of the behavioral and psychosocial sequelae associated with brain injury.

### **American Academy of Certified Brain Injury Specialists**

A 1990 survey of 565 acute, subacute, and post-acute programs regarding the training needs of licensed and non-licensed staff brain injury services noted that seventy-five percent of the respondents (45 percent response rate) indicated that specialized training is needed for licensed staff, and 84 percent indicated that training is needed for non-licensed staff. This was further supported by Becker (18) who reported that respondents to their survey about education and training needs for staff endorsed specialized training for paraprofessionals, even more than for professionals.

As a result, the Brain Injury Association of America established the American Academy of Certified Brain Injury Specialists (AACBIS) as a standing committee of the association to address training needs. AACBIS operates under its own by-laws as approved by the Board of Directors of the Brain Injury Association of America. AACBIS Committee members are experienced professionals in the field of brain injury rehabilitation who volunteer their time and expertise to developing a certification program that meets the needs of the brain injury community. AACBIS currently offers certification for Brain Injury Specialists. The program is governed by

AACBIS and is administered by the Brain Injury Association of America in McLean, Virginia.

In 1996, AACBIS was established to assure the highest possible standards of rehabilitation and care for persons with brain injuries. The AACBIS is the only organization offering specialized training and certification programs for care givers of persons with brain injuries. AACBIS offers national certification programs improving the quality of care through the establishment of best practices for the education and training of individuals working in the field of brain injury services. The AACBIS offers a voluntary national certification program for both entry-level staff and experienced professionals working in brain injury services. AACBIS provides staff and professionals the opportunity to learn important information about brain injury, to demonstrate their learning in a written examination, and to earn a nationally recognized credential. Since its inception the program has certified more than 520 professionals. The AACBIS certification program is specially designed to address specific training issues in brain injury services and complement other credentials.

The AACBIS program is divided into three levels: Certified Brain Injury Specialist (CBIS)—Basic, CBIS—Instructor, and CBIS—Examiner. The curriculum includes units in the following areas:

- Brain Behavior Relationships
- Functional Impact of Brain Injury
- Health and Medical Issues
- Philosophy of Treatment
- Children and Adolescents with Brain Injury
- Brain Injury: A Family Perspective
- Legal and Ethical Issues

Critics of the examination focus on it being knowledge based when many of the skills integral for effective work with this population rely upon technique. Carnevale (24) developed a model that was both knowledge and practice based. The model utilized a mobile team approach, educating caregivers and persons with brain injury on how to implement and sustain home-based behavior management programs. The natural environment (e.g. home, community) brought to light the importance of flexible interventions that addressed both client and care giver needs. Training programs should focus on the "real life" or functional impact that brain injury has on an individual. Ideally, trainers could incorporate a model that includes visiting the settings in which the care giving is taking place or at least viewing videotapes of every day interactions between the person with the TBI and his/her environment. In short, at least a portion of training must be contextualized to increase the likelihood of positive impact given the cognitive and behavioral sequelae of TBI. Training programs specifically fashioned

to provide knowledge and skills training regarding brain injury are needed to facilitate both the caregiver's and the person with brain injury's adjustment to providing/receiving services.

### SUMMARY

With advancements in research and science, there have been improvements in acute and emergency medical care, with a significant increase in the numbers of persons who survive brain injury. Residual impairments from the brain injury include a variety of conditions, however cognitive impairments are often the most difficult to manage. Health professionals with expertise in brain injury medicine are required to provide ongoing services and support. Consumers and professionals recognize the importance of subspecialty training and certification.

Program accreditation has provided a base for delivery of quality services at a systems level. Individuals providing those services should also receive appropriate training, and ultimately certification, to further assure high quality care and avoidance of medical errors. The establishment of the American Academy for the Certification of Brain Injury Specialists (AACBIS) is a dynamic step toward addressing the needs and concerns of the brain injury community. Subspecialty training and certification in brain injury medicine and rehabilitation should be considered across all disciplines serving the needs of persons with brain injury. Programs offering such training narrow the information gap between healthcare professionals in the tertiary care hospitals and those in the long-term care facilities, contributing to the integration of brain injury services across the continuum of care. Partnerships among professional organizations, credentialing bodies, service agencies, and accrediting bodies must be forged in order to further integration of knowledge and skill sets into community based brain injury services.

## Conducting Research in TBI: Current Concepts and Issues

*Amy K. Wagner*

### INTRODUCTION

The National Center for Injury Prevention and Control suggests that injuries have a substantial impact on the lives of individual Americans, their families, and society. The consequences of injuries can be extensive and wide ranging. They are physical, emotional, and financial; in the case of disabling injuries, the consequences are enduring (1). TBI is no exception to these consequences. TBI is an epidemic in the United States with an overall incidence of 200 per 100,000 per year (2). It has been well established that TBI causes chronic debilitation and functional loss over a lifetime. Unlike other disease processes with later onset, survivors of TBI often have many decades of productive life loss, costing themselves, their families, and society much with loss of the capability for competitive employment and other meaningful community roles. An estimated 5.3 million Americans, or 2 percent of the population, currently live with disabilities resulting from brain injury, and the national cost to society is estimated to be \$48.3 billion per year (3). Injury is the leading cause of years of potential life lost before age 65, and TBI is responsible for a greater proportion of this mortality rate than most other types of injury (1). For survivors, TBI often results in disturbances of cognitive, behavioral, emotional, & physical functioning. Impairments within these domains can be a persistent & debilitating problem. Mild TBI is often

undiagnosed, making the public health burden even larger than reported estimates indicate.

The magnitude of TBI related public health burden mandates that TBI researchers delineate the contributing mechanisms of injury and recovery, evaluate and implement effective treatments, and accurately prognosticate outcome with effective assessment tools. In the population with TBI, patients can have markedly different outcomes, despite similarities in the extent of the initial insult and in type of clinical management. Additionally, the population sustaining TBI is diverse, and a broad and complex range of internal and external factors can influence injury and recovery. These factors make accurate prognostication, sensitive outcome assessment, and effective conduct of clinical trials challenging issues in TBI research. To date, there is a paucity of proven interventions shown to significantly reduce morbidity and mortality or improve recovery and quality of life. Mechanisms of injury, neuroplasticity, and recovery are not fully understood, and outcome prognostication unrefined. In this chapter we discuss unique issues with conducting research in the population with TBI and appropriate outcome assessment in this population. We also highlight the importance of translational research and preclinical trials, evaluate challenges and pitfalls with conducting clinical trial research in this population, and outline issues with statistical approach and research design. Finally, we will discuss future considerations and pioneering directions for the field of TBI research.

### **Unique Aspects Associated with TBI Research**

TBI is a complex disease involving both primary (focal and diffuse injuries) and secondary injury, with secondary injury involving complex biochemical cascades that lead to excitotoxicity (4–6), brain swelling (7), loss of cerebral blood flow autoregulation (8), oxidative injury (9, 10), inflammation (11, 12), and cellular necrosis and apoptosis (13, 14). Overlaid on this complex myriad of pathophysiological cascades are the influences of genetic make-up, and other premorbid and demographic characteristics that can influence the extent of injury or recovery. For instance, genetic polymorphisms associated with APOE have linked ApoE-4 expression to outcome after TBI (15–17). Other factors such as age, gender, minority status, and previous education may also impact outcome (18–21). Further, there is variability in the type and intensity of both acute and rehabilitation care that patients may receive. These factors are often influenced by treatment location, social supports, and source of payment (22–24). The multidisciplinary approach to therapies also provides unique challenges in understanding what portions of the rehabilitation process are crucial in improving a particular individual's recovery course. All of the differences in injury variables, personal characteristics, and treatments outlined above can create variability in recovery from TBI. This variability creates unique challenges for researcher in TBI to tease out the important mechanisms associate with injury and recovery, identify appropriate and effective therapeutic targets, and accurately prognosticate outcome.

### **Researching the Population with TBI**

Researching the population with TBI poses other unique methodological challenges to researchers regarding recruitment, population characteristics and follow-up. Biases with recruitment may introduce systematic bias into the study population. One study evaluated this issue in mild TBI by comparing demographic, premorbid, and injury related characteristics of their population. Those who had more severe injuries, who were hospitalized, and who had a significant additional major injury were more likely to consent to participate in the study (25). In studies requiring the evaluation of patients who are unable to consent themselves for enrollment in a research study and/or the immediate implementation of a treatment intervention, obtaining consent can be a challenging issue that impacts recruitment and study design. Recently, one multicenter trial investigated the efficacy of early hypothermia treatment implemented within the first six hours from injury for patients with severe TBI. At the beginning of the study, informed consent was required for each study patient. During the course of the study, federal regulations changed

to allow waived informed consent. Post-hoc analysis of this study population showed that with waived informed consent, time to randomization and treatment implementation decreased, patient accrual increased, and minority representation in the study population increased (26). This analysis illustrates the potential importance of waived informed consent on the integrity of early treatment interventions and in minimizing recruitment bias.

Alternatively, systematic bias may be introduced into a clinical data set through loss to follow-up. Loss to follow-up is an inherent problem when conducting research in the population with TBI. One study evaluating loss to follow-up using a variety of data sets, including a single center, multicenter, and statewide surveillance data set, found a loss to follow-up rate of approximately 37 percent and 58 percent one year and two years after injury respectively. Additionally, there appeared to be a selective bias to lose those who were socioeconomically disadvantaged, with violent etiologies of injury, and with a history of substance abuse (27). Systematic bias with loss to follow-up can significantly decrease the generalizability of study findings and potentially confound apparent treatment efficacy with clinical trials.

A myriad of variables, including patient comorbidities and complications (28, 29), gender (18, 30, 31), cognitive reserve (32), injury severity (18, 32, 33), injury type (34–37) minority status (38), social supports (39) and acute discharge location (24) may all influence outcome. Additionally, patient recovery can occur over a prolonged period (40–42), and outcome assessment may vary with the type of individual (patient, caregiver, clinician) interviewed (43). Each of these issues must be considered carefully when designing studies. The appropriate use of covariate analysis, including time variables for longitudinal studies, and stratification is often necessary to avoid confounders obscuring research results. Time post injury is also an important consideration when designing clinical trials to minimize the effects of natural recovery on the apparent treatment effect.

### **Outcome Assessment Tools in TBI Research**

The World Health Organization (WHO) has provided widely accepted definitions of impairment, disability, and handicap that have resulted in a conceptual framework by which world wide research has been conducted investigating the impact of injury and illness on individual function (44). This system more recently has been replaced by the International Classification of Functioning, Disability and Health (ICF) (45), providing an updated framework for rehabilitation research (46). Several existing TBI assessments measure outcome within more than one of these domains. Commonly utilized TBI outcome assessments vary in scope and mode of measurement. Some outcome assessments are general and

designed to provide a global index of outcome, [e.g. Glasgow Outcome Scale-extended (GOS-E) (47), Disability Rating Scale (DRS) (48)]. Others are meant to measure functional abilities for daily activities [Functional Independence Measure (FIM) (49)] or community integration [Community Integration Questionnaire (CIQ) (50, 51)]. Assessments may also focus on quality of life (42, 52, 53), caregiver needs (54, 55), while others focus specifically on neuropsychological performance (41) or psychiatric dysfunction (56, 57). Finally, measurement tools may target specific populations, such as those with mild TBI (58). In particular, outcomes assessment is an important aspect of TBI rehabilitation research. However, studies often published in rehabilitation journals do not report the validity and reliability of the outcome measures used (59). Variable definitions and operationalization as well as associated social values and target population can be difficult to address when developing new or utilizing existing TBI outcomes assessments (60).

Multimodal assessments are often necessary to effectively reflect the complex range of factors affecting TBI outcome. However, no single measurement tool can encompass all relevant areas of TBI outcome. Additionally, there are limitations with the collection and analysis of many existing measurements. There are ceiling effects associated with some measures as individuals with TBI improve over time (61), and some outcome measures have a limited ability to measure group differences in function over long evaluation intervals (62). Attention to cultural, minority, age and gender related differences in response range for outcome assessments should also be considered when selecting assessments and interpreting results (19, 63–66). Choosing an appropriate primary outcome measure is of critical importance when designing clinical trials, selecting a proposed treatment effect size, and for developing effective models for prognostication. Appropriate and well validated outcome measures are often most effective when they target a population with a varied demographic profile and broad range of injury severity, are able to accurately place subjects in appropriate outcome categories at given time intervals, and are sensitive to change over time. Additionally good outcome assessments often link impairments to disability to handicap. For clinical trials, the GOS-E has gained popularity as a primary outcome assessment tool and is thought to be more sensitive than the standard GOS (47). However, The Functional Status Examination (FSE) is a well-validated new instrument that has been utilized in long-term studies for the population with moderate and severe TBI (42, 67). Its measurement properties are linked with other constructs such as family burden, depression, and satisfaction with functioning that make it an effective multi-modal assessment (42) that should also be considered when designing clinical studies.

Researchers should also examine prospective outcome assessments they plan to use to determine if appropriate steps have taken previously to validate that measure in their population of interest. Mode of assessment administration presents some unique concern regarding the validity of the assessment tool chosen. Some measures, including FIM (68) and CIQ (51) have been validated for administration over the telephone, however, many other measures have not been formally validated for multiple modes of administration, despite their widespread use in this manner. Telephone and mailings result in the study population becoming an unseen entity, which can introduce variability and bias into the responses generated.

Cognitive impairments of persons with TBI often make the use of proxies for outcome assessment and evaluation attractive. However, self-awareness of deficits for people with TBI (69) and participant-proxy differences in disability perceptions and quality of life (70) may preclude participant-proxy responses from being interchangeable. Some measures have been specifically evaluated for their reliability and accuracy when administered to both individuals with TBI and their proxies (68, 71), while others have not been evaluated for participant-proxy agreement. Recently, the intraclass correlations between participants with TBI and participant selected proxies on the Craig Handicap Assessment and Reporting Technique (CHART), the CIQ, and the FIM were evaluated. Results showed a high intraclass correlation for participants and proxies, with the highest values occurring on items assessing concrete or observable information (72). Other studies in a variety of patient populations also indicate that patient proxy agreement is generally better for questions regarding physical dimensions of functional status, and agreement is less consistent for questions regarding subjective or affective aspects of outcome assessment (70). Investigators should take time to carefully consider their primary outcome measure and choose their criteria for considering persons with TBI to be a capable respondent. The agreement between patient and proxy responses should be evaluated prior to an outcome assessment's inclusion in a study in order to avoid over or under estimation of treatment effects or invalid conclusions. Further, consistent criteria for the selection of a knowledgeable caregiver or significant other should be considered in the research design.

### Clinical Trials in TBI

Randomized clinical trials are the gold standard by which researchers in any field of medicine test the efficacy and safety of treatment interventions. Clinical trials, particularly randomized clinical trials, provide a strong foundation for evidence based clinical practice and justification of payors to reimburse for treatments and therapies (73). However, in the area of TBI, there have been few clinical trials that have definitively identified any effective

treatments for reducing morbidity or improving recovery. Numerous TBI clinical trials of acute pharmacological interventions, intended to improve functional & neuropsychological outcomes, have been conducted over the last 25 years, with often disappointing results (2, 74–80). The justification for virtually all of these trials were positive findings in animal studies, using rodent models, testing the trial drug or intervention that could not capture variables that may influence treatment outcome, such as, gender, age, and genetic variability (81, 82). As mentioned above, TBI is a heterogeneous disease, with a multitude of secondary injury cascades, affecting a diverse population. The complexity of the disease and diversity of the population it affects makes designing clinical trials in TBI particularly challenging.

For TBI rehabilitation research, double blind randomized control trials are particularly difficult to carry out. Sample sizes tend to be small, and the number of confounding variables are often quite high. There is a lack of consensus on appropriate outcome measures or how to objectively quantify rehabilitation based interventions, and (unlike acute care trials) post-intervention improvements may not be seen for months or years. Rehabilitation research also focuses on the improvement of functional abilities, participation in the community, and quality of life (46). For instance, social interventions such as caregiver education may improve community integration and quality of life for the population with TBI. Rehabilitation outcome often can be considered context specific and affected by a patient's physical environment, social environment, and personal attitudes and expectations (83). Contextual factors may influence rehabilitation outcome and decrease the generalizability of clinical study results. Despite these challenges, some high quality rehabilitation based randomized clinical trials have occurred in the areas of seizure prophylaxis (84, 85), community based rehabilitation for long term survivors of TBI (86), Methylphenidate treatment (87), and cognitive rehabilitation (88). However, replication studies, studies with large population numbers, and the generalizability of findings to a large population are difficult to find in any area of TBI rehabilitation research.

A recent analysis regarding clinical trials in rehabilitation (89) suggests that characterizing participants in rehabilitation research studies is of critical importance to eliminate confounding, to ensure comparability across treatment conditions, and to adjust for differences in prognosis among participants. Additionally, the treatment or intervention must be adequately and objectively characterized in terms of mechanism of action, dose, route, intensity, and subject participation. Outcome measures utilized for characterizing treatment efficacy need to be sensitive and appropriate. Investigators should identify the appropriate target of their outcome assessment (e.g. disease, impairment, activity, participation, quality of life) and

ensure the measureability of their outcome target with the treatment intervention. Often, broadly defined outcomes such as quality of life have several factors that impact it. As such, a single intervention may impact specific impairments after TBI, but those changes may not be large enough to translate into a meaningful change in quality of life (89). Additional challenges in rehabilitation research occurs with blinding of physical treatments and with limitations of crossover designs when significant contamination of the study population from cross-training might dilute the effectiveness of the treatment intervention (90).

Multicenter clinical trials in TBI are considered necessary since the ability of a single center to recruit enough subjects to provide adequate statistical power is often limited. However, several statistical and design issues have been identified by investigators directing multi-center clinical trials that begin during emergency and intensive care. Intercenter variance in patient care and adherence to the research protocol has been a fatally flaw in some recent multicenter clinical trials. For example, it has been reported that intercenter variation, not explicable by injury severity or type, was responsible for approximately 40 percent of the variation in a multicenter clinical trial evaluating the effectiveness of tirilizad mesylate (77, 91). Intercenter variation was noted with a variety of intensive care treatments, including narcotic use for sedation, and with a number of physiological variables, including mean arterial pressure and cerebral perfusion pressure for a multicenter clinical trial evaluating the efficacy of hypothermia (92). Interestingly, recent studies with an experimental TBI model suggests that choice of anesthesia or sedation, including Fentanyl and Isoflurane, can have marked effects on outcome and in the context of hypothermia treatment (93, 94). This example demonstrates the potential impact that variation in standard care may play in recovery and outcome. Centers who can enroll small numbers of patients may contribute the most variability to standard care treatment regimens because they are often less likely to follow consensus recommendations for standard treatment (91). Misclassification of outcomes can also influence study results. Interestingly, one study reports, that as the numbers of outcome categories increase, the greater the likelihood of outcome misclassification and erroneous results (95). While dichotomous outcomes are not reasonable for each and every clinical trial, care must be taken to create effective algorithms for accurate data collection, and the use of pilot data may be helpful in determining an effective outcome measure with a minimum necessary requirement of categories. Subset analysis of data, even in negative multicenter trials, is recommended to identify potential subpopulations who might benefit from a particular treatment (96).

Recently, the NINDS May 2000 Clinical Trials in Head Injury Study Group identified and discussed many

of the issues associated with failure to produce positive results with several recent trials (91). The Study Group concluded that in order for clinical trials to be effective, it is essential to: (i) establish that a drug or proposed intervention is having the desired effect on a specific mechanism of injury *in vivo*, (ii) to obtain adequate pre-clinical data, (iii) target subpopulations of patients most likely to benefit from the treatment, (iv) standardize clinical care, (v) choose appropriate outcome measures or endpoints, and (vi) have reasonable expectations for treatment effect (91). Priority should be placed on conducting experimental and clinical studies aimed at understanding mechanisms of injury and recovery, since they are critical when designing future clinical trials and identifying possible therapeutic targets. Evaluating the most effective window of treatment, dose response curves, drug pharmacokinetics and drug delivery to the brain, and multiple models of experimental TBI are needed for adequate pre-clinical trial data (91). Utilizing injury related prognostic variables in the selection criteria for studies may allow investigators to effectively target subpopulations for particular interventions. Functional status at the time of entry into rehabilitation trials may be more prognostic of outcome and a relevant way to group patients than injury variables (91). Other intrinsic variables such as age, gender, and genetic make-up are emerging as important variables to consider in trial design (15, 97). Strict adherence to clinical care guidelines, centralization of some study variables (e.g. CT scan interpretation), collection of concurrent medications, and collection of only essential study variables may improve the management of clinical trials. Finally, smaller effect sizes (5–7.5 percent), the careful design and use of sensitive outcomes as well as the judicious use of relevant proxy variables may allow investigators to appreciate subtle treatment effects for specific interventions (91).

### **Alternatives to Clinical Trials and Research Design**

While randomized clinical trials are considered the gold standard for clinical research, they are not always feasible or practical for each research question. Ethical issues and the inability to obtain the resources necessary to conduct a full scale randomized clinical trials may preclude this study design (98). However, randomized clinical trials may have their own limitations in that they may not provide a representative measure of the effectiveness of the treatment in common clinical practice settings (99). Observational studies may be one alternative technique by which to study necessary research questions, particularly when treatment variables of interest are not assigned based on prognostic factors influencing outcome (98). Some reports suggest that effect sizes generated from well

done observational studies can be comparable to those obtained from randomized clinical trials (100). However, observational studies are vulnerable to confounding variables impacting the outcome variable of interest and require the use of covariate analysis. Common issues associated with exploratory analyses or observational studies, such as appropriate correction for multiple comparisons, avoiding type II experimental error, and appropriate sample size also need to be considered in the study design (101, 102), in order to provide accurate conclusions and a solid foundation for the design of a future clinical trial. Single subject research designs can be valuable, particularly in clinical practice, to determine effectiveness of treatments and lay the ground-work for larger studies (103).

### **Translational Research in TBI**

Translational research is an important area of focus for TBI in that it identifies mechanisms of injury and recovery and lays the groundwork for the conduct of clinical trials. Advances in genomics and proteomics may provide a novel approach to identifying and exploring therapeutic targets (104, 105). Utilizing functional imaging technology (106–109) or quantitative EEG (110) may be some contemporary avenues by which to explore injury and recovery mechanisms directly in the clinical population with TBI. However, the majority of translational research requires the effective use of experimental models that reproduce the physiological and behavioral sequelae associated with injury. Several models, including fluid percussion (111) and controlled cortical impact (CCI) (112) are commonly used in rodents. Characteristics of the CCI model include not only a representative contusion, but also reproducible brain edema and marked changes in cerebral blood flow in surrounding cortex (113). Rodent models are cost effective, can provide a relevant and reproducible injury, and are effective in studying a variety of behavioral paradigms (114–117). Rodents, however, are not gyrocephalic animals, and the use of larger animal models, including primate models, may be necessary to fully characterize pathology associated with diffuse axonal injury. Experimental models of TBI have largely been utilized to study acute pathology and neuroprotection, however, they can be a useful approach for examining long term outcome, mechanisms of recovery, and relevant rehabilitation interventions. For example, the CCI model recently was utilized to study the differential effects of gender and environmental enrichment, an experimental correlate to therapy, on behavioral recovery (118). In order for TBI rehabilitation research to move forward, collaborative efforts with other basic science disciplines, such as neuroscience and psychology, to tackle complex issues such as cortical reorganization, neural plasticity, and the effects of rehabilitation strategies like forced

use will be required (119). Future work will also require that researchers find ways to actively link studies involving acute mechanisms of injury and treatment inventions with central nervous system repair and recovery.

### Priority Areas for TBI Rehabilitation Research

In 1999, an NIH consensus group identified and published some research priorities in the area of TBI (120). Highlighted among these priorities include a need for epidemiological studies targeting different demographic groups and to study mild TBI. The therapeutic window for treatment interventions needs to be studied, and the neurobiology of clinical TBI, using state-of-the-art technology needs to be addressed. Specific prognostic equations should be developed, and the relationship between impairments and global outcome evaluated. Finally, the long term consequences of TBI and the developmental impact of TBI on children should also be a focus of study (120).

Several priority areas for TBI, injury prevention, and rehabilitation research have been set by primary federal organizations that fund TBI research. The National Institute for Disability and Rehabilitation Research's Long Range Plan has research priorities in the areas of employment outcomes, individual health and function, technology for access and function, and independent living and community integration (121). The development of sensitive and effective outcome measures is a priority. Research in rehabilitation science, disability studies, and disability policy are also current NIDRR research priorities. Investigators, particularly in the field of TBI rehabilitation research, have had a long history of utilizing NIDRR funding to evaluate important questions in the area of TBI outcome. The TBI model system centers (122, 123) have been an important part of this endeavor. NIDRR based collaborative networks for TBI research also foster increased interactions between a varied group of investigators and allow for the recruitment of large samples to answer important TBI rehabilitation research questions.

The Centers for Disease Control's (CDC) injury center interact with researchers in acute care and rehabilitation in order to "advance a broad based, multidisciplinary approach to injury" (1). Highlighted among their many priorities relevant to TBI are to (i) identify risk factors and develop and evaluate interventions for secondary conditions following TBI, particularly for patients not treated at state-of-the-art facilities; (ii) identify methods to ensure that people with TBI receive services; (iii) develop and apply methods for calculating population-based estimates of the incidence costs and consequences of those non-hospitalized after TBI; (iv) determine the impact of TBI on special populations; (v) develop and implement interventions for reducing disability after mild TBI; (vi) determine how the environment impacts disability after TBI;

and (vii) investigate the long-term effects of TBI on the health and longevity of persons with TBI. These priorities indicate that the CDC has a wide range of research opportunities for investigators to utilize that integrate aspects of secondary and tertiary injury control.

"Healthy People 2010" is a collection of national health objectives highlighted by the NIH as research priorities. The goals of Healthy People 2010 are designed to identify significant threats to national health and to establish goals aimed at reducing these threats. One priority of Healthy People 2010 is to eliminate health disparities among different segments of the population, including those with disabilities. In particular, Healthy People 2010 aims to "promote the health of people with disabilities, prevent secondary conditions, and eliminate disparities between people with and without disabilities in the U.S. population" (124). These particular aims suggest that National Institutes of Health (NIH) views disability related research, including research on assessing and preventing secondary conditions associated with TBI, as an important priority area of research.

In 2002, the NIH began developing its roadmap for medical research in the twenty-first century and identifying new pathways to discovery, research teams of the future, and re-engineering the clinical research enterprise (125). Future NIH funded TBI research will likely incorporate many of the new research paradigms outlined within this roadmap. TBI research teams of the future will likely be multidisciplinary in nature, integrating several distinct areas of science to evaluate broad research questions. NIH hopes to increase interactions between clinicians and basic scientist with the thought that this interaction will generate studies that are effectively able to translate basic research findings into meaningful changes in individual health. NIH is committed to training clinician researchers to take part in multidisciplinary and translational research endeavors. Contemporary and integrated networks of researchers able to conduct large-scale clinical trials to efficiently study relevant research questions and rapidly disseminate their findings in the context of best practices are a priority. Standardized data collection, sample sharing and the development of effective outcome measurements are also a priority. The NIH hopes to leverage significant advances in molecular biology, bioinformatics, computer science and engineering to encourage innovative ideas and perspectives that lead to seminal breakthroughs in scientific research that lead to improvements with human health. Finally, the NIH hopes to develop private-public partnerships to extend and accelerate research. As investigators incorporate this new vision into their scientific approach and programs of research, we will move forward in understanding key mechanisms of injury and recovery, and effectively identifying and implementing therapeutic strategies for the population with TBI.

## The Epidemiology of TBI: Implications for Public Health

*David J. Thurman*  
*Victor Coronado*  
*Anbesaw Selassie*

### INTRODUCTION

In the United States, traumatic brain injury (TBI) has been associated with more than 50,000 deaths annually, which is a third of all injury-related deaths. In addition, annually there are some 230,000 hospitalizations for nonfatal TBI, with an estimated 80,000 resulting in long-term disability (1). The incidence of TBI in the world population is unknown, but its magnitude is suggested by the *Global Burden of Disease Study* (2), which estimated the incidence of several categories of TBI severe enough to warrant medical care or result in death. For 1990, the estimates totaled over 9,500,000, but this may be conservative, as some categories (e.g., fall-related TBIs with short-term consequences) were not included. The uncertainty of these estimates notwithstanding, TBI clearly imposes a great burden on public health throughout the world. The purpose of this chapter is to characterize this burden by summarizing studies of the epidemiology of TBI, emphasizing findings about its frequency, risk factors, severity, and outcomes in populations. An understanding of the epidemiology of TBI is essential for developing effective prevention programs

and for planning appropriate health care services for those injured.

### DEFINITIONS

#### Traumatic Brain Injury

Case definitions for TBI have varied among epidemiologic studies, creating some difficulties in comparing their findings (3). For example, not all of the studies have included cases with skull fracture that lacked other documentation of neurologic symptoms or brain injury per se. In addition, the term “head injury” has often been used in place of TBI. An effort to standardize the epidemiologic case definition of TBI (as well as methods of data collection) led to the publication of *Guidelines for Surveillance of Central Nervous System Injury* by the Centers for Disease Control and Prevention (CDC) in 1995 (4). The CDC defined TBI as craniocerebral trauma, specifically, an occurrence of injury to the head (arising from blunt or penetrating trauma or from acceleration/deceleration forces) that is associated with any of these symptoms attributable to the injury: decreased level

of consciousness, amnesia, other neurologic or neuropsychological abnormalities, skull fracture, diagnosed intracranial lesions, or death.\*

The guidelines also provided a standard case definition for data systems, which includes International Classification of Diseases, Ninth Revision (ICD-9) (5), or International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) (6), diagnostic codes in the ranges 800.0–801.9, 803.0–804.9, and 850.0–854.1 for cases regardless of survival status, with the addition of codes 873.0–873.9, 905.0, and 907.0 for cases resulting in death. Since the publication of the guidelines, most surveillance of TBI in the United States has relied on these definitions (7,8).

### Severity

In epidemiologic reports, TBI severity refers to the amount of acute disruption of brain physiology or structure. Assessments of severity derive from clinical evaluations conducted early in the course of acute medical care; sometimes they also take into account the results of neuroimaging tests. Epidemiologic studies have used various classifications of TBI severity, such as the Glasgow Coma Scale (GCS) (9), the Abbreviated Injury Severity Scale (AIS) (10), and ICDMAP (11,12), an approximation of the AIS based on ICD-9-CM diagnostic codes. Severity is of interest to the extent that it helps to predict the course and eventual outcome of the injury, but should not be confused with outcome.

The ordinal categories of these severity scales are sometimes combined into the broader categories of mild (or minor), moderate, and severe TBI (13,14). Defining the boundaries of these categories has been difficult, especially defining the minimum criteria of a mild TBI. To address the latter issue, CDC recently convened an expert panel; the consensus-based definition they developed may be summarized as follows:

Mild TBI is an injury to the head (arising from blunt trauma or acceleration or deceleration forces) that results in one or more of the following: any period of confusion, disorientation, or impaired consciousness; any dysfunction of memory around the time of injury; loss of consciousness lasting less than 30 minutes; or the onset of

observed signs or symptoms of neurological or neuropsychological dysfunction (15).

The term “mild” can be misleading if interpreted to mean inconsequential injury or injury with only minimal and transient effects. Clinical data indicate that some mild injuries have significant sequelae; the frequency with which these occur among people experiencing mild TBI remains to be determined by epidemiologic studies.

### Outcome

TBI outcome refers to survival status after injury and to the extent of impairment and disability after there has been an opportunity for recovery. Because of methodologic difficulties, relatively few epidemiologic studies have addressed TBI outcomes. Some of these have used the Glasgow Outcome Scale (GOS), a five-point ordinal measure of global outcome (16).

### Incidence and Prevalence

The measurement of TBI incidence (rate of occurrence of new cases) and prevalence (proportion of a population with TBI-related disability) requires population-based studies focused either on the entire population of interest or a representative sample of that population. Such epidemiological studies differ from descriptive studies of hospital case series, which constitute most of the clinical literature on TBI. Clearly, the latter cannot be assumed to reflect the entire population of persons with brain injury. Thus, such case series cannot accurately describe incidence rates or distribution of risk factors, causes, or severity in the entire population.

### Public Health Surveillance

Surveillance is the ongoing, systematic collection and analysis of information to monitor health problems (17,18). Recent TBI surveillance has often focused on temporal trends in the incidence of these injuries (8,19).

## METHODOLOGICAL ISSUES

### Availability of Data

Several data sources in the United States provide quantitative data for population-based assessment of TBI (20). The most easily obtainable of these sources are designed for other administrative purposes, e.g., hospital billing, and thus they contain only limited information regarding the clinical manifestations and causes of TBI. The information they include can sometimes be enhanced by linkage with other data sources, e.g., data abstracted separately from medical records. The following data sources

\*The CDC case definition of TBI was developed as a tool for public health surveillance, not clinical practice. As such, it attempts to identify not only cases of craniocerebral trauma where transient or persistent sequelae are noted but also cases where sequelae are possible. For this reason, the definition includes skull fractures in which medical records lack indications of neurologic injury per se, and also includes mild injuries in which records document only minimal and transient neurologic symptoms. The definition does not assume that the outcomes in such cases are necessarily adverse or of significant neurologic effect.

are widely available and useful for epidemiologic studies or surveillance.

**Mortality** The National Center for Health Statistics (NCHS) collects death certificate data from vital statistics records from all U.S. states and territories. These Multiple Causes of Death Data (MCDD) include information on demographics as well as the nature and external causes of injury, coded according to the International Classification of Diseases. The recent tenth revision of this classification (ICD-10) (21), incorporated major changes by forming new cause-of-death titles and codes and a restructuring of the leading causes of death (22). The effect of these changes on the comparability of mortality data collected before and after the implementation of ICD-10 has not yet been evaluated.

Most countries that belong to the World Health Organization (WHO) maintain some form of national death records using the ICD coding system. In general, developed countries have more reliable reporting systems than less-developed countries. Thus, comparisons of TBI mortality between countries must be made with caution, taking into account variability in the completeness of reporting systems and coding criteria.

**Morbidity** Developed countries often have national or regional data sets that allow descriptions of TBI-related hospital admissions, accurate to the extent that coding practices and reporting are reliable in individual hospitals. International comparisons of TBI using hospital discharge data systems are possible when uniform case definitions are used. The WHO *Standards for Surveillance of Neurotrauma* (23) contains such case definitions; these are consistent with CDC case definitions. The WHO Department of Injuries and Violence Prevention Program has many collaborating nations that provide aggregate data for international comparisons.

In the United States, the availability of such morbidity data is limited because the health care system is not centralized. Even so, several U.S. data sources are available:

The National Health Interview Survey (NHIS), conducted by NCHS, is an annual interview of a sample of households that in some years includes supplemental questions on injury. These allow estimates of TBI incidence, stratified by the level of care received (e.g., physician visit, hospital emergency department visit, or hospital admission). Survey data are limited by the accuracy of the information recalled by respondents.

The National Hospital Discharge Survey (NHDS), also conducted by NCHS, is an annual survey of patient discharges from a sample of

nonfederal hospitals. NHDS provides information on primary diagnosis and up to six secondary diagnoses, length of stay, payer information, and demographics. This enables estimates of the incidence of TBIs that result in hospital admission.

Many states aggregate claims data for hospital care to create hospital discharge data (HDD) sets. These data are standardized and coded according to the Uniform Billing form (UB-92), promulgated in 1992 by the U.S. Health Care Financing Administration (now the Center for Medicare and Medicaid Services). As long as states require all hospitals within their jurisdiction to report these data, HDD sets can enable reliable estimates of the incidence of TBI-related hospital discharges, and thus, they have become increasingly popular as primary sources of information for surveillance. These administrative claims data provide only limited information, however. In some state surveillance programs, additional information on severity, circumstances of injury, and short-term outcome is obtained by abstracting medical records in a representative sample of TBI cases identified from HDD sets.

Some emergency department data are also available with which to estimate the incidence of TBI among persons not admitted to hospitals. Since 1992, the NCHS's National Hospital Ambulatory Medical Care Survey (NHAMCS) has included a national sample of visits to emergency and outpatient departments of noninstitutional general and short-stay hospitals (24). In addition, some states maintain aggregate statewide emergency department visit data sets that can also be used for estimates of TBI incidence.

The NCHS National Ambulatory Medical Care Survey (NAMCS), another annual survey, provides information on ambulatory medical care provided by offices of physicians who are not federally employed. Although this data source affords some opportunity to estimate the incidence of injuries treated in an outpatient setting, the accuracy of physician office coding for specific diagnoses such as TBI has not been evaluated.

In many states, data on outpatient visits are available from state employee and workers' compensation insurance programs. These data sources provide detailed information on outpatient encounters for subscribers and their families. These sources may have limited use for the surveillance of minor injuries.

### Quality of Data Sources

The quality of the data that come from vital and health care data systems is limited for several reasons. First, because such data sets are often collected for nonresearch purposes, such as reimbursement, they may omit some important clinical information, such as indicators of outcome. Second, these data are often collected on a large scale and recorded, coded, and transcribed by many persons with varying degrees of skill. Third, diagnostic coding may reflect a need to maximize reimbursement. Finally, many hospitals and health care systems may lack the means to validate the coding derived from the medical record and ensure high quality data.

The availability of medical care and medical technologies, the integration of health care systems, the quality of the public health infrastructure (including vital records and medical examiner or coroner systems), and the availability of information technologies can all affect the completeness of TBI diagnosis and reporting. Not surprisingly, these vary greatly among nations and regions, and thus, international comparisons of TBI have to be carefully interpreted with consideration given to bias in case-ascertainment and information.

Although mortality data systems are less prone to error from duplicate reports, morbidity data aggregated from HDD sets may be subject to overreporting due to hospital readmissions and inter-hospital transfers, unless data can be linked to identify these occurrences.

The incompleteness of data elements that are critical for understanding TBI occurrence is a major problem in hospital discharge and emergency department data systems. ICD-9-CM external-cause-of-injury coding (E-coding) is usually incomplete in hospital discharge data sets (25,26), rarely exceeding 90 percent unless augmented by medical record review. In addition, the 5th-digits of ICD-9-CM codes, which provide additional clinical detail, are often incomplete. These are particularly useful, if coded correctly, to assess severity. Other crucial data that are often missing include source of admission, secondary payers, secondary E-codes that describe place of occurrence, and information regarding impairments and disability noted at the time of hospital discharge.

Finally, there are substantial limitations in the quality of clinical information that health care providers record, upon which accurate ICD-9-CM coding (including 5th digit information) depends. Notably, Glasgow Coma Scale scores are not recorded in about 40 percent of hospital medical records of people with TBI (8). Sometimes this is due to inherent difficulties in applying the GCS; for example, it may be difficult to assign an accurate score in the presence of injury complications or medical interventions such as periorbital swelling, intubation, or the use of drugs (e.g., sedatives or paralytic agents). Also, the GCS does not account for the amount of stimulation needed to obtain a response, which may affect its

reproducibility (27). In addition, the GCS is often not scored at consistent intervals following injury. Furthermore, numeric scales that are ordinal in nature, such as the GCS, are not linear. Thus, a 1-point change in a lower range of these scales may not represent the same degree of functional change as a 1-point change in a higher range (28). As well, the apparent simplicity of the GCS is misleading because it can be interpreted variously, even among neurosurgeons (29). Finally, its predictive value, especially when applied early, is limited (30).

## PUBLISHED POPULATION-BASED STUDIES

### Trends in TBI Incidence—United States

The incidence rates reported in selected epidemiological studies of TBI-related hospitalizations or TBI-related hospitalizations and death in U.S. localities are summarized in Table 6-1 (7, 8, 31–45). The rates should be compared with caution, because criteria for including cases and the use of rate adjustments vary (3). Still, these studies suggest that rates of TBI related hospitalization have decreased substantially in the last two decades.

From 1979 through 1992, the TBI-associated death rate in the United States decreased 22 percent, from 24.6 per 100,000 population to 19.3 per 100,000 (46). Most of the decrease resulted from a 42 percent decline in motor vehicle-related deaths, from 11.4 per 100,000 in 1979 to 6.6 per 100,000 in 1992. During the same period, firearm-related TBI deaths increased 9 percent, from 7.7 to 8.5 per 100,000, thus surpassing transportation crashes as the leading cause of TBI mortality. Rates of TBI-associated death due to falls and other causes decreased slightly during this period.

In contrast, an analysis of data from the NHDS for 1980 through 1995 documented a steep decline of 51 percent in TBI-related hospital discharge rates; they decreased from 199 to 98 per 100,000 per year over this period (47). The decline in rates of discharge occurred mainly among injuries classified as non-life-threatening. A comparison of findings in the 1979–1992 and the 1980–1995 analyses indicates a disproportionately large reduction in rates of nonfatal TBI resulting in hospitalization. This decrease may reflect some success in injury prevention, but it appears also to be the result of recent changes in admission policies that discourage inpatient care for less severe injuries (47). The apparent shift away from inpatient care underscores the need for surveillance of TBI patients treated in emergency departments and other outpatient settings.

### TBI-Related Hospitalizations and Deaths—Other Countries

countries (48–56) in Table 6-2 and developing countries (57–61) in Table 6-3. Variations in case definitions, criteria for hospital admission, access to hospital care, and quality of national or regional health data sources, as well as different methods of identifying cases and collecting data hinder comparisons between these studies. These problems are especially difficult in developing countries (62). At present, there are too few published studies to form confident

conclusions about TBI incidence worldwide or to describe international trends. Population-based studies from South Africa, India, and Taiwan suggest higher rates in developing countries, however, with a predominance of road traffic injuries, but clearly more data are needed. The dissemination and adoption of international standards for TBI surveillance such as those published by WHO (23) should improve the amount and quality of international data.

### Recent Epidemiological Findings from the United States

**Mortality** A recent report from the CDC summarizes information on TBI deaths, using data from NCHS MCDD collected from 1989 through 1998 (19). During that decade, an annual average of 53,288 deaths were associated with TBI, a rate of 20.6 per 100,000 population. During this interval, TBI-related death rates declined 11.4 percent, from 21.9 to 19.4 per 100,000. Most of these deaths were related to firearms, transportation (involving motor vehicle occupants, pedestrians, bicyclists, motorcyclists, and others), or falls.

According to this CDC study, death rates among males were 3.4 times as high as among females (33.0 per 100,000 males and 9.8 per 100,000 females). Rates were highest among persons aged 75 years and older, with a smaller peak among those aged 15–24 years. The leading causes of TBI-associated death varied with age, with firearm-related injuries ranking first among persons aged 20–74 years, transportation-related injuries first among those under 20, and falls the leading cause among persons 75 and older. Rates for males were consistently higher than those for females: for firearm-related rates they were 6 times as high (14.5 versus 2.4 per 100,000); motor vehicle-related rates, over 2.3 times as high (9.9 versus 4.3 per 100,000); and fall-related rates, 2.5 times as high (3.2 versus 1.2 per 100,000). TBI-associated death rates for the 1989–1998 period differed by race as well: per 100,000 they were 27.2 for American Indians and Alaska Natives, 25.0 for African Americans; 20.1 for whites; and 11.9 for all other racial groups combined.

**Morbidity and Mortality** In the last decade, CDC has supported statewide surveillance of TBI-related hospitalizations and deaths in several states, using standard case definitions and methods noted above. An epidemiologic analysis of TBIs occurring in 1994 in Arizona, Colorado, Minnesota, Missouri, Oklahoma, New York (excluding New York City), and South Carolina (7) revealed an

annual incidence rate of TBI for the combined population of 91.8 per 100,000 (age adjusted to the 1990 U.S. population). This rate included TBI-related deaths (20.7 per 100,000), leaving an age-adjusted rate of 71.1 per 100,000 TBI-related live hospital discharges. For hospitalizations and fatalities combined, the median age at the time of injury was 32 years. The incidence rate was highest among persons 75 years and older (191.1 per 100,000) and among persons aged 15–24 years (145.1 per 100,000) (Figure 6-1). Two-thirds of TBIs (66.7 percent) occurred among males, with the crude rate among males about twice that among females (124.1 versus 59.1 per 100,000).

Transportation-related crashes (involving motor vehicles, bicycles, pedestrians, and recreational vehicles) accounted for 49 percent of all TBIs in the seven states; falls accounted for an additional 26 percent (Figure 6-2). Firearm use accounted for another 10 percent, and assaults not involving firearms accounted for 8 percent. Nearly two-thirds of firearm-related TBIs (66.5 percent) were classified as suicidal in intent. The leading causes of TBI varied by age in the seven states (Figure 6-3); falls were by far the leading cause among persons aged 75 years and older (126.6 per 100,000), while transportation-related crashes led the list for persons aged 15–24 (97.9 per 100,000).

A more recent report describes similar findings for nonfatal brain injuries admitted to hospitals in 14 states during 1997 (8).\* The age-adjusted TBI-related live hospital discharge rate for this 14-state population was 69.7 per 100,000, with age and sex distributions similar to those described in the earlier report from seven states. The more recent report describes differences in age-adjusted rates of TBI by race, with somewhat higher rates among American Indians/Alaska Natives (76.7 per 100,000) and African Americans (74.2 per 100,000) than among whites (63.0 per 100,000).

**Nonfatal TBIs Not Admitted to Hospitals** In the United States, the NCHS's NHIS has provided some information on TBI treated on an outpatient basis (63). In 1991, an estimated 1.54 million noninstitutionalized U.S. civilians sustained a brain injury that resulted in loss of consciousness but was not severe enough to cause death or long-term institutionalization, according to self-reported NHIS data collected with the 1991 Injury Supplement. Of these 1.54 million persons, 25 percent received no medical care for their TBI; 49 percent, care in an emergency department or other outpatient site, and 9 percent, overnight hospital care; 16 percent were admitted to a hospital for 2 or more days. The limitations of the survey methods and respondent recall may limit the accuracy of these estimates. Data from the NHAMCS of 1995–1996 may provide a more accurate estimate of the incidence of nonfatal TBIs in which the patient was treated and released from hospital emergency departments (64). This analysis indicates an average annual incidence rate of 392 such emergency department visits per 100,000 population, or about 1 million visits annually.

**Severity and Outcome** Several measures of TBI severity have been used in epidemiological studies. The case fatality rate, which is the proportion of cases resulting in death, is the simplest epidemiological measure of severity as well as outcome. In the study of TBI-related hospitalizations and deaths in seven states during 1994, (7) 22.6 percent of all reported TBIs were fatal within the acute period of injury. Of all persons with reported TBIs, 16.9 percent died without being admitted to a hospital, while 5.6 percent died while receiving acute inpatient care. The case fatality rate varies greatly by cause; in this study, 90.4 percent of firearm-related TBIs resulted in death, but only 10.2 percent of fall-related TBIs proved fatal.

In the analysis of NHDS data for 1980–1995 described earlier, the authors used ICDMAP-generated ICD/AIS scores to estimate the severity distributions of hospitalized cases (47). In the NHDS data for the last 2 years of the study period (1994–1995), 52 percent were *mild* (ICD/AIS score 2), 21 percent were *moderate* (ICD/AIS score 3), 19 percent were *severe* (ICD/AIS score 4–6), and 7 percent were unknown. The proportion of TBIs classified as mild among the 1994–95 cases was considerably smaller than the corresponding proportion of 1980–1981 cases and was also smaller than proportions reported in earlier studies (3). These findings support a conclusion that persons in the United States with less severe TBI are now less likely to be admitted to the hospital.

**Incidence of TBI-Related Disability** Few studies have addressed the incidence of TBI-related disability. From limited available epidemiological data, Kraus estimated that in 1990 about 83,000 or more U.S. residents were

disabled by TBI. (3) The CDC published a similar estimate based on 1994 data from the NHDS and 1996–1997 data from the Colorado TBI Registry and Follow-up System (1, 65). The latter system surveyed TBI survivors one year after injury and measured long-term disability with the Functional Independence Measure (66). NHDS data indicate that during 1994, 230,000 persons hospitalized with TBI survived, and data from the Colorado TBI Registry and Follow-up System indicate that approximately 35 percent of hospitalized survivors of TBI are disabled 1 year after injury (7). Combining these figures suggests that more than 80,000 persons in the United States experience the onset of long-term disability each year following hospitalization for TBI. This estimate may be conservative, however, because it excludes the unknown number persons who are not hospitalized after TBI but still experience long-term disability as a consequence of their injury.

*Prevalence of TBI-Related Disability* Despite the recent publication of reports on the incidence of TBI-related hospitalization in several countries, few reports are available on the population-based prevalence of TBI-related disability and relatively little of the published data was collected with sufficient rigor to enable confident estimates. Most studies of disability occurrence after TBI have examined series of patients admitted to research hospitals. Such studies, by not including persons hospitalized in nonresearch and community hospitals, may not be representative of the underlying population. In addition, they do not address the outcomes of TBIs that are treated only in hospital emergency departments. These limitations notwithstanding, several of such studies—reviewed in other chapters of this book—have a sufficiently broad inclusion of participants to permit important generalizations regarding outcomes following TBI-related admission. Such studies document high proportions of patients who experience long-term sequelae, including substantial psychosocial and physical disabilities that are often associated with cognitive impairments (67).

The information obtained from population-based follow-up studies in Colorado and South Carolina is expected to enable more accurate estimates of disability associated with those TBIs severe enough to warrant hospitalization. In addition, the CDC has provided a provisional estimate of the prevalence of disability from TBI in the United States, based on preliminary follow-up data from the Colorado TBI Registry and Follow-up System and historical and current estimates of national TBI incidence. Together these sources suggest that approximately 2 percent of the U.S. population (5.3 million in 1996) are living with disability as a result of a TBI. (7) This estimate does not, however, account for disability among people with TBI who visited emergency departments or outpatient clinics but were not admitted. Improvements

on this estimate can be expected as more data are obtained and analyzed from these studies.

*Using Severity Indicators in TBI Surveillance to Predict Outcome* The Glasgow Coma Scale score is a widely used predictor of outcome, both mortality and disability (68–71), and yet its ability to predict the latter is limited in the population of TBI survivors who receive rehabilitation (72). Some research indicates that the prediction of the distribution of TBI disability outcomes in population-based studies may be improved by supplementing GCS data with information about computed tomography (CT) findings (73). Currently, state surveillance programs in the United States collect both GCS and CT scan data, but population distributions of severity based on the combination of these data elements have not yet been published. Other research has found predictive value in the duration of post-traumatic amnesia (74–78), and Nell and Yates proposed an enhancement of the GCS that incorporates a measure of duration of post-traumatic amnesia in persons with little or no depression of consciousness (79). Population-based studies that describe TBI severity with these measures have not yet been published; when available, such studies will help to predict the magnitude of ongoing health care needs among people with TBI.

*Economic Costs* Max and colleagues, who analyzed 1985 U.S. incidence and cost data for TBIs that resulted in hospital admission or death (80), estimated that total lifetime costs for those injured were approximately \$37.8 billion, with 12 percent for direct costs of medical care (hospital, extended, and other medical care and services); 55 percent, injury-related work loss and disability; and 34 percent, lost income resulting from premature death. A reexamination of this study that adjusted its estimates for inflation and more recent TBI incidence data, yielded total lifetime costs of \$56.3 billion for injuries sustained in 1995 (81). New studies are needed that use recent healthcare cost data to update this estimate.

Studies of trends in the economic cost of TBI are of particular interest in public health. The Model Systems Traumatic Brain Injury program, funded by the U.S. Department of Education's National Institute on Disability and Rehabilitation Research, collects data from multiple centers, enabling trend analyses of the cost of medical care for enrolled TBI patients. A recent study indicates that from 1990 to 1996, average daily inpatient charges in this group of patients increased by 98 percent for acute care and 41 percent for rehabilitation (82). During this interval, however, these increases were offset by reductions in average lengths of stay of 42 percent in acute care and 38 percent in rehabilitation. The authors note that the steady downward trends in length of stay for both acute care and rehabilitation raise concerns about diminishing availability of health care services to persons with

TBI. The generalizability of their findings is uncertain, however, because they came from a study population that was likely skewed toward more serious injuries. Still, these findings support the need for current population-based assessments of trends in costs and care for TBI.

### APPLYING FINDINGS TO PUBLIC HEALTH: PREVENTING TBI

The evidence reviewed in this chapter makes clear the great importance of TBI to public health. Despite progress in reducing the incidence of these injuries—especially those associated with motor vehicle crashes (19,46)—the need for more effective primary prevention programs remains. To be most effective, such programs must be guided by current findings regarding the principal causes of TBI—transportation injuries, falls, and violence—as well as an understanding of populations at increased risk and individual risk factors.

Because the primary prevention of TBI occurrence is incomplete, an effective public health response to TBI also requires concerted programs to minimize adverse outcomes and disability. Such secondary and tertiary prevention comprises acute care and rehabilitation of persons with TBI, the subjects of other chapters in this book. To this end we need comprehensive strategies to ensure that people with TBI have access to appropriate care and services and we need effective policies to promote their independence and integration into the community.

To help persons living with deficits from TBI, we need better information on the nature and scope of these disabilities, including who experiences disability, which rehabilitation treatment methods are most effective, and what services are useful and readily available. Population-based follow-up surveillance is needed to provide more precise information on the longer-term impacts of these injuries. Standard measures for TBI outcomes need to be refined so they will readily identify the types of impairment and disability most amenable to prevention through rehabilitation and social support. Better understanding of the relationship between the initial severity of an injury and its long-term outcome will help identify those persons who need ongoing medical care, rehabilitation, and other services. Such information will also help health practitioners and policy makers ensure that these services are available in the community.

### SUMMARY

This chapter has reviewed epidemiological measures and estimates of TBI incidence, severity, long-term outcomes, and cost. All of these findings indicate that these injuries have a major impact on public health. Effective primary

prevention programs are needed that are informed by accurate epidemiologic data regarding causes and the populations at highest risk. Doing this requires improved public health data systems that record those TBIs that do not result in hospital admission as well as those that do. More basic and clinical research is needed to improve the acute care and rehabilitation of TBI. Finally, more epidemiological research regarding TBI outcomes and disability is needed to develop policies that will ensure the availability of effective acute care, rehabilitation, and other services that will minimize disability among injured persons and promote their reintegration into the community.

### INTRODUCTION

The intent of this chapter is to review common prevention strategies and their overall effectiveness in this patient population, with an emphasis on the need for further preventative measures. The importance of these efforts will be obvious to readers after the following discussion that addresses the data on the incidence, severity, and consequences of traumatic brain injury (TBI).

Injury is the leading source of death for Americans under age 44 (1) and one-third of all injury-related deaths from 1979 to 1992 were associated with a TBI (2). Approximately 1.5 million Americans sustain a TBI every year (3). From 1979 to 1992, 50,000 American deaths and 230,000 hospitalizations occurred annually as a result of TBIs (2). In addition, each year over 80,000–90,000 people develop long-term disability secondary to TBI with approximately 14 million days of restricted activity secondary to TBI (4–6). The number of Americans who have some form of disability as a result of TBI is estimated to be around 5.3 million (7,8). The annual overall cost to the United States was estimated to be \$37.8 billion in 1985 and \$44 billion in 1988 (9).

In 1996, approximately 150,000 children and adolescents were left permanently disabled and in need of long-term follow-up as a result of unintentional injuries including brain and spinal cord injury (10). Injury mainly

affects the younger population and encompasses more years of potential life lost than any other cause with estimates yearly totaling 3.5 million years (1). Most individuals who have sustained a TBI are unable to return to work and if they do return, their work capacity is limited. The estimated morbidity cost (injury related work loss and disability) was approximately \$20.6 billion in 1985 (9).

There was a decrease in the incidence of TBI related death and hospitalization from 1979 to 1992. From 1974 to 1986, TBI incidence, morbidity, and death rate was approximately 50 percent higher than current estimates. Currently the TBI hospitalization incidence is about 100/100,000 (5). This differs from previous reports rates of 200/100,000 that were reported between 1974 and 1986 (7,11–13). The decrease may in part be a result of a decrease in severity of injury, overall change in admission policies, and a push to treat these injuries in the outpatient environment as well as possible benefit from prevention efforts. In 1980, the rate of TBI related mortality in the United States was 24.7/100,000; this had fallen 20 percent by 1994 to a rate of 19.8, with motor vehicle related mortality showing the greatest decline. With various prevention efforts such as use of air bags, seat belts, and child safety seats, mortality dropped 38 percent from 11.1 to 6.9/100,000 between 1980 and 1994.

## TRAUMATIC BRAIN INJURY VS. OTHER DISABLING CONDITIONS

TBI has often been called the silent, or invisible, epidemic (7), a stepchild that has only received minimal public awareness and dedication of financial resources to its treatment and prevention. This is a grave mistake, as the annual incidence of TBI is greater than that of the more widely known conditions of spinal cord injury, breast cancer, multiple sclerosis, and HIV (See Figure 7-1.). For example, there are 50,000 deaths per year as a result of a traumatic brain injury versus 16,273 deaths reported in 1999 as a result of HIV (14). The mortality rate for HIV has dropped over the past few years, which can be mainly attributed to public awareness, dedication to preventative measures, research, and treatment. The same trend is potentially possible in TBI if efforts are directed to awareness and prevention. It may take multiple strategies, targeting various communities, to enhance public awareness (15). Meeting communities' individual needs can possibly lead to implementation of more effective preventative measures.

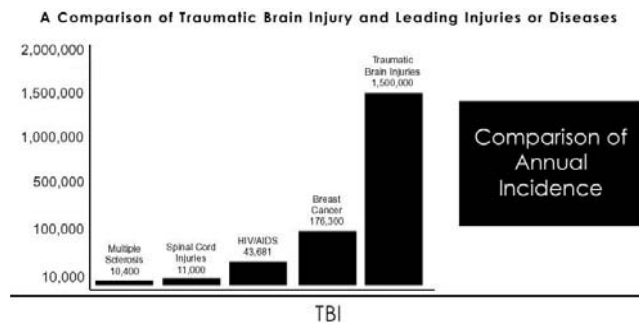

FIGURE 7-1

## ECONOMICS OF TBI: COSTS, BURDEN, AND ITS PREVENTION

There are monumental economic costs associated with TBI, when one includes both direct medical care and indirect costs such as loss of productivity. It was estimated that in 1985 the lifetime cost of injury amounted to \$38 billion for those injured enough to result in death or hospitalization (9). Ten years later, approximately \$260 billion dollars was spent on injury in the United States (16).

With the growing medical costs in today's world, the cost/benefit ratio of a prevention program is an issue of importance. Some of the more accepted preventative measures such as Hepatitis B vaccinations in newborns, child safety belts, bicycle helmets, and smoke detectors have proven to be very cost effective. Injury prevention programs vary in their cost effectiveness; however, many of them have shown their worth. In regards to TBI, programs such as zero alcohol tolerance for drivers under 21 years of age and graduated licensing have also proven to be of benefit (1).

A study that examined the time and money spent counseling families of young children regarding injury prevention efforts, reported that \$13 was saved for every dollar spent on counseling (17). Emphasis must be placed on community education for better public awareness. There appears to be a correlation between public awareness and the listener's educational level and income. This is an important point in patient education that should not be overlooked and should be factored into injury prevention programs.

There is a significant need to increase funding for prevention efforts. This may be problematic as funding may actually decrease as a result of an increased pressure to reduce spending by the federal government. As a result, it is probable that funding from the Preventative Health Services Block Grant will be reduced, which is a major funding source for injury prevention programs and chronic disease prevention (10).

## WHAT IS PREVENTION?

Prevention can be subdivided into primary, secondary, and tertiary prevention. Primary prevention efforts are designed to prevent the actual injury. Examples of primary prevention include screening tests, fall-proofing homes, traffic laws and their enforcement, salting of ice-covered roads, and education on topics such as drinking and driving. Primary preventative measures has been shown to work with other conditions. Adjusting workstations for individual workers have had an impact on decreasing musculoskeletal disorders and injury from their use (18). Secondary prevention is described as lessening the impact of the damage resulting from injury. Examples include engineering methods, such as automobile seatbelts and airbags, which have had a significant effect at controlling injury (18). Developments of advanced trauma care and emergency management services are examples of tertiary prevention, with their purpose being to lessen the secondary sequelae of injury (1).

The USPS Task Force was a large four-year multi-disciplinary effort to assess various preventative health measures. The summarized assessment contained 169 interventions in three different areas: screening, counseling and immunization/chemoprophylaxis. The predominant finding was that personal health behavior, such as smoking, diet and exercise, is the main contributor to mortality and disability. The task force emphasized the importance of physicians educating their patients while simultaneously giving them more responsibility for their own health. It was recommended that various strategies should be used to counsel the patients including support groups, written material and audiovisual aids (19).

## INJURY CONTROL THEORY

Originally, the general belief was that TBI was a result of accidents, which implied that all persons had equal

probability of sustaining injury (20,21). After a review of TBI epidemiology literature it appears that this may not be the case. Careful consideration must be made to a person's age, sex, and other individual risk factors that increase the likelihood of sustaining an injury (19). For example, falls among the elderly may be secondary to sedatives, antidepressants, lower extremity disability or balance impairments (5). There has been substantial work devoted to the identification of people at risk and developing effective preventive countermeasures (21,22) and as a result there has been a substantial increase in the science of injury control theory over the last 50 years

### THE HADDON MATRIX

The Haddon Matrix is a model that divides injury into various components including a host, vector and the environment, both physical and social, that the host and vector interact within. An elderly person falling on the ice and breaking their hip can serve as an example. In this case, the host is the injured human, the vector the age of the person and the environment is the weather conditions during the time of injury.

Haddon also identifies three different phases of injury, the pre-injury, injury and post-injury phases. This is comparable to the primary, secondary and tertiary prevention efforts mentioned above (1). Using these sets of variables a table can be created where each cell represents an area and a temporal component. All the different variables that contribute to an injury can be placed into one of the table's cells.

To best illustrate this concept, consider the factors related to a motor vehicle accident in the preinjury phase. Age and alcohol use would be placed in the host pre-crash or pre-injury cell, the vector would include the condition of the vehicle and the environmental cell would contain the roadway design. The cell, which includes the socio-economic environment, takes into account the affordability to the consumer and their safety risks. It would account for risks associated with purchasing an older cheaper vehicle without safety features or poorer road handling capabilities.

By studying the epidemiology of injury, efforts can be made at breaking various injury patterns in the different phases. Potentially the most efficacious way to prevent an injury is to target the vector or injuring agent and thereby alter the mechanism of energy transmission. Creating better designed cars, better engineered roads and improving conditions of the vehicle would greatly impact injury prevention.

### APPROACH TO HEALTH MAINTENANCE

To address the important issue of health maintenance there must be a comprehensive approach at controlling

injury and promoting health. It must include passive and active strategies, education and legislation. Passive strategies include those in which the host does not have an active role in its use (23). By nature, they offer protection to a larger percentage of the population and have the advantage of demonstrating effect without requiring any effort by the host that requires protection (24). Some examples of these include airbags, road barriers, fingerprint based gunlocks and car safety engineering. Active strategies are ones that require the host's participation, with the donning of a seat belt, avoiding driving when under the influence, motorcycle helmet usage and car seats as examples. Active prevention is dependent upon the public's awareness of such measures and their overall compliance with them. It may take a tremendous amount of societal effort to encourage the host to adopt these active measures of prevention. While this is a disadvantage as compared to passive measures, their potential for increased efficacy makes them potentially both important and possibly extremely effective when used in combination with passive measures.

In regards to education, professional health organizations are groups comprised of individuals who have met a standard of training and whose purpose is to serve the public. It is only natural that these groups use their position and expertise to further educational efforts to educate the lay community. This can be implemented through journals, publications and testimonies to legislative groups. The American Cancer Society, founded in 1913, is an example of a nonprofit voluntary health agency, organized to spread knowledge about cancer and is supported by voluntary donation (25). The Center for Disease Control is a federal agency responsible for surveillance of communicable diseases in the United States, investigation of epidemic diseases and promotes immunization and health education programs (18). On a smaller scale, education at the community and individual level by both physicians and other health care professionals must be emphasized as it can have a tremendous impact on injury prevention (15).

In general, changing human behavior can be a very challenging endeavor and there is still some controversy on the appropriate approach. Haddon stated that targeting the vector with passive interventions and the environment may be the most effective in decreasing death and injury. This does not negate the potential benefit of using a combined approach, of active and passive measures of intervention. An example of this is the use of seatbelts in combination with airbags. Each prevention method has shown its benefit, however using both together has been shown to be more effective than either one by themselves.

If one factors in legislation, to increase compliance with active prevention efforts further benefits can be attained. The states that strengthened existing seatbelt laws and adopted primary enforcement seatbelt legislation had

an estimated 79 percent compliance with belt use in 1998. This was an increase from 62 percent seat belt compliance in 1992 prior to the addition of primary enforcement legislation (1,26).

### DEVELOPMENT OF A COMPREHENSIVE INJURY PREVENTION PROGRAM

The components critical to development of a comprehensive injury prevention program are active and passive strategies, education and legislation. Engineering solutions are an important component of the passive interventions and include items such as energy absorbing car bodies, road barriers and air bags. Active strategies, such as education, are also critical, both at the individual and community level (1). Some of the most effective interventions include hands on demonstrations and reinforcement at subsequent visits (27). However, the listener is more inclined to change their behavior if there is some incentive to do so.

It has been shown that if only education is used then the general public may not change their overall behavior (28). Community based intervention programs combining education with legislative options has been shown to be effective in increasing bicycle helmet usage (15). Work performed in three separate Maryland counties explored bike helmet usage by children under three separate conditions. In one county, helmet use improved significantly when education and legislation were combined (43 percent increase). Another county, which used education alone, showed only an 11 percent increase, which was not statistically significant (29). The third county, which did nothing, actually demonstrated a decreased rate of helmet use from 19 to 4 percent.

Enforcement of legislation is critical to maximize its potential benefit, with seatbelts being an example. By 1984 passenger cars were required to have seatbelts, but only 15 percent of people used them while driving. By 1987 education combined with seatbelt legislation increased this rate to 42 percent. This was further increased to 62 percent when secondary enforcement laws were enacted for nonuse. A secondary enforcement law is one that allows the giving of a citation when the driver has been pulled over for another traffic offense. This rate stayed the same through 1998 in the states that used secondary enforcement laws. When some states increased legislation and enforcement efforts with the enactment of primary enforcement legislation, which allowed ticketing when the only infraction was seatbelt nonuse, compliance increased to 79 percent (26).

In summary, a comprehensive approach to injury control including active and passive measures, education at both the community and individual level and appropriate legislation is the most efficacious way to facilitate

injury prevention. It is necessary to take a multifaceted approach, targeting as many components of the Haddon Matrix as possible to promote injury prevention.

### MOTOR VEHICLE

To begin the exploration of TBI prevention efforts, it is most fitting to approach this issue by examining the leading cause of TBI in the United States: motor vehicle accidents (7). Motor vehicle accidents are the most common cause of brain trauma in the United States and are responsible for approximately half of all brain injuries each year (30). The prevention strategies that have targeted motor vehicles have resulted in a decreased occurrence of transportation related brain trauma. There has been a 38 percent decrease in motor vehicle related deaths from 1980 to 1994 (7). In 1970, there were 4.6 highway fatalities per 100 million passenger miles traveled. This number dropped 50 percent to 2.3 fatalities per 100 million passenger miles by 1989 (31). The reason for this reduction in fatalities is multifaceted and includes airbags, seatbelts, safety features and a higher legal drinking age, all of which will be further addressed in this discussion. Transportation related TBI prevention efforts could be approached, using both passive and active methods and, as with other preventative measures, the more comprehensive the approach, the better the overall effectiveness.

### AIRBAGS AND SEATBELTS

Airbags are designed to rapidly and automatically deploy during a frontal vehicle collision with the intent of creating an absorptive impact barrier between the vehicle's occupants and the automobile's front interior paneling. This barrier allows for the safer transfer of energy that occurs with impact. An airbag is deployed after the vehicle either comes into contact with a fixed obstacle, such as a brick wall, at 15 miles per hour or when it collides with an equally sized vehicle at 20 to 30 miles per hour. The entire cycle of deployment and subsequent deflation of airbags occurs within one second. It takes merely 1/20th of a second to inflate after impact with the deflation portion beginning within 4/20th of a second. The advantages of this rapid cycle lie in the ability of the driver to maintain control of the vehicle and also prevent trapping of passengers (32).

Advocacy for airbags has resulted in their installation as standard equipment in all passenger cars. Jagger has stated early in the 1990's that making airbags standard equipment would be of greater benefit in the prevention of TBI than any other prevention method (30). She surmised that of the number of patients admitted to a hospital who had acquired TBI, 25 percent could have been prevented

by the use of airbags. While they have been of some benefit, Jagger's prediction has been somewhat off the mark as will be discussed later in this section.

Airbags are designed to protect against frontal impact collisions and are not designed to prevent ejection from the vehicle, a major cause of vehicle collision mortality, which requires seatbelt usage to prevent. Another issue, is that they were designed to be effective with frontal injuries and are less beneficial with impact that do not occur between 11 and 1 O'clock with 12 O'clock as direct head on collision (32). Newly developed side impact bags are being introduced into the market that provide much needed protection against side and rear impact collisions and vehicle rollovers. The issue of side air bags is important because it is thought of as an important way of protecting the torso in a side impact collision. It is an alternative to padding as it occupies less space in the car. There are still challenges with perfecting this method of prevention such as the timing of deployment of the bag and length of time for inflation. The best location of deployment also needs to be determined to minimize the risk of injury, particularly those of the upper extremities (33). It is important to ensure that the bag does not deflate too rapidly and become stiff because as the volume of the bag decreases, it automatically gets stiffer (34). Women are particularly vulnerable as they tend to sit closer to the steering wheel. One must be careful in the design of an airbag system as excessive stiffness may result in head injury (35). It is also difficult to make a side bag that would be appropriate for all torso sizes. It was suggested by Parkin et al. that the ideal "smart" restraint system would be programmed for the sex and age of the patient. The literature is yet to determine if side airbags will prevent brain injury. They continue to hold promise as frontal airbags are not foolproof and have limitations in the area of the body that they protect and the type of collision it protects against. Further research in this area is both exciting and still warranted.

The combined utilization of seatbelts and airbags has been proven to be the most protective. In the National Highway Safety Administration's Third Report to Congress in 1996, airbags were reported to reduce fatalities in pure frontal crashes, excluding rollovers, by 34 percent and 18 percent in near frontal collisions. In this analysis, the fatality rate using airbags alone was reduced by 13 percent taking all crashes into consideration. This is in comparison to a 45 percent reduction rate using lap-shoulder belts alone and 50 percent reduction using both modalities (32).

The National Highway Traffic Safety Administration's Crashworthiness Data System reported interesting information regarding the efficacy of airbag and seatbelt use in moderate and severe injuries. Tests studying the effects of airbags alone did not demonstrate a statistically significant result as moderate and severe injuries were

reduced by merely 18 percent and 7 percent, respectively, when looking at all organ systems. This was in sharp contrast to the reported reduction of 49 percent and 59 percent with the use of a lap-shoulder belt system. Interestingly, the combination of both systems reduced risk by 60 percent. From this information one might conclude that airbags provide very little added benefit to the use of lap-shoulder belt system restraints. However, while injury severity to different body systems must be taken into consideration, TBI has been shown to be the major source of mortality in the multiple trauma occupant (36). With this in mind, a restraint system that protects against head and brain injury is of great importance. The use of manual lap-shoulder belt and airbags in combination resulted in an 83 percent and 75 percent reduction in moderate and severe head injuries, respectively. This data is significant when compared to the risk reduction of 59 percent and 38 percent with the use of a lap-shoulder belt alone. Although much of the risk reduction results from the use of the lap-shoulder belt alone, it is important to realize that lap-shoulder belts must be "used," which differs from the automatic deployment of an airbag restraint system.

The preventative benefits of seatbelts and airbags are clearly demonstrable. However, there have been a number of injuries associated with their use. Some of these injuries include spinal, brachial plexopathy, liver lacerations, small bowel tears, traumatic hernias, aortic tears, ocular and facial trauma, neck sprains, kidney trauma, sternal fractures, lung perforation, and placental/fetal injury (37-55). Airbags have also been reported to cause a number of injuries including skull fracture and facial injury (56-58), ocular trauma (59-63), burn injuries (64-66), reflex sympathetic dystrophy (67,68), extremity fracture (69, 70), chest injuries, spinal injury (71,72), ear and hearing loss (73,74). There is substantial evidence that children are most susceptible to injury due to airbag deployment (59,71,75-81). These injuries have been severe and even fatal in situations where children have been both properly and improperly positioned (59,71, 75, 80,82,83). Efforts are currently underway to ensure that the protective benefits of airbags are extended to include children.

## MOTORCYCLES

TBI due to motorcycle accidents is a serious problem in the United States. Although motorcycle accidents account for only 6 percent of all related transportation accidents, it may very well be the most dangerous form of transportation (84). There have been nearly 10,000 deaths related to motorcycle accidents from 1989 to 1991(85) with an additional 15,000 motorcycle deaths associated with head injury from 1979 to 1986 (21). A fatality rate of 1.2/100,000 and a hospitalization rate of 24.7/100,000

were reported in a study from Connecticut with 22 percent of injuries occurring to the head, brain, or spinal areas (86). Comparatively, a study reported from New Zealand found a higher mortality rate of 3.6/100,000 and hospitalization rate of 80.4/100,000 related to motorcycle accidents (87).

Factors related to motorcycle fatalities include driver error (76 percent), most commonly excessive speed (21), failing to wear a helmet, and elevated blood alcohol levels. Amongst all methods of transportation, alcohol seems to be the greatest problem for motorcycle drivers with a study finding that they have the highest rates of both alcohol use and legal intoxication (88).

Probably the most critical mitigating factor relating to TBI and fatalities due to motorcycle accidents is the utilization of helmets. A study in 1982 reported that a helmetless rider has a 2.3 times greater likelihood of having head, neck, or facial injury and are 3.19 times as likely to suffer a fatality than those who wear helmets (89). Bachulis et al. (90), found the rate of brain injury to be double and severe brain injury six times more likely in helmetless riders. Similar findings were reported by Gabella et al. (91), with brain injury occurring 2.5 times as often in riders without helmets. The benefits of helmet use laws have also been demonstrated. After the implementation of a mandatory helmet law in Spain a 25 percent reduction in fatalities due to motorcycles related accidents was observed (92), as well as a decrease in injury severity, shorter hospital lengths of stay and better outcomes. Similar legislation passed in Taiwan resulted in a 33 percent reduction in head injuries (93). Similar findings have been reported from other areas of the world after mandatory helmet laws were enacted. The overwhelming result of this legislation has led to a reduced rate of overall fatalities, TBI related fatalities, overall TBI incidence, injury severity (92–99), length of hospitalization (96,97), and overall cost to society (96,97,100).

Despite this strong evidence from countries around the world, there are still a number of states across the United States that have not enacted mandatory helmet laws. In 2001, there were three states with no helmet legislation, 27 states with helmets required solely for teenage riders and only 20 states with mandatory helmet use for all motorcycle riders (100). Many states have had mandatory helmet laws in the 1970s that have since been repealed or revised.

In 1967, the Federal Government required states to pass a motorcycle helmet law in order to continue to receive federal safety funds. As a result, by 1975, 47 states had passed legislation requiring the use of helmets. However, as opposition mounted against the use of helmets, Congress overturned the helmet requirement. Following this action, more than half of all states with mandatory helmet laws revised their laws (101), with a resultant

decrease use of helmets in those states. Within 9 months of the repeal, the states of Texas and Arkansas saw a decline in helmet usage from 97 percent to 66 percent and 52 percent, respectively. There was a concomitant increase in overall motorcycle injuries, head injuries, and an increased proportion of those injured having suffered head injuries according to data obtained from the Arkansas Trauma Registry (101). This trend was also seen in Miami Dade County with an increased incidence of TBI and fatalities in the post repeal era that saw helmet usage dropping from 83 percent to 56 percent (102). Bledsoe et al. (103), reported on the Arkansas experience of helmet law repeal. A 6-year retrospective review of the trauma registry compared the results of the three years prior to repeal as compared to the three years afterwards. There was no statistical change in total and fatal collisions; however there was a major increase in nonhelmeted deaths at the scene of the accident. The nonhelmeted had significantly higher Abbreviated Injury Scores involving the head and neck, more expensive, longer ICU stays and substantially higher nonreimbursed hospital charges. This of course was a cost borne by the remainder of the community.

As mentioned above, the financial costs to society following the repeals of mandatory helmet laws have been substantial. A study in Texas concluded the median cost of motorcycle related injury increased 300 percent to \$22,531 per event, with TBI costs increasing 75 percent to over \$32,000. Most of these costs exceed limits set by insurance coverage and, so, the financial burden often falls on society (104).

Another issue that also arises is the relationship between alcohol and motorcycle driving. Since handling a motorcycle requires more coordination and judgment than driving a car, there may be a need to lower the blood alcohol level that classifies a motorcyclist as being under the influence. This is supported by a study that examined the blood alcohol levels of drivers of motorcycles and cars brought to trauma centers, with the motorcyclists having lower levels (105). This may indicate that a lower level of acceptable blood alcohol levels may be needed to determine when a motorcyclist is considered to be under the influence.

## ROADWAY DESIGN

Accident prevention can also be achieved by identifying hazardous road locations with specific collision patterns. Various approaches can be used to correct these accident-prone areas through road engineering and technology. The first step in this area was in the 1930's when skidding resistance was added to wet roads (106). It was not until 20 years ago that a major movement in developing safer roads was initiated. *The Road Safety Code of Good*

*Practice* was a publication from the Local Authority Associations that included engineering in addition to education and enforcement, the three E's, for better road safety (107). One study attempted to identify crash problems on various urban arterial streets in Washington, DC (108). Data was retrieved from police reports of a total of 2013 crashes. The locations that had a large number of crashes were analyzed to identify pre-crash movements and travel directions of the crash – involved vehicles. It was found that, at some intersections, drivers had difficulty turning left from a private driveway whereas some intersections had extremely high traffic speeds with crashes likely to occur at the end of a ramp. Left turn signals were not provided at some of the intersections. Based on the analysis of the accident data recommendations were then provided. Changes made included the addition of left turn signals, prohibition of left turns from a driveway, improvement of storm drainage, increased pavement skid resistance as well as the initiation of pavement milling. It was also noted that stopped buses obstructed drivers' visual fields. Relocating bus stops, as well as removing large fixed objects, was a simple intervention that was effective in reducing accidents.

Sabey suggested that the use of four investigative techniques could be the foundation for intervention and treatment of the problem. These four areas included *single sites* where accidents cluster or "blackspots", *mass action* or locations that have common accident factors, *route action* or lengths of road with above average accident rates and *area action* including areas requiring a more global approach aimed at dealing with scattered accidents. He also provided examples of proposed treatments for each of the four variables. For instance, route action could be addressed with road marking to deter overtaking, increasing skidding resistance or installing roundabouts at key junctions to provide access to adjacent neighborhoods. In one trial of a 3km road with a large number of accidents per year, a roundabout was added as well as a new light to control crossings in addition to right turn bans. This resulted in a 12 percent reduction in accidents that resulted in injury (106).

Rear end collisions can also be reduced by engineering methods. In British Columbia, road factors account for about a third of collisions (109). The Insurance Corporation of British Columbia (ICBC) has provided funding for road improvement programs and countermeasures for rear end collisions since 1993, with the amount of funding from the ICBC having been increased substantially from 1993 to 1996. Some interventions that resulted from this movement included creating left or right turn lanes in areas where there are a large number of turning vehicles, acceleration/deceleration lanes, medians with turn protections, prohibiting turns and/or providing a special phase for left turning vehicles. These interventions resulted in a decrease of rear end collisions by 20–40 percent (109).

Simple techniques such as enhancing signal visibility also resulted in a decrease frequency of rear end collisions.

Speed bumps may be of value but this is controversial. Some argue that alone they may not reduce a driver's speed but may be effective if used in combination with other traffic control techniques (110). Further studies are still warranted. Other intervention methods such as matured in-service red light cameras (RLC) at T-intersections have also shown to result in an increased stopping frequency at these junctions. One study looked at three T-intersections in Singapore and found that the odds ratio to stop when approaching a camera was slightly higher than 17 times that if there were no camera surveillance (111).

The "three E's" education, engineering and enforcement are all important parts of injury prevention. Although there have been improvements noted in the roads over the past few years, there is still a need for further efforts, including assessment and treatment of accident-prone locations. There still is a strong need for further funding and legislation in this critical area of injury prevention in the United States.

## FALLS

Falls have consistently been identified as the second most common cause of TBI (11–13,112–115). They occur in the greatest number among young children under the age of 5 and in the elderly (21). Younger children have a much larger head-to-body ratio and thus the head strikes the ground more frequently during play (116). Also as a result, a fall of only a few feet can have serious consequences in young children (117). Over two decades ago, falls from extreme heights accounted for 12 percent of all unintentional traumatic deaths in New York City children. Overall, in the United States, it has been estimated that falls comprise almost 9 percent of pediatric trauma deaths (118). Benoit et al. demonstrated that falls accounted for 41 percent of admissions to a suburban hospital for children age 0 to 14 years of age (119). Turning our attention to the elderly, fatalities as a result of TBI are most common over age 75 and falls are the number one cause of TBI in the elderly (7). Jagger et al. found that there was a stable pattern of occurrence of fall related TBI up to about 59 years old. Between the ages of 60–69, there was a dramatic rise in the occurrence, which continued to rise in those 70 years old and older (13). The financial burden from falls is enormous. In 1994 the estimated cost in the United States from falls approached \$20.2 billion (120).

Efforts at fall prevention have been effective with legislation and education. In 1972, the New York City Department of Health developed a health education program termed "Children Can't Fly." This initiated installation of window guards in all New York City apartments

that had children less than 11 years old residing in them. This resulted in a 96 percent decrease in falls from windows after implementation (118). The use of safety devices for windows in suburban areas has also shown to be helpful (119). There have been positive results in fall prevention both abroad such as in Sweden (121), as well as in American urban neighborhoods (122,123).

The issue of playground related falls can be addressed by the use of protective surfaces including adding a safe 12 inch border of a soft material such as wood chips, and sand or rubber around the play area (123–125). Adult supervision and education of the parents is still critical. Educational efforts directed at both children and the communities have also been shown to have benefits (126,127).

Fall prevention in the elderly requires several strategies that often require a doctor's input. Physicians must identify various factors that may contribute to falls in the elderly population. Miller et al. (128), mentioned four common issues that have been implicated in increasing the risk of falls in the elderly. They are postural hypotension, gait and balance instability, polypharmacy and the use of sedating medications. Other host related factors that have been associated with falls include musculoskeletal or neurological abnormalities, visual disturbances, dementia (129) and frailty (130).

Balance deficits in the elderly appear to be related to the deterioration of various input systems necessary for postural control. It has been demonstrated that in subjects over 70 years of age, there is a 40 percent reduction in sensory cells of the vestibular system (131). These elderly adults are more likely to fall if other systems required for postural control, such as vision and proprioception, are impaired (132). Impaired balance in the elderly can also be attributed to multiple deficits in the neuromuscular system. It has been consistently shown that disuse atrophy; motor weakness, deconditioning, abnormal tone and posturing contribute to impaired balance in the elderly (133,134). There may be generalized slowing of central-processing areas in the elderly that involve integration and coordination of multiple inputs and outputs in the brain including the motor cortex, basal ganglia, and cerebellum (133). Lesions within these pathways, such as that sustained by an ischemic stroke or intracerebral hemorrhage, may compound the problem. It is also important to realize that approximately one third of patients with severe closed head injury experience subsequent postural imbalance due to disruption of these various pathways (135).

Assessing patients for balance dysfunction is an important component in prevention. Various measures at measuring body sway have been looked at for reliability and repeatability in assessing our elderly population. One method, such as the posturographic quiet standing test, has been referred to in the literature. Helbostad et al.

evaluated subjects after asking them to stand as still as possible for thirty seconds. Task conditions were performed in random order amongst the subjects and included both eyes open or closed, wide or narrow stance and firm or compliant surface. Some patients were also asked to perform a cognitive task. It appears across all domains one can consistently and appropriately assess the frail elderly with repeated testing. Clinicians need to develop simple assessment measures, such as those described, that can be taken into the office setting. In this manner clinicians can initiate preventative measures once frail elderly patients at risk for balance instability and falls are identified (136).

Prevention must then be aimed at the various contributing factors. Balance training in physical therapy can be directed at lower extremity strengthening as well as proprioceptive and visual system training with repetitive feedback and continual cueing. Various approaches have been tried to enhance balance in therapy. The utilization of force-plate biofeedback system to improve standing ability has been reported to have positive effects (137). There is no standard physical therapy program or protocol for balance training and more research in this area is warranted. In addition to targeting the physical aspects, one must address a common, iatrogenic and possibly avoidable cause of balance impairment in the aged population and that is identification of polypharmacy. It appears the prevalence of inappropriate medication use in the elderly appears to be 20 percent in both the US and various countries in Europe. The result may lead to balance instability, sedation and confusion in our elderly population. Physician awareness of those at increased risk, such as elders treated with psychotropic medications and those with depression is important as it allows us to target modifiable variables as well as to avoid inappropriate prescription writing. Physicians must constantly readdress prescription medication to avoid both inappropriate use and polypharmacy (138). It is important to review all medications and try to decrease or eliminate the medications that may not be absolutely necessary (139).

The environment plays an important part in falls of the elderly. Speechley, M & Tinetti, M (130). found in a sample community of elderly persons that 15 percent of fallers did not have a chronic intrinsic risk factor and would not be considered frail. It appeared that environmental risk factors played a major role in the robust elderly population of fallers. Thus the elderly population must be counseled on safe performance of certain physical activities, such as climbing stairs and ladders and avoiding hazardous obstacles around the house such as throw rugs. The national bureau of standards has identified various household factors contributing to falls in the elderly. It was estimated that highly waxed floors, loose rugs, sharp furniture, poor lighting or problems

with tubs and showers have contributed to 18–50 percent of falls (21). One study demonstrated that 10 hours of non-skilled time and \$93 of supplies per person was all that was needed to make an elderly person's environment substantially safer (140).

Physicians can play an important role in fall prevention, especially after a first fall. More aggressive efforts at assessing the cause of falls are needed by physicians. Risk factors for osteoporosis should be identified as low bone mineral density (BMD) has been shown to contribute to falls. BMD screening must be considered in high risk patients such as chronic steroid users, those with a sedentary lifestyle and patients on antiepileptic medications. In one study, approximately 75 percent of women have never been screened for bone loss and less than 1/3 ever received recommendations for BMD screening. Osteoporosis prevention strategies including calcium supplementation can then be initiated when appropriate. It has been shown that most people in the US have inadequate calcium intake, making education with each visit necessary in our clinics. Education on the reduction of alcohol and caffeine intake in addition to the encouragement of weight bearing exercises should also part of our management plan. It is also important to address hormone status in addition to frequency and dose duration of steroids in chronic steroid users (141).

## SPORTS AND RECREATIONAL INJURY

Recreational and sporting activities can be a significant cause of TBI with the majority of injuries being concussions (11,12,21,113). Unlike musculoskeletal training the brain cannot be conditioned to withstand the energy assault that is the cause of concussion (142). Therefore preventative efforts must instead be directed at improving equipment safety, behavior of the athlete, development of rules to mitigate risks and rigorous enforcement of rules and regulations to promote safety and prevent injury. This includes proper equipment design such as helmets for contact sports, sport rules that discourage dangerous activities and training and educational efforts for coaches and participants.

### CYCLING

Bicycle related TBI is a significant concern given their large numbers each year. Every year 1,300 people die from bicycle related accidents, almost half of them under 21 years of age (120,143). Financially, the cost of non-fatal bicycle injuries in children under 14 years of age approaches \$113 million every year (120). Fife et al. in a study conducted in Dade County Florida found that serious injuries related to bicycle riding were sustained

in 676 out of 1,252 total injuries. Almost half of the serious injuries were located in the head and neck region (144). In patients admitted to a hospital secondary to a head injury the risk of death was 20 times higher for those who were not wearing a helmet (145). Spence et al. (146), evaluated fatal bicycle accidents in children aged 0–15 years old in Ontario from 1985–1989. They found that 70 percent of the accidents were a result of the cyclists themselves. In a similar study, the cyclist was responsible for 78 percent of all bicycle accidents with the major errors reported as riding through a stop sign (22 percent) and emerging from a minor road without caution (27 percent) (147). It was pointed out by Spence et al. that children this young might not have the psychomotor skills to ride safely in traffic. Instead the goal should be to prevent these children from riding on busy streets.

The most effective way to immediately protect the cyclist is to have him wear a helmet. In five case controlled studies that were reviewed, the data demonstrated that wearing a bicycle helmet had a large impact on reducing the risk of head or brain injury during a crash or collision. Estimates regarding the effectiveness of helmet use is that they decrease the risk of brain injury by 88 percent, severe brain injury by at least 75 percent and facial injury, particularly in the upper and mid facial regions, by 65 percent (148).

Thompson et al. (149), performed an extensive review of the literature to evaluate risk reduction for cyclists and helmet use during riding. The authors found that helmets were beneficial in the reduction of head, brain and severe brain injury in all age groups and included not only bicycle injuries but also motor vehicle and other types of crashes. The reduction in risk was estimated to be approximately 70 percent. This is a conservative value when compared to the numbers suggested by Koplan et al. in their CDC sponsored work, which reported a risk difference of 85 percent for head injury and 88 percent for TBI (120).

Helmet usage is only one component of the Haddon Matrix in regards to cycling injuries. As stated previously, a comprehensive approach is the most effective intervention for injury control and this must be incorporated for bicycle injuries. Passive measures such as helmets, road engineering, bicycle lanes and speed bumps must be employed (120). Active strategies such as modifying cyclists behavior and counseling children on safety skills while riding must be aggressively pursued. Helmet use should be mandatory for all child cyclists and legislation is still warranted in all states given its overall effectiveness.

### BOXING

As expected the sport of boxing where the participants attempt to give each other concussions has the highest rate of TBI. Atha et al. (150), compared the blow thrown

by a top quality heavyweight to a 13-pound mallet swung at 20 miles an hour. In this sport record keeping in regards to brain injury has not been as precise as in football but between the period of 1945 and 1979 there was documentation of 335 deaths from boxing related head injury (151). In one report, the incidence of TBI in professional boxers was estimated to be approximately 20 percent (152). In 1983 it was reported that minor head injury rate for amateurs was 5 percent which increased to 6.3 percent at the professional level (153). Fatalities at both levels are substantial (154). Various risk factors that have been identified that increase the chances that a boxer will sustain brain injury include career length, number of bouts, poor showings in the ring and apolipoprotein (APOE) genotype.

There has been an increase in the public's awareness of boxing related brain injury with Muhammed Ali's illness over the years. Various preventative measures have been attempted such as guidelines for determining when a player should return to play after a head injury. For instance, The National Amateur Athletic Union (AAU) Junior Olympic Boxing Program specifies the length of time a participant must remain out of competition after a knockout. Wilberger and Maroon, noted that the New York State Boxing Commission enforced a mandatory suspension of 45 days for mild concussions and 60 and 90 days for moderate and severe concussions (151). A problem identified with professional boxing is that there is not enough consistency between the various states. A boxer who has been suspended in one state may be able to participate in another state without any restrictions. Other preventative measures such as changes to increase ring safety and improved monitoring by the referee and an on site physician have resulted in decreased mortality (154). There is a strong need for physicians to take a more active role in education of both the amateur and professional athletes as well as all others such as all referee's and ring side physicians. LeClerc and Herrera (155) have suggested that physicians must take an active role in educating the public regarding the risks of boxing. Their statement, "a watchful agnostic position among sport physicians is no longer justifiable" is a call to arms for health care providers to work diligently to educate the public concerning the dangers of boxing. While abolishing boxing may be an ultimate, but unrealistic goal, one must at a minimum strongly advocate for even greater safety measures (21).

## FOOTBALL

The game of football has been associated with an increased risk of sustaining a TBI. The National Football Head and Neck Injury Registry reported 59 intracranial football injuries that resulted in death between the

years of 1971 and 1975. In 1974, Blyth and Mueller (156) reported that while TBI accounted for only 5 percent of overall football injuries it accounted for 70 percent of the fatalities, with 75 percent of them occurring during tackling. The estimates for football related TBI are up to 250,000 concussions and 8 fatalities every year nationally. From 1985 to 1994, high school players sustained 81 percent of head injuries and 100 percent of cervical spine injuries (157). Furthermore, up to 20 percent of high school football players sustain a concussion per season played (1,158,159).

Given the popularity of the sport and interest to play among high school athletes, it is a sport that will likely continue to have many fans and participants. The focus must therefore be on injury prevention in addition to good clinical judgment in removing players from play at the greatest risk. The highest percentage of head and cervical spine fatalities associated with football was between 1965 and 1974. There was a significant decrease in head fatalities from 1985 through 1994 representing 5.4 percent of the fatalities from 1985 to 1994 (157). This is attributed to the multidisciplinary team involved in the football family including coaches, administrators, athletic trainers, physicians, national organizations; all of whom have provided education and public awareness.

Prevention efforts utilized for football have been effective. The issue of legislation and enforcement as well as passive and active strategies should again be revisited. With immediate punishment and consequences from illegal plays called by the officials, illegal dangerous plays can be discouraged and their incidence greatly reduced. There was a key rule change in 1976 that played a role in reducing head and spine fatalities. The rule prohibited initial contact with the helmet, also known as "head butting", or face mask, also known as "face tackling", when tackling or blocking. Tackling was responsible for 40.6 percent of all head fatalities from 1985-1994 and it is therefore imperative to adhere to this rule as a violation of it may result in a serious injury (157). There have been other important preventative efforts associated with football which include preseason conditioning, safe use of equipment and training for proper technique (160). In addition, proper fitting of helmets and physician evaluation post injury are also key components to any prevention program (21).

Second impact system is a potentially fatal complication that can result from repeated injuries prior to recovery from previous injury. It is important to mention this syndrome in the discussion of football related injuries. It may be missed clinically and appear as a minor injury but can be associated with massive cerebral edema, resultant brainstem compression and possible death (161). There are very few warning signs that would clue a physician to make the diagnosis of second impact syndrome. It is therefore important to abide by guidelines published

by the Colorado Medical Society regarding assessing concussive symptoms during play. These are considered the best guidelines for return the play post concussion (158).

## SOCCER

Another major sport that can account for a significant number of TBI is soccer or football to the rest of the non North American world. It has been estimated that head injuries account for between 4 and 22 percent of soccer injuries (162). Soccer is increasing in popularity and is considered to be the most popular sport worldwide. There were more than 40 million amateur participants noted in 1989 (163). Due to the large number of participants worldwide, the number of potential injuries can be significant, even if the rate of injury, may be lower than that of other higher contact sport (164). There is one Australian study the estimated injury rate occurred 96 per 1000 player hours (165). In Sweden, soccer is the number one source of recreational related injury with a rate of 39 percent reported (166). Data collected in Norway over an eight-year period, noted that 45 percent of all sports related head injuries were accounted for by soccer (167). Tysvaer and Storli looked at 69 active soccer players and 37 former players of a Norwegian national team and found that one third of the players had central cerebral atrophy and 81 percent had some form of neuropsychological impairment (162,168,169). Dvorak et al. have worked out both a risk analysis for prediction of injuries and the development of a prevention program focusing on the trainers, medical professionals and players. Recommendations included structured training, better medical supervision, player reaction time, rule design and enforcement that could result in an overall decrease in injury (170).

The use of controlled head contact with the ball is an important part of soccer. Some would argue that it plays a major role in TBI but this remains a controversial issue (1). It has been shown that older leather balls absorb water and increase the weight of the ball by 20 percent or more making them more dangerous (171). Soccer balls are now made of waterproof synthetic leather covered with urethane which repels water, which has decreased the injury potential (172). Head gear that has been designed to protect players playing soccer has been of limited value (173). A review of the literature has suggested that heading the ball plays a very small part of in soccer related TBI. Instead, accidental unplanned contact against goalposts, head to head contact, elbow contact and a ball kicked directly at the head are more likely to be the source of problems (1, 174). Tysvaer and Storli also noted that the younger players with less experience heading the ball had greater EEG, radiographic and neuropsychological changes than their older more experienced counterparts (162).

Prevention efforts therefore should be directed to better training techniques, proper coaching, adhering to return to play guidelines, medical supervision post injury, rule changes and enforcement. These strategies would minimize unintentional head contact. The use of protective headgear by goalies and development of better head protection would also add to better injury control (172,174).

## HOCKEY

Another sport that can be extremely rough and place the player at a high risk of TBI is hockey (175). Studies have estimated that the range for the incidence of head and neck injuries, excluding facial lacerations, was 6.3 percent to 45.12 percent (176,177). As in football the vast majority of these injuries are concussive in nature. However, in contrast to football, where most injuries occur at the high school level, hockey injuries occur throughout the spectrum of competition; including small children, high school, college and the elite professional teams (178).

The majority of injuries occur during checking, both legal and illegal (179,180). In one study it was found that 57 percent of children with ice hockey related injuries resulted from checking and that more than half of these injuries were considered significant (180). It was also found that the children were not educated on safety and injury prevention as 45 percent of the children reported that they could not sustain a TBI with a helmet on.

Attempts have been made at decreasing injury associated with the game of hockey. There was some thought previously that the use of face masks in hockey players may increase head and neck injuries because the players were more aggressive during play once the mask was on. This has proven to be a fallacy. In one study it was found that there was no significant increase in head and neck injuries with the use of face masks and there was an overall decreased incidence of facial lacerations (181) There have been other reports that mandatory facemasks reduced both facial injuries and TBI (178,182). It has been demonstrated that more hockey injuries occur early in the season, late in the periods and in the final period of games suggesting that conditioning may assist in injury prevention (183).

Education at the younger level is imperative and the emphasis should not be entirely on winning. In one study it was alarming that almost a third of the children would check illegally to win and 6 percent would intentionally injure another player to win (180). Parental attitudes should encourage nonviolence so these behaviors can be learned by their children and taken into adolescence and adulthood.

On the professional level, statistics show that in the Stanley Cup Finals the team with the least penalties secondary to violent behavior win the majority of the series (184).

In summary, sport related injuries account for a significant number of head injuries, which can be severe, fatal, result in long-term debility and/or be the cause of the termination of a player's career. It is important to stress a multifaceted approach to prevention of injury including education, rule enforcement, improvement in safety equipment and better-conditioned athletes with encouragement of nonviolent behaviors.

## VIOLENCE AND SUICIDE

Violence in the United States is a major cause of morbidity and mortality and the statistics raise a significant amount of concern. The fatalities in children and adolescents from firearms have increased from an estimated 3000 fatalities per year in the mid-1980's to 4500 fatalities per year in 1992 (118). Approximately 73 percent of people who sustained a gunshot injury die at the scene, 12 percent die within three hours and 7 percent die after three hours (185). It has been estimated that 90 percent of all persons who sustain a gunshot wound to the head die (186). Upon review of the literature, self-inflicted injuries range from 11–50 percent, with an unclear percentage being accidental (187,188). There are strong demographic factors that contribute to firearm mortality (189). There is a reported tenfold higher rate of homicide in black males related to firearms between the ages of 15 to 19 years old when compared to white males in the same age group (118).

## GUN CONTROL

Handguns continue to be purchased and remain in many American homes. They contribute to a significant amount of morbidity and mortality in the United States annually. Depending on the specific region, it has been estimated that between 15.7 percent and 30.1 percent of all homes contain a handgun (190,191).

Dresang evaluated gun deaths in urban and rural areas and it was found that in rural areas there was a higher amount of shotgun and rifle injuries with handguns accounting for more than 50 percent of gun deaths (192). Those who own handguns are twice as likely to have their gun loaded than an owner of any other type of firearm (193). Homicide risk is increased by threefold and suicide by fivefold among those with a gun in the home (194,195).

It still remains controversial how to enforce handgun control. There have been attempts at legislation, education and safety devices. However more strict regulation is warranted. For example, sales of firearms at gun shows still occur outside of the realm of regulation (196). It is important to realize that more legislation may not meet

that much resistance from the general public. In one report, a large percentage of the public (68 percent) would support government regulation of handgun safety (197). Some believe that only the power of litigation will result in better prevention (196). Past legislation has proven to have a positive effect on injury control. One report noted that a 2-week ban on handguns in parts of Columbia was associated with a reduction in homicide rates in those cities (198). There was also a reported decrease in the number of accidental and home deaths in Maryland after handgun legislation was enacted in Maryland in 1987 (118).

## GUN SAFETY

There continues to be a significant portion of the public that wants to keep a handgun in their homes. In one survey, 29 percent of respondents felt that owning a gun made their homes safer (199). Education of the public should be one of the major components of our preventative measures regarding handgun related injuries. Community based education programs have had some success in encouraging proper storage of firearms (200).

Different technological approaches have been tried to improve handgun safety. Safety locks (trigger lock being the most common), manual thumb safeties, loaded chamber indicators and magazine disconnectors are all attempts to prevent unintentional injuries (201). However, these devices do not protect from intentional injuries such as suicide or homicide. A grip safety feature is a passive preventative method designed to protect children from using the gun. Young children do not have the strength, coordination or hand size to press the safety lever and pull the trigger at the same time. Personalized handguns, a new developing technology, allow only the authorized owner to use the gun. Its features include a built-in locking system and the ability to recognize the authorized user. There are still some concerns regarding its use such as reliability, maintenance and cost. However there is a strong public desire for legislation requiring handguns to be personalized (197). There is no real possibility of an immediate answer to the issue of gun related violence. Zakcos has noted that only legislative lobbying has been linked to organizational resources (202). While Rodriguez stated that only the power of litigation will bring some response to these issues (196).

## OTHER SOURCES OF VIOLENT INJURY

Violence continues to be a major contributing factor to TBI. This continues to be a major concern in urban areas. However it must be noted that there is a reasonable amount of violence in rural areas as well. Jagger et al.

evaluated the epidemiology of head injury in the rural area of north central Virginia. It was found that interpersonal violence accounted for 23/100,000 of head injuries in this area. This number was more than half of that seen for falls alone and overall was a fairly large number (13). The highest number of these types of injuries was in the 30–39 age group. Interpersonal violence included injuries with firearms, blunt weapons, knives or battery without a weapon. These other types of injuries are a worldwide problem. Stab wound injuries, for instance, are extremely high in parts of South Africa (203). Blunt trauma specifically can be mostly attributed to fists, baseball bats, bricks and bottles (204). There have been very little in the way of preventative measures and public education to minimize these other sources of injury.

### DEPRESSION, SUICIDE, AND TBI

There have been reports that intentional TBI has been associated with gender, minority status, age, substance abuse and low socioeconomic status, with the most predictive of these variables being minority status and substance abuse (205). Additionally, a major concern is the risk of suicide among those with TBI. It has been estimated that suicide rates in the TBI population are 2.7 and 4 times higher than the general population when matched for age and sex (206). It has been shown that suicide risk is greater among patients with physical illness than among the general population (207). Simpson and Tate identified various factors of suicide risk in TBI outpatients including hopelessness (35 percent), suicide ideation (23 percent) and suicide attempts (18 percent) (208). A study of several disability groups noted 25 percent of patients had major depression and 7.3 percent reported clinically significant suicidal ideation (209).

There is considerable variability in TBI prevention worldwide. Although there is agreement about goals including general knowledge about suicide and development of skills in suicide risk assessment and management, prevention programs have a wide range of variability (210). The length of training programs for those with professionals and nonprofessional backgrounds range from 1 hour to 16 hours (211,212). Instructional materials used include anything from written materials, self-instructional videos to other methods such as didactic sessions. Some suicide preventative programs are broader and include a more general disabled population. If the TBI population is targeted and appropriate intervention occurs early then some suicides may be prevented. Physicians need to identify risk factors such as suicidal ideation, perform further research on other prognostic factors and be able to manage these patients once their risk has been identified. Simpson et al. created a training workshop for suicide assessment and management for staff in a

rehabilitation center in New South Wales. The length of the workshop totaled approximately 5.25 hours of training in one day. There was improved staff knowledge and skills in suicide assessment and management (210). A larger more multifaceted approach is warranted. In addition to staff training including appropriate agency policies and procedures, collection of appropriate funding and involving more community support (213).

### DRUGS AND ALCOHOL

Recreational pharmaceutical agents greatly complicate the problem of TBI. There have been several reports that head injuries and fractures are the two most common alcohol related types of trauma (214). In its white paper released in 1988 the National Head Injury Foundation Substance Abuse Task Force stated, "neither age, nor occupation, nor any other factors place an individual at a greater risk of a TBI than does alcohol" (215). Many factors contribute to alcohol's exacerbation of TBI. First is the fact that a large minority of the consumers of alcohol are heavy consumers. With Kreutzer et al. estimating that 12 percent of American drinkers can be classified as "problem drinkers" (216). In addition to the large numbers of problem consumers, there is the additional problem of greater injury risk (217). The presence of intoxication at the time of trauma admission increased the odds ratio of a repeat trauma admission within the next 2 years, 2.5 times. In 1999 (218), there were 15,786 deaths and 300,000 injuries as a result of alcohol related MVA. Legal intoxication has been reported in up to 51 percent of people involved in TBI while up to 2/3rd have some history of drug or alcohol abuse (219–221). Positive testing for drugs or alcohol as high as 70 percent has been reported (222). While Anderson reported that 51 percent of non-belted passengers had alcohol on board. High School students demonstrated very significant risk tasking behavior in regards to alcohol. It is alarming that over third of high school students would ride with a driver who had been drinking and over 17 percent would drive after they themselves had been drinking (223).

The importance of preventing teenage drinking has been further clarified by the work of Hingson's group (224). They conducted a survey of college students and demonstrated that there was a relationship between getting drunk for the first time before the age of 19 and drinking and driving, driving after five or more drinks, riding with a driver who was high or drunk and, after drinking, sustaining injuries that required medical attention. In another publication (225) the authors estimated that among college students there were over half a million full-time college students who were unintentionally injured while under the influence of alcohol and over 600,000 assaulted by another student who had been drinking.

Alcohol and drugs can also be involved in other etiologies of TBI. The commencement of drinking prior to age 17 tripled the likelihood that an individual would be involved in a physical fight in the last year (226). A survey performed by Gerhart et. al. demonstrated that alcohol abusers were more likely to sustain a violent TBI as compared to other TBI populations as well as having a worse outcome (227). The incidence of alcohol use in both TBI and SCI patients preinjury is very high. In one report it has been estimated the rate for heavy drinking was 42 and 57 percent respectively (228,229).

There is still some controversy regarding the effect of alcohol on outcomes in the acute setting. Some authors have reported an increased risk of pulmonary complications (230) while other studies have not supported the idea. Cornwell et al. (221). reported that sepsis, complications and mortality were correlated with injury severity and not to the presence or absence of alcohol or drugs. In regards to rehabilitation, Sparedo and Gill (231) reported an association between acute intoxication and lower functional levels at discharge as well as a longer period of post-traumatic agitation. Acute intoxication has also been correlated with longer acute hospitalization and a longer period of posttraumatic amnesia (232). There have also been reports that reported a positive correlation of impaired verbal memory and visiospatial function in those with positive alcohol and drug screens on trauma admission (233,234).

The performance of alcohol screens is not universally performed on all trauma patients (220), with some studies reporting less than 1/2 the trauma patients being tested. This may in part be secondary to a fear of a patient being subject to legal prosecution or denial of insurance coverage if tests are positive. However, this practice is problematic as this hinders both clinical care as well as further research efforts.

While a clear relationship has been established between alcohol and brain injury in the literature, questions still arise as to the most effective means of preventing alcohol related TBI. Prevention efforts must be directed at both passive and active measures as passive efforts alone have had a limited effect. Passive efforts such as breathalyzer testing, mental status or coordination testing prior to starting a car has been discussed for years but have not become a reality. Another intervention, that is passive to the alcohol consumer is the modification of the server's behavior. This is part based on the concept that many people who drink and drive are consuming alcohol at bars, clubs and restaurants (218). It has been reported that about half of the people who received a DUI left a place that served alcohol (235, 236). Efforts that focus on educating servers to carefully screen underage drinkers, refuse service to rapid drinkers, calling taxi services for consumers that seem unfit to drive and the offering of food to those drinking are all ways to delay potential intoxication and

driving under the influence. Currently there is no uniformity between the educational programs across the country with some states having mandatory programs, while others voluntary educational programs for servers. The programs are not standardized across the country and address different issues such as legislation regarding intoxication, DUI, recognizing the signs of intoxication as well as liability issues. The fear of litigation may assist the management structure of these establishments to be supportive of their employees' efforts to mitigate this national problem and run a safer establishment (218).

These programs have been proven to be effective in both improving servers' decision making abilities (237) and in decreasing patrons' level of intoxication (238–240). Holder et al. (241). demonstrated that using these measures in three experimental communities resulted in a 10 percent reduction in alcohol related traffic accidents and significantly reduced the sale of alcohol to minors. These interventions have been shown to only be effective for about a year with some drop off after 15 months (242). It is therefore important to recognize the need for continuing education, which may be needed on a yearly basis. Mandatory legislation is still warranted for continuing education targeting servers.

Significant progress has been achieved due to alcohol related prevention programs. Since 1982, the rate of alcohol related MVA fatality has steadily dropped from a rate of 57 percent to 38 percent (218). Zobeck et al. also reported similar findings with a 10 percent decrease in alcohol related MVA fatalities from 1979–1990 (243). Not only that, but fatality rates per 100 million vehicles miles traveled, and per 100,000 population, registered vehicles and licensed drivers have decreased even more sharply. This may be due the multifaceted approach of various interventions such as public education, community programs, legislation and enforcement.

Recently, The Internal Medicine News has reported about the decrease in the use of alcohol and illicit drugs in the young. Kirn reported results of a national survey that questioned 50,000 students that were attending either public or private schools regarding their usage of illicit drug within the previous month. It demonstrated a 7 percent decrease in illicit drug use from 2003 to 2004. In addition he reported an overall decline in drug use over the past three years among high school seniors and the last eight years for younger teens (244). Jancin reported on the potential value of early recognition of young children who are at risk for developing problems with substance abuse later in life; in particular, evaluating preschoolers for the presence of temperament traits such as aggressiveness, impulsivity, poor attentiveness. Once these "red flags" are identified, some suggest that early comprehensive psychological evaluation with early intervention may help reduce the risk of problems later on in the teen and adolescent years (245)

Community programs such as Mothers Against Drunk Driving (MADD) have been instrumental in having the legal drinking age raised to 21 throughout the United States (21). However, raising the legal drinking age to 21 has not totally eliminated alcohol as a problem for teenage drivers. Alcohol has clearly been found in adolescents involved in trauma (246). In 1997, 21 percent of those killed driving while driving intoxicated were 15–20 years of age (120). In addition, 41 percent of college students report episodes of binge drinking during the previous 2 weeks (247). Control of access clearly is not enough to address the problem of alcohol related MVA.

Active preventative measures have been suggested to prevent TBI. Previously suggested strategies include involving survivors in policy making, working with journalists to improve media coverage of head injury and speaking to high-risk groups to encourage use of protective gear (248). Although all survivors cannot participate in every domain suggested, simple tasks associated with office maintenance, for example, could still contribute to head injury prevention. It is therefore important to channel the brain injury community to programs that facilitate education, legislation, public policy, lobbying, advertising and media, all aspects of prevention that need to be addressed by both survivors and health care professionals (214).

Preinjury family dynamics must be addressed after a TBI. A brain injury may magnify a dysfunctional family structure. There must be strategies for the family to learn how to cope with substance abuse and brain injury. This may help prevent a second injury or repetitive abuse behavior (219). The family must be involved in collaborative approaches between the health care provider and abuser. There must be consistent use of support groups with family participation. The family must be educated on the risk factors for abuse as well as be provided with coping mechanisms on how to handle and separate TBI related issues from abuse issues.

It is estimated that there are over 1.4 million DUI arrests every year in the United States. While this seems like a large number it is relatively small when it is compared to the number of actual occurrences. There are estimates of up to 126 million episodes of DUI that actually occurs every year in the United States (120). The original threshold for determining that one was driving while intoxicated or under the influence laws was 0.10 grams per deciliter. Evidence arose that even lower levels of blood alcohol could impair one's driving ability and in 1983 Utah and Oregon were the first two states that lowered the level to 0.08 grams per deciliter. By May 2001 24 states had lowered the acceptable blood alcohol level to less than 0.08 gm/deciliter for drivers 21 years of age (218). For those 20 and under a zero tolerance policy was adopted and any evidence of blood alcohol is considered illegal and subject to legal sanction (218,249).

Several studies have addressed the impact of this lowering of acceptable blood alcohol levels (250–258), which have been reviewed by Shults et al. (218). As a result of these changes, the overall rate of alcohol related MVA fatality dropped by 7 percent. In California and some of the other states, immediate confiscation of licensure, called administrative license revocation (ALR) was also implemented. In an effort to isolate the effects Hingson et al. looked at the effect of the BAC change in states which already had ALR rules on the books and noted a 5 percent decrease in alcohol related fatalities when the lower BAC rule was instituted (253). Voas et al. used a statistical approach to separate the different factors. Using multivariate analysis he demonstrated that there was a reduction of 8 percent in alcohol related fatalities as a result of lowering of the acceptable BAC level by itself (258). There are great cultural, demographic and geographical differences between the states studies so it is assumed that the results of these studies are likely to be representative of the United States (218). The U.S. Congress has been impressed enough by the evidence to require all states to lower the BAC to 0.08 gm/dl by October 2003 or they will lose federal highway funds (259).

Younger drivers, partake in other risk taking behaviors and are at greater risk of MVA than their more experienced counterparts. This may be a result of decreased experience or partaking in other risk taking behaviors that are associated with alcohol ingestion. The work of Anderson et al. that demonstrated that over half of non seat belt wearing drivers involved in a MVA were positive for alcohol as compared to 22 percent of those wearing shoulder belts serves as an example (260). Similarly, there is a much lower use of restraints among those who ingest alcohol. This is especially true with adolescents where only 7 percent with positive alcohol screens were using a restraint system as compared to 22 percent that had no alcohol (246). While, Peek-Asa and Kraus (88) demonstrated that motorcyclists involved in accidents who tested positive for alcohol were more likely to be speeding and not be wearing a helmet. Finally, Zador et al. (261) demonstrated that a 16 to 20 year old male who had a BAC level between 0.08 and 0.1 had a 24 times greater chance of dying from a MVA as compared to a BAC of zero. The benefit of Congressional mandates was again noted when its threat to withhold highway funding, prompted all states to pass legislation that requiring a BAC level of less than 0.02 for all drivers under 21 years of age (220). The minimum drinking age was first raised to 21 in several states by the 1970s. By 1987, all 50 states had raised the minimum drinking age to 21 (218). As a result of this change a double-digit decrease in both fatal and non-fatal MVA's was noted.

Legislation requires enforcement to be effective. There is a need to improve these efforts to facilitate prevention efforts. Sobriety checkpoints are an effective

means of addressing this issue. There are two types of sobriety checkpoints, random breath testing (RBT) and selective breath testing (SBT). RBT has been used with Australia and Europe with great benefit. It is not currently available in the United States because of a lack of "probable cause." Instead in the United States only SBT sobriety checkpoints are utilized. With SBT checkpoints, the officer must have reasonable suspicion of intoxication in order for breath testing to be performed. Because of the nature of these checkpoints, they better serve the purpose of deterrence rather than actual identification of offenders (218).

SBT checkpoints have proven their efficacy and have been shown to reduce fatal car crashes 20–26 percent (262), as well as reducing overall crashes anywhere from 5 to 23 percent (218). RBT has been tested and has shown similar results (263–271). The studies of RBT showed a reduction in fatal crashes between 13–36 percent (264, 268, 269, 271) and 11–20 percent for all crashes (263, 265–271). RBT has also been shown to modify drivers' behavior in regards to drinking and driving. Work from Australia reported a 13 percent drop in drivers with any detectable alcohol on board and a 24 percent decrease in BAC level over 0.08 with RBT (223). The literature has shown that both the selective and random method of testing has been useful in reducing crashes of all types. While RBT is more sensitive than SBT relative to detecting elevated BAC, the literature has not demonstrated any difference in efficacy between the two methods relative to crash prevention (218). Technologic breakthroughs such as the addition of passive sensors that can sample for the presence of alcohol are being developed which may further increase the sensitivity of SBT by 50 percent which will further increase the sensitivity of SBT (272).

Even with proven efficacy, these programs face resistance as a possible violation of an individual's civil rights. The United States Supreme Court has weighed in and ruled on the appropriateness of a properly performed brief sobriety check. The sense of the court was that this minor intrusion on human rights was more than balanced out by the public benefit of reducing DUI (273). Cost benefit issues is another issue raised regarding the use of SBT and the cost benefit ratio of having police officers man these checkpoints. Miller et al. (274), have addressed this issue. In their model of a community of 100,000 licensed drivers and assumed that the intervention would reduce accidents by 15 percent, a number chosen after reviewing the literature on SBT. Incorporating all of the costs of alcohol related MVA including medical, property etc, and their estimates were that \$9.2 millions would be saved with an expenditure of \$1.6 million with a ratio of nearly 6 to 1. An actual study performed in California was even more promising. Four communities introduced SBT for over ninth months at a relatively small cost of \$165,000. The savings that resulted from this intervention resulted

in a 23 times as large a benefit of \$3.86 million. RBT testing may be more effective than SBT financially. Work from Australia and New South Wales has suggested that at an annual cost of \$4 million per year a savings of \$228 million was realized as a result of accident prevention (264). The efficacy of these programs both from a financial as well as from crash prevention requires society to take a look at these papers.

## PEDIATRIC HEAD TRAUMA

Pediatric injuries are a significant cause of morbidity and mortality throughout the world. Approximately 600,000 children are hospitalized every year and more than 15 million children are seen in the emergency room each year because of their injuries (116). Head trauma accounts for over 500,000 emergency department visits annually (275). The annual costs exceed over 1 billion annually and 29,000 children sustain permanent disabilities.

## CHILD ABUSE

Homicide from child abuse is the leading cause of death in infants in the United States (118). In 1999, approximately 4.1 percent of children less than 18 years old were victims of physical, emotional or sexual abuse (276). In a survey of pediatric head trauma, abuse accounted for 19 percent of cases and was associated with a higher rate of subdural hematoma (SDH), subarachnoid hemorrhage, as well as retinal hemorrhages (277). Child abuse is not only a form of violence but contributes to adverse consequences in maltreated children. Abuse in childhood has been associated with early pregnancy, drug abuse, school failure, mental illness, suicidal and aggressive behavior and violence later in life. Center (276).

Shaken baby syndrome results from severe movements of a child's head, can result in retinal hemorrhages, cerebral axonal injury, occult cervical injury, and coagulopathy (278, 279). Young infants have weak neck muscles leaving them vulnerable to sustain SDH and shearing injuries. For a retinal hemorrhage to occur, it takes an extraordinary force and is usually not associated with an accidental injury (280). There are many educational programs in place to educate the community of the severe danger of shaking infants.

Child abuse has been associated with single-parent homes, low-income families and parents with alcohol and drug abuse and many home visitation programs in the United States are therefore directed toward these high risk populations. The Center of Disease Control and Prevention noted that preventative programs delivered by nurses demonstrated a median reduction in child abuse of 48.7 percent and programs delivered by mental health

workers demonstrated a median reduction in child abuse of 44.5 percent (276). In one study sample evaluating the cost-benefit ratio of home visits to low-income mothers, there was a net benefit of \$350 dollars per family in 1997. Clinicians should also continue to target high-risk populations such as teenage parents, single mothers, families of low socioeconomic status and parents with alcohol, drug or mental health problems. Further programs are warranted to reach the goal of reduction of homicides from 6.5 to 3.0 per 100,000 populations by 2010 (281).

### **CAR SEATS AND AIR BAGS**

Motor vehicle accidents are the major cause of death in children and adolescents. It has been estimated that motor vehicle accidents and traffic-related injuries account for 56 percent of injury fatalities (118), with front seat passengers appearing to be at the highest risk. There was legislation early on in the 1990's that focused its attention on placing young children in the back seat in addition to standardized three point restraints in all vehicles. The 1990s saw a decline in front seating of children in vehicles involved in fatal crashes likely attributed to public awareness and education and legislation (282). However children ages 6 to 12 remained at high risk for being front seated (282). Pediatric air bags systems pose a threat to the front-seated child passenger, with resultant cranial and cervical spine trauma (79). Patterns of injury in the child or adolescent will be different than that for an adult given the seat location, height and weight of the individual type of restraint and the biomechanics at impact placing the child closer to the deploying air bag all have an effect (283). Both age and weight of the child determine the appropriate restraint system. There has been legislation regarding child restraint system utilization, however, the poor compliance with these devices is concerning (284).

It has been estimated that 500 deaths and 53,000 injuries could be prevented each year if there were 100 percent compliance with existing state law and there was proper use of child safety belts (118). It is encouraging that education and legislation, including passive and active strategies, can result in a decrease in childhood injury.

### **PLAYGROUND AND RECREATIONAL INJURIES**

In 1986, the United States Consumer Product Safety Commission estimated that approximately 7,000 children under the age of 15 had sustained a playground related injury that required hospitalization (116). Between 1990–1994, more than 200,000 playground injuries were reported (285). It has been estimated that 8 percent of

sport and recreation related head injuries are playground related (286).

A large proportion of injuries are related to climbing activities including monkey bars, jungle gyms, swings and slides, with approximately 25 percent of such injuries requiring hospitalization (287). In one study of Boston's playgrounds, 34 percent of playground hazards were related to climbers, 30 percent with slides and 22 percent with swings (288). Lillis & Jaffee evaluated all children injured on playground equipment in a metropolitan center in Canada. It was found that 39 percent of the children were under age 5 and 58 percent of those younger than 5 years old had head and cervical injuries (116).

Lessening the incidence and consequences of falls from playground equipment is a promising potential target for prevention efforts (289). Multifaceted efforts are important. Parents need to be educated and provide appropriate supervision in the playground environment. One study suggests one of the main contributing factors to playground injury is "lack of active competent adult supervision." (290) Educating children not to jump off a moving swing or walk behind a moving swing must be reinforced to the parents. The use of equipment by older children designed for younger children such as certain slides and climbing equipment that are very narrow can be dangerous. As a result the older child may slip or fall. Some slides are elevated 10–15 feet off the ground and the danger of the slide increases with increasing height. Unfortunately, the drive for safer design of playground sites has been pushed more by litigation than public policy.

The riding bicycles by children is another important area for prevention efforts and the use of helmets during bicycle riding is critical. It has been estimated that wearing helmets resulted in a 88 percent less risk of brain injury compared to those people who did not wear helmets (149). The problem is that use of helmets by North American children is less than 1 percent (146). This may be because children may feel like they do not fit in with their peers. If so, this is a strong reason to make helmet use mandatory and legislation is warranted to mandate helmet use in children. Legislation in addition to education of parents and children may improve compliance with helmet use. Skateboards are a common source of head injuries in the pediatric population. It appears that the rate of injury secondary to skateboards has surpassed that of bicyclists for those under 25 (291). The role of helmets in preventing serious injury related to skateboarding is also critical.

### **CONCLUSION**

Traumatic brain injury is a major health problem for society. It is an area where prevention efforts can make a substantial difference in the overall public health. Prevention

efforts must be directed at many different components that include legislation, education and motivation of the public to control this area of injury. There has been a tremendous progress made in TBI prevention over the last few decades. However, there is still a large amount of work needed to target all the different aspects, or "cells" in the Haddon Matrix, that contribute to TBI. Health care providers must continue to educate the lay public and assist politicians in recognizing the benefits of injury control. Hopefully as public awareness, technology and legislation improve so will prevention efforts.

## TBI: Pathobiology

*Patrick M. Kochanek*  
*Robert S.B. Clark*  
*Larry W. Jenkins*

### INTRODUCTION

In the United States, over 50,000 people die and over 200,000 are hospitalized each year from traumatic brain injury (TBI) (1). Severe TBI is an important contributor to both this level of mortality and the associated morbidity. Treatment is usually supportive neurointensive care focused on the control of intracranial hypertension. Breakthroughs in the treatment of TBI have been hampered by a lack of understanding of the key mechanisms operating in the injured brain.

TBI involves a primary injury that includes direct disruption of brain parenchyma, and a secondary injury characterized by a cascade of biochemical, cellular, and molecular events involved in the evolution of secondary damage.

### PRIMARY INJURY

Primary injury has traditionally been characterized as the damage that results directly from the shear forces at impact. Consequently, this topic has been of greater interest to investigators in the fields of injury prevention and biomechanics than those focused on the treatment of the evolution of secondary damage. A detailed discussion of the biomechanics of primary injury is beyond the scope of this chapter. Nevertheless, some insight into its

components is valuable. Key components of primary injury include cortical disruption, axonal injury, vascular injury, hemorrhage, and unusual, albeit important, miscellaneous forms of primary injury.

Primary injury has been modeled *in vitro* using approaches such as mechanical stretch of cultured neurons (2). Clinically, a number of aspects of primary injury can be appreciated when viewing the initial post-injury cranial computed tomographic (CT) scan or cranial magnetic resonance imaging (MRI) of patients. Direct cortical disruption seen in the initial minutes to hours after the insult represents primary injury that is not likely to be amenable to resuscitative therapy. In addition to direct cortical disruption, axonal injury and vascular disruption can result from primary injury. Indeed, because it is likely related to the anatomical association between axons and blood vessels, primary injury often results in coupled injury to these structures—and the commonly observed clinical picture of petechial hemorrhages in white matter signaling diffuse axonal injury (DAI) (3).

Classically, axonal disruption with retraction was believed to result only from direct shearing. However, work from the laboratory of Povlishock (4) over the past decade has identified a parallel secondary injury cascade in axons. Thus, as with gray matter injury, both primary and secondary axonal damage can occur after severe TBI. The concept of secondary axonal damage will be discussed in greater detail later in this chapter. Finally, there are a number of

miscellaneous forms of primary injury—and several of these can have critical consequences in the setting of acute injury. For example, pituitary stalk transection from shear forces has been reported (5) and leads to acute pituitary failure. Primary injury to the brain stem can also occur and often is associated with poor outcome (6). Similarly, primary injury from violent shaking in the setting of inflicted childhood neurotrauma (shaken baby syndrome) can include direct shearing of nerve roots in the upper cervical spine (7).

Another important aspect of primary injury is impact depolarization. At the time of severe injury, impact depolarization occurs, with massive increases in extracellular potassium ion and the indiscriminate release of the excitatory neurotransmitter glutamate (8). This immediate event initiates excitotoxicity—a key secondary mechanism that is discussed in detail latter in this chapter.

Although by definition, primary injury is not likely to be responsive to resuscitative approaches; it is interesting that our thinking on the lack of therapeutic approaches to primary injury may require reconsideration in the emerging era of tissue engineering and stem cell therapeutics (9). It is possible, that tissue replacement therapy in the future may allow successful therapeutic avenues even to lesions produced by primary injury and previously felt to lack therapeutic options. This could be particularly important as an adjunctive therapy in rehabilitation.

### EVOLUTION OF SECONDARY INJURY

Secondary injury includes both the endogenous evolution of damage within the brain and the effects of secondary

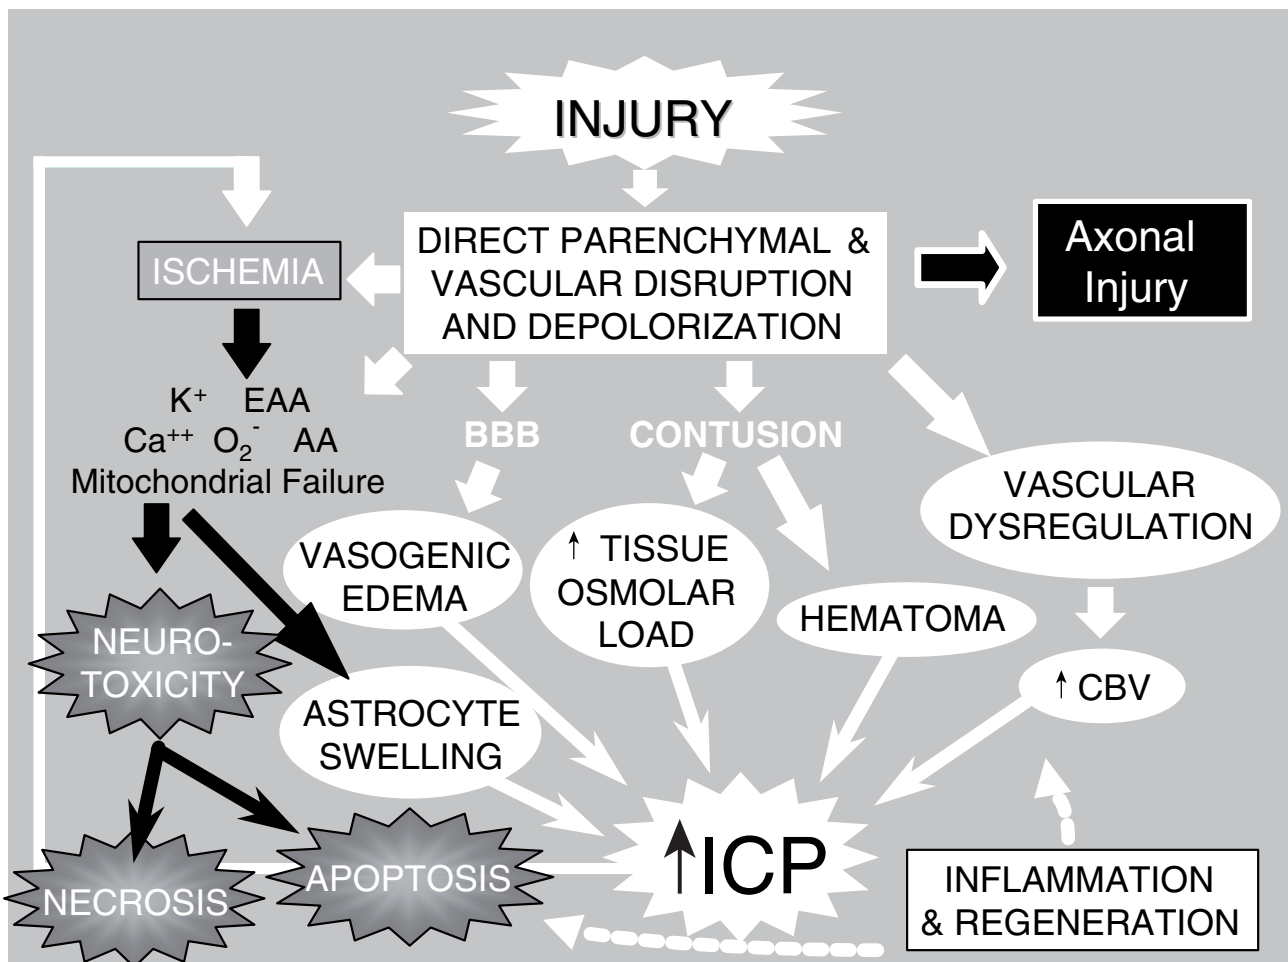

FIGURE 8-1

Categories of mechanisms proposed to be involved in the evolution of secondary damage after severe TBI in infants and children. Three major categories for these secondary mechanisms include (i) ischemia, excitotoxicity, energy failure, and cell death cascades; (ii) cerebral swelling; and (iii) axonal injury. A fourth category, inflammation and regeneration, contributes to each of these cascades.  $K^+$  = potassium; EAA = excitatory amino acids;  $Ca^{++}$  = calcium;  $O_2^-$  = superoxide; AA = arachidonic acid; BBB = blood brain barrier; ICP = intracranial pressure; CBV = cerebral blood volume

extra-cerebral insults (i.e., hypotension, hypoxemia) from the injury scene through the intensive care unit (ICU).

Studies in models of TBI have begun to unravel the mechanisms producing secondary damage. Four categories of mechanisms can be defined (Figure 8-1), those associated with (i) ischemia, excitotoxicity, energy failure, and resultant cell death cascades; (ii) secondary cerebral swelling; (iii) axonal injury; and (iv) inflammation and regeneration. Within each category, a constellation of mediators of secondary damage, endogenous neuroprotection repair, and regeneration are involved. The quantitative contribution of each mediator to outcome and the interplay between these mediators remains poorly defined.

A variety of methods have been used to study the evolution of secondary damage in human head injury including (i) the analysis of brain biochemistry and molecular biology via of ventricular cerebrospinal fluid (CSF) drained in the treatment of intracranial hypertension, (ii) assessment of brain interstitial fluid by cerebral microdialysis, (iii) imaging techniques linked to assessment of cerebral blood flow (CBF) and cerebral metabolism, and (iv) the assessment of molecular markers in brain tissue obtained from patients treated with surgical decompression for refractory intracranial hypertension. We discuss these studies and cite the clinical evidence supporting proposed mechanisms of secondary damage. It is impossible to address all of the mediators that may be involved; however, key mechanisms will be considered.

## POST-TRAUMATIC ISCHEMIA

Clinical studies in adults have indicated that soon after severe TBI, CBF is reduced and suggest that early post-traumatic ischemia might represent a therapeutic target (10,11). Clinical studies applying the stable xenon computed tomographic (CT) method of CBF assessment in the initial hours after severe TBI have been the most important in this regard. Early hypoperfusion or ischemia after severe TBI appears to represent a finding that is seen in most cases and is associated with poor outcome. The devastating consequences of secondary extra-cerebral insults early after injury (i.e., hypotension, hypoxemia) early post-trauma are also consistent with this possibility—because a hypoperfused brain is at high risk and may be incapable of mounting an appropriate vasodilatory response during these added insults (12). This is not to suggest that secondary insults are limited to the field or emergency department. Secondary ischemic insults can also occur in the ICU. This was best described in the classic report of Gopinath et al., (13) who used a jugular venous catheter to identify episodes of jugular venous desaturation ( $SjvO_2 < 50$  percent for more than 10 minutes) in the ICU in 116 patients with severe TBI. In that study, 46 of the 116 patients had at least one episode of

desaturation—suggesting ischemia. The causes of these episodes were either systemic such as hypotension or cerebral such as refractory intracranial hypertension. Episodes of desaturation were strongly associated with a poor neurological outcome. Just a single desaturation increased the incidence of poor outcome from 55 percent to 74 percent.

Numerous mechanisms may underlie the early post-traumatic hypoperfusion. Armstead reported reductions in the vasodilatory response to nitric oxide (NO), cGMP, cAMP, and prostanoids after experimental TBI in pigs, along with the release of superoxide anion (14,15). Also, greater injury-induced release of the potent vasoconstrictor peptide endothelin-1 in the newborn versus the juvenile pig was posed to mediate the hypoperfusion (16). Others have suggested a loss of either endothelial NO production, or reduced responsivity to NO as mediating hypoperfusion. Treatment with L-arginine (the substrate for NO production) improved CBF after TBI in rats (17). Similarly, treatment with L-arginine improved CBF and reduced contusion volume after TBI in rats (18). L-arginine is being tested in a clinical TBI trial in adults (personal communication, C. Robertson, MD). Loss of vasodilators and elaboration of vasoconstrictors, or other mechanisms, might be involved in producing early post-traumatic hypoperfusion (Figure 8-2).

Increases in metabolic demands, related to uptake of glutamate, as reflected by increases in brain tissue and CSF lactate, early after TBI have been reported in both models (19) and humans (20–22). Thus, reduced metabolic demands with a coupled CBF reduction in severely injured brain regions, early after injury, is an unlikely explanation for the hypoperfusion.

At more delayed times after injury (several hours to days), oxidative metabolism has been noted to be reduced to levels of ~50 percent of baseline for the

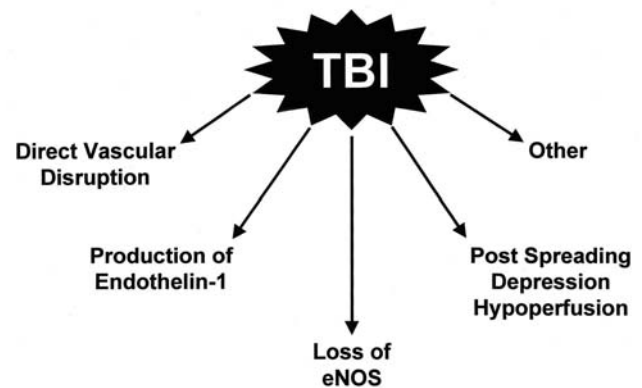

FIGURE 8-2

Schematic outlining putative mediators involved in the production of early post-traumatic hypoperfusion and/or ischemia after severe TBI. NOS = NO synthase. (See text for details.)

majority of the ICU course (20). The complex issue of issue alterations in metabolic demands after severe TBI is discussed in greater detail in the section on brain swelling later in this chapter.

### EXCITOTOXICITY

Excitotoxicity describes the process by which glutamate and other excitatory amino acids (EAAs) cause neuronal damage. Lucas and Newhouse (23) first described the toxicity of glutamate. Olney (24) subsequently reported that intraperitoneal administration of glutamate produces brain injury. Although glutamate is the most abundant neurotransmitter in the brain, exposure to toxic levels produces neuronal death (25).

Glutamate exposure produces neuronal injury in two phases. Minutes after exposure sodium-dependent neuronal swelling occurs (26). This is followed by delayed,

calcium-dependent degeneration. These effects are mediated through both ionophore-linked receptors, labeled according to specific agonists (N-methyl-D-aspartate [NMDA], kainate and  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid [AMPA]), and receptors linked to second messenger systems, called metabotropic receptors. Activation of these receptors leads to calcium influx through receptor-gated or voltage-gated channels, or through the release of intracellular calcium stores. Increased intracellular calcium concentration is the trigger for a number of processes that can lead to cellular injury or death (Figure 8-3). One mechanism involves activation of constitutive NO synthase, leading to NO production, peroxynitrite formation and resultant DNA damage. Poly(ADP-ribose) polymerase (PARP) is an enzyme operative in DNA repair, and in the face of DNA damage, PARP activation leads to ATP depletion, metabolic failure and cell death (27). This may be important since PARP knock-out mice exhibit improved outcome versus controls (28).

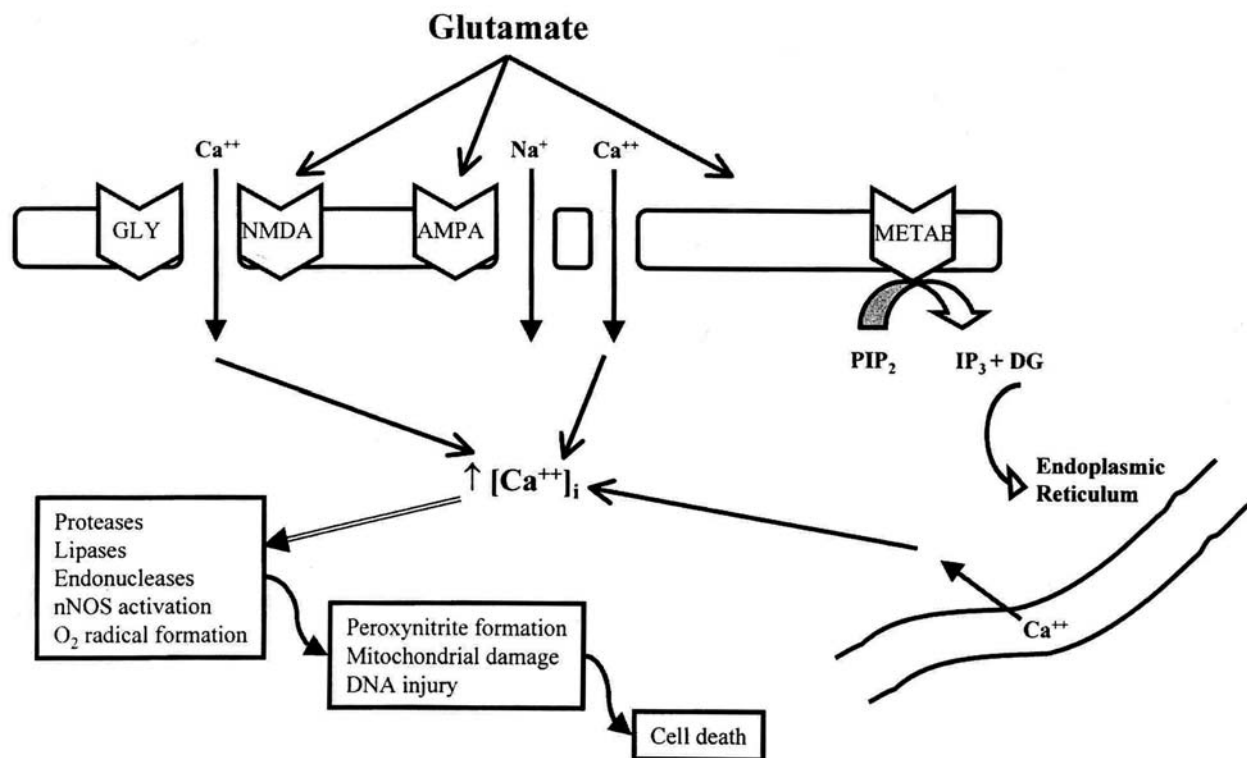

FIGURE 8-3

Mechanisms involved in excitotoxicity. Glutamate causes an increase in intracellular calcium concentration through stimulation of (i) the NMDA receptor with opening of the receptor-linked calcium ionophore, (ii) the AMPA receptor with opening of the voltage-gated calcium channels, and (iii) the metabotropic receptor, with the release of intracellular calcium stores via the second messengers inositol triphosphate and diacylglycerol. Increased intracellular calcium concentration leads to activation of proteases, lipases and endonucleases, along with neuronal NOS stimulation and production of oxygen radicals. This results in peroxynitrite formation, mitochondrial damage and DNA injury with subsequent cellular injury and death.

*Abbreviations:* GLY: glycine coagonist site; NMDA: N-methyl-D-aspartate receptor; AMPA:  $\alpha$ -amino-3-hydroxy-5-methylisoxazole-4-propionic acid receptor; METAB: glutamate metabotropic receptor; PIP<sub>2</sub>: phosphoinositide; IP<sub>3</sub>: inositol triphosphate; DG: diacylglycerol

Recent evidence suggests that activation of PARP within mitochondria may contribute importantly to their failure (29).

Faden et al. (30) first reported an increase in interstitial EAAs to neurotoxic levels after experimental TBI. Anti-excitotoxic therapies improve outcome after experimental TBI. Pretreatment with NMDA antagonists (phencyclidine, MK-801) attenuate behavioral deficits after TBI in rats (31, 32). Other therapies that modify the glutamate-NMDA receptor interaction and improve outcome following experimental TBI are magnesium (33), glycine site antagonists (34), hypothermia (35), and pentobarbital (36).

Palmer et al. (37) first demonstrated increased concentrations of EAAs in ventricular CSF from adult patients with TBI. Glutamate concentrations were about 5-fold greater than in control patients (up to 7  $\mu\text{M}$ )—levels sufficient to cause neuronal death in cell culture (38). However, CSF glutamate concentrations do not correlate to outcome after TBI in adults (39). Bullock et al. (40) characterized patterns of glutamate release by measuring EAAs by microdialysis after adult TBI. Patients with a normal head CT and no secondary ischemic events had interstitial concentrations of glutamate that were increased early in their course, then returned to normal, similar to the pattern seen in most experimental models. A second group of patients had an intermediate increase in glutamate concentration (5–20  $\mu\text{M}$ ) that declined over time, but remained higher than normal. Most of these patients had ischemic events or intracranial hypertension. A third group of patients had markedly increased concentrations of glutamate (over 20  $\mu\text{M}$ ). All patients with a progressively rising level of glutamate died.

Despite these findings, clinical trials with anti-excitotoxic therapies have been unsuccessful. This may be due to the fact that most therapies have been applied to all patients with TBI rather than those with excitotoxicity (41). Also, treatment may have been initiated too late. Inhibition of plasticity by anti-excitotoxic therapies may limit their efficacy—especially at the interface between the acute and subacute periods after injury (42).

## ENDOGENOUS NEUROPROTECTANTS

Ischemia, excitotoxicity, or their combination is a key facet of secondary injury. These mechanisms are linked to calcium overload, oxidative stress, and mitochondrial failure. Studies have begun to define, in infants and children with severe TBI, the endogenous retaliatory response to these ischemic and excitotoxic insults. Space limitations have directed us to focus on two examples of this cascade—namely, adenosine and heat shock protein 70 (HSP 70). Endogenous neuroprotective responses related to the apoptosis, cell signaling, and inflammatory cascades are discussed later.

Adenosine is an endogenous neuroprotectant produced in response to both ischemia and excitotoxicity. Adenosine antagonizes a number of events thought to mediate neuronal death (43). Breakdown of adenosine triphosphate (ATP) leads to formation of adenosine, a purine nucleoside that decreases neuronal metabolism and increases CBF, among other mechanisms. Adenosine binding to A1 receptors decreases metabolism by increasing  $\text{K}^+$  and  $\text{Cl}^-$  and decreasing  $\text{Ca}^{++}$  conductances in the neuronal membrane. A1 receptors are located on neurons in brain regions that are susceptible to injury (i.e., hippocampus) and are spatially associated with NMDA receptors (44). Thus, released adenosine minimizes excitotoxicity. Binding of adenosine to A2 receptors (on cerebrovascular smooth muscle) causes vasodilation, although binding to A2a receptors on neurons may be detrimental. Brain interstitial levels of adenosine are increased early after TBI in rats (45–47). In experimental TBI, brain interstitial adenosine increases immediately after injury to levels 50- to 100-fold greater than baseline (47). In clinical studies, marked increases in brain interstitial levels of adenosine in adults with TBI, were seen during episodes of jugular venous desaturation (secondary insults), supporting a role of adenosine as a “retaliatory” defense metabolite (48).

Another putative endogenous neuroprotectant that plays a role after severe TBI is HSP 70. This protein is induced as part of the classic preconditioning response in brain and has recently been shown to be increased in both CSF and brain tissue after severe TBI in humans (49–51). HSP 70 is believed to play an important role in optimizing protein folding as a molecular chaperone. It also inhibits pro-inflammatory signaling (52). Thus, the brain mounts an important endogenous defense response to TBI. Therapies designed to augment these pathways have not been examined adequately.

## APOPTOSIS CASCADES

It is now increasingly clear from experimental models and human data that cells dying after TBI can be categorized on a morphological continuum ranging from necrosis to apoptosis (53,54). Apoptosis is a morphological description of cell death defined by cell shrinkage and nuclear condensation, internucleosomal DNA fragmentation, and the formation of apoptotic bodies (55). In contrast, cells dying of necrosis display cellular and nuclear swelling with dissolution of membranes. Apoptosis requires a cascade of intracellular events for completion of cell death; thus, “programmed-cell death” is the currently accepted term for the process of cell death that leads to apoptosis (56). In diseases with complex and multiple mechanisms, such as TBI, it is typically difficult to distinguish clinical apoptotic vs. necrotic cell death as classically defined (57).

Some cells may display DNA fragmentation and activation of proteases involved in programmed-cell death, despite having nuclear and cellular swelling. Dying cells with mixed phenotypes may represent particularly difficult therapeutic targets after TBI.

In mature tissues, programmed-cell death requires initiation via either intracellular or extracellular signals (see Figure 8-4). These signals have now been well characterized *in vitro*, and are becoming better characterized *in vivo*. Intracellular signaling appears to be initiated in mitochondria, triggered by disturbances in cellular homeostasis such as ATP depletion, oxidative stress, or calcium fluxes (58). Mitochondrial dysfunction leads to egress of cytochrome c from the inner mitochondrial membrane into the cytosol. Cytochrome c release can be blocked by anti-apoptotic members of the bcl-2 family (e.g., bcl-2, bcl-xL, bcl-w, and Mcl-1), and promoted by pro-apoptotic members of the bcl-2 family (e.g., bax, bcl-xS, bad, and bid) (59).

Cytochrome c in the presence of dATP and a specific apoptotic-protease activating factor (Apaf-1) in cytosol activates the initiator cysteine protease caspase-9 (60). Caspase-9 then activates the effector cysteine protease caspase-3, a key apoptosis effector that cleaves cytoskeletal proteins, DNA repair proteins, and activators of endonucleases (61).

An additional intracellular cascade of programmed cell death linked to mitochondrial injury is the apoptosis-inducing factor (AIF) pathway (62–66). This caspase-independent pathway is activated by mitochondrial permeability transition and results in the release of AIF from the mitochondrial membrane. AIF release leads to large-scale DNA fragmentation (50–700 kilo-base-pair in size). Recently, Zhang et al. (67) reported that the AIF pathway is activated in experimental TBI. To date, specific pharmacologic inhibitors of this pathway are lacking, however, this alternative form of delayed neuronal death may represent an important therapeutic target.

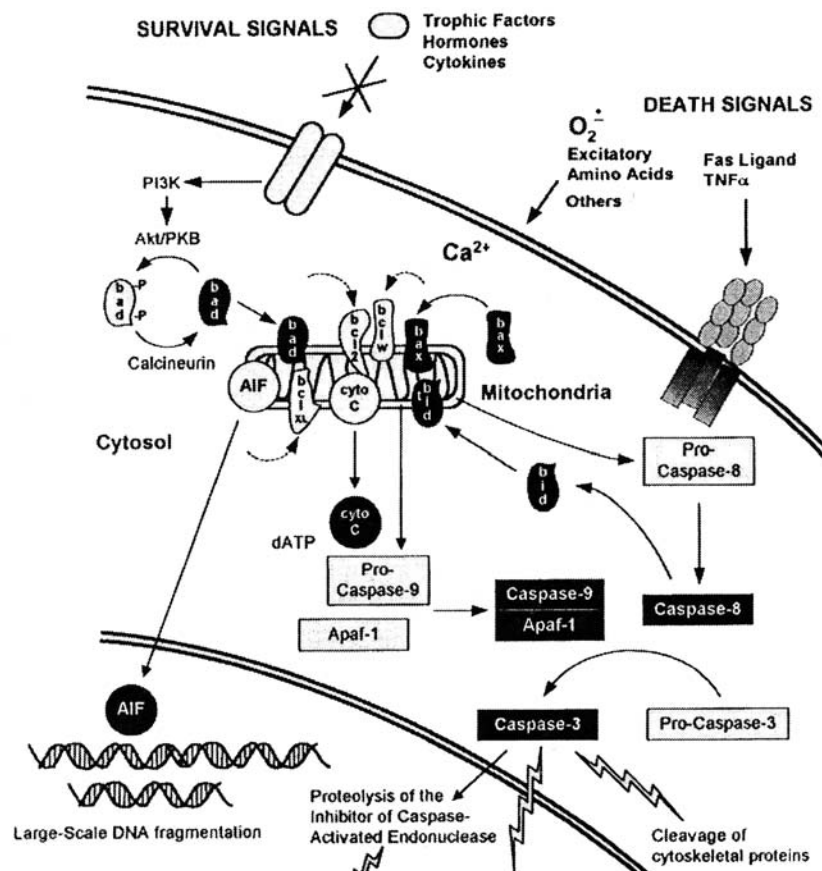

FIGURE 8-4

Simplified schematic depicting intracellular and extracellular pathways for programmed-cell death. Mitochondrial dysfunction caused by injurious stimuli such as oxidative stress or calcium fluxes can trigger release of cytochrome c or apoptosis inducing factor (AIF). Cytochrome c in the cytosol along with other enzymes and cofactors initiates activation of a cascade of caspases, culminating in apoptotic DNA cleavage. AIF triggers caspase-independent large-scale DNA fragmentation (see text for details). Programmed cell death can also be initiated by cell death receptors on the cell surface. Fas-ligand (Fas-L), either presented by an effector cell or in soluble form, binding to Fas-receptor (Fas-Rc), or TNF binding to TNF-receptor (TNF-Rc), can also initiate a cascade of caspases via intracellular death domains

Extracellular signaling of apoptosis occurs through the TNF superfamily of cell surface death receptors which include TNFR1 and Fas/Apo1/CD95 (68). Receptor-ligand binding of TNFR1-TNF $\alpha$  or Fas-FasL promotes formation of a trimeric complex of TNF- or Fas-associated death domains, respectively. These death domains contain caspase recruitment domains. The proximity of multiple caspases, in this case caspase-8, allows for activation of the effector cysteine protease followed by activation of caspase-3, where the mitochondrial- and cell death receptor-pathways converge. The cell death receptor pathway can also be regulated by soluble receptors and ligands that prevent and promote apoptosis, respectively, and by receptors lacking death domains. Finally, there is cross-talk between mitochondrial- and cell death receptor-pathways (69).

Bcl-2 is an important endogenous inhibitor of programmed-cell death *in vitro* (70). It is induced after experimental TBI (71) and reduces cortical tissue loss (72). Bcl-2 is increased in injured brain after severe TBI in humans (54). CSF levels of bcl-2 were increased ~4-fold in TBI compared with control patients. Moreover, CSF bcl-2 was associated with patient survival (73).

Clearly there is now substantial evidence, even in the clinical setting, for an important role for delayed neuronal death by apoptosis or mixed “apo-necrotic” phenotypes after severe TBI. This may represent a valuable opportunity for the development of new therapeutic approaches in the future.

#### CELL SIGNALING ABNORMALITIES IN NEURONAL DEATH

Neuronal death occurs after both experimental and clinical TBI. In addition to regions of brain directly contused, the hippocampus appears particularly vulnerable to TBI (74–78). As previously discussed, cell death execution pathways are activated by a sufficient severity of TBI involving mitochondrial injury, cytochrome C release with caspase activation, AIF release, and receptor-coupled pro-death pathways. Neurotransmitters, neurotrophins, cytokines, other growth factors, and oxidative stress activate multiple upstream signaling pathways linked to either pro-survival or pro-death activities (79). These receptors couple to signal transduction pathways involving interactions and cross-talk between multiple serine/threonine and tyrosine protein kinase cascades.

Many kinases involved in cell death process are serine/threonine protein kinases. Important participants in the cell death cascades include the mitogen activated protein kinases (MAPK). MAPKs cascades are complex and are mediated by successive protein kinases that sequentially activate each other by phosphorylation. They are importantly linked to two key components of

the cell death cascade, jun kinase (JNK) and P38 MAPK (Figure 8-5). JNK and p38 MAPK pathways activate caspase-3 (80–82). Activation of JNK leads to induction of pro-death genes including FasL (81–83). JNK increases p53 and Bax levels which increase cell death. JNK and p38 function in different stress signaling pathways and both target similar nuclear transcription factors that can be activated by pro death stimuli such as oxidative stress (84). Studies in various TBI models have documented significant changes in both JNK, and p38 MAPKs that may be related to cell death and functional impairment after injury (85–87). MAPKs are also linked to survival signals through the ERK pathway, highlighting the complex cross-talk between these cascades (Figure 8-5).

Several protein kinase cascades play a major survival role. Phosphoinositide 3-kinase (PI3-K), protein kinase B (PKB), and protein kinase A (PKA) pathways are prototype examples (Figure 8-6). PKB is also called akt; the complex nomenclature of these kinases has evolved across many disease processes. PKB is activated upstream by PI3K in response to survival signals, and have numerous pro-survival, growth, differentiation and synaptic plasticity actions (88, 89). PKB affects survival by a number of mechanisms including the phosphorylation and inactivation of several pro-death mediators such as Bad. Bad, a member of the Bcl-2 family, is phosphorylated by PKB at ser136 resulting in Bad dissociation from Bcl-xL and binding to 14-3-3 proteins inhibiting cell death

FIGURE 8-5

Cartoon showing the role of mitogen-activated protein kinases (MAPK) in transducing the signals involved in neuronal death. For example, oxidative stress triggers MAPK activation with resultant activation of jun kinase (JNK) which facilitates neuronal death mediated by a number of mechanisms including death receptors (Fas-Fas-L), P53 and Bax. MAPK also involves cross talk with some survival pathways such as ERK

FIGURE 8-6

Cartoon showing the role of important survival signal-mediated kinase activation in promoting neuronal survival. Phosphoinositide 3-kinase (PI3-K), protein kinase B (PKB), and protein kinase A (PKA) pathways are involved. PKB affects survival by a number of mechanisms including the phosphorylation and inactivation of the pro-death mediator Bad. Phosphorylation of Bad results in its dissociation from Bcl-xL inhibiting cell death. CAMP-mediated activation of PKA can also lead to formation of the transcription factor “cAMP response element binding protein” (CREB), which also promotes cell survival

(Figure 8-6) (90). CAMP-mediated activation of PKA can also lead to formation of the transcription factor “cAMP response element binding protein” (CREB), which is similarly associated with cell survival. These pro-survival kinase pathways are outlined in Figure 6 (83). Survival signals are exemplified by growth factors, cytokines, hormones, cell-cell interactions as well as extracellular matrix adhesion molecules. Of course, inactivation of two pro-death members of the MAPK family, p38 and JNK/SAPK, have also been proposed as promoting survival by extracellular stimuli (91). Finally, activation of some PKC isoforms by PI3K can transduce pro-death signals, once again highlighting the complexity of these kinase cascades (Figure 8-6).

In summary, the complex but important kinase pathways are critically involved in the control of neuronal death and plasticity. Further insight into these cascades will likely lead to the development of powerful new tools to manipulate both neuronal death and rewiring after injury. Proteomics approaches may be essential to unraveling the cybernetic nature of these kinase pathways (92).

## AXONAL INJURY

Traumatic axonal injury (TAI) encompasses the spectrum of mild to severe TBI, both clinically (93–96) and in

models (97–99). The extent and distribution of TAI depend on injury severity and category (focal versus diffuse) (100).

The classical view that TAI occurs due to immediate physical shearing is represented primarily in severe injury where frank axonal tears occur (93,94,101,102). However, recent experimental studies suggest that TAI predominantly occurs by a delayed process termed “secondary axotomy” (98,103,104). Two hypothetical sequences have attempted to explain secondary axotomy, one attributing axolemmal permeability and calcium influx as the initiating event (Figure 8-7), the other a direct cytoskeletal abnormality impairing axoplasmic flow (98,104,105). It has been posited that both forms of reactive axonal swelling take place but in different proportions depending on the severity of injury. Superimposed on these theories is the finding that hypoxic/ischemic insults can also produce axonal swelling that resembles retraction balls. As a result, differing as well as unifying theories for axonal injuries in brain injury have been proposed (98,104–107). Common mechanistic features include focal ion flux, calcium dysregulation, and mitochondrial and cytoskeletal dysfunction.

TAI contributes to the morbidity after TBI (98, 100–102). Until recently the contributions of TAI to morbidity, have remained speculative since TAI has remained refractory to treatment even in the laboratory. However, recent studies in experimental TBI models have shown that hypothermia or cyclosporin A can both reduce TAI (108,109). In contradistinction, hypothermia reduces growth factor signaling after experimental TBI (110,111) that could blunt regeneration. These therapeutic advances should help determine more definitively the contributions of TAI to secondary damage. Recent application of MRI to the study of TAI (112,113) and axonal connectivity (114,115) may improve our understanding of TAI and regeneration.

## CEREBRAL SWELLING

In addition to cascades of neuronal death and axonal damage, brain swelling is a hallmark finding in severe TBI and results in the development of intracranial hypertension, which can have devastating consequences. Cerebral swelling and accompanying intracranial hypertension contributes to secondary damage in two ways. Intracranial hypertension can compromise cerebral perfusion leading to secondary ischemia. In addition, it can produce the devastating consequences of deformation through herniation syndromes. Intracranial hypertension results from increases in intracranial volume from a variety of sources, which are outlined in Figure 8-1. In some cases, such as with epidural, subdural or parenchymal hematoma formation, an extra-axial or parenchymal blood collection is the key culprit—and is generally

FIGURE 8-7

Reactive axonal swellings have been proposed to result from focal axolemmal disruption, ionic shifts and neurofilamentous compaction at site (A) results in a reactive swelling at site (B) in an upstream region of the axon. At the site of ionic influx, neurofilamentous compaction and mitochondrial swelling is seen (C). Neurofilament compaction is associated with neurofilament sidearm loss (D). Obstructed axonal transport results in upstream axonal enlargement, neurofilament misalignment, organelle accumulation, and formation of the typical reactive axonal swelling (E)

addressed by surgical evacuation (116). However, there are several important mechanisms that are more uniformly involved in the development of intracranial hypertension. These are related to either brain swelling from vasogenic edema, astrocyte swelling, and an increase in tissue osmolar load, or vascular dysregulation with swelling secondary to an increase in cerebral blood volume (CBV).

Recent data suggest that brain swelling after severe TBI results from edema rather than increased CBV. Marmarou et al. (117) measured both CBV and brain water in adults with TBI. Using a dye indicator technique (coupled to CT) to measure CBV and magnetic resonance imaging [MRI] to quantify brain water, increases in brain water were commonly observed, but were generally associated with reduced (not increased) CBV (Figure 8-8).

Thus, edema rather than increased CBV appears to be the predominant contributor to cerebral swelling after TBI. Both cytotoxic and vasogenic edema may play important roles in cerebral swelling. However, our traditional concept of cytotoxic and vasogenic edema is evolving.

There appear to be four putative mechanisms for edema formation in the injured brain. First, vasogenic edema may form in the extracellular space as a result of blood-brain barrier (BBB) disruption. Second, cellular swelling can be produced in two ways. Astrocyte swelling can occur as part of the homeostatic uptake of substances such as glutamate. Glutamate uptake is coupled to glucose utilization via a sodium/potassium ATPase, with sodium and water accumulation in astrocytes. Swelling of both neurons and other cells in the neuropil can also result from ischemia- or trauma-induced ionic pump failure. Finally, osmolar swelling may also contribute to edema formation in the extracellular space, particularly in contusions. Osmolar swelling, however, is actually dependent on an intact BBB or an alternative solute barrier.

Cellular swelling may be of greatest importance. Using a model of diffuse TBI in rats, Barzo et al. (118) applied diffusion-weighted MRI to localize the increase in brain water. A decrease in the apparent diffuse coefficient after injury suggested predominantly cellular swelling, rather than vasogenic edema, in the development

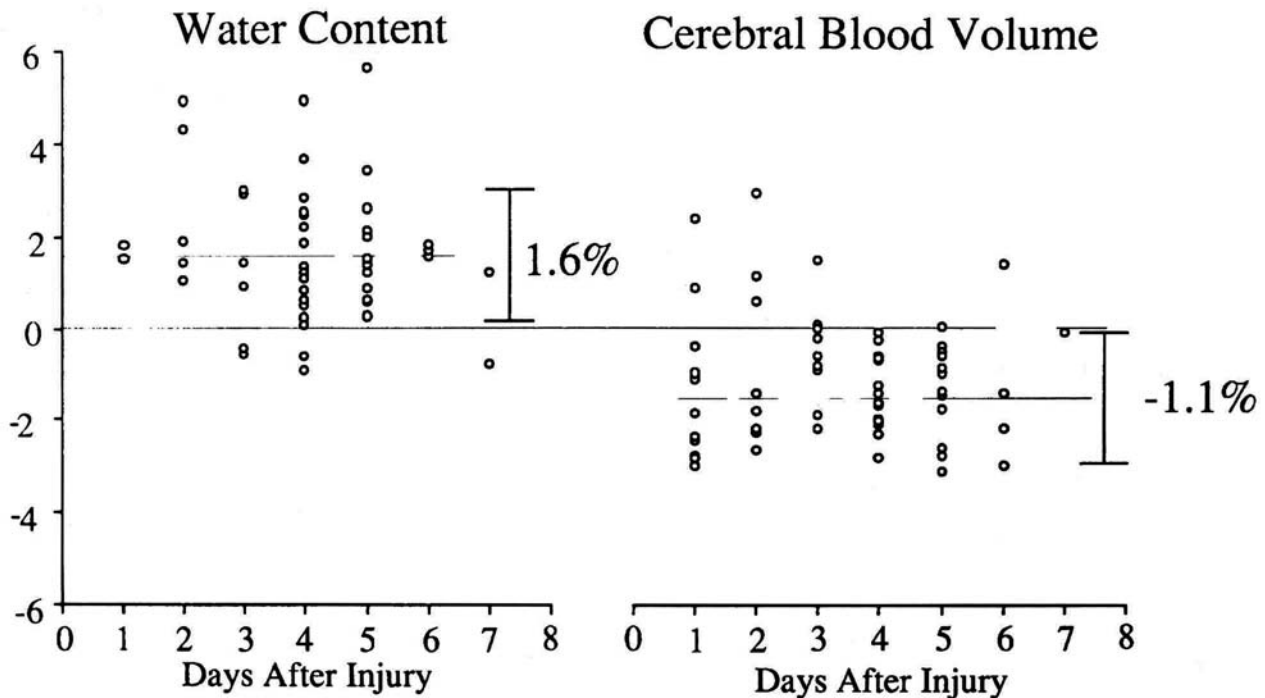

FIGURE 8-8

The percentage change in brain water content as assessed by MRI and cerebral blood volume (CBV) as measured by CT and indicator dilution technique in 109 studies of adults with TBI. Brain water is increased and CBV is reduced in adults with severe TBI. Reprinted from the work of Marmarou et al. (121) with permission

of intracranial hypertension. Cellular swelling may be of even greater importance in the setting of TBI with a secondary hypoxic-ischemic insult (119).

Katayama et al. (120) also suggested that the role of BBB in the development of post-traumatic edema may have been overstated—even in the setting of cerebral contusion. One intriguing possibility is that as macromolecules are degraded within injured brain regions, the osmolar load in the contused tissue increases. As the BBB reconstitutes (or as other osmolar barriers are formed), a considerable osmolar driving force for the local accumulation of water develops, resulting in the marked swelling so often seen in and around cerebral contusions (Figure 8-9).

In some cases, increases in CBV can be seen after TBI and contribute to intracranial hypertension. When an increase in CBV is seen, it may result from local increases in cerebral glycolysis “hyperglycolysis” as described by Bergsneider et al. (22). In regions with increases in glutamate levels, such as in contusions, increases in glycolysis are observed because astrocyte uptake of glutamate is coupled to glycolysis rather than oxidative metabolism. Recall that oxidative metabolism is generally depressed by ~50 percent in comatose victims of severe TBI in the ICU (20). Hyperglycolysis results in a marked local increase in cerebral glucose utilization with a coupled increase in CBF and CBV and resultant local brain swelling. A detailed discussion of this topic is beyond the scope of this chapter.

As MRI and MR-spectroscopic methods continue to develop and become applied to critically ill patients (121) our “black box” knowledge of the mechanisms involved in cerebral swelling should greatly advance. It must be remembered that although neuronal and axonal injury are key downstream events in the evolution of damage after severe TBI, brain swelling and resultant intracranial hypertension is still the principal target for titration of therapy in the ICU.

## INFLAMMATION AND REGENERATION

There appear to be both acute detrimental and sub-acute/chronic beneficial aspects of inflammation. There is robust acute inflammation after TBI. This has been shown in models of TBI (122–124), and in adult patients (125–128). NF- $\kappa$ B (129), TNF $\alpha$  (130, 131), IL-1 $\beta$  (132, 133), eicosanoids (134), neutrophils (123,135), and macrophages (136,137) contribute to both secondary damage and repair.

Markers of inflammation after TBI have been assessed in humans using two general strategies, (i) examination of inflammation in contused brain tissue resected from patients with refractory intracranial hypertension, and (ii) study of mediator levels in CSF. Consistent with a role for IL-1 $\beta$  in the evolution of tissue damage in

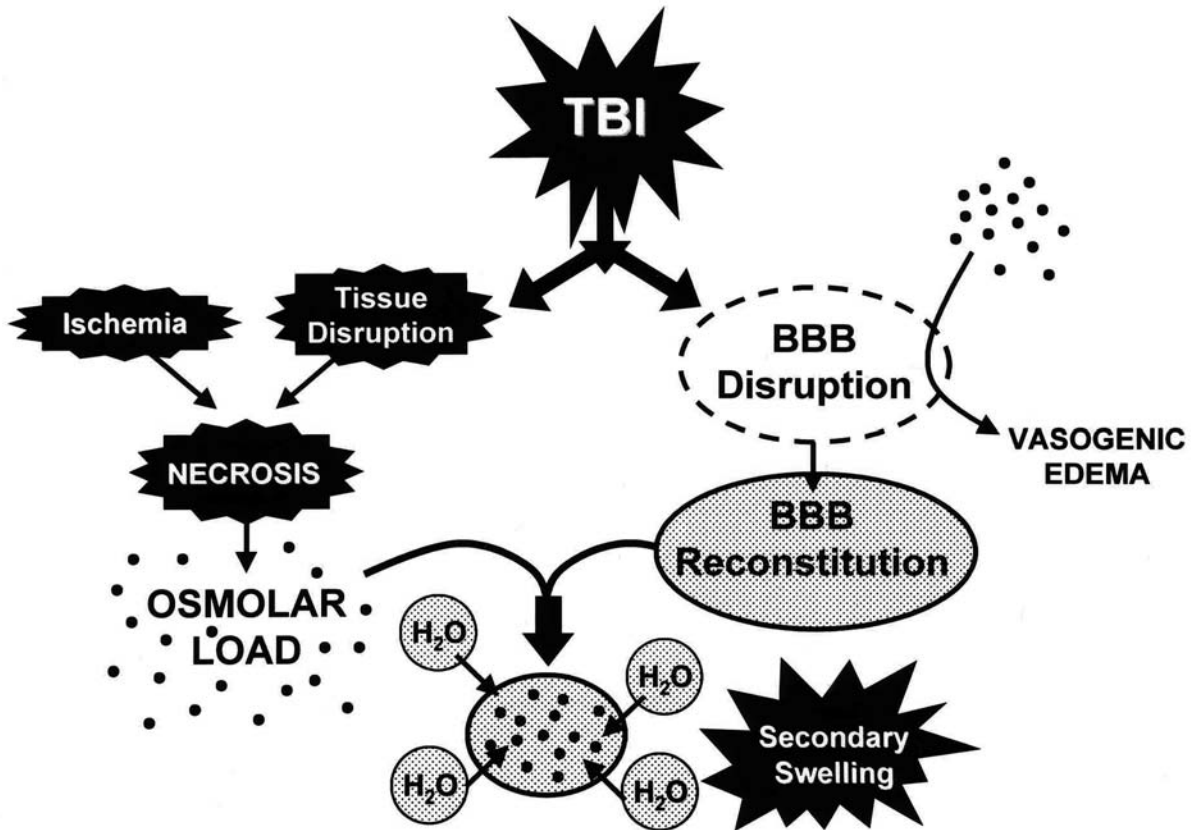

FIGURE 8-9

Schematic based on hypothesis of Katayama et al. (120) suggesting that as the osmolar load increases (breakdown of macromolecules in the region of contusion necrosis), a considerable driving force develops for the accumulation of water, resulting in the secondary swelling so often seen in and around cerebral contusions

FIGURE 8-10

Evidence for activation of IL-1 $\beta$  converting enzyme (ICE) activation in cerebral contusions resected from adult patients with severe TBI and refractory intracranial hypertension. Western analysis demonstrating cleavage of the intact 45 kD pro-caspase-1 to the 10 kD fragment in each of eight victims of severe TBI but in none of 6 control brain samples from patients that died of non-CNS causes. Reprinted from Clark et al. (63) with permission

human TBI, Clark et al. (54) performed western analysis of brain samples resected from adults with refractory intracranial hypertension secondary to severe contusion. Interleukin-1-converting enzyme (ICE) was activated, as evidenced by specific cleavage in patients with TBI. ICE activation is critical to the production of IL-1 $\beta$ . ICE acti-

vation was not detected in patients that died of non-CNS etiologies (Figure 8-10). This supports the production of IL-1 $\beta$ , a pivotal pro-inflammatory mediator, in the traumatically injured brain in humans.

Studies of CSF further support a role for inflammation in TBI. Marion et al. (126) demonstrated increases

in IL-1 $\beta$  in CSF after severe TBI in adults. These increases were attenuated by the use of moderate therapeutic hypothermia. Similarly, there are increases of a number of cytokines in CSF after severe TBI including IL-6, and IL-8 (128,138). Contusion and local tissue necrosis appear to be important to trigger neutrophil influx with resultant secondary tissue damage (123). Neutrophil influx is accompanied by increases in inducible nitric oxide synthase (iNOS) levels in brain (124) and is followed by macrophage infiltration, which peaks between 24–72 hours after injury (139). Macrophage infiltration and the differentiation of endogenous microglia into resident macrophages may signal the link between inflammation and regeneration, with elaboration of a number of trophic factors (i.e., nerve growth factor (NGF), nitrosothiols, vascular endothelial growth factor) (133, 138,140,141).

Kossmann et al (138) reported a link between IL-6 production and the production of neurotrophins, such as NGF. Cultured astrocytes treated with either IL-6, IL-8 or CSF from brain-injured adults, produced NGF. Cytokine production after TBI may be important to neuronal plasticity and repair, as discussed below.

Studies in models of TBI (131, 142) suggest beneficial aspects of inflammation on long-term outcome. Mice deficient in TNF $\alpha$  exhibit improved functional outcome (versus wild-type) early after TBI. However, the long-term consequences of TNF $\alpha$  deficiency on outcome are detrimental (131). Similarly, despite a detrimental role for iNOS in the initial 72 h posttrauma (143), iNOS deficient mice demonstrated impaired long-term outcome vs controls (142). iNOS is important in wound healing and iNOS-derived nitrosylation of proteins may play a role (141,144). Regeneration and plasticity play important roles in mediating beneficial long-term effects on recovery, and these responses are linked to inflammation.

The contribution of the inflammatory response to TBI remains to be determined. Although there are a few promising reports in models of the use of anti-inflammatory therapies in TBI and ischemia (targeting IL-1 $\beta$ , ICE, and TNF $\alpha$ ) it is unclear whether anti-inflammatory therapies will improve outcome after clinical TBI. If inhibition of the inflammatory response is considered, exacerbation of infection risk must also be anticipated (145). Also, the link between inflammation and regeneration must be recognized.

## CONCLUSIONS

Mechanisms involved in the evolution of secondary brain injury after TBI have been reviewed. Particular attention has been paid to studies at the bedside. Our understanding of the biochemical, cellular, and molecular responses has progressed—particularly with the application of

molecular biology methods to human materials. Additional details on these mechanisms have also been reviewed in a companion article to this chapter which addresses the unique setting of pediatric TBI (146). Future investigation should integrate these findings with bedside physiology and an improved assessment of outcome. Finally, novel imaging and diagnostic methods, particularly MRI and MRS must be coupled with biochemical and molecular methods to clarify the mechanisms involved in secondary damage and the local effects of novel therapies.

## ACKNOWLEDGEMENTS

The authors dedicate this chapter to the late Dr. Peter Safar for his vision and inspiration. We thank the National Institutes of Health/NINDS NS38087 (PMK), NS38620 (RSBC), NS 40049 (LJ) and NS30318 (PMK, RSBC), Center for Disease Control/University of Pittsburgh CIRCL (PMK), and the Laerdal Foundation for supporting this work. We thank Marci Provins and Fran Mistrick for preparation of the manuscript.

## Concepts of CNS Plasticity and Their Implications for Understanding Recovery After Brain Damage\*

*Donald G. Stein*

### CONCEPTUAL AND THEORETICAL ISSUES IN RECOVERY OF FUNCTION: BACKGROUND

It is often taken for granted that after brain injury, “plasticity” and recovery may be possible, but their underlying mechanisms remain a matter of debate. The term “plasticity” is seldom explicitly defined in reports on neurorehabilitation. When any functional restitution or recovery after brain injury is observed, the assumption is that the inherent plasticity of the brain is responsible for the beneficial outcome. But what does this really explain about what is actually taking place in response to brain damage?

Until the 1960s, very few people in the field of neurorehabilitation supported the idea that the adult central nervous system (CNS) was capable of undergoing any substantial reorganization in response to brain damage, so any “recovery” was attributed to strategic behavioral tricks that brain-injured subjects were able to master in order to overcome their deficits (1). These were referred to as “compensatory strategies,” but the argument was circular: you had behavioral recovery because of compensatory strategies which were inferred because you had behavioral recovery—hardly a meaningful explanation of mechanism!

One of the main dogmas that blocked substantive research and clinical understanding of the mechanisms of recovery in response to brain damage was promoted by the Nobel prize-winning neuroanatomist Ramon y Cajal (2), who forcefully argued that once development was over, any regeneration in the adult brain would be very limited, if it occurred at all. During that era, neuroanatomists who observed structural changes in the damaged adult brain—now considered characteristic of neuronal repair, such as axonal or dendritic sprouting, or even neurogenesis—often reported such changes as mere artifacts of histological techniques rather than as real evidence of CNS structural plasticity.

The paradigm shift that led to acceptance of the idea of CNS plasticity in response to injury began with the work of Raisman (3). Using then state-of-the-art electron microscopic techniques, Raisman first mapped the two primary afferent pathways into the subcortical structure he called the “septal nuclear complex” in adult rats. Once the pathways were identified, Raisman made separate and selective knife-cuts to disrupt one of the two paths to observe what changes would take place in the intact pathway in response to the injury. After waiting a suitable period of time he observed that (1) degenerating fibers

---

\*This article is substantially revised from a previous version published as Stein DG, Hoffman SW: Concepts of CNS plasticity in the context of brain damage and repair, *J Head Trauma Rehabil* 18, 317–341, 2003.

caused by the cut left synapses in the septal nucleus vacated, and (2) fibers from the surviving pathway reoccupied the vacated synapses. Particularly interesting was that the new afferents were “heterotypic”: they did not provide the same neurotransmitter to the septal cells as had the original fibers. Raisman concluded that:

the finding that the distribution of one fibre pathway to the septum is altered by the destruction of another system of septal afferents suggests that synapses in the central nervous system of adult mammals may be far more labile than had been previously suspected. It is interesting to speculate why, in view of this anatomical plasticity, so little functional recovery accompanies lesions of the brain (p. 45).

Raisman and his colleagues did not follow up his remarkable observations with behavioral studies, but his work did lead others to change the view of the adult CNS from a static, phrenological collection of structures with fixed functions to a much more dynamic system capable of reorganization in response to injury (see, e.g., Cotman [4] and Steward [5]).

Although studies on promoting recovery of function appeared as early as the first few decades of the twentieth century (see Finger and Stein [6] for examples), until the early 1970s they were largely dismissed by the field as describing “anomalous” events not worthy of serious study. At the behavioral level, those adhering to the static view of the adult CNS could claim that when functional recovery was observed, it was simply because the tests being used were not sensitive enough to detect the underlying deficits.

The idea that recovery of function can be promoted by pharmacological agents, the transplantation of fetal or stem cell tissues, environmental stimulation, hormonal factors, and other means, is a very new concept in the history of the science and is still not completely accepted. For example, the indisputably best-selling textbook in neuroscience, used today in almost all comprehensive graduate neuroscience classes, is *Principles of Neural Science* (7). This work refers to plasticity only once (p. 34), and despite its comprehensive coverage and its heavy use by medical and biomedical professionals, it offers no discussion of recovery of function and its implications for thinking about the organization and adaptability of the brain in response to injury.

Grounds for cautious optimism may exist, however. In a new textbook closely modeled after Kandel et al., *Fundamental Neuroscience* (8), the authors do refer to “experience-driven plasticity” in the cortex and other neural systems, but they say nothing about any aspect of recovery of function and its potential underlying mechanisms. This blind spot in the basic education of young neuroscientists can have profound effects on the treatment of CNS injury and the allocation of resources for

research. Certainly no one is claiming that physiological repair of the damaged brain or spinal cord is going to occur under *all* conditions, but it is becoming impossible to ignore or deny the many hundreds of laboratory animal and human studies which have shown that some extent of repair, regeneration and functional recovery can be stimulated under some conditions. The focus should now be on determining what those conditions are, and applying them to achieve repair after degenerative or traumatic injuries to the brain or spinal cord.

The remainder of this chapter reviews several concepts of recovery that were proposed in the fields of neuropsychology and neurorehabilitation before there was much empirical and clinical data to support them. Given the large body of evidence we now have for dramatic reorganization and repair after injury, are these early concepts of functional recovery consistent with the well-accepted ‘principle’ of strict functional localization in the brain? Are plasticity concepts and localization dogma consistent with each other? Is localization dogma supported by the evidence, both modern high-tech data and the older intuitive clinical approach (9)?

First, is it clear what we mean when we use the term “neuroplasticity”? Is it a specific, well-defined phenomenon that can be applied as an explanatory construct? Over the last decade or so, there has been an explosion of interest in neuroplasticity and it is often taken for granted that what the term implies is well understood and accepted. PubMed, the National Institutes of Health’s literature search engine, is a powerful tool for finding the most current articles in the biomedical sciences. Type in the word “neuroplasticity” and about *eleven thousand* articles appear. Neuroplasticity is applied to the symptoms of Alzheimer’s disease, alterations in apolipoprotein E synthesis, chronic pain, mood disorders, recovery from stroke, long-term potentiation in the hippocampus, changes in memory in development and aging, allodynia, presynaptic neurotransmitter vesicle release, changes in synaptic terminal arborization, alterations during critical periods of development, alterations in glutamate receptors, changes in trans-cranial stimulation-induced excitability of the motor cortex, alterations in sensory-cortical maps, neurogenesis during development and aging, stem cell effects, axonal sprouting, epileptic seizure activity, and augmentation of immune-induced neural inflammatory response, all in the first twenty references that come up in PubMed! How can such ubiquitous use of the term be of any use in understanding what is actually occurring in the damaged nervous system in response to injury? One argument is that, clearly, ‘plasticity’ has manifold ways of expressing itself in both the intact and the damaged nervous system. But if every type of change in neural tissue is seen as plasticity, what then is NOT an example of the phenomenon?

Here is a case, taken from the field of neurogenesis, that illustrates the problem: recently, Parent and

Lowenstein (10) reviewed the literature on the effectiveness of stem cell proliferation in the adult nervous system of rodents. These authors reported that there is, indeed, a five- to tenfold increase in the number of dentate granule cells in the hippocampus following chemotoxic injury to the brain, and this could certainly be considered a dramatic example of injury-induced neuroplasticity. However, their review of the literature also showed that the neurogenesis was associated with increases in kindling and seizure activity in the hippocampus and with a later increase in apoptotic cell death. This is not to imply that, under all conditions, injury-induced neurogenesis would be detrimental. But this is a typical example of neuroplasticity that has a negative outcome. But if such a phenomenon (i.e., neurogenesis as a cause for post-traumatic epilepsy) is also an example of ‘plasticity,’ then just how useful is the concept for explaining recovery of function? Perhaps we need to distinguish between *negative* and *positive* plasticity and to think more critically about how we use the term to describe events in the central nervous system (CNS) associated with functional recovery and rehabilitation.

For the purposes of this review, “neuroplasticity” will be used only for verifiable examples of functional and adaptive recovery after brain injury. This is the behavioral concept that cognitive, sensory, or motor impairments gradually diminish or are eliminated over time rather than getting worse. Limiting the term in this way implies that there can be acute or chronic deficits which disappear spontaneously, or which can be reduced by pharmacological, physiological, surgical, or behavioral treatments over time (11–15).

### **“LOCALIZATION OF FUNCTION,” RECOVERY OF FUNCTION, AND DEFINITIONS OF NEUROPLASTICITY**

In the clinic, it may be difficult to accept a very limited definition of plasticity. This is because it is often necessary for brain-damaged patients to succeed in a variety of activities of daily living by substituting new behavioral strategies. This substitution is considered a form of ‘compensation’ or adaptation to a deficit. As noted earlier, some critics of the concept postulate that recovery of function does not really exist. They hold that all recovery is only a type of compensation (see [1] and [16] for a good discussion of this issue). This view is an offshoot of the idea that specific areas of the brain are genetically programmed to control or mediate behaviors, so the destruction or perturbation of a center in which such specific functions are localized leads to the permanent loss (or serious impairment) of that function.

The battle between those who argue for precise localization and those who think that functions are more widely

distributed throughout the brain has been going on for more than a hundred years, and despite breakthroughs in brain imaging techniques, no resolution is in sight. Within this framework the limits or extent of localization seem to shift with the latest fashions in technology. For example, cortical maps grow or shrink according to how imaging methods are applied, and this determines how the loci of control are defined. As imaging studies proliferate, structures are added or subtracted at will to the number required to mediate a particular function, with the expansion taking place in the serial or parallel circuits so popular in computer-based metaphors of the brain. The more recovery observed, especially in the case of bilateral structural removal, the more structures have to be added to account for the observed plasticity. This issue is discussed further below.

Providing technical support for this conceptual approach to brain function is the rapid progress in molecular biological assays, which has led to a plethora of functional activities being assigned to the expression or inhibition of specific genes, a form of localization doctrine gone wild—a molecular biology of phrenology, so to speak, which is of growing concern to some investigators in this field. In an excellent brief review of the issue, Kosik cautions that:

Genes, neurons and brain regions are annotated with functional descriptors that fail to capture the interactive nature of these units. The temptation is strong to jump beyond what a biological unit actually does, to a more encompassing functional label. For example, a mutant gene does not cause a disease; it merely encodes a mutant protein that leads to a cascade of events and, eventually, to a disease. The methodology to ascertain function can also be limiting. Just as the carpenter, whose only tool is a hammer, treats all objects like nails, so neurophysiologists and brain ‘imagers’ probe the brain with their own hammers and have cobbled a picture of brain function that is not explicitly integrated (17).

This discussion is not just an academic exercise, because one corollary of the ‘strong’ form of localization is that one can never expect to see any ‘true’ recovery of function, and perhaps it is because of this belief that recovery of function per se is rarely discussed in the major textbooks of basic neuroscience currently in use. These argue that subtle “tricks” must be used by the organism to perform effectively, and that the tricks may be too subtle to detect without sophisticated behavioral testing designed to reveal the underlying deficits and shifts in behavior (1). If no deficits are observed, it is because the tests are insensitive, or the wrong tests have been used, rather than because any true recovery of function has occurred. From this perspective, the job of the neuropsychological diagnostician is to tease out the deficits and prove the localization.

The only goal of rehabilitation, in this context, is to teach the patient new strategies to replace functions lost by the injury, and plasticity is defined by the extent to which such substitution is possible. For those who envision the nervous system as a kind of 'black box,' there is no need to speculate about underlying neural mechanisms or to worry about providing neuroprotection or enhancing neuroregeneration through a pharmacological or physiological substrate. The remaining brain tissue just does what it does to varying degrees of effectiveness, so why bother with trying to 'add' neurons or rebuild damaged circuits? Thus it is argued that while the brain-damaged patient may eventually accomplish the same goals as an intact individual, the means by which the task is accomplished may be very different.

### EQUIPOTENTIALITY, VICARIATION, CNS REORGANIZATION AND RECOVERY OF FUNCTION

The assumption of substitution rather than restitution of function after brain damage fits well with the idea that intact parts of the brain can take over the functions of tissue lost or destroyed after injury or disease. In this paradigm, remaining healthy tissue is said to modulate its physiological activities to compensate for the damage to a specific area. But there is evidence to support a different model for response to injury. Thus, in laboratory rats and monkeys, if injury occurs during certain critical periods in early development, recovery of cognitive and motor functions can sometimes be greater than that seen in adults with similar kinds of CNS damage. Is this merely a form of compensatory strategy or is structural reorganization of the brain itself a major factor in the resulting plasticity?

In humans with early brain injury, the issues are more complex and controversial than for adult brain injury, especially with respect to intellectual skills, language and cognition. For example, there are many studies in both animals and children that provide strong substantiation that early brain damage is associated with long-term deficits and intellectual impairments in later life (18, 19). Other studies support what has been called the Kennard principle (20), that early brain lesions lead to much more sparing than the same injury in a more mature organism (21, 22).

How is it possible to reconcile these divergent findings? It now appears that there are a number of factors that can predispose to better recovery if injury occurs during early development, but there are also factors that can make matters worse. One of the most important of these factors appears to be a very specific, critical period for plasticity such that very early-occurring injury to the brain may be much worse than if the injury were to occur just

a few weeks or months later (23). Bryan Kolb and his colleagues have repeatedly demonstrated this phenomenon in laboratory rats. They also review evidence in human infants showing that if a cortical injury occurs within the first months of life, the results can be devastating, but if the same cortical area is damaged at around one to two years of age, there is much better recovery. Kolb and Cioe (24) found that even as little as one week of difference in age could have dramatic impact on morphogenesis and sparing of function after medial frontal cortical lesions in rats. Thus, if the lesions were done on post-natal day 2, animals tested as adults on spatial learning and reaching tasks were very impaired. If the same surgery was done on post-natal day 9, there was extensive recovery and apparently substantial generation of new neurons to replace those that were removed by the surgery. In development, then, the precise timing of the injury *may be critical* in determining whether or not recovery will be observed, and when or whether rebuilding of neuronal circuits may occur. Injuries occurring slightly or moderately later than immediately after birth, when one might assume the most plasticity, could lead to much better outcomes. This calls for a more modulated evaluation and interpretation of the Kennard Principle that the earlier the injury the better the outcome.

When such sparing of function is observed during development or at maturity, it is often attributed to the equipotentiality or vicarious function of cerebral (usually cortical) areas. Equipotentiality refers to the capacity of anatomically distinct areas of the brain to mediate a rather wide variety of functions. Despite the caveats discussed above, such plasticity is thought to be more likely when the brain is developing and not yet specialized for particular activities such as speech or patterned movement, but there is both historical and contemporary evidence to suggest that both equipotentiality and vicarious function can be induced in the adult organism as well.

The concept of neural vicariation implies that even the mature CNS has a certain number of redundant or backup subsystems that participate in this takeover of function (25). However, the mechanisms by which area *a* could "take over the function" of damaged area *b* and still perform function *a* are usually not described. If there is substitution or vicarious function, how can it be determined at the physiological and/or behavioral levels of analysis? In one study in adult squirrel and owl monkeys, Xerri, Merzenich, Peterson and Jenkins (26) trained the animals to retrieve small objects, used microelectrode techniques to map responsivity to afferent activity when the animals performed the tactile discrimination tasks, and then selectively damaged specific parts of the sensorimotor cortex by electrocoagulation of surface blood vessels. The brain tissue was then checked to make sure that it was completely unresponsive to any peripheral stimulation.

Immediately after the lesions the monkeys were retrained on the tasks and cortical remapping was performed. The resulting changes in post-injury behaviors were complex and highly individualistic, suggesting from the outset that early experience and perhaps genetic factors played a role in the extent of cortical reorganization and recovery of digit and hand use. Performance initially deteriorated, then started to get better with re-training, and appeared to be proportional to the difficulty of the task. In some cases, animals with large lesions actually recovered better than those with less damage. The two different strains of monkeys did not perform the same way, indicating that initial brain organization and reorganization may be different across strains.

Most dramatic was the fact that the post-lesion reorganization of the cortex was very variable across monkeys; completely new cortical fields representing the fingers emerged and were enlarged in cortical areas that are not normally responsive to cutaneous stimulation. The changes appeared to be due both to the lesion and to the training procedures. According to the authors, the representation of the hands in the SI region of the somatosensory cortex is topographically organized into discrete cytoarchitectonic and functional regions, so that when these regions are damaged, area-specific deficits can be observed. For example, damage to area 1 leads to deficits in the discrimination of textures, while damage to area 2 impairs recognition of size and shape. Damage to area 3 causes significant deficits in texture, size and shape discriminations. These observations suggest that areas not normally involved in mediating certain types of behaviors can 'take over' those functions under the right circumstances—an example of vicarious function as we have used it here. This means that when behavioral substitution occurs, there are specific physiological mechanisms to subserve the changes. More important, we also think it means that the brain is not just functioning as it did before but without a part. Rather, there is extensive permissive reorganization of neuronal activity (and structure) underlying vicarious function. These findings also highlight the importance of applying the appropriate rehabilitation strategies at the appropriate time to enhance adaptive cortical reorganization (27, 28).

Yet such reorganization may demand a high price: the emerging patterns could prevent true restitution of function by encumbering the brain with an experience-induced reorganization that would be difficult or impossible to undo. Until the recent development of sophisticated imaging and electrophysiological techniques, it was not possible to determine whether such equipotential, vicarious, or pluripotent systems did or did not exist. Recent studies using functional magnetic resonance imaging (fMRI) and other related techniques such as positron emission tomography (PET) scanning show that functional compensation may be due to extensive reorganization of activity in the damaged brain.

For instance, after an infarct in the striatum of human patients, a number of subcortical areas both ipsilateral and contralateral to the injury site become activated as behavioral recovery progresses. The activation, measured by increases in cerebral blood flow (CBF) and glucose metabolism, is not observed when normal, healthy volunteers are asked to perform the same motor tasks. Thus, if 'tricks' are being employed to compensate for lost functions, they could be mediated by shifts in the activity of cerebral structures that are not initially involved in the behaviors (or at least not in the same way) under normal circumstances. This type of reorganization can take weeks, months, or years to occur (29).

In an earlier report typical of studies on compensation, Castro-Alamancos, Garcia Segura and Borrell (30) showed that after bilateral injury of the sensory-motor cortex in rats there is a substantial deficit in bar-pressing response to prevent aversive stimulation. If the injury is followed by direct-brain stimulation of the ventral tegmental nucleus, substantial recovery of the bar-press behavior is observed. Under these conditions if the hindlimb sensory cortex in the recovered animals is ablated, the deficit returns. It is important to note that the ablation of this area in the first place does not cause the same deficit, and this is taken as evidence of compensatory shifts in cortical function; the hindlimb area "assumes the role of another area after induced recovery from brain damage".

In another example of shifts in function thought to be compensatory, Buckner et al. (31) used PET and fMRI scanning techniques to examine the preservation of speech using a variety of linguistic and cognitive tests in a 72-year-old patient one month after a stroke in the left-inferior frontal cortex. Although the patient was impaired in speech generation tasks, he was able to access words when given partial words as cues, a task that usually depends (according to the authors) on an intact left-inferior frontal cortex. The scanning during performance showed that the right-inferior prefrontal area was activated during the tasks. "This area is not typically activated by normal subjects performing word-stem completion and appears to be used (by the patient) to compensate for his damaged cortex" (p. 1253).

One of the most interesting forms of 'spontaneous' recovery in both animals and humans is seen in the 'serial lesion' effect (see [6] for a more detailed review). In this type of injury, lesions are inflicted in stages so that, for example, the left frontal cortex may be extirpated and then a second operation takes the homologous right frontal cortex thirty days later. Under these conditions, both animals and humans show remarkable and robust post-injury sparing of function compared to counterparts with the same damage inflicted in one stage [again, see (6)]. In humans, slow-growing injuries often do not lead to either the severity or sometimes even the appearance

of the functional impairments noted when the same extent of injury occurs after a stroke or acute traumatic damage (32). Although there are numerous replications of the serial lesion effect in fully mature subjects, the research has not been the focus of much attention in contemporary neuroscience. This is probably because the instances of plasticity as demonstrated by considerable sparing of function *in the absence of special training or treatment* is problematic for current theories of highly organized modular function (see 6, 33–36 for examples). Thus, in the face of bilateral removal of a structure with no loss of function, it is difficult to sustain the notion that individual aggregates of cells or structures are critical for the expression of that function. Fortunately, current literature is beginning to take another look at what such plasticity implies for concepts about the organization of function in the adult CNS.

A few years ago, Seitz and Freund (37) reviewed human studies showing that slowly progressive lesions often remain asymptomatic for years because the space-occupying tumors cause a substantial reorganization of function as measured by regional CBF (rCBF) studies. These investigators studied a group of patients with brain tumors which invaded all of the hand/arm motor cortex, and who had developed seizures but were normal on neurologic examination. The rCBF showed that during finger movements the areas of activation were substantially displaced to more lateral positions, even to cortical areas outside the motor strip. The authors concluded that “the astonishing discrepancy between the functional consequences of acute versus chronic lesions of the nervous system raises the possibility that reorganization (of function) is not restricted to within-system recovery in the motor cortex” (p. 329). This type of slowly developing reorganization can be considered as evidence for equipotentiality or vicarious function in the broad sense. The authors also point out that over time, the patients learn to use and refine other behavioral strategies often seen in normal subjects. It is thought that such patients can be given substantial skill training to recruit other cortical areas into the functional reorganization produced by the demands on the damaged CNS.

Equipotentiality and vicarious function are perhaps most easily dramatized (and contested) in cases of brain injury during postnatal development. In the 1960's, the developmental psychologist Eric Lenneberg (38) proposed that, at birth, the two cerebral hemispheres are equipotential for cognitive and language functions, and only gradually become specialized as the child matures. This idea seemed to be supported by the now classic studies of Margaret Kennard in monkeys. She showed that animals with large cortical lesions inflicted early in life showed none of the extensive deficits seen when the same type of damage was inflicted at a later age (39). Subsequently, Patricia Goldman was able to show that early

brain lesions in monkeys led to substantially more sparing of cognitive functions than when the damage was inflicted in later life. Goldman and Galkin (40) reported that lesions of the frontal cortex in a fetal rhesus monkey operated on and returned to the womb until term not only showed complete sparing of cognitive function, but also demonstrated a radical reorganization of the entire cortical mantle evidenced by numerous ectopic gyri and sulci not seen in the intact animal.

It has become increasingly clear that the twin dogmas of specific localization and complete equipotentiality need to be re-evaluated in the face of better data and experimentation. In an excellent brief review of this literature, Vargha-Khadem et al. (41) reported that better testing of children has revealed residual deficits after early hemispheric removals. They note that some of these residual deficits could have been due to medications, seizures, and nutritional and other environmental factors. When such variables are controlled, the authors observe that, as equipotentiality theory would predict, the deficits are extremely mild considering the extent of tissue loss. According to Vargha-Khadem et al., either hemisphere does appear to be able to subserve linguistic and cognitive functions during the early stages of development; however, the cost of such ‘compensation’ may be a generally reduced level of such functions as visuospatial behaviors, caused by ‘crowding’ of the supposedly lateralized functions into the one remaining hemisphere (25).

#### DIASCHISIS, FUNCTIONAL INHIBITION, AND RECOVERY

More sophisticated imaging and electrophysiological techniques have been employed with increasing frequency to support the idea of diaschisis proposed by von Monakow at the beginning of the last century (42). In this early concept, brain injury triggers a form of long-lasting inhibition of neural activity that von Monakow called diaschisis. The inhibition is not limited to the site of injury but can spread to distal regions by means that were not clearly understood until fairly recently. Now we know that injury-induced biochemical and genomic alterations in protein synthesis can generate actions that are many synapses removed from the initial site of damage. The changes occur not only in the affected hemisphere, but also in the ‘intact’ contralateral homologues (see [51] below). Von Monakow postulated that recovery of function occurred as diaschisis dissipated over time, while permanent deficits were the result of permanent diaschisis.

Although the logic may appear circular, current research shows that injury to the brain does produce chronic suppression of activity associated with behavioral impairments (43–46). Agonist drugs which increase neurotransmitter activity or block inhibitory neurotransmitters

have been used to promote functional recovery after stroke in both animal (47) and human (12) subjects. However, clinical trials with these agents have had apparently limited success (48). Can behavioral therapy (e.g., the forced-use paradigm) or treatment with stimulants (e.g., amphetamine) reduce or eliminate the diaschisis caused by the injury? Do other brain areas ‘take over the function’ of the area of stroke? Current evidence can be cautiously interpreted to suggest that this may be the case (14). It is often reported that a stroke (experimental or naturally induced) leads to functional reorganization in brain tissue immediately adjacent to the injured area, but there are also significant changes in the contralateral homologous regions. In one study, twelve patients with acute strokes had unilateral arm weakness and some ability to move the arm after one month. Six of the patients showed good recovery and six did not. The six with good recovery showed much more activation of the cerebellar hemisphere opposite the damaged corticospinal tract than did the poorly recovered patients (49). The authors suggested that the recovery could have been due to diaschisis, or unmasking, of the functions in the contralateral cerebellum.

In a recent review, Price and colleagues (50) introduce the concept of dynamic diaschisis. They suggest that the environmental context as well as the locus of damage can play a role in determining functional outcome (36). Price et al. propose that:

the basic idea behind dynamic diaschisis is that an otherwise viable cortical region expresses aberrant neuronal responses when those responses depend on interactions with a damaged region. This effect might arise because normal responses in any given region depend upon driving and modulatory inputs from, and reciprocal interactions with, many other regions. The regions involved will depend on the cognitive and sensorimotor operation engaged in at any particular time (p. 419).

In other words, areas of the brain that are distant from the area of injury, even including the contralateral hemisphere, can show abnormal responses when the functional demand on the damaged tissue increases.

The authors conclude that dynamic diaschisis can be measured only with whole-brain functional imaging because one has to take into consideration the functional integration of many different brain regions. More important, “pathophysiological expression depends on the functional brain state *at the time the measurements are made*” ([50] p. 426, my italics). This can be taken to mean that brain structures may move ‘in and out’ of a state of diaschisis, depending on the functional demands made on them at a given time in the patient’s experience. It is interesting to note that, well before there was sophisticated imaging, this same point was made by the neuropsychologist Alexander Luria in 1966 (51).

### NEURONAL REORGANIZATION, UNMASKING, SPARING, LATENT SYNAPSES, AND FUNCTIONAL PLASTICITY

Thanks to refinements in microelectrode recording techniques, it has now been amply demonstrated in primates that certain brain areas such as the sensory motor cortex are capable of very rapid electrophysiological reorganization in response to brain injury. Thus, within very short periods of time after lesions of the afferent pathways or even after cortical damage, tissue adjacent to the affected areas reorganizes or expands its receptive fields to capture and mediate at least some of the original physiological activities that were destroyed by the injury. There is no doubt that such rapid reorganization occurs in a number of sensory and motor areas, but as noted earlier it must be emphasized that not all the reorganization is necessarily adaptive or beneficial to the organism.

Among the first to demonstrate injury-induced plasticity in the adult nervous system were Patrick D. Wall and his colleagues in the United Kingdom (52). Wall and his group first mapped the body surface of the ventral posterior lateral nucleus of the thalamus (VPL). This was done by tactile stimulation on the surface of the arms and legs of various laboratory animals. In a normal animal, the arm takes up two-thirds of the medial VPL and the leg occupies the lateral third. When inputs to the leg area were removed by unilateral excision of the gracile nucleus, the arm area expanded to “occupy two-thirds of the area previously responding to stimulation of the leg.” This change was noted within three days of the lesion. While this is an example of reorganization and cellular plasticity in response to injury, it is hardly an adaptive response to have an area that previously subserved inputs from the leg area now responding primarily to stimulation of the arm. Using other forms of temporary “deafferentation” such as blockage of nerve conduction by ice, Wall’s group was able to produce instantaneous remapping of cells in the lateral nucleus gracilis (LNG). Thus, the cells in the leg, normally activated by stimulation of the paws, now responded only to stimulation of the abdomen. In this case the unmasking of latent pathways was almost instantaneous, but, again, hardly adaptive with respect to behavioral utility.

Such changes in reorganization may be very long-lasting and dependent on post-injury experience. A number of years after the Wall experiments, Pons et al. were able to show that up to eleven years after a dorsal rhizotomy in adult rhesus monkeys, the brain region responding to stimulation of the hand (area 3b) responded instead to tactile stimulation of the face (53). In human patients, similar reorganization can be seen in phantom limb phenomena in response to amputation. This too has been taken as an example of neural plasticity in the adult nervous system (54, 55). These investigators found that

tactile stimulation of the face often led to referred sensations somewhere out on the phantom limb. Thus “there was a topographically organized map of the hand on the lower face region and the referred sensations were modality specific,” e.g., heat, cold, vibration, rubbing, etc. were felt as these same sensations at specific points on the phantom limb. The authors noted that this modality-specific referral from the face to the limb could occur only within a few hours after amputation, implying that the reorganized ‘localization’ of sensations must have been due to unmasking of previously silent pathways rather than any kind of structural or morphological changes *per se*.

Some patients report that, after a time, the phantom limb feels as if it is paralyzed or frozen into an excruciatingly painful clench with the fingers digging deeply into the palm. The patients cannot “will” the fingers to open and relieve the pain. Ramachandran and his group developed an ingeniously simple technique to provide relief, and in doing so again demonstrated the rapid reorganization of function that can occur in the appropriate context. Investigators asked patients to put their ‘normal hand’ into a box with a mirror in the sagittal plane of the hand. This gave a mirror-image of the normal hand, so it looked to the patients as if they had two hands opposing one another in the mirror-box. Now the investigators asked the patients to slowly open and close the normal hand while looking at the image in the mirror so it would seem as if the phantom hand was now opening and closing. The patients were surprised to find that while doing this exercise they actually felt movements in the phantom hand, but, more important, a number of the patients reported that seeing the phantom hand paradoxically unclench (because it was the normal hand they were seeing) relieved the cramping pain. This observation indicates that the amputation-induced reorganization may be undone by training and experience, with a novel engram replacing the maladaptive one.

Phantom limb effects are dramatic examples of reorganizational plasticity in the adult brain, but similar mechanisms can be seen in the visual and auditory systems when injuries are inflicted during early development. Thus Rauschecker (56, 57) has shown that if the visual (occipital) cortex is deprived of its inputs from the optic nerves, that same cortex can then be stimulated by auditory input. In other words, the ‘visual’ cells are ‘taken over’ by the auditory and somatosensory nerve fibers and thus both the auditory and somatosensory cortex could be said to expand into the territory previously controlled and occupied by visual inputs. Likewise, if the auditory cortex is destroyed or the auditory nerve is cut, the auditory cortex will be captured by visual inputs that have expanded into the deafferented zone.

Rapid reorganization tends to be more robust during early development, and this may be one reason why

young subjects with brain damage recover better than older counterparts with the same injury. Rauschecker asks what the post-recovery perception of animals brain-damaged during early development is like. Do they ‘see’ sounds and touches as in purported synesthesias, or does the visual cortex ‘change’ its functions to become auditory and/or somatosensory? What are the implications for the concepts of localization of function in the CNS during development and later in life?

Investigators also have shown that reorganization and expansion of functional cortical maps can be made to occur simply by providing intensive training experience in normal animals. Further, it appears that specific kinds of sensory training may be beneficial as rehabilitation therapy in brain-damaged subjects because it directly enhances the extent of rapid reorganization and functional plasticity. Nudo and his colleagues have recently reported that injury-induced reorganization and recovery of function can occur in the adult organism (58). Such recovery often requires experience-induced modifications in synaptic and cellular systems throughout the remaining healthy brain tissue that may not necessarily be contiguous to, or immediately involved in, the affected area and its functions. In other words, functions are widely distributed and in a constant state of dynamic interaction and change, not fixed and static as they are often represented in neuroscience texts.

It is clearly time to accept the idea that dynamic reorganization of functions is an ongoing event, not just a characteristic of the damaged brain, but a process that occurs in the course of normal activity and learning. Indeed, these changes may well serve as the basis for recovery mechanisms when there is an attack on the brain. For example, in accomplished musicians and athletes, somatosensory fields are markedly expanded compared to nontrained individuals. According to Nudo et al., highly repetitive practice on a tactile task in humans leads to marked expansion of the receptive field in the motor cortex which can persist for several months after the training is terminated. Maps also expand during the initial phases of training when the procedures are unfamiliar, and then shrink once explicit knowledge of the task has become habitual. (Nudo and his colleagues provide an excellent review of the various theories to account for this plasticity and the reader is urged to consult this paper.)

There are also apparently dramatic individual differences in the location and size of cortical receptive fields in normal individuals, which, in turn, vary in their degree of modifiability according to the subject’s experiential history (59, 60). At the very least, the notion that neuronal pathways can be rewired by the use of drugs or stimulation needs to be approached carefully, because the wiring diagrams for each individual may be heavily influenced by early experience and training (60). In designing

rehabilitation therapy, it should be noted that certain therapies or treatments used routinely in some rehabilitation settings could result in the formation of inappropriate connections and the prevention of functional recovery, even a form of learned helplessness (61). For instance, if the current paradigm of structure-function relationships is valid, it is hard to imagine how the capture of auditory input by visual fibers would automatically lead to an adaptive outcome.

In conjunction with electrophysiological experiments in primates, computer-assisted rapid fMRI studies in humans have shown that multiple systems throughout the brain become activated during selected cognitive tasks such as naming objects or performing simple mathematical calculations. Many neuroscientists now accept the view that widely distributed neural modules are involved in even simple cognitive or sensory processing. However, there is much less agreement as to the number of modules (brain areas) required to mediate even a simple behavior like reaching for a small piece of food. For example, over a period of about ten years, the number of CNS structures in the network said to be in control of 'vision' has increased from about 12 to well over 50. A corollary of this assumption is that highly focalized damage would cause very widespread changes both serially and in parallel throughout the brain. Therefore, recovery of behavioral functions may depend upon equally widespread changes in synaptic connectivity and their metabolic consequences.

### WHAT HAVE WE LEARNED FROM CONSIDERING THE CONCEPTUAL ISSUES SURROUNDING NEURAL "PLASTICITY"?

"Those who forget history are condemned to repeat it" means as much in neuroscience as it does in political and social philosophy. Theories and hypotheses now in vogue rarely acknowledge early twentieth-century literature pleading for more acceptance of a dynamic and modular view of function to replace the idea that the adult nervous system is fixed and immutable in its structure-function relationships. In particular, in the 1960s, 1970s, and 1980s, many neurobiologists, dependent on molecular and reductionistic techniques, seemed to take pleasure in deriding the ideas of Karl Lashley, who wrote in 1937 that "the function of cells may be deduced from their position and connections, but their position is not therefore a necessary consequence of their function." Lashley goes on to say that "the mere existence of specialized regions in the brain is not conclusive evidence that the specialization is necessary or important for the integrative functions" (62). Given the subsequent observations of reorganizational changes in response to brain injury that we have discussed,

Lashley's position now has a contemporary ring. Writing just two years later, Goldstein (63), a German neurologist, stressed that

the destruction of one part of the brain never leaves unchanged the activity of the rest of the organism, especially the rest of the brain. On the contrary, there usually occurs a widespread change of the distribution of excitation. Whether a certain symptom will appear on account of a local injury, especially whether it will become a permanent symptom, certainly depends on many other factors: the nature of the disease process, the condition of the rest of the brain, the difficulty of the performance requirements and the reaction of the entire organism to the defect. The localization of a performance (after an injury) no longer means an excitation in a certain place, but a dynamic process which occurs in the entire nervous system, even in the whole organism (pp. 258–259).

Thirty years after Goldstein, Alexander Luria argued that "the facts suggest that a disturbance of a particular form of activity may arise in far more extensive lesions than was hitherto supposed. Consequently, the performance of a given function necessitates the integrity of far more extensive and far more structurally varied zones of the cortex than was assumed by classical neurology" (51). Thus, almost four decades ago, Luria was arguing for a more dynamic view of nervous system function to account for how recovery from brain injury might occur. Luria felt it would eventually be recognized that "complex forms of psychological functions are never localized in isolated areas of the brain, but are always dependent on entire working constellations of cerebral zones, appearing in the course of postnatal development and changing dynamically as a particular functional system reaches a higher level of development." He predicted that the loss of any one link must inevitably lead to a disturbance of the normal working of the functional system as a whole (p. 70).

Luria's views were essentially ignored by the cerebral cartographers, who continued to add to the complexity of their diagrams without much concern for understanding how the parts worked together in the intact and the damaged brain. It was as if drawing the lines between anatomical components was a sufficient explanatory tool. Fortunately this view, so inimical to understanding the inherent plasticity of the CNS, is now being reconsidered in some quarters, although it is still far from extinction.

It must be said that contemporary research on localization of complex functions to specific areas of the cerebral cortex marshals some of neuroscience's most elegant techniques in support of its paradigm. This often entails careful testing of complex behaviors or components of behaviors while using microelectrodes to record

from specific cells in anatomically defined loci. Testing for speech generation or cognitive responses in humans often uses highly sophisticated imaging techniques. Some of the most elegant work in this domain has been performed by Goldman-Rakic and her colleagues, who have focused on defining and elaborating the role of the prefrontal cortex in spatial performance, memory and cognition. Goldman-Rakic's work investigates the hypothesis that highly discrete areas of the frontal cortex are critical in the mediation of spatial and object cognition (64–67). Monkeys show significant increases in electrophysical activity in individual neurons in circumscribed areas of the prefrontal cortex. During object recognition, one set of neurons is activated, while in a spatial cognition task other cells in a different anatomical region become more active. Both electrophysiological and metabolic recording techniques are used to demonstrate changes in activity. In Goldman-Rakic's view, "a signal advance attributable to research in non-human primates over the past decades has been the fine-grained functional mapping of the cerebral cortex and the realization that cytoarchitectonically defined areas are not homogenous with respect to circuitry or to physiology . . . . It is to be confidently expected that functional specializations will surely follow the lines of these anatomical divisions when the appropriate tests are applied." She concludes, "In view of the parcellation of these fundamental information processing domains, it is far too early to reject cortical specialization so well grounded in cytoarchitectonic, hodological and neurochemical parcellation . . ." (64). To be sure, the rigorous and refined techniques employed and the elegance of the results make for very compelling support for the doctrine of localization, but such findings and interpretations do not allow for the plasticity and reorganization seen after injury and are difficult to explain in the context of behavioral sparing or recovery of function in the adult organism. Studies not supporting parcellation theory are often dismissed as lacking technical sophistication or as having inappropriate behavioral tests.

Moreover, where plasticity of function is acknowledged it is often limited to the idea that immediately adjacent *cortical* tissue can be reorganized to mediate behaviors. Wall and Wang refer to these notions as "cortico-centric theories," because plasticity is thought to be limited primarily to cortical structures, where the most dynamic changes in maps are registered (67). In a more radical approach, these authors argue that changes in response to injury are far more ubiquitous in both subcortical and cortical substrates and include molecular, morphological, neurochemical and anatomical changes that reorganize basically the entire functioning of the organism. The authors take a position similar to that of the neurologists of the mid-twentieth century, who believed that the deficits as well as the recovery seen were

the result of such total organization, rather than the result of loss of a particular part in the brain.

In response to injury initial multilevel changes emerge surprisingly rapidly. Functional changes can appear concurrently within minutes in spinal, brainstem, thalamic and cortical substrates. With the passage of time during the subsequent days, weeks, months and longer, acute changes in normal substrates apparently continue, spread and are further supplemented by subcortical and cortical abilities to regenerate and sprout new connections (pp. 204–205).

The perspective of Wall et al. is consistent with the earlier work of Jones (68) and Nudo (58). Jones presents evidence that even very small changes in subcortical organization caused by a peripheral or CNS injury can lead to highly amplified changes in the organizational maps of the cerebral cortex. Others such as Chen et al. (69) argue that the brain is constantly being modified by experience and that 'pre-determined' wiring diagrams do not represent the kinds of rapid and long-lasting injury-induced plasticity seen in developmental and adult brain damage. The authors also note that not all types of reorganization are beneficial and that one must distinguish between those changes that lead to recovery and those plastic changes that result in permanent impairments.

Although not always given the credit they deserve, the early investigators into plasticity of function—Lashley, Goldstein, Luria—had only their clinical and observational skills to evaluate patient behavior and draw conclusions that today are based on a wide variety of sophisticated molecular and physiological techniques. Nonetheless, their conclusions resonate well with those of contemporary neuroscientists.

For example, considering his own work on phantom limb plasticity, Ramachandran (54) concluded that new findings (on reorganization after amputation) "allow us to test some of the most widely accepted assumptions of sensory psychology and neurophysiology, such as Müller's law of specific nerve energies, 'pattern coding' versus 'place coding' (i.e., the notion that perception depends exclusively on which particular neuron fires rather than the overall pattern of activity)." Furthermore, the work showing that sensations associated with phantom limbs by training "suggests that the modular, hierarchical 'bucket brigade' model of the brain popularized by computer engineers needs to be replaced by a more dynamic view of the brain in which there is a tremendous amount of back-and-forth interaction between different levels in the hierarchy and across different modules" (p. 319). Finally, with respect to motor cortex damage, Nudo et al. (58) conclude their review of the literature by stating that "both human and animal studies have demonstrated both acute and chronic changes in functional topography and anatomy of intact cortical tissue adjacent to the injury,

and of more remote cortical areas, including those of the contralateral (uninjured) hemisphere” (p. 1013).

Recent findings and the revised concepts of how adaptive and maladaptive plasticity occur in the adult human brain after injury clearly demonstrate that the adult CNS is capable of much more dynamic change in function and structure than had been thought over the last few decades of research in this area.

## Advances in Innovative Therapies to Enhance Neural Recovery

*C. Edward Dixon  
Anthony E. Kline*

**T**his chapter reviews experimental neuroprotective agents, which are strictly defined as such if they have been reported to reduce morphological and/or functional deficits after traumatic brain injury (TBI). The categories below are not necessarily mutually exclusive. The pathways to cell dysfunction and death are not necessarily linear, but involve an intertwined network. The discussion also focuses on exogenous treatments rather than genetically induced manipulations (i.e., transgenic modification). Lastly, there will be no distinctions made between the various contemporary TBI models (1), although it is possible that the neuroprotective effects of some treatments may be model dependent.

### EXCITOTOXICITY

Excitotoxicity is an important mechanism in secondary neuronal injury following TBI. Glutamate, aspartate, and glycine are amongst the most abundant excitatory neurotransmitters and the most commonly implicated in excitotoxic injury. Glutamate, the most prominent of these amino acids, activates receptors that are classified according to specific agonists. Receptors that modulate ionic channels are divided into those stimulated by N-methyl-D-aspartate (NMDA receptors) or those stimulated by

$\alpha$ -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) or kainic acid (together referred to as non-NMDA receptors). Glutamate also acts at metabotropic receptors that act via second messenger systems (2). Excitotoxicity resulting from the TBI-induced release of excitatory amino acids and the damaging effects of increased intracellular calcium associated with glutamate receptor activation has been the target of intense investigation for over a decade.

### Inhibiting Release of Excitotoxins

Inhibiting glutamate release has been demonstrated to attenuate functional and morphological deficits after experimental TBI. Sun and Faden (3) reported that early treatment with 619C89, a sodium channel blocker that inhibits glutamate release, attenuates behavioral deficits and hippocampal neuronal loss. Riluzole (2-amino-6-trifluoromethoxy benzothiazole) has properties that include inhibition of glutamate release and has also been reported to attenuate functional (4) and morphological damage (5) after TBI. Treatment with galanin, a neuropeptide that inhibits neurotransmitter release by opening potassium channels and closing N-type calcium channels, attenuates motor, but not Morris water maze (MWM) deficits after TBI (6). However, blocking post-injury ion fluxes with tetrodotoxin was not found to be protective against behavioral deficits (7).

### Blocking Receptor Activation

As summarized below, treatment with NMDA and non-NMDA receptor blockers has led to improved functional recovery and reduced hippocampal cell death and cortical damage after experimental TBI. NMDA-receptor blockade has been shown in several models of TBI to attenuate neurological deficits. Hayes et al. (8) reported behavioral protection by the noncompetitive NMDA antagonist phencyclidine after TBI. Studies by Faden et al. (9) found behavioral protection by dextromethorphan, a noncompetitive NMDA antagonist and 3-(2-carboxypiperazin-4-yl)propyl-l-phosphonic acid (CPP), a competitive NMDA antagonist. The NMDA-antagonist, MK-801, has been reported in numerous studies to be neuroprotective (10–13). Cortical and hippocampal damage is attenuated by both pretreatment with the NMDA antagonist CPP and the non-NMDA antagonist NBQX (14). Additionally, delayed treatment with NBQX, but not CPP, beginning 1 and 7 hr after TBI prevented hippocampal damage.

Remacemide hydrochloride, an NMDA receptor-associated ionophore blocker, has been reported to reduce post-traumatic cortical lesion volume, but not to improve MWM function (15). Gacyclidine, a noncompetitive NMDA receptor antagonist has been shown to attenuate neuronal death and deficits in MWM performance following frontal cortex contusion (16). Treatment with kynureate, an NMDA and non-NMDA antagonist, has been reported to attenuate hippocampal CA<sub>3</sub> neuronal loss after TBI (17). Animals treated with HU-211, a synthetic, nonpsychotropic cannabinoid that acts as a noncompetitive NMDA receptor antagonist has been reported to enhance motor function recovery after TBI (18). The NMDA antagonist ketamine has been demonstrated to attenuate post-injury neurological (19) and cognitive deficits (20). Treatment with CP-98,113, an NMDA receptor blocker, has been shown to attenuate neurologic motor function and cognitive performance assessed in a MWM task (21). Increasing inhibitory function through stimulation of  $\gamma$ -aminobutyric acid (GABA(A)) receptors via bicuculline administration has been reported to attenuate MWM deficits after TBI (22).

In addition to playing an essential role in normal cell function, magnesium also has an antagonist effect on the NMDA receptor by blocking the NMDA receptor ion channel. The effects of magnesium after experimental TBI are presented in the “neutraceuticals” section of this chapter.

Many noncompetitive NMDA receptor antagonists have undesirable side effects. NPS 1506 is a noncompetitive NMDA receptor antagonist that appears less toxic than earlier agents (23). NPS 1506 has been reported to attenuate MWM performance and hippocampal CA<sub>3</sub> cell death, but not cortical lesion (23).

TBI-induced glutamate release can also damage tissue by activating metabotropic glutamate receptors

(mGluR), which are coupled to second messenger cascades through G-proteins. Modulation of mGluRs has been shown to confer neuroprotection. Gong et al. (24) reported that intraventricular administration of  $\alpha$ -methyl-4-carboxyphenylglycine (MCPG), a mGluR antagonist, prior to TBI attenuated motor and MWM deficits. Administration of 2-methyl-6-(phenylethynyl)-pyridine (MTEP), a mGluR5 antagonist, has been reported to reduce lesion volume and to attenuate motor and MWM deficits following TBI (25). Administration of a group II mGluR agonist 30 min after TBI can improve behavioral recovery (26). Selective mGluR1 antagonists have also been reported to attenuate motor deficits and MRI-assessed lesion volume (27). The compound ZJ-43, which inhibits N-acetylaspartylglutamate through selective activation of presynaptic Group II mGluR3, has been recently shown to attenuate neuronal and glial degeneration after TBI (28).

### Calcium Channel Blockers

Calcium channel blockers to reduce excessive accumulation of intracellular calcium have been examined as possible neuroprotective agents for TBI. Post-injury administration of the voltage-sensitive calcium channel blocker Ziconotide (also SNX-111 and CI-1009) has been reported to attenuate motor and cognitive deficits (29). Similarly, post-injury treatment of LOE 908, a broad-spectrum inhibitor of voltage-operated cation channels and store-operated cation channels has been demonstrated to reduce neuromotor and visuospatial memory deficits (30). Recently, treatment with the specific N-type voltage-gated calcium channel blocker SNX-185 has been shown to attenuate functional deficits and enhance neuronal survival after TBI (31). Pharmacologically blocking calcium entry has been another important strategy to reduce post-injury excitotoxicity. Treatment with (S)-emopamil, a calcium channel blocker, has been reported to attenuate post-injury motor deficits (32). Inhibiting polyamine-dependent calcium influx is another therapeutic target for attenuating post-injury excitotoxicity. Ifenprodil, a polyamine-site NMDA receptor antagonist, has been reported to reduce cortical morphology after TBI (33).

### OXIDATIVE INJURY

Oxidative stress has been implicated in the pathology of TBI. Several agents with antioxidant properties have been evaluated in animal models of TBI. Hall and colleagues (34) reported that administration of a non-glucocorticoid 21-aminosteroid U74006F (tirilazad) enhanced neurological recovery in mice. Tirilazad has also been reported to attenuate axonal injury following TBI (35). Clifton et al. (36) reported that pretreatment and acute posttreatment with

$\alpha$ -tocopherol succinate plus polyethylene glycol attenuated motor deficits following TBI. Analogues of  $\alpha$ -tocopherol have also been reported to be neuroprotective in mice following TBI (37). Lidocaine, a local anesthetic, has been found to be a potent scavenger of hydroxyl radicals (38). Administration of lidocaine has been reported to attenuate postinjury neurological and motor function, but not cognitive function (39). Deferoxamine is an iron-chelating agent that can inhibit the iron-dependent hydroxyl radical production, and has been reported to improve spatial memory performance following TBI (40). Interestingly, deferoxamine was found not to improve functional outcome when combined with moderate hypothermia treatment (41). Superoxide dismutase (SOD) is a metalloenzyme, which catalyzes the dismutation of superoxide ion into oxygen and hydrogen peroxide. Administration of polyethylene glycol-conjugated SOD has been reported to reduce motor, but not MWM deficits following TBI (42). OPC-14117, is a superoxide scavenger that has been reported to attenuate tissue damage (43) and behavioral deficits (44,45) following TBI. Early treatment with LY341122, an inhibitor of lipid peroxidation and an antioxidant, has been reported to provide significant histopathological protection (46). Penicillamine is a scavenging compound that has been reported to improve motor performance in mice after TBI (47). The pineal hormone melatonin is a scavenger of free radicals has been found to reduce contusion volume following cortical impact in rats (48). Endothelin-1, a 21 amino acid peptide, has been closely linked to oxidative stress after TBI (49). The endothelin receptor subtype A antagonist, Ro 61-1790 has been shown to attenuate Purkinje cell loss in the cerebellum after TBI. Kline and colleagues have recently shown that acute administration of the dopamine D2 receptor agonist bromocriptine, which exhibits significant antioxidant properties, reduced TBI-induced lipid peroxidation (i.e., oxidative stress) and enhanced spatial learning in a MWM task and increased hippocampal CA3 neuron survival after controlled cortical impact injury (50).

## EXOGENOUS GROWTH FACTORS

Exogenous administration of several growth factors has been reported to produce beneficial effects on both cognitive performance and histological outcome measures after TBI. Sinson and colleagues have shown that nerve growth factor (NGF) attenuates cognitive dysfunction following fluid percussion brain injury (51). The same group has also reported an attenuation of cognitive deficits and cholinergic cell loss after fluid percussion injury and NGF infusion (52). Dixon et al. (53) have reported that intraventricular NGF infusion reverses the post-traumatic reduction in scopolamine-evoked ACh release, and significantly improves spatial memory retention following

controlled cortical impact injury. Increasing NGF protein levels by intraventricular injections of liposome/NGF cDNA complexes similarly attenuates the loss of cholinergic neuronal immunostaining in the rat septum after TBI (54).

Utilizing the fluid percussion injury device, Frank and Ragel (55) demonstrated via histochemical quantification that at 48 hr after injury there is a significant difference in FGF-2-positive cells between the injured and contralateral cortex. Dietrich et al. (56) administered fibroblast growth factor-2 (FGF-2) intravenously for 3 hr beginning 30 min after fluid percussion injury and found a 50 percent decrease in the total number of necrotic neurons compared to controls. Furthermore, the overall contusion lesion volume was decreased by almost a third. Employing the same injury model, McDermott and colleagues (57) reported that post-injury FGF-2 treatment significantly attenuated post-traumatic memory dysfunction relative to vehicle-treated controls. However, no attenuation in histological damage was observed. In contrast to the beneficial effects reported by Dietrich et al. (56) and McDermott et al. (57) with FGF-2 treatment after fluid percussion injury, Guluma and colleagues failed to see a neurological improvement at 7 days after an injury of moderate severity in a similar same model (58). Using the controlled cortical impact injury model in rats, Yan and colleagues have shown that FGF-2 administration moderately improves MWM performance compared to controls, but has no effect on histological outcome (59). Recently, Yoshimura and colleagues reported that overexpression of FGF-2 increases neurogenesis in the adult mouse hippocampus after cortical impact injury and that neurogenesis is reduced in FGF-2 deficient mice (60). The authors conclude that supplementation of FGF-2 may be effective in treating TBI by simultaneously enhancing neurogenesis and reducing neurodegeneration.

Insulin-like growth factor 1 (IGF-1) is a mitogenic polypeptide structurally similar to insulin that is involved in repair and regeneration following injury to the brain. IGF-1 has been shown to be upregulated following cerebral cortical contusion via a weight drop injury model (61). A follow-up study found that the upregulation of IGF-1 mRNA levels can be blocked by NMDA receptor antagonists (62). Exogenous administration of IGF-1 has been demonstrated to improve neurological and cognitive outcome after fluid percussion brain injury in rats (63). IGF-1 has recently been evaluated in a unilateral penetration brain injury model. IGF-1 administration resulted in a significant decrease in Hsp70 and TUNEL positive cells in the peritrauma region. The neuroprotective effects of IGF-1 treatment were not limited to the cellular level, but also on behavioral outcome. Specifically, IGF-1 treated animals lost less postoperative weight and survived the trauma longer than controls (64).

## HYPOTHERMIA

During the past decade, several experimental studies have provided evidence that mild to moderate hypothermia can provide behavioral protection following TBI. Studies employing multiple models have reported that moderate hypothermia can reduce neurological deficits (65–69) and improve cognitive function (59,65,67,69). Reports of histological protection by moderate hypothermia have been less consistent. Some investigators have reported reductions in contusion volume (70,71) decreased cortical necrotic neurons (70), reductions in axonal injury (72), and reduced ventricular enlargement (73). However, in a rat model of severe TBI with secondary insult, moderate hypothermia for 4 hr post-injury failed to improve motor function, cognitive function, lesion volume, or hippocampal neuronal survival (74). Furthermore, moderate hypothermia was found to be detrimental in fentanyl-anesthetized rats (75). Factors such as treatment window, injury severity, anesthesia, and rates of re-warming need to be further defined to optimize hypothermia treatment. (See Figure 10-1.)

## PROTEASE INHIBITORS

Both intracellular proteases (e.g., calpains and caspases) and extracellular proteases (plasminogen activator and matrix metalloproteinase) are believed to contribute to the pathophysiology of neuronal cell death (76). Treatments that target these processes have been evaluated in experimental TBI. Post-injury uncontrolled activation of calpain, a calcium-dependent neutral protease, can destroy neurons. Calpain inhibitors have been the most researched target for TBI treatment. (Caspase inhibitors are reviewed below.) Saatman et al. (77) reported that treatment with the calpain inhibitor AK245 attenuated motor and cognitive deficits following TBI. A follow-up study found that AK245 did not attenuate cell death (78). Treatment with calpain inhibitor 2 has been demonstrated to reduce cortical loss following TBI (79). Administration of the calpain inhibitor SJA6017 has been found to inhibit functional deficits 24-hr postinjury (80). Treatment with the nonimmunosuppressive neuroimmunophilin (NIMM) ligand V-10,367 has been found to reduce calpain-mediated cytoskeletal damage (81). It has been recently

FIGURE 10-1

Histologic assessment performed 72 hr after traumatic brain injury in rats ( $n = 8$  per group) treated with normothermia vs. hypothermia. **A**, surprisingly, contusion volume was markedly larger in hypothermic rats ( $*p < 0.05$ ). **B**, representative coronal brain sections. The site of impact is marked by arrows. Contusion volume, demarcated by swollen, hypochromic cells, was nearly doubled in hypothermic rats. The hippocampus appeared largely unaffected in both experimental groups. **C**, hippocampal neuronal survival did not differ between experimental groups. Controlled cortical impact was delivered to the cortex overlying the left dorsal hippocampus. [From Statler et al., *Crit Care Med*, 2003; 31(4):1134–1139 (Ref. 75).]

demonstrated that preinjury administration of the calpain inhibitor MDL-28170 significantly reduced immunomarker of axonal injury after TBI (82).

### INFLAMMATION

TBI can initiate a number of inflammatory processes that may contribute to secondary tissue damage. For instance, TBI can produce polymorphonuclear leukocyte migration into the brain that can result in neuronal damage. P-selectin blockade has been reported to reduce probe trial performance on a MWM task following TBI (83). Knobloch and Faden (84) demonstrated that anti-intracellular adhesion molecule-1 (ICAM-1) can attenuate motor deficits and neutrophil invasion after TBI. Systemic administration of a high, but not a low dose of interleukin-1 receptor antagonist has been reported to attenuate neurological recovery after TBI (85). The same study observed that motor function was impaired by the high dose of interleukin-1 receptor antagonist (85). Further work by Knobloch and Faden (86) failed to find a beneficial effect of selective IL-1 antagonists and suggested that the post-traumatic increases in IL-1-beta may not contribute to subsequent neurological impairment. Administration of anti-CD11B, a monoclonal antibody directed against the leukocyte adhesion molecules CD11B, reduced neutrophil influx after TBI, but did not improve function (87). Nitric oxide (NO) derived from the inducible isoform of NO synthase (iNOS) is an inflammatory product implicated both in secondary damage and in recovery from brain injury. Sinz et al. (88) reported that rats treated with iNOS inhibitors aminoguanidine and L-N-iminothyl-lysine exacerbated functional outcome and histological damage thereby suggesting a beneficial role for iNOS in TBI. In contrast, Lu et al. (89) found that aminoguanidine treatment improved neurobehavioral outcome. Acute administration of a selective iNOS inhibitor, 1400W, has been shown to reduce lesion volume after lateral fluid percussion injury (90). Treatment with interleukin-10 has been reported to enhance neurological recovery following fluid percussion brain injury (91). However, the administration of interleukin-10 thirty min after experimental TBI via a controlled cortical impact was ineffective in attenuating functional and histopathological deficits with a dose that prevents neurotrophil accumulation in injured tissue (92). Cyclooxygenases (COX) play an important role in inflammatory cascades and increased expression of COX after experimental TBI has been well documented (93–96). Cernak et al. (95) found that chronic administration of the COX-2 inhibitor nimesulide improves cognitive function after TBI. Pre- and post-injury treatment with DFU has been shown to attenuate functional deficits and neuronal cell death after controlled cortical impact (97). At present, anti-inflammatory treatments remain a viable strategy.

### ETHANOL

The neuroprotective effects of ethanol have been disputed for years. Yamakami et al. (98) demonstrated that following severe brain injury, animals pretreated with high-dose ethanol showed significantly worsened neurological deficits at 24 hr postinjury. Shapira et al. (99) reported that acute, but not chronic, ethanol exposure increased neurological deficit and hemorrhagic necrosis volume in rats following TBI. Janis et al. (100) reported that low dose acute ethanol treatment could reduce MWM performance deficits. A low-dose of ethanol has been found to be associated with a marked attenuation of immediate post-injury hyperglycolysis and with more normal glucose metabolism in the injury penumbra over the ensuing 3 days post-injury (101). It was further observed that the reduction in CBF typically seen within the contusion core and penumbra after TBI is less severe when ethanol is present. In contrast, in a model of multiple episodes of mild TBI, acute ethanol intoxication acute ethanol treatment was not neuroprotective in rats (102). Acute pre-injury administration of ethanol has been shown to attenuate the cytokine response to injury (103). Recently, a treatment consisting of a low amount of ethanol combined with caffeine (caffeinol), has been found to be neuroprotective (104). If there is a beneficial effect of ethanol, the conditions by which it can be neuroprotective remain to be clarified.

### HORMONAL AND GENDER INFLUENCES

It has been postulated in animal studies that the effects of female hormones may play a positive role in outcome from brain injury. Roof et al. (105) found that the presence of circulating endogenous or synthetic progesterone had a neuroprotective effect on the reduction of cerebral edema in female rats compared to males. However, in a temporal response study, Galani et al. (106) found that a 4 mg/kg dose of progesterone was more effective in reducing edema after medial frontal cortex contusions when given for 5 consecutive days versus 3 days. The authors speculate that the longer duration of progesterone treatment was more effective because there are two phases of edema—one that begins within hr after trauma and another that begins several days later (106). Apparently, the longer treatment was able to effectively attenuate the later phase of edema. In a similar study from the same group, 5 days of progesterone treatment was shown to protect against necrotic damage and behavioral abnormalities (107). Progesterone has also been reported to confer protection against lipid peroxidation and to facilitate cognitive recovery and reduce secondary neuronal loss after cortical contusion in male rats (105,108). It has recently been reported that allopregnanolone

(4,8, or 16 mg/kg), which is a metabolite of progesterone, and progesterone (16 mg/kg) administered at 1 and 6 hr after controlled cortical impact to the pre-frontal cortex and every day thereafter for 5 days resulted in less cell loss in the medio-dorsal nucleus of the thalamus and less learning and memory deficits compared with the vehicle-treated controls (109).

Animal studies also show that estrogen treatment immediately after TBI has a protective effect in males, but increases mortality and exacerbates outcome in females when assessing neurologic motor function one week after injury (110). Other studies (111,112) show a protective role of estrogen in maintaining cerebral blood flow, mortality, and cell death after experimental TBI. A recent study by Wagner et al. examined the effects of pre-injury hormonal status and gender on neurobehavioral and cognitive performance after controlled cortical impact injury. The results showed that females performed significantly better than males on motor performance measures, but were not significantly different on cognitive outcome as assessed in the MWM. Furthermore, there were no differences in performance between pro-estrous and non-proestrous females, suggesting that neither estrous cycle stage nor hormone level at the time of TBI have significant effects on behavioral recovery (113). These findings are supported by the results of a study in which nonovariectomized rats were subjected to a right parasagittal fluid percussion brain injury during either proestrous or nonproestrous and compared to ovariectomized female and male rats. Rats were sacrificed three days after TBI to assess neuropathology. The results showed that both the proestrous and nonproestrous rats had significantly smaller cortical lesions relative to males. In contrast, the ovariectomized females had contusion volumes that were significantly larger than both the proestrous and nonproestrous intact rats (114). Taken together, these data provide evidence that endogenous circulating hormones confer histopathological and behavioral protection after TBI.

### MITOCHONDRIA

Sequestration of calcium loads within the mitochondrial matrix can open the mitochondrial permeability transition pore leading to cellular oxidative and metabolic stress. Acute treatment with cyclosporin A (CsA), an inhibitor of calcium-induced mitochondrial permeability transition pore, has been reported to reduce tissue damage following TBI in rats (115–117). CsA has also been found to enhance cognitive function after TBI (118). A single dose of CsA has also been reported to blunt axonal damage following TBI (119). Continuous infusion of CsA after TBI has been found to reduce cortical damage (117). Improved mitochondrial function and

behavioral outcome has been achieved by treatment with ziconitide, a calcium channel blocker (120,121).

### CATECHOLAMINE AGONISTS

The role that catecholamines play in promoting functional recovery after TBI is well documented (122–127). Feeney and colleagues have shown that a single dose of d-amphetamine administered 24 hr after a sensorimotor cortex injury produces an immediate and enduring acceleration in beam walking recovery in rats (122) and that multiple doses of amphetamine restore binocular depth perception in cats with bilateral visual cortex ablation (128). Beneficial effects of other catecholamine agonists on functional outcome in rat and/or cat following either weight drop cortical contusion or cortical aspirations have also been reported (129). Because the administration of norepinephrine antagonists block or reinstate deficits, the noradrenergic system has been implicated in the aforementioned studies. However, as suggested by the following reports, the dopaminergic system is also involved in the rehabilitative process.

The psychostimulant methylphenidate has been reported to have pharmacological properties similar to amphetamine, but without the undesirable sympathomimetic effect. A single administration followed by significant symptom relevant experience (i.e., beam walking experience) enhances recovery of motor function following sensorimotor cortex lesions (126). Moreover, daily methylphenidate treatments beginning as late as 24 hr after TBI in rats reveal significantly less spatial memory performance deficits versus saline treatment (127). Recently, the effect of daily administrations of amantadine beginning one day post-injury and continuing for 20 days was examined. Rats treated with amantadine had significantly less spatial memory performance deficits than their saline-treated counterparts (130). Biochemical studies have demonstrated that amantadine increases release of DA into extracellular pools by blocking reuptake and by facilitating the synthesis of DA (131–134). In addition to acting pre-synaptically, amantadine has been demonstrated to act post-synaptically to increase the density of post-synaptic DA receptors (134) or to alter their conformation (135). Evidence of a post-synaptic mechanism is clinically promising since the mechanisms of actions may not depend solely on the presence of surviving post-synaptic terminals. Because the mechanism of action of amantadine differs from other DA releasing drugs (see 136 for review), it is likely that the dopaminergic effects of amantadine are a combination of pre-synaptic and post-synaptic effects.

Rats receiving delayed and chronic pharmacological treatment with the dopamine D<sub>2</sub> receptor agonist bromocriptine exhibited both enhanced working memory

**FIGURE 10-2**

Mean ( $\pm$  SE) latency (sec) to locate a submerged platform in a spatial learning acquisition paradigm. \* $P < 0.05$  vs. injury/vehicle. [From Kline et al., *J Neurotrauma* 2002; 19:415–425 (Ref. 50).]

and spatial acquisition in a MWM. Specifically, both injured groups exhibited significant impairments initially, but in marked contrast to the performance of the vehicle-treated group, the bromocriptine-treated animals required significantly less time to locate the platform (50). The dose of 5 mg/kg bromocriptine has been shown via microdialysis to increase extracellular DA levels in rats (137), suggesting that enhanced DA neurotransmission mediated the beneficial effects. However, as indicated in the “oxidative injury” section, the same dose of bromocriptine has also been reported to attenuate lipid peroxidation, suggesting that bromocriptine’s antioxidant properties may also contribute to its therapeutic effects (50). (See Figure 10-2.)

The administration of selegiline (L-deprenyl) once daily for seven days beginning 24 hr after fluid percussion injury has been reported to improve cognitive function in the MWM and enhance neuroplasticity (138). L-deprenyl is used to enhance the action of DA by inhibiting its main catabolic enzyme in the brain, monoamine oxidase-B. Clinical studies also exist attesting to the benefits of DA augmentation following TBI (139,140).

These positive finding with delayed treatment suggests that strategies that enhance catecholamine neurotransmission during the chronic post-injury phase may be a useful adjunct in ameliorating some of the neurobehavioral sequelae following TBI in humans.

## SEROTONIN AND TBI

Investigations regarding the role of serotonergic (5-HT) responses after TBI have not been as prolific as with other

neurotransmitter systems. Utilizing a fluid percussion rat brain injury model, Busto et al. (141) reported that 5-HT levels increased from  $18.85 \pm 7.12$  to  $65.78 \pm 11.36$  pm/ml (mean  $\pm$  SD) in the first 10 min after injury. The levels of 5-HT remained significantly higher than controls for the first 90-min sampling period. In parallel to the rise in 5-HT levels a significant 71 percent decrease in extracellular 5-HIAA levels was noted in the first 10 min after injury. These findings suggest that there is a rapid rise in extracellular 5-HT levels in cortical regions proximal to the injury site. Because 5-HT potentiation of excitatory amino acids has been reported in cat neocortex (142), the trauma-induced release of 5-HT might negatively impact recovery by promoting excitotoxic processes.

Serotonergic pathways originating in the raphe nuclei have extensive projections to brain areas involved in cognitive processing, and 5-HT receptor agonists and antagonists alter these processes (143,144). Of all the 5-HT receptors (5-HT<sub>R</sub>) characterized thus far (5-HT<sub>1</sub>–5-HT<sub>7</sub>), the 5-HT<sub>1A</sub> is the most widely studied. 5-HT<sub>1A</sub>Rs are abundantly expressed in brain regions, such as the cortex and hippocampus, that play key roles in learning and memory and that are susceptible to neuronal damage induced by brain injury (145,146). Numerous studies have reported on the effects of 5-HT<sub>1A</sub>R agonists after focal or global cerebral ischemia in both rats and mice (145–150). These studies have focused on either pre or post-injury administration of various 5-HT<sub>1A</sub>R agonists and their potential neuroprotective effects. What is generally found is that 5-HT<sub>1A</sub>R agonism decreases histopathology after ischemic injury.

The investigation of 5-HT<sub>1A</sub>R agonists on neurobehavioral and cognitive recovery after TBI produced by a well-established controlled cortical impact injury model, which produces deficits resembling those seen clinically, has only recently begun. Kline and colleagues have shown that a 4-hr continuous infusion of Repinotan HCL (BAY  $\times$  3702; 10  $\mu$ g/kg/hr i.v.), a high-affinity, highly selective 5-HT<sub>1A</sub>R agonist, commencing 5 min after cortical impact produced a marked attenuation of TBI-induced learning and memory deficits assessed in the MWM. Moreover, this treatment regimen attenuated hippocampal CA<sub>1</sub> and CA<sub>3</sub> cell loss, and decreased cortical lesion volume relative to vehicle-treated controls (151). Utilizing the same TBI model, Kline et al. (152) have also demonstrated that the classic 5-HT<sub>1A</sub>R agonist 8-hydroxy-2-(di-*n*-propylamino)tetralin (8-OH-DPAT) produces similar effects on functional and histological outcome. Briefly, in a dose response study, a single dose of 0.5 mg/kg administered intraperitoneally 15 min following cortical impact significantly attenuated water maze performance relative to the vehicle controls. Additionally, 8-OHDPAT attenuated hippocampal CA<sub>3</sub> cell loss. The administration of the 5-HT<sub>1A</sub> receptor antagonist WAY 100635 did not significantly impact functional or histological outcome following TBI. (See Figure 10-3.)

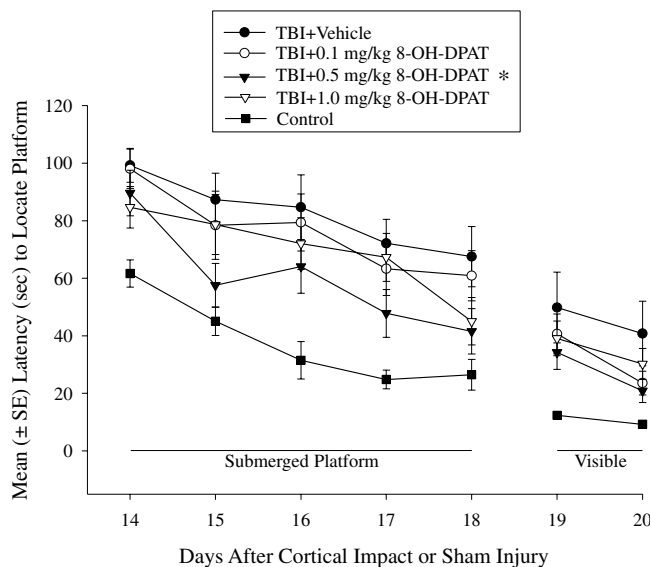

FIGURE 10-3

Mean ( $\pm$  SE) latency (sec) to locate either a submerged (hidden) or raised (visible) platform in a spatial learning acquisition paradigm in the Morris water maze. \* $P < 0.05$  vs. TBI+Vehicle (Scheffé). [From Kline et al., *Neurosci Lett* 2002; 333:179–182 (Ref. 152).]

Although potential mechanisms contributing to the beneficial effects observed after a single treatment with 8-OH-DPAT in our TBI paradigm have not been reported, the results from other studies investigating 5-HT<sub>1A</sub>R agonists suggest that it is via an attenuation of excitotoxicity. Electrophysiological studies have shown that 8-OH-DPAT, repinotan HCL, and other 5-HT<sub>1A</sub>R agonists induce neuronal hyperpolarization by activating G-protein coupled inwardly rectifying K<sup>+</sup> channels (153,154) and decrease glutamate release after brain insult (145, 147,148). The latter effect is likely produced by activation of pre-synaptic 5-HT<sub>1A</sub> receptors on glutamatergic terminals (155,156). 5-HT<sub>1A</sub>R activation may also contribute to neuroprotection by directly interacting with voltage-gated Na<sup>+</sup> channels to reduce Na<sup>+</sup> influx (157). 8-OH-DPAT and other 5-HT<sub>1A</sub>R agonists also induce hypothermia (157–160), which may be another potential mechanism contributing to the neuroprotective effects observed in our studies. As indicated in a separate section of this chapter, hypothermia is a potent neuroprotective strategy after brain injury. However, we have recently reported that the beneficial effects observed with a single and early intraperitoneal injection of 8-OH-DPAT is not mediated by concomitant hypothermia. Briefly, following TBI and 8-OH-DPAT administration (same dose, route, and time frame as in the previous study, (152), we controlled temperature (normothermia) in one group of 8-OH-DPAT treated rats and allowed the other group to cool spontaneously. A comparison of both 8-OH-DPAT treatment groups did not reveal a difference in functional

or histological outcome, but both did perform significantly better than the vehicle control group (161).

## ACUTE CHOLINERGIC TREATMENT

Acetylcholine (ACh) levels have been reported to change in brain and cerebral spinal fluid (CSF) following TBI. Gorman et al. (162) reported that hippocampal ACh levels (measured by microdialysis) increased significantly above control within 10 min after fluid percussion TBI. Saija et al. (163,164) found that ACh turnover rate (measured by a phosphoryl [<sup>2</sup>H<sub>5</sub>]choline method) increased significantly in the brainstem at 12 min and was still elevated at 4 hr after moderate fluid percussion TBI in the rat. Thus, moderate TBI appears to produce a transient release of ACh and increased cholinergic neuronal activity in some brain regions for several hr after injury.

Laboratory studies have demonstrated that excessive activation of acetylcholine (ACh) muscarinic receptors contribute significantly to functional deficits associated with experimental TBI in the rat. TBI induced muscarinic receptor activation mediates excitotoxic processes by modulating ionic fluxes via altered protein kinase C activity or inositol 1,4,5-triphosphate associated G-protein coupled PI turnover. The role of ACh in the induction of brain injury is further strengthened by evidence indicating that blockade of muscarinic cholinergic receptors during the acute phase can reduce injury and improve outcome. For example, pre-treatment (165,166) or immediate post-treatment (166) with the muscarinic receptor antagonist scopolamine has been demonstrated to significantly reduce functional motor deficits associated with TBI in the rat. Post-TBI administration of rivastigmine, an anticholinesterase drug that increases activity at both muscarinic and nicotinic receptors, has been shown to attenuate neurobehavioral and cognitive performance in mice.

In contrast, several lines of evidence indicate that experimental TBI in rats, in addition to transiently increasing ACh, also chronically decreases cholinergic neurotransmission, which may be related to disturbances in cognitive performance. Microdialysis studies at 2 weeks post-TBI have shown a reduction in the release of ACh evoked by the muscarinic autoreceptor antagonist, scopolamine (167,168). TBI can also produce increased sensitivity to disruption of spatial memory function by scopolamine that occurs concurrently with a reduction in scopolamine-evoked ACh release (169). A time-dependent loss of choline acetyltransferase (ChAT) enzymatic activity (162) and ChAT immunohistochemical staining (49,170,171) has also been reported after TBI. Dixon et al. (169) have reported a selective decrease in the  $V_{max}$  of choline uptake in the absence of any change in  $K_m$  after controlled cortical impact injury. However, alterations in synaptosomal choline uptake have not been

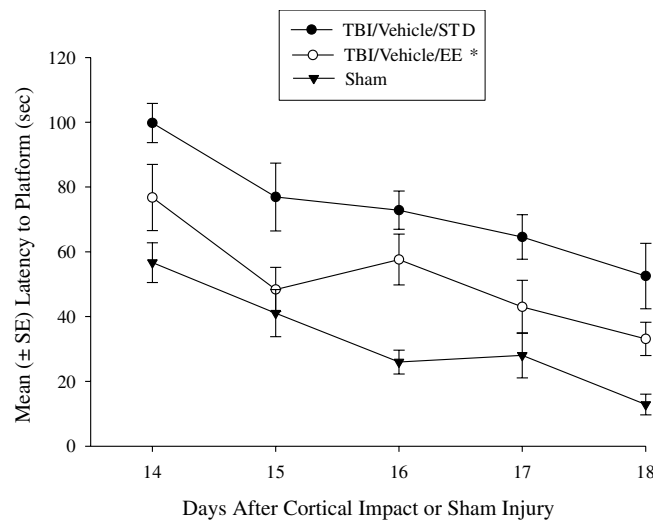

reported at 1 week after closed head impact in rats (172). Ciallella and colleagues have reported chronic changes in vesicular ACh transporter (VACHT) and M<sub>2</sub> cholinergic muscarinic receptor, two proteins involved in cholinergic neurotransmission after TBI (173). Chronic mRNA changes in VACHT and M<sub>2</sub> have been evaluated at 4 weeks after moderate brain trauma in rats. VACHT and M<sub>2</sub> medial septal mRNA levels evaluated by RT-PCR revealed an increase in VACHT mRNA, but no significant change in M<sub>2</sub> mRNA levels compared to sham controls (174). Changes in VACHT and M<sub>2</sub> protein have been demonstrated to persist for up to one year following TBI (175). These changes may represent a compensatory response of cholinergic neurons to increase the efficiency of ACh neurotransmission chronically after TBI through differential transcriptional regulation.

Increasing levels of ACh pharmacologically can attenuate post-traumatic spatial memory performance deficits. For example, increasing ACh synthesis by increasing the availability of choline using CDP-choline treatment has been reported to enhance spatial memory performance (176). Additionally, chronic post-TBI administration of BIBM 99, a selective muscarinic M<sub>2</sub> receptor antagonist that increases ACh release by blocking pre-synaptic autoreceptors, has been reported to attenuate spatial memory deficits after TBI (177). Similarly, chronic post-TBI administration of MDL 26,479 (suritazole), a negative modulator at the  $\gamma$ -aminobutyric acid (GABA) receptor that enhances cholinergic function, attenuates spatial memory deficits after TBI (178). Several clinical reports have described beneficial effects on memory dysfunction with the acetylcholine-esterase inhibitor aricept (donepezil) after TBI in humans (179–182). Taken together, the studies described in this section suggest that therapies that attenuate the transient increase in ACh and/or alleviate the chronic decrease seen after TBI are capable of producing beneficial effects on functional outcome.

## ENVIRONMENTAL ENRICHMENT

Exposing rats to complex, stimulatory and social housing (enriched environment (EE)) may be considered a rodent correlate of physiotherapeutic intervention and has been extensively studied in numerous experimental conditions. EE has been reported to increase brain weight, cortical volume, dendritic arborization, synaptogenesis, and neuronal survival (183,184). EE has also been shown to decrease apoptosis of neuronal precursor cells in the hippocampal dentate gyrus (185–187). Rats housed in EE for 30 days exhibit significantly higher levels of nerve growth factor mRNA in the rat visual cortex and hippocampus than those living in standard conditions (188). EE selectively increases 5-HT<sub>1A</sub> receptor mRNA

expression and binding in the rat hippocampus (189). This finding demonstrates the importance of 5-HT-receptor subtypes in the effects of housing environment on hippocampal functions, such as synaptic plasticity. EE has also been shown to increase the expression of brain-derived neurotrophic factor mRNA in the rodent hippocampus, which correlates with improved spatial memory (190). Somatostatin levels (191), glucocorticoid receptor, and the nerve growth factor-induced immediate early gene NGFI-A (192) are also increased following exposure to an EE. In contrast to the studies observing increases in gene and neurotrophic expression (193,194), Hicks et al. (195) did not see alterations in BDNF, TrkB, or NT-3 gene expression in lateral fluid percussion injured rats exposed to an EE, but did see an attenuation of cognitive deficits. Hamm et al. (196) also reported improved MWM performance in rats exposed to an environment consisting of objects that provided motor, olfactory, tactile, and visual stimulation for 15 days following moderate fluid percussion injury. Furthermore, rats exposed to EE for 11 days after severe fluid percussion injury demonstrated improved MWM performance and reduced contusion lesion volume (197). EE has also been demonstrated to improve motor performance on a beam walk task or sensory neglect after cortical lesions (198–200). Wagner and colleagues have recently demonstrated that placing rats in an EE immediately after controlled cortical impact injury facilitates cognitive function in a spatial learning and memory task in the MWM (201). Briefly, as depicted in Figure 10.4, the rats in the EE (i.e., large cage with toys and objects designed to provide enhanced sensory stimulation) performed significantly better than the rats in standard conditions

**FIGURE 10-4**

Mean ( $\pm$  SE) latency (sec) to locate a submerged platform in a spatial learning acquisition paradigm. \* $P < 0.05$  vs. standard conditions. [From Wagner et al., *Neurosci Lett* 2002; 334:165–168 (Ref .201).]

(i.e., 2 rats per standard [STD] size cage with no enhanced sensory stimuli). Taken together, these reports attest to the beneficial effects conferred by EE after brain injury. Further studies investigating the combined effects of EE and pharmacotherapies known to also provide benefit after TBI, such as those outlined in this chapter, are warranted to examine this potentially efficacious, and perhaps synergistic, therapeutic approach. (See Figure 10-4.)

### STEM CELL THERAPY

Multipotential stem cells are a contemporary choice for cell therapy TBI, as replacement of multiple cell types may be required for functional recovery. Several investigators have demonstrated that following TBI in adult rats, the number of proliferating cells labeled with bromodeoxyuridine is significantly increased in the bilateral subventricular zone and dentate gyrus (202–205). A better understanding of these endogenous neural stem cells may lead a less invasive model of stem cell therapy. There are several promising studies in which the transplantation of various progenitor cells have improved tissue survival and functional outcome. Bone marrow stromal cells, which normally give rise to bone, cartilage, adipose tissue, and hematopoiesis-supporting cells, have been shown to differentiate *in vitro* and *in vivo* into neural-like cells. Following TBI, treatment with bone marrow stromal cells has been shown to be functionally beneficial using intracerebral (206), intraarterial (207) and intravenous routes of administration (208). Transplantation of the neural stem cells (clone C17.2) has been reported to survive in the traumatically injured brain, differentiate into neurons and/or glia, and attenuate motor dysfunction after traumatic brain injury (209). Transplantation of embryonic stem cells has resulted in improved sensorimotor, but not cognitive function after TBI (210). Lu et al. (211) found that human umbilical cord blood cells injected i.v. into traumatic brain injured rats significantly reduced motor and neurological deficits compared with control groups by day 28 after the treatment. The cells were observed to preferentially enter the brain and migrate into the parenchyma and express the neuronal markers, NeuN and MAP-2, and the astrocytic marker, GFAP. These data suggest that the transplantation of progenitor cells into the brain may be a potential therapy for patients who have sustained traumatic brain injuries

### NUTRACEUTICALS

Several empirical research studies have demonstrated that “natural” treatments can be effective in reducing some of the sequelae of TBI. An excellent example of a nutraceutical that has been extensively reported to reduce

secondary effects of TBI and improve behavioral outcome is magnesium ( $Mg^{2+}$ ). Early work has shown that the administration of  $Mg^{2+}$  30 min after a fluid percussion injury in rats provides significant improvement in neurological function when compared to saline-treated rats (212). Follow-up studies from the same group have shown that  $Mg^{2+}$  therapy is also effective in decreasing cognitive and motor deficits (58,213), histological damage (214,215), and expression of a gene (p53) associated with the induction of cell death (216). The beneficial effects of  $Mg^{2+}$  have been observed for up to 8-mo after TBI (217). Using an impact-acceleration model of severe traumatic diffuse axonal brain injury, Heath and Vink (218) have shown that intramuscular administration of  $MgSO_4$  (750  $\mu$ mol/kg) at 30 min or at 8, 12, or 24 hr after TBI significantly improves motor performance as assessed on a rotarod test vs. untreated-control animals. Although the rats treated at 24 hr displayed a slower rate of recovery during the early testing period, they eventually recovered significantly beyond the vehicle-treated group by the end of the testing session, suggesting that even delayed magnesium treatment is effective after TBI (218). A more recent finding by the same group reports that  $MgSO_4$  (250  $\mu$ mol/kg) at 30 min after diffuse TBI significantly improves sensorimotor function and learning performance (219).  $Mg^{2+}$  therapy has also been shown to facilitate functional recovery and prevent subcortical atrophy after lesions of the rat sensorimotor cortex (220).

Other nutraceuticals that have been reported to positively impact the neuroprotective and/or rehabilitative process after TBI include, but are not limited to, cytidinediphosphocholine (CDP-choline), creatine, and vitamins B3 and E. CDP-choline or citicholine is a naturally occurring endogenous nucleoside and an intermediate of phosphatidylcholine synthesis. When administered as a treatment after controlled cortical impact injury (100 mg/kg, 1–18 days post-TBI), CDP-choline-treated rats performed significantly better than vehicle-treated rats on both motor and cognitive tasks (176). Also utilizing the controlled cortical impact injury model, Baskaya et al. (221) demonstrated that intraperitoneal injections of CDP-choline (100 or 400 mg/kg twice after TBI) significantly decreased brain edema and BBB breakdown. In a more recent study, Dempsey and colleague reported that two treatments of CDP-choline (200 or 400 mg/kg, immediately post-TBI and 6 hr later) after cortical impact injury significantly prevented hippocampal neuron loss, decreased cortical contusion volume, and improved neurological recovery (222). Taken together, these studies indicate that CDP-choline is an effective neuroprotective agent on secondary injuries and neurobehavioral dysfunctions that are manifested after TBI. Creatine, a common food supplement used by individuals as a performance enhancer, has been demonstrated to attenuate the extent of cortical damage in mice and rats by as much as 36 percent and 50 percent,

respectively (223). The authors suggested that protection might have been mediated by mechanisms involving creatine-induced maintenance of mitochondrial membrane potential, decreased intramitochondrial levels of reactive oxygen species and calcium, and preservation of adenosine triphosphate levels. In a study investigating the effects of vitamin B3, Hoane et al. (224) reported that a 500 mg/kg dose provided 15 min and 24 hr after TBI produced by a cortical contusion model significantly reduced the size of the lesion and glial fibrillary acidic protein positive astrocytes compared to saline-treated rats. Furthermore, vitamin B3 treatment also significantly improved behavioral outcome (224). The data suggest that vitamin B3 may have therapeutic potential for the treatment of TBI. In an investigation of vitamin E or  $\alpha$ -tocopherol, Inci and colleagues have demonstrated that this nutraceutical also exhibits protective effects after TBI. Specifically, guinea pigs were subjected to a TBI utilizing a weight drop injury model and then administered 100 mg/kg of vitamin E. Lipid peroxidation was measured using the thiobarbituric acid reactive substances method immediately, 1 hour, or 36 hr after trauma. The results indicated that  $\alpha$ -tocopherol significantly suppressed the rise in lipid peroxide levels in traumatized brain tissue, suggesting that this treatment regimen has a protective effect against oxygen free radical-mediated lipid peroxidation after TBI (225).

## CONCLUSIONS

The experimental control afforded with the utilization of animal models of TBI has allowed for the testing of several classes of neuroprotective therapies. Empirical studies have revealed several potential treatments that attenuate a range of neurobehavioral and morphological derangements. However, the translation of experimental neuroprotective treatments to humans has been limited. This situation may be improved by screening therapies under experimental conditions that better reproduce the clinical environment (e.g., ICU-like care, large animal models, etc.), and by conducting clinical trials that better mimic laboratory treatment administration protocols (e.g., earlier treatment windows).

### INTRODUCTION

Traumatic brain injury is a common problem in emergency facilities—especially in urban trauma centers. Surgical and medical management depend on the specific injuries a patient has sustained and a timely diagnosis at the time he or she enters the emergency center. Surgical and medical management also depends on both clinical data and imaging results. Both are essential for the appropriate selection of therapy.

Medical imaging has progressed substantially in the last several years, in part due to advances in neurological imaging. Imaging is a representation of the underlying vital structures that are deep below the skin. The human brain is a three-dimensional entity, but it is converted by hardware, software, and digital technology into a two-dimensional image that can be viewed on a sheet of film or at a computer workstation. One of the principal reasons that the field of radiology has advanced so much in the last several years has been the computer industry. The ability to digitally display and store high-resolution images has improved substantially.

Plain film radiography provides very little useful information for patients with traumatic brain injury (1). Plain films may be used to look for foreign bodies or visualize fractures, however computed tomography (CT) and magnetic resonance imaging (MRI) are essential for the

accurate diagnosis and subsequent management of patients with traumatic brain injury. While MRI has made remarkable advances in the past 10 years, CT continues to be the initial imaging modality for the brain in the acute setting (2). Three-dimensional reconstructions of axial CT data may now be obtained, essentially eliminating plain film radiography from the imaging arsenal used in the work-up of acute trauma.

One should understand the pathophysiology of different brain injuries and recognize these injuries in any form of imaging. While technology does change, the pathophysiology and appearance of these lesions remains the same. It is our hope that by the end of this chapter, the reader will have formed a sound understanding of the imaging appearance of the major pathologic entities of traumatic brain injury encountered in clinical practice. Both CT and MRI are described separately below, followed by the specific traumatic entities that are organized in a systematic fashion.

### IMAGING TECHNIQUE

Modern digital imaging technology allows manipulation of data to reconstruct images in multiple planes. This manipulation of data allows the interpreting physician to gain three-dimensional information about the human

brain from two-dimensional data. In addition, there are currently many three-dimensional techniques available for certain applications, although not practical in the acute setting. Imaging of the traumatically injured brain should be fast, reliable, diagnostic, and widely available. The workhorse of any facility continues to be CT scanning. Helical CT is extremely fast. It allows the technician to obtain whole-body images in a single breath hold. This is of paramount importance in patients who have sustained polytrauma of other organs in addition to brain injuries.

Many investigators have attempted to develop criteria for obtaining a CT scan in the acute setting for the evaluation of traumatic brain injury. The American College of Radiology (ACR) conducted a study in 1986 that ultimately divided neurologically traumatized patients into three groups of risk: low, moderate, and high. The low-risk group consisted of patients with minor symptoms without neurological deficits such as headache, dizziness, or scalp injuries. It was proposed that this group of patients could be observed without the need for imaging. The moderate- and high-risk groups included those patients with neurological deficits, altered consciousness, seizures, depressed skull fractures, or penetrating injuries. It was proposed that these patients should receive a non-contrast CT scan of the brain as part of the initial work-up (3). Although the ACR and others have attempted to define the indications for obtaining an imaging study in minor trauma, currently this is a multifactorial decision made in emergency centers across the country. Some researchers have also found that brain injuries detectable by CT imaging may occur in people with relatively minor complaints, normal neurological exam and/or a normal Glasgow Coma Scale (GCS) of 15 (4). Issues such as cost, risk-to-benefit ratio, and medical/legal concerns play roles in the decision to image patients with mild brain injuries or post-concussive disorders.

### Computed Tomography

Sir Godfrey N. Hounsfield of Great Britain and Allan M. Cormack of the United States won the 1979 Nobel Prize in Medicine for their groundbreaking work that made CT a reality in the 1970s. A conventional CT scanner consists of a gantry, table, and computer workstation. Early CT scanners were slow and cumbersome. Only one slice could be acquired at a time. The incorporation of slipping technology in the 1990s allowed helical CT units with a continually rotating gantry to become available. With helical CT, the table and the patient are continually moving through the gantry. Many of these units also employ multiple detector arrays that increase the volume of tissue imaged and improve the speed with which the study is performed. Current multiple detector helical CT scanners produce remarkable images and allow versatile

reconstruction of volume data in multiple planes—axial, sagittal, coronal, and oblique projections. These units are four to six times faster than older helical units. An entire CT of the abdomen and pelvis may be performed in a trauma patient with a single breath hold in less than 30 sec. CT scans of the brain may be performed even faster.

The raw data obtained from CT detectors is mathematically manipulated using several algorithms and filters to obtain visual data that offers both spatial and contrast information. The visual contrast between different tissues when viewing a CT image is due to differences in the absorption of x-rays. The properties that govern x-ray absorption on plain films are identical for CT. As x-ray photons pass through air and tissue, the useful beam is subject to attenuation—or removal of photons (5). The x-rays may be attenuated (absorbed), scattered in a new direction, or pass through the tissue of interest.

The two extremes of air and metal have characteristic appearances on CT because no x-rays are absorbed by air while nearly all x-rays are absorbed by metal. Everything in between these two extremes has a spectrum of CT appearances. Visually, air is black, fat is dark, and soft tissue and fluid are shades of gray. Bone is white and metal is extremely bright—often causing streak artifact on the CT images. The Hounsfield Scale, named for the father of computed tomography, allows one to quantitate the actual tomographic densities of these different tissues. In fact, CT's ability to distinguish between subtle differences of similar tissues—or contrast resolution, is the true advantage of CT as an imaging modality. Hounsfield Units (HU) are numerical values that are assigned to each pixel (picture element) in a CT image. The scale is roughly  $-1000$  to  $+3000$ . Water or simple fluid like cerebrospinal fluid (CSF) is set as the baseline of zero. Air is black, or  $-1000$ , while bright metal or iodinated contrast material is close to  $+3000$ . Soft tissue ranges from about  $-200$  to  $+200$ . Gray matter of the brain is typically around  $30-40$  Hounsfield units. When interpreting a CT image of the brain, the density of surrounding structures or abnormalities is often compared to gray matter. A typical radiology report may read, "there is an intra-axial mass that is isodense (the same density) to gray matter."

Another advantage of CT is the ability to manipulate the raw data to augment certain visual characteristics for the person interpreting the image. Bone windows, brain windows, soft tissue windows, lung windows, and so on, are simply different ways of viewing the same raw data to take advantage of contrast differences. These different window settings are made by employing unique computer algorithms, or filters, to manipulate the raw data. These settings have both a window level and a window width. A window level is the center value of a certain setting, while the window width is the range around the center value. It is the window width that determines

the visual contrast or “shades of gray” displayed for a certain setting (5). The window level accounts for the tissue brightness that is displayed (6).

The only absolute contraindication to obtaining a non-contrast CT is an unstable patient. Because CT imaging uses ionizing radiation, special care should be used with children and pregnant patients. Organs that are not included in the region of interest may be shielded with lead to protect them from unnecessary exposure to radiation. Although there is no danger with obtaining CT in patients with aneurysm clips or intracranial metal, these objects do create artifacts that render the interpretation of a CT difficult.

In order to perform a CT, the patient is placed in the supine position on the table and moved into the gantry. A CT scout image, or topogram, is obtained in order to determine the area that should be scanned. The scout image looks like a lateral plain film of the skull. The technologist can then orient the plane of the scan and set the slice thickness. Typically, the axial images are obtained parallel to the orbital roof. A trauma CT scan of the brain is performed without contrast in order to identify acute hemorrhage, which appears hyperdense (bright) on CT.

CT may also be obtained after the administration of intravenous, iodinated contrast material. Contrast is usually not needed in the evaluation of acute traumatic brain injury, unless screening of the vasculature is warranted. For suspected vascular injury, dedicated conventional angiography is often performed rather than CT angiography because of increased sensitivity and the ability for therapeutic intervention to be performed quickly if needed. Thus, routinely giving contrast for a CT in the acute setting for a patient with suspected brain injuries is a wasted step and may obscure underlying acute hemorrhage.

Contrast is administered in order to evaluate medical pathology for which the blood-brain barrier has been violated. These include inflammatory, infectious, vascular, and neoplastic abnormalities. Contrast is given to identify the enhancement patterns of intracranial mass, cerebral abscess, subdural empyema, encephalitis, and vasculitis. Contrast material is also required for performing CT angiography in order to visualize the enhancing arteries and veins.

With the advent of multidetector CT (MDCT), fast imaging of large volumes of tissue is possible, without sacrificing spatial resolution. MDCT with thin slices can be combined with software packages that optimize vascular enhancement. This allows one to control the intravenous bolus of contrast, specifying arterial phase and delayed venous phase scanning. This becomes important for CT angiography and evaluation of intracranial vasculature noninvasively. Post-processing techniques such as maximum intensity projection (MIP), volume rendering (VR), shaded surface display (SSD), and curved planar reformatted images allow one to manipulate the MDCT data to optimally display intracranial vascular

structures and detect pathology such as arterial occlusion, dissection, pseudoaneurysm formation, and vasospasm. Goldsher et al. evaluated 36 patients presenting with subarachnoid hemorrhage using MDCT angiography of the vertebrobasilar system. Their results suggest that cerebral MDCT angiography is a reliable, rapid, and minimally invasive diagnostic method, for assessing vasospasm of the posterior circulation in patients with subarachnoid hemorrhage (7). More studies are needed at large volume trauma centers to further define the role of MDCT angiography in the evaluation of traumatic intracranial vascular injury.

Sequential axial nonenhanced images of the brain are performed from the base of the skull through the vertex with slices that vary in thickness from 5 mm to 7 mm. Current helical scanners obtain overlapping voxels (volume elements) of tissue continuously from start to finish. The raw CT data is manipulated and sent to a workstation for processing. Images may then be viewed in different window settings on the workstation, film or Picture Archiving and Communication System (PACS). CT scans of the brain are often viewed in bone windows (window level: 700, window width: 3500), brain windows (window level: 40, window width: 100) and intermediate windows (window level: 80, window width 250)—for purposes of identifying subtle hemorrhages along the surface of the brain (1). Many hospitals are now converting to digital PACS systems in order to take advantage of the ability to manipulate data, eliminate film costs and allow clinicians to access a computer version of images and reports.

### Magnetic Resonance Imaging

Magnetic Resonance Imaging (MRI) is an imaging technique that plays an adjunctive role in brain injury. The ability for tissue/fluid characterization and multiplanar imaging are advantages of MRI. While the imaging times of MRI have shortened with improved equipment and stronger magnets, performing an MRI is still much longer than performing a CT scan. Thus, the use of MRI in patients with acute traumatic brain injury is limited to certain patient populations. When compared to CT, MRI provides exquisite soft tissue detail, evaluation of the brainstem, skull base, and cranial nerves. It displays particularly well the posterior fossa, which is often obscured by a beam-hardening artifact that occurs with CT.

MRI is used primarily in the work-up of chronic conditions or for following the sequelae of traumatic brain injury. It is more accurate in assessing the general age of intracranial blood products. The appearance of evolving intracranial hemorrhage is described in detail later in the text. MR angiography is a technique that is useful to screen for concurrent vascular injuries in the head and neck. However, conventional angiography

remains the gold standard in the evaluation of traumatic vascular injury, both for diagnosis and the opportunity for endovascular therapy such as embolization, angioplasty or stenting.

The human body is made up of water, natural elements, minerals and macromolecules such as proteins, fats, and carbohydrates. One of the main components is the hydrogen proton. Magnetic resonance imaging relies on the signal emitted by relaxing protons as they are disturbed by external magnetic fields and radiofrequency pulses. An MRI unit consists of a powerful external magnetic field, transmitting coils, receiving coils, patient table and a digital workstation (Figure 11-1). With the application of a strong external magnetic field, hydrogen protons in the body align themselves either parallel or anti-parallel with this field. Most of the protons align themselves with the lower energy parallel state, creating a net magnetic moment in the direction of the external magnetic field (8). This net magnetic moment in the direction of the external magnetic field is called the longitudinal vector.

Each proton has a spin and a motion called precession. The frequency with which the protons precess depend on the strength of the external magnetic field. The relationship between the precession frequency and the external magnetic field is described by the Larmor equation (5, 8):

$$\omega_0 = \gamma B_0$$

$\omega_0$  is the precession frequency (Hz)

$\gamma$  is the gyro magnetic ratio

$B_0$  is the strength of the external magnetic field (Tesla)

It can be derived from the equation that the precession of protons varies directly with the strength of the magnetic field. Stronger magnets produce faster precession.

FIGURE 11-1

Standard 1.5 Tesla MRI gantry

This property allows for a higher signal and improved image quality. Most diagnostic quality magnets available in hospitals or outpatient facilities are in the 1.0–1.5 Tesla range. Magnets in the 3.0–7.0 Tesla range are now being used in academic centers for human and animal research. Stronger magnets will improve the quality, signal-to-noise ratio, and speed of acquisition of MR images in the future.

A radiofrequency pulse (RF) at the same frequency as the precessing protons is then turned on. This pulse disrupts the parallel/antiparallel equilibrium of the protons within the external magnetic field. Some protons are flipped into the higher-energy state, or antiparallel orientation. This eliminates the net magnetic longitudinal vector that had been in the direction of the external magnetic field. This disruption of the longitudinal vector, or transfer of energy from the RF pulse to the precessing protons is called *resonance* (8). The RF pulse results in a decrease or elimination of the longitudinal net magnetization and also allows the protons to precess in phase with one another. Because the protons are precessing in phase during the RF pulse, a net magnetization in the transverse direction is then created. Thus, after the RF pulse is turned on, the longitudinal magnetization in the direction of external magnetic field decreases, while a new transverse magnetization is created due to the protons now precessing in phase.

The RF pulse is then turned off. Protons gradually flip back to the lower-energy parallel orientation in the direction of the external magnetic field. The longitudinal magnetization vector gradually reappears. The reappearance of the longitudinal vector is called longitudinal relaxation and is described by the time constant  $T_1$ , or longitudinal relaxation time. The transverse magnetization that had been created by the protons precessing in phase disappears when the RF pulse is turned off. This is described by the transverse relaxation time,  $T_2$ .  $T_1$  relaxation depends on the strength of the external magnetic field, tissue composition and structure.  $T_2$  relaxation is affected by magnetic field inhomogeneities.

Each type of tissue has unique  $T_1$  and  $T_2$  properties that affect how they will appear on an MR image. When the RF pulse is turned off, special coils around the patient detect the signal of the increasing longitudinal vector and decreasing transverse vector (8). The decay and growth of these relaxation properties may be plotted on a graph. By changing different parameters and imaging times of the MRI sequence, one can take advantage of the different points along these relaxation curves, thereby affecting the signal of different tissues. These parameters can render an image  $T_1$  weighted,  $T_2$  weighted, or a combination of the two. In addition, each tissue has a certain proportion of protons per unit volume. Parameters can also be changed to take advantage of this proton density. For instance, water or fluid has a long  $T_1$  and is typically dark on a  $T_1$  weighted image and bright on a  $T_2$  weighted

image. Fat has a short  $T_1$  and is typically bright on both  $T_1$  and  $T_2$  weighted images.

In order to localize the protons or the signal created within tissue, gradient magnetic fields are applied in a multiplanar fashion. The applied external magnetic field created by the MR gantry is fairly uniform or homogeneous. Gradients are applied to the main magnetic field to create local differences across the area of interest. In other words, the magnetic field will change across the patient in several directions, determined by the gradients applied. These magnetic field gradients are imposed on the external field in order to change the precession frequency of each proton in the body slightly, allowing spatial localization to take place. Each proton can be identified in space and location because of its unique spin created by applying these known gradient fields across the regions of interest. The magnetic field gradients and radiofrequency excitations help to localize the signal from each voxel (volume element) within the patient being imaged (5, 8). It is beyond the scope of this chapter to describe the specific appearance of each tissue within a myriad of MR pulse sequences that seem to change daily.

CT is the dominant imaging modality for the detection of traumatic brain injury in the acute setting, while MRI is very helpful for the detection of occult lesions, follow-up and the long-term management of patients with traumatic brain injuries. Most initial decisions concerning management, such as surgery or no surgery in the emergency setting, are made based on the findings of a non-contrast CT of the brain. MRI may be obtained in the acute setting if there are clinical findings out of proportion to the CT findings, suggesting diffuse axonal injury or stroke. MRI also shows the chronic sequelae of the initial injury with excellent detail. Some common indications for obtaining an MRI in a post-traumatic work-up include chronic headaches, stroke, pseudoaneurysm, dementia, hydrocephalus, cranial nerve palsy, cavernous sinus injuries, persistent neurological deficits, or patients with diffuse axonal injury in light of a normal CT of the brain (1, 9, 10). The findings on MRI have implications on predicting patient outcome as well, and this topic will be discussed at the end of the chapter.

Gadolinium is a rare earth element with an atomic number of 64 that can be chelated to form MRI contrast material. Intravenous gadolinium chelate is non-iodinated and contrast reactions or renal failure are much less common than with iodinated contrast material. Gadolinium is paramagnetic, meaning that it affects the  $T_1$  and  $T_2$  characteristics in such a way that enhancement on post-contrast  $T_1$  images can be seen. Gadolinium provides the same information that iodinated contrast provides on CT—it allows visualization of vasculature and areas of breakdown of the blood-brain barrier. MRI is often used in the subacute or chronic setting of relatively stable patients. Gadolinium is extremely safe and it is often used

in many protocols after noncontrast MR images have been obtained.

## BRAIN INJURY

Imaging technology changes quickly; thus it is advantageous to learn pathology in an organ-based fashion. No matter how the technology changes, the pathology remains the same. With the basic knowledge of pathophysiology, one can learn and adapt to how a particular condition appears within a myriad of changing imaging modalities. Imaging of patients with traumatic brain injury in the acute setting often begins with a noncontrast CT of the brain (6). All of the available data including history, physical exam, mechanism of injury, and vital signs are used in conjunction with the imaging evaluation to triage these patients into surgical or medical management. If surgery will be needed, decisions as to the timing of surgery are also made based on the clinical presentation and imaging results. These acute injuries may require early neurosurgical intervention and a timely interpretation of the imaging findings is advantageous in the emergency room setting (11).

When interpreting an emergent CT scan of the brain, particular attention should be paid to the midline structures, presence of shift, ventricles, basal cisterns, the presence of herniation, cerebral convexities, and mass effect (12). The skull of infants and young children has open sutures and fontanelles; thus there is more plasticity of the cranial vault, should pathology develop. The adult brain exists in a closed box, the densely ossified skull that does not yield to intracranial pathology. Skull fractures, particularly depressed fractures often herald underlying brain injuries. Another advantage of CT is the exquisite bony detail it offers. Subtle, nondisplaced fractures in the plane of the scan may go undetected; however, these are felt by many researchers to be clinically insignificant (3,13). CT allows one to characterize fractures, the extent of bony injury and the sequelae of these fractures to the underlying brain parenchyma.

Air present within the skull or brain is termed pneumocephalus. The presence of pneumocephalus often heralds the presence of a fracture, usually communicating with air in the sinuses or outside of the skull. It is imperative to recognize fractures involving neurologically exquisite areas such as the orbit or the temporal bone. Temporal bone fractures, depending on type may lead to cerebrospinal fluid otorrhea, conductive hearing loss, sensorineural hearing loss or facial nerve paralysis. Other fractures such as nondisplaced calvareal fractures may be managed conservatively.

There is a finite amount of space within the adult skull. If something occurs within the skull to occupy the space, it occurs at the expense of the brain that is soft and

very pliable. In response to a space-occupying intracranial lesion, the brain may become deformed, swollen or edematous. If the mass effect within the skull is severe enough, a herniation syndrome may result. The brain is made up of gray and white matter. The gray matter consists of the cerebral cortex, cerebellar cortex, and deep nuclei. The white matter consists of a network of axons—connections and tracts between these nuclei. Injuries involving the brain itself—the gray or white matter of the brain parenchyma, are called intra-axial injuries. The extra-axial space, on the other hand, is outside of the brain parenchyma. The brain is separated from the inner table of the calvarium by several layers of tissue called meninges.

The meninges are composed of different layers of connective tissue. The dura is the outer layer that is firmly attached to the inner table and periosteum of the skull. The arachnoid exists between the dura and the pia. The pia is a thin lining that covers the brain and spinal cord. It follows the cortex of the brain and lines each gyrus, while dipping into the intervening sulci. The subarachnoid space is the space bounded by the arachnoid layer and pia. It contains cerebrospinal fluid and blood vessels. There are several areas within the brain where the subarachnoid space expands to create cisterns. Abnormalities that affect the subarachnoid space may extend into these cisterns (14). The pia and arachnoid comprise the leptomeninges. Injuries outside of the brain parenchyma are called extra-axial injuries.

The brain and spinal cord are bathed in cerebrospinal fluid (CSF). This fluid is also present in the ventricles and cisterns of the brain. There are two lateral ventricles, with frontal, temporal, and occipital horns. The third and fourth ventricles are unpaired, midline structures. The lateral ventricles communicate with the third ventricle through the paired foramina of Monro. The third ventricle communicates with the fourth ventricle—which is in the posterior fossa of the brain through the cerebral aqueduct. In the normal state, the CSF volume remains relatively constant, although it is constantly in flux. A homeostasis is reached where the amount of CSF produced in the choroids plexus is the same as the amount of CSF being absorbed into the venous sinuses. Cerebral capillaries form an impermeable blood-brain barrier and the capillaries and ependymal cells form a blood-CSF barrier (14). These barriers may break down in pathological conditions such as trauma, infection or tumor. Injuries within the ventricles or CSF spaces, while inside the confines of the brain, are actually outside the brain parenchyma and thus are extra-axial injuries. Sometimes, it is difficult to determine whether a lesion is intra-axial or extra-axial, however there are signs on imaging that help to define the location of lesions.

In the sections that follow, several types of traumatic brain injury will be discussed. The injuries are organized

according to location. Injuries involving the brain parenchyma, or intra-axial space will be discussed first, followed by a discussion of extra-axial manifestations of traumatic brain injury.

### Intra-axial: Brain Contusions

Some authors have described brain injuries based on the mechanism of injury—such as impact injuries versus inertial injuries, or primary versus secondary injuries (15). The traumatic neuropathology described in this chapter will be divided into intra-axial injuries and extra-axial injuries. Injury of the brain may occur from blunt or penetrating forces. Lesions such as brain contusions or epidural hematomas occur due to direct force, while other injuries, described later, occur due to acceleration/deceleration or rotational forces.

Direct forces may impact on the skull and underlying brain to cause injury to the brain parenchyma. These manifest acutely as brain contusions (Figure 11-2). A contusion may be hemorrhagic (Figure 11-3) or nonhemorrhagic, and all involve the gray matter of the brain. The two main reasons for not giving contrast prior to imaging a patient with acute intracranial injuries are to perform the exam quickly and to look for intracranial blood products.

FIGURE 11-2

Intra-axial hematomas: Axial noncontrast CT demonstrates intra-axial contusions in the bilateral frontal lobes and left temporal lobe (arrows). There is associated vasogenic edema

**FIGURE 11-3**

Hemorrhagic contusion: Axial noncontrast CT demonstrates a hemorrhagic contusion (arrow) in the left frontal lobe that extends across the midline and is associated with left to right shift and subfalcine herniation

Acute blood within the brain is bright on a non-contrast CT of the head, as is contrast material. Thus, contrast is withheld when evaluating the brain. The brightness of blood occurs due to the globin moiety of hemoglobin. Dehydration or an increase in hematocrit, may lead to a dense appearance of normal intracranial vasculature. In addition, hemorrhage may also appear denser than expected in these conditions (16).

Everything bright in the brain on CT may not always be due to acute hemorrhage. Calcification is also bright, and presents physiologically in the pineal gland and choroid plexus. In addition, the basal ganglia may exhibit calcification that is usually symmetrical from side to side. Dystrophic calcifications sometimes occur within the brain parenchyma due to prior infection or trauma. These dystrophic calcifications do not have mass effect or edema associated with them and will not enhance. Hemorrhagic contusions typically have a hypodense (dark) rim around them that represents edema (6). Arterial and venous malformations may also appear bright on CT, but are non-traumatic in nature. These conditions are associated with avid, tubular enhancement. In the case of an arterial-venous malformation, one may detect a nidus of tangled vessels that are associated with a prominent draining vein. These congenital or acquired vascular malformations are occasionally mistaken for traumatic injuries to the

untrained eye. Follow-up imaging such as MRI or angiography are obtained to further characterize these lesions as vascular malformations.

Hypodense lesions on CT (dark lesions) usually indicate the presence of ischemia, infarction or contusions that are non-hemorrhagic (17). While bright contusions are hemorrhagic, non-hemorrhagic contusions are hypodense—or darker than the surrounding brain on noncontrast CT images. This is due to local edema and fluid. Small lesions are often nonhemorrhagic or the blood is beyond the resolution of CT and not visible on the image. These types of lesions may be missed on CT. Other dark, nontraumatic lesions such as lipomas, dermoids, or arachnoid cysts can be characterized as such due to the presence of fat or fluid density.

By definition, all brain contusions are intra-axial and involve the brain parenchyma. Specifically, they involve the gray matter of the brain cortex and typically occur in the anterior and basal aspects of the frontal, temporal, and occipital lobes. These regions are most susceptible to contusions because of the bony ridges immediately adjacent to the aforementioned locations. Temporal lobe injuries are adjacent to the petrous bone or greater wing of the sphenoid bone. Frontal lobe contusions are adjacent to the cribriform plate or lesser wing of the sphenoid bone (12). Contusions occur in 5–10 percent of patients with moderate or severe head trauma (18). They cause local mass effect of surrounding structures and efface adjacent sulci, ventricles and cisterns. When at the brain periphery, they form acute angles with the skull. If the contusion is located immediately adjacent to the site of external trauma, it is a coup injury. If the contusion is opposite to the site of external trauma, it is a contra-coup injury. If the contusions are large enough, they may cause severe mass effect, midline shift or herniation. These large contusions may require neurosurgical intervention to prevent secondary injuries to the remaining brain such as infarction due to vascular compression, hydrocephalus or cranial nerve palsy. Hemorrhages of the deep gray matter nuclei such as the basal ganglia sometimes occurs after severe mechanisms of injury due to rupture of perforating vessels.

In contrast to the CT appearance of hemorrhage—which depends upon the globin moiety of hemoglobin—the MRI appearance of hemorrhage is quite variable. MRI provides much more detailed information, regarding the chronicity of blood products. This is due to the ability of MRI to characterize, in a temporal fashion, the process of blood product degradation. The MRI imaging parameters, the timing of the hemorrhage and the oxidation of iron in hemoglobin all affect the appearance of blood products on MRI. Acute hemorrhage contains oxygenated hemoglobin, or oxyhemoglobin inside red blood cells. Acute blood within minutes after bleeding is composed of oxyhemoglobin appears similar to fluid (low T1, high T2).

Oxyhemoglobin is isointense (similar) to gray matter on T1-weighting, and hyperintense (bright) relative to gray matter on T2-weighting. Oxyhemoglobin is rarely detected with MRI unless the patient is actively bleeding or is sustaining intermittent bleeds prior to the MRI. Active bleeding is rarely appreciated on MRI because the exam is obtained in a delayed fashion, after the patient is stable. This is in contrast to CT, where patients are often imaged in the acute setting, and often require emergent therapy while in the gantry. Many of the treatment decisions prior to obtaining an MRI have already been made from the findings seen on noncontrast CT.

Within hours after acute intracranial hemorrhage, blood within the red blood cells becomes deoxygenated (8–72 hr), resulting in conversion from oxyhemoglobin to deoxyhemoglobin. This appears hypointense (dark) on both T1- and T2-weighting. During this phase, hemorrhage may be difficult to detect or qualify based on routine MRI parameters. Gradient echo sequences are often helpful in these instances, because of the magnetic susceptibility artifact caused by the iron moiety in hemoglobin (19). Magnetic susceptibility occurs due to drastic changes in tissue magnetization at tissue/air or tissue/metal interfaces (5). This entity causes a blooming appearance, or an enlarged hypointense (dark) halo around areas of metal, hemosiderin or air. The iron that becomes deposited within areas of hemorrhage is often detectable months after the injury on gradient echo MRI, when other MRI sequences have normalized (20).

After 3 to 7 days, intracellular deoxyhemoglobin becomes oxidized into intracellular methemoglobin, that appears hyperintense (bright) on T1-weighting and hypointense (dark) on T2-weighting. After 10 to 14 days, the red blood cells are broken down, releasing extracellular methemoglobin—that is, a paramagnetic substance and appears bright on both T1- and T2-weighting. Other substances that are bright on a T1 weighted image include gadolinium, fat, melanin and proteinaceous substances. Blood products are classically described as one of the causes of hyperintense (bright) foci on a precontrast T1-weighted MRI image. As stated earlier, because an MRI is usually obtained well after the acute insult, blood products are usually in the methemoglobin phase, which is bright on T1.

As white blood cells are mobilized to the site of chronic blood (months to years after hemorrhage), the extracellular methemoglobin is stored as ferritin and hemosiderin. Ferritin and hemosiderin appear hypointense (dark) to gray matter on both T1- and T2-weighting (1, 21–23). This appears as a dark ring—the hemosiderin ring around areas of old hemorrhage. Gradient echo and susceptibility sequences, as mentioned previously are exquisitely sensitive to iron or metal. This allows the sequelae of prior hemorrhage to be detected months to years after the inciting injury. In addition, these sequences are good for detecting

blood products or hemosiderin within the sulci and subarachnoid spaces—leptomeningeal hemosiderosis. Leptomeningeal hemosiderosis involves deposits of hemosiderin (iron) within the sulci, causing diffuse low signal intensity within sulci on T1 and T2 weighting.

In summary, the appearance of blood products on MRI is quite variable and depends on the timing of imaging in relation to when the injury occurred. The ability of MRI to image the physiologic degradation and evolution of hemorrhage allows one to more accurately describe the age of blood products. To review, hemorrhage evolves from hyperacute oxyhemoglobin (high T2) to acute deoxyhemoglobin (low T1, low T2) to early subacute intracellular methemoglobin (high T1, low T2) to late subacute extracellular methemoglobin (high T1, high T2), and finally to chronic hemosiderin (low T1/T2 ring; magnetic susceptibility).

### **Intra-axial: Shearing Injuries**

Shearing injuries, like parenchymal contusions, may be either hemorrhagic or nonhemorrhagic. They typically occur at the gray/white matter junction, in a subcortical location. These injuries result from acceleration or deceleration of the brain during trauma. Shearing injuries may also occur in the brainstem, corpus callosum and septum pellucidum (24). Like any small abnormality in the brain, subtle lesions may not be appreciated with CT. Occasionally, shearing injuries are manifested as 1–5 mm petechial areas of hemorrhage. MRI has the advantage of gradient echo and magnetic susceptibility sequences that take advantage of the blooming phenomenon that occurs in areas of hemorrhage on MRI. Thus, MRI may detect a greater number of small hemorrhages that may not be seen with non-contrast CT (25). Shearing injuries may manifest clinically as neurological, cognitive or behavioral impairment. Shearing injuries may also occur in infants and young children due to non-accidental trauma. Shaken baby syndrome classically produces shearing injuries within the brain as well as retinal hemorrhages (26). Shearing injuries may also result from the rotational forces and impact injuries that occur during certain types of athletic pursuits, most notably contact sports (27).

A normal CT scan in light of a neurologically devastated patient is a classic finding in diffuse axonal injury (DAI). It is the most common cause of a post-traumatic vegetative state (1). DAI consists of innumerable shearing injuries that are often beyond the resolution of CT (28). The injuries typically occur at the gray-white matter junction in the frontal and temporal lobes. In very severe trauma, diffuse axonal injury may occur in the lobar white matter, corpus callosum and brainstem (Figure 11-4). In the brainstem, these shearing injuries are typically located in the dorsolateral aspects of the pons and midbrain. DAI occurs after acute acceleration/deceleration forces disrupt

**FIGURE 11-4**

DAI: Axial noncontrast CT demonstrates shearing injuries involving the splenium of the corpus callosum and deep white matter (arrows)

neuronal axons. The mechanism of injury is typically severe such as that seen in high-speed motor vehicle accidents. If the axonal injuries are nonhemorrhagic, they will likely not be seen on CT. Because CT often misses these injuries, follow-up MRI in patients with DAI may demonstrate bright T2 foci at the gray-white interfaces or even delayed petechial hemorrhages (23). MRI is much more sensitive in the detection of diffuse axonal injuries than is CT (Figure 11-5). Many of these injuries likely go undetected on any imaging modality. Gradient echo MR sequences are sensitive for subtle blood products by taking advantage of the blooming, or magnetic susceptibility artifact that iron containing compounds produce, as previously discussed. Gradient Recalled Echo (GRE) and fluid-attenuated inversion recovery (FLAIR) MRI sequences are very sensitive for the subtle findings seen in patients with petechial hemorrhage and diffuse axonal injury (29).

As mentioned earlier, CT markedly underestimates the extent of these injuries. The CT appearance may be normal or near normal. Patients who have sustained diffuse axonal injury have a worse long-term prognosis than those patients with gray matter contusions, thus it is helpful to employ MRI for diagnosis in these situations. Contusions often occur due to direct impact injuries that occur in focal locations. Shearing injuries and DAI, on the other hand, occur from global rotational forces imparted to the brain. These types of forces result in more extensive and generalized injuries to the brain. MRI is also useful for imaging the long-term sequelae of patients with

**FIGURE 11-5**

DAI: Axial FLAIR MRI (a) demonstrates foci of increased signal intensity within the deep bifrontal and left parietal white matter (arrows). Axial gradient echo (b) demonstrates a focus of magnetic susceptibility in the left frontal white matter (arrowhead). These foci are typical of petechial hemorrhages seen in DAI

global brain injury. The long-term sequelae of DAI will be discussed in more detail at the end of the chapter.

### Intra-axial: Herniation Syndromes

Severe intracranial injuries such as large hematomas or brain swelling, exert mass effect on the pliable brain within the closed-box of the adult cranium. The production of CSF and cerebral blood flow vary inversely with increasing intracranial pressure. Intracranial pressure will change if there are additions or subtractions to the fixed intracranial contents (brain, CSF, blood). This is called the Monro–Kellie Doctrine (14). Mechanical displacement of the brain, if severe enough, may lead to herniation syndromes. These include subfalcine, transtentorial, tonsillar, transsphenoidal, or external herniation.

Subfalcine herniation consists of midline shift of the cingulate gyrus under the midline dural reflection of the falx cerebri. This results in effacement of the ipsilateral lateral ventricle and noncommunicating hydrocephalus of the contralateral lateral ventricle (23). Dilation of the contralateral ventricle in subfalcine herniation occurs because of obstruction at the level of the foramen of Monro. If severe enough, cerebral infarction in the anterior cerebral artery distribution may occur because of compression of the vessels under the falx cerebri. Subfalcine herniation is the most common herniation syndrome (30).

If the uncus portion of the temporal lobe herniates across the tentorium (Figure 11-6), the midbrain is compressed, leading to injury of the contralateral cerebral peduncle (Kernohan's notch) or ischemia/infarction in the posterior cerebral artery distribution. Uncal herniation may also cause an ipsilateral cranial nerve III (oculomotor nerve) palsy. Uncal herniation may manifest clinically as ipsilateral dilated pupil and an ipsilateral hemiparesis, the latter due to compression of the contralateral cerebral peduncle.

Transtentorial herniation occurs in a cranial or caudal direction across the tentorium, that separates the posterior fossa contents from the supratentorial compartment. Descending herniation through the tentorium appears on CT as effacement of the suprasellar and perimesencephalic cisterns. Transtentorial herniation may lead to disruption of brainstem perforating vessels, causing petechial hemorrhages in the midline brainstem, Duret hemorrhages. If the cerebellum herniates upward through the tentorium, the basilar cisterns are effaced. This typically occurs due to a posterior fossa hemorrhage or mass.

Cerebellar tonsillar herniation occurs when the inferior portion of the cerebellum herniates downward through the foramen magnum. Tonsillar herniation may cause infarction in the posterior inferior cerebellar artery territory (PICA). Cerebellar tonsillar herniation occurs due to a posterior fossa mass, hemorrhage or swelling. This is important to distinguish from nontraumatic

FIGURE 11-6

Uncal herniation: Axial noncontrast CT demonstrates a left-temporal subdural hematoma (arrow) associated with uncal herniation and compression of the midbrain (arrowhead). There is also contra-lateral dilatation of the temporal horn

cerebellar tonsillar herniation of greater than 5 mm through the foramen magnum—Chiari I malformation. Some of these patients with this congenital malformation are subject to trauma; however the herniation in these cases is not due to the trauma itself.

Transsphenoidal herniation occurs when the frontal or temporal lobes are displaced posteriorly or anteriorly across the greater wing of the sphenoid bone respectively. External herniation occurs when brain contents herniate through a bony defect—either fracture or surgical defect, outside of the calvarium. Any of the aforementioned herniation syndromes may occur due to mass effect from trauma, hemorrhage or neoplasm (12, 23). In some patients with severe mass effect, a combination of different herniation syndromes may result (Figure 11-7).

### Intra-axial: Cerebral Edema

The term *cerebral edema* is often misused or misunderstood. Global cell injury or cell swelling has been called cerebral edema in the past. Multiple injuries to the brain or anoxic insult may present as diffuse abnormality, or brain swelling. Brain swelling occurs because of increased cerebral blood volume, loss of autoregulation of cerebral blood flow, or a generalized increase in tissue fluid. This manifests clinically as elevated intracranial pressure. Radiologically, brain swelling manifests as diffuse effacement of

**FIGURE 11-7**

Herniation: Axial noncontrast CT demonstrates a right fronto-temporal subdural hematoma and right frontal hemorrhagic contusion associated with both subfalcine (arrow) and uncal herniation (arrowhead)

sulci, ventricles and cisterns. The normal appearing gray/white matter interface is also lost and the brain appears somewhat featureless throughout (Figure 11-8). As mentioned earlier, severe brain swelling may lead to herniation syndromes in the craniocaudal axis—transtentorial, or inferiorly through the foramen magnum.

The prior confusion of the term “cerebral edema” stems from the fact that there are many different types of edema that have specific pathophysiology. Cytotoxic edema occurs when there is cell injury, ischemia or death. Ion gradients that maintain cell homeostasis are lost, due to inactivation of the sodium/potassium ATP-ase. When ion gradients cannot be maintained, the cells eventually swell with fluid. An increase in water within the cell results in cytotoxic edema. This may be seen on CT as areas of subtle low density or loss of the normal gray/white interface—usually in a focal area or vascular territory. The visual density of gray and white matter on CT is abnormally uniform. Diffusion-weighted MRI (DWI) is very sensitive for areas of cytotoxic edema. Cytotoxic edema manifests as high signal on DWI sequences, or restricted diffusion (31). DWI has gained widespread use in the work-up of acute stroke, among other abnormalities that demonstrate restricted diffusion. An emerging role for DWI in predicting outcome of patients presenting with traumatic brain injury will be discussed later.

Vasogenic edema occurs when there is an increase in extracellular free water. This often occurs around masses, abscesses or hemorrhages. It manifests on CT and routine

**FIGURE 11-8**

Brain Swelling: Axial noncontrast CT [(a) and (b)] demonstrate a left fronto-parietal subdural hematoma (arrow) and diffuse effacement of sulci and decreased gray/white matter differentiation. These findings are consistent with brain swelling

MRI sequences as fingerlike areas of hypodensity extending from the mass/hemorrhage into the adjacent white matter. Because vasogenic edema is free extracellular water, there is no restricted diffusion on diffusion-weighted MRI sequences. The diffusion MRI sequence and apparent diffusion coefficient (ADC) map, a calculated parameter, can distinguish between cytotoxic edema (irreversible) and vasogenic edema (reversible). Cytotoxic edema is high in signal intensity on DWI and low in signal intensity on the ADC map, while free water or vasogenic edema is low in signal intensity on DWI. DWI has properties that reflect relative  $T_2$  weighting. Thus, anything that is bright on  $T_2$  or FLAIR sequences, may be bright on DWI. This is termed  $T_2$  shine-through. The ADC map image is devoid of  $T_2$  weighting, and should always be checked in the setting of bright foci on DWI, to confirm that restricted diffusion of water is actually present.

Interstitial edema is seen in the setting of hydrocephalus and increased intracranial pressure. There is transependymal resorption of CSF from the dilated ventricles into the periventricular regions. There is also an increase in extracellular free water. On imaging, interstitial edema appears as hypodensity in the periventricular locations.

### Extra-axial: Subdural Collections

Our discussion of the pathophysiology and imaging appearances of brain injury will now turn to the extra-axial space. As discussed earlier, the dura is a layer of tissue intimately applied to the inner table of the skull and periosteum. The arachnoid is a network of tissue between the outer dura and inner pia—which lines the cortex of the brain. A fundamental understanding of the dural vascular anatomy, including the middle meningeal artery and dural venous sinuses allows one to predict the etiology of an extra-axial hematoma (32). The subdural space is a potential space that becomes evident radiologically if there is fluid, hemorrhage or purulent material between the dura and arachnoid. Subdural collections are confined to the dural reflections and will not cross midline, although they may cross sutures. These boundaries are helpful if the collection is small and indeterminate. The midline dural reflection is the falx cerebri. Separating the cerebrum and cerebellum is the falx cerebelli. Subdural collections near the midline or cerebellum, may layer on these dural reflections. Sometimes it is difficult to characterize a collection as subdural or epidural in location. Furthermore, it may be difficult to characterize a hematoma as above or below the falx cerebri. In these instances, the indeterminate collections should be referred to as simply extra-axial.

A subdural hematoma is an extra-axial collection of blood that may occur if there is traumatic injury to the

FIGURE 11-9

SDH: Axial noncontrast CT demonstrates an acute left frontoparietal subdural hematoma with mass effect on the underlying cortex

bridging veins beneath the dura (Figure 11-9). These bridging veins travel within the subdural space, toward the main dural sinuses. Acceleration and deceleration forces may lead to tearing of the bridging veins and subsequently, a subdural hematoma. Arterial injury may rarely cause a subdural hematoma. Following vessel injury, blood collects between the dura and arachnoid. An acute subdural hematoma appears hyperdense (bright) on a noncontrast CT of the brain. It is often crescent-shaped and conforms to the inner table of the skull on axial images. Unlike the epidural space that is confined and may exert a tamponade effect to limit the size of the hematoma, subdural hematomas may become large because of the relatively unconfined nature of the subdural space, subarachnoid space and underlying brain. Because subdural hematomas may cross sutures, they are often seen layering along an entire hemisphere. If large enough, these hematomas will exert mass effect on the underlying brain, causing effacement of sulci, ventricles or even midline shift. Severe midline shift may progress to subfalcine herniation as described previously.

The natural evolution of a subdural hematoma may be followed with serial CT scans. The hematoma will become isodense (similar density) when compared to brain, making it difficult to detect between 5–20 days after injury (Figure 11-10). This decrease in density of a subdural hematoma is due to breakdown of hemoglobin and protein products within the collection. These subacute collections are subtle on imaging and secondary signs such as mass effect and sulcal effacement must be searched for in order to diagnose them. Eventually these

FIGURE 11-10

Subacute SDH: Axial noncontrast CT (10a) demonstrates subtle effacement of sulci on the left convexity (arrowhead). An image more superior (10b) shows the isodense left fronto-parietal SDH (arrows)

collections will become chronic and appear hypodense (dark) compared to underlying brain more than 3 weeks after injury (6, 18). Occasionally, a subacute or chronic subdural hematoma will rebleed, causing a heterogeneous appearance to the collection, with mixed areas of hyper and hypodensity. These collections composed of acute hemorrhage superimposed on chronic blood products appear as a blood-fluid levels in the supine patient. The blood-fluid level is due to differences in density of the blood, or the hematocrit effect. This leads to an appearance of acute, bright blood inferior to the more chronic, serous collection layering dependently.

The mortality rate from traumatic subdural hematomas may be lowered from 90 percent to 30 percent if diagnosis and treatment occur in a timely fashion, usually within the first 4 hr (33). The timing of surgical intervention depends on many factors such as co-existing injuries and the neurological status of the patient. Patients who receive early surgical evacuation of a symptomatic SDH have an improved neurological outcome with relief from increasing intracranial pressure (34).

Subdural hygromas are collections within the subdural space that are hypodense, much like chronic subdural hematomas. They are collections of cerebrospinal fluid (CSF) that result from traumatic leakage from the surface of the brain after injury to the arachnoid membrane (18). It may be difficult to distinguish a chronic subdural hematoma from a subdural hygroma or an expanded extra-axial space. This issue often arises when imaging elderly patients, who have some degree of atrophy and

expansion of the extra-axial spaces. MRI is helpful in these cases, for subdural hygromas and expanded extra-axial spaces will have identical signal characteristics with the CSF in the ventricles and cisterns on all MRI pulse sequences. Subdural hematomas, even if chronic will typically differ from CSF on one or more pulse sequences.

#### Extra-axial: Epidural Collections

The epidural space is another potential space that exists between the inner table of the skull and the closely adherent dura. Collections in the epidural space may dissect between these tissue layers to create an extra-axial epidural collection. Because of the firm attachment of the dura to the inner table of the skull, epidural hematomas tend to be smaller and more confined than the larger, subdural hematomas. Acute epidural hematomas result from injury to the middle meningeal artery or its branches due to fractures of the squamosal portion of the temporal bone (35). Occasionally, acute epidural hematomas contain air within them. These air containing epidural hematomas are associated with fractures that communicate with the sinuses or extra-cranially (36). Ninety-five percent of epidural hematomas are associated with skull fractures and are supratentorial, typically unilateral (1). Injuries of the dural venous sinuses may also lead to epidural hematomas (1). Injuries at the vertex of the skull may lead to disruption of the superior sagittal sinus, creating an epidural hematoma that crosses the midline. The collections typically appear biconvex, much like a lens,

between the brain and skull on axial CT images. Unlike subdural hematomas, epidural hematomas can cross the midline. However, these collections are outside of the dura and cannot cross suture lines, for the dura is firmly attached to the skull at the sutures. If an acute epidural hematoma presents infratentorially, it is usually associated with trauma to the posterior fossa or fracture of the occipital bone (37, 38). An extra-axial hematoma in the posterior fossa is usually epidural in nature and typically unilateral (39). Rarely, acute epidural hematomas may be bilateral in approximately 5 percent of patients (Figure 11-11). When these collections are bilateral, they are often bifrontal in location (40).

Approximately one-third of patients with epidural hematomas are lucid clinically prior to neurological deterioration (35). Like all other forms of acute hemorrhage on CT, acute epidural hematomas are hyperdense (bright) compared to brain. These hematomas evolve to become isodense, then hypodense (dark) compared to brain over several days to weeks. Like any extra-axial collection, epidural hematomas will exert mass effect on the underlying brain and result in effacement of sulci and ventricles. When severe, these collections present with midline shift and herniation. In contrast to a peripherally located hemorrhagic contusion, epidural hematomas will typically form obtuse angles with the underlying brain, revealing their extra-axial location.

The mortality rate is lower for epidural hematomas (10 percent) when compared to subdural hematomas. The reported mortality rate is variable and ranges from

20 to 90 percent (1, 35, 41). Because of firm dural attachments, there is usually a tamponade effect for epidural hematomas, while subdural hematomas are less confined and may be larger or appear in a delayed fashion as discussed above. Most epidural hematomas are acute and are detected during the initial imaging work-up. Occasionally a patient may present subacutely with a delayed epidural hematoma. About 6–13 percent of epidural hematomas are delayed in presentation while some authors have reported this as high as 30 percent (42).

### Extra-axial: Subarachnoid Hemorrhage

The subarachnoid space is the CSF containing space between the arachnoid membrane and the pia that covers the brain. CSF originates in the choroids plexus and flows from the ventricular system to the basilar cisterns, then finally to the surface of the brain. CSF is then absorbed by the small arachnoid granulations within the dural venous sinuses. CSF bathes the brain surface and extends into the sulci.

Subarachnoid hemorrhage (SAH) most commonly (90 percent) occurs secondary to a ruptured aneurysm involving the Circle of Willis. Usually subarachnoid hemorrhage secondary to a ruptured aneurysm is larger than bleeding caused by trauma. The locations are different as well. A ruptured aneurysm typically has most of the blood near the site of rupture. For example, if the aneurysm is located in the Circle of Willis, the basal cisterns usually fill with blood. Traumatic subarachnoid hemorrhage is

(a)

(b)

FIGURE 11-11

Acute EDH: Axial noncontrast CT (11a) demonstrates bilateral, biconvex epidural hematomas (arrows). An image more superior (11b) shows a large right-sided EDH with mixed, swirling density suggesting active bleeding

FIGURE 11-12

SAH: Axial noncontrast CT images [(a) & (b)] demonstrate traumatic subarachnoid hemorrhage filling right-sided sulci (arrows). Also note the right scalp soft tissue swelling (arrowhead)

much more variable in location. SAH presents on CT as hyperdense blood within the sulci (Figure 11-12) or basal cisterns. CT is very sensitive for the detection of acute SAH (18). MRI is less sensitive for the detection of acute SAH, however is very good for imaging chronic blood products or hemosiderin.

Besides a ruptured aneurysm or trauma, other causes of subarachnoid hemorrhage include arteriovenous malformations and coagulopathies (23). There are also many complications that may occur with SAH and follow-up imaging is recommended. These include vasospasm, stroke, communicating hydrocephalus, and arachnoiditis. MRI imaging in patients with SAH may show blood products in varying stages within the sulci or cisterns. Fluid attenuated inversion recovery (FLAIR) sequences employ a longer T1 and a 180-degree inversion pulse to reduce the signal level of CSF and detect abnormalities in the sulci such as SAH with a greater degree of certainty (5). As described earlier, chronic SAH may present on gradient echo or magnetic susceptibility sequences as leptomeningeal hemosiderosis—hypointense (dark) meninges on  $T_2$ -weighting (23).

#### Extra-axial: Intraventricular Hemorrhage

The intraventricular space is a CSF-containing space within the paired lateral, third and fourth ventricles. Intraventricular hemorrhage (IVH) may occur within any ventricle; however, often occurs in the lateral ventricles after trauma. It may be a primary event or secondary event such as extension from a parenchymal contusion or

existing SAH. Primary IVH in the trauma patient is due to injury of the subependymal veins surrounding the ventricles. As described for mixed subdural hematomas with blood–blood levels, the acute intraventricular hematoma will layer in the dependent portions of the ventricle in a supine patient. If the hemorrhage is within the lateral ventricle, the blood is often seen in the occipital horns posteriorly. It has been reported to occur in 35 percent of patients with moderate to severe brain injury (1, 35). IVH may lead to a non-communicating hydrocephalus (described below) due to obstruction of CSF flow at the level of the foramina of Monro or the cerebral aqueduct (Figure 11-13).

#### Extra-axial: Hydrocephalus

Hydrocephalus is dilatation of the ventricles that contain cerebrospinal fluid (CSF). It involves an increase in the volume of CSF within the subarachnoid space, ventricles and cisterns (14). Ventriculomegaly is a generic radiological term meaning enlargement of the ventricles, while hydrocephalus implies a pathologic state that may lead to elevated intracranial pressure. Cerebral atrophy or old age may cause ventriculomegaly secondarily. The CSF-spaces dilate to compensate for the loss in brain parenchyma over time. Patients over the age of 65 usually have some degree of brain volume loss, or atrophy. The enlargement of the ventricles in this case is termed hydrocephalus ex vacuo. The ventricles, sulci and cisterns appear larger radiologically because of underlying brain parenchymal loss. Hydrocephalus ex vacuo occurs

**FIGURE 11-13**

IVH: Axial noncontrast CT demonstrates intraventricular hemorrhage filling the third and lateral ventricles (arrows). There is also hydrocephalus present

physiologically and does not result in elevated intracranial pressure.

There are two types of pathological hydrocephalus: communicating hydrocephalus and noncommunicating hydrocephalus. In these conditions, there is an increase in CSF volume without brain atrophy. Communicating hydrocephalus is a global dilatation of all of the ventricles, while the connections between the ventricles remain patent. Typically, there is disruption of CSF reabsorption at the level of the arachnoid granulations of the dural venous sinuses. Conditions that cause communicating hydrocephalus include subarachnoid hemorrhage, meningitis and meningeal carcinomatosis (23). Communicating hydrocephalus can be differentiated from hydrocephalus ex vacuo by signs of elevated intracranial pressure and radiologically by dilated ventricles in the setting of cisternal and sulcal effacement.

Increased production of CSF may also cause communicating hydrocephalus, as in normal pressure hydrocephalus (NPH) and tumors of the choroid plexus. Prior to sampling CSF, clinicians often obtain an imaging study, usually a noncontrast CT of the brain to evaluate for hydrocephalus or mass effect. If too much CSF is removed in the acute setting, intracranial hypotension or herniation syndromes may develop (43–45).

Noncommunicating hydrocephalus is a condition in which there is obstruction of the ventricular system

somewhere between the lateral ventricles and the fourth ventricle. Congenital causes such as cerebral aqueductal stenosis may result in dilated lateral and third ventricles. Intraventricular hemorrhage, meningitis and infection may also result in obstruction of the ventricles. Obstruction may also occur at the level of the foramina of Monro leading from the paired lateral ventricles to the midline third ventricle. Thus, non-communicating hydrocephalus would be expected to cause asymmetric dilatation of the ventricles, while communicating hydrocephalus causes diffuse dilatation of the ventricular system on MRI and CT.

### IMAGING: PREDICTING OUTCOME

As mentioned at the beginning of this chapter, it is important to understand the pathological conditions that occur within the skull and brain and the appearances of these injuries on CT and MRI. As the technology improves, the lexicon used for discussing imaging findings may change, however the pathology will not change. It is important to realize the limitations of CT and MRI and many injuries are currently beyond the resolution of any imaging modality. To review, CT is the initial imaging modality of choice in traumatic brain injury. The routine emergency non-contrast CT of the brain allows clinicians to rapidly decide if an injury requires emergent surgery, delayed surgery or only medical therapy.

CT also provides indirect signs of increased intracranial pressure through compression of brain stem cisterns, compression of the ventricles, midline shifts, and loss of gray-white matter differentiation (46). Because CT can be performed so quickly, there is less opportunity for motion artifacts that can ruin a study. In addition, there are essentially no contraindications other than an unstable patient, and CT can also be performed in patients with extensive life-support hardware.

After the initial work-up and management of neurologically traumatized patients occurs in the emergency room or intensive care unit settings, decisions must be made that concern the post-acute management of these patients. extra-axial collections, large contusions, midline shift and herniation syndromes are readily diagnosed with routine CT, and will allow the emergency room physician to appropriately triage these patients to surgery. As described previously, diffuse axonal injury (DAI) is often a neurologically devastating injury that may be missed in CT imaging. A normal CT scan in a patient that is comatose after sustaining traumatic brain injury is a classic finding. This is one of the reasons why clinical presentation and imaging are complementary and must be correlated with each another.

In a series of 448 patients with a GCS below 8, 70 patients had a normal CT scan on the day of admission and 47 of these remained normal with serial scanning.

This number represented 25 percent of those with DAI. Although 76 percent of those with normal scans made a good recovery, 19 percent had coma persisting longer than 2 weeks with subsequent severe disability. Brain atrophy at 6 months was a common result, despite the initial normal CT scan, implying diffuse injury. Delayed lesions (usually contusions) occurred in 24 patients, of which 9 had no clinical deterioration. Therefore, although a normal CT scan may be obtained initially in a patient with severe traumatic brain injury, abnormalities on serial imaging may evolve even in the absence of clinical deterioration. Likewise, abnormalities on CT imaging may appear in patients with very mild head injuries with few if any clinical findings (46).

To date, there is no agreed upon classification system for patients with head injury, the severity of clinical presentation, and the findings on imaging. Several different schemes, however, have been evaluated. One such classification is the National Traumatic Coma Data Bank (TCDB). This classification scheme is based on a multicenter study of patients with severe, blunt, traumatic head injuries. Clinically, all of these patients had a Glasgow Coma Scale of less than 8. The TCDB in these patients focused on the imaging findings of basal cistern effacement and midline shift, with the operative findings to predict mortality (47). Caroli et al identified several clinical and radiologic predictors of prognosis in patients with multiple post-traumatic intracranial lesions. The type of lesion—such as subdural hematoma or intracerebral hematoma, the Glasgow Coma Scale (GCS), the presence of prolonged increased intracranial pressure, and the absence of pupillary reflexes were found to all be statistically significant predictors of a poor outcome. Poor outcome in these patients was defined as death or a persistent vegetative state. The authors concluded that multiple lesions have the same prognosis as the corresponding single lesions and that management should be guided by the predominant pathology (48).

Toutant et al. noted that assessment of the basal cisterns can be used as an early noninvasive method to assist in determining prognosis. Compression of the basal cisterns in patients with traumatic brain injury was associated with a high mortality rate in both surgical and nonsurgical patients. One-hundred percent of the deceased patients had cistern compression. The mortality rates were 77 percent, 39 percent, and 22 percent among patients with absent, compressed, and normal basal cisterns, respectively (49). Lannoo et al. studied patients with severe brain injury and the resulting mortality and morbidity in relation to age, and early (< 24 hr) clinical data and the imaging findings after CT. Patients with traumatic injuries to parts of the body other than the brain were used as controls. Of the group with traumatic brain injury, the mortality rate was 51 percent. Analyses combined 13 predictors into a model with an accuracy

of 93 percent, a sensitivity of 90 percent, and a specificity of 95 percent. These 13 predictors included the following: 1, age; 2, GCS score; 3, pupillary reactivity; 4, blood pressure; 5, ICP; 6, blood glucose; 7, platelet count; 8, body temperature; 9, cerebral lactate; and 10, subdural; 11, intracranial; 12, subarachnoid; and 13, ventricular hemorrhage. Further analysis resulted in the GCS score being the best predictor of neuropsychological functioning, and pupillary reactivity being the most predictive for self-reported quality of life. Those factors important for predicting mortality such as elevated intracranial pressure and the CT observations failed to show any significant relationship with morbidity (50).

The anatomical location and mechanism of injury to the brain are crucial factors in determining future neurological functioning of patients. CT is the imaging study of choice in patients presenting acutely with penetrating injuries to the brain. Gonul et al. studied 35 patients presenting with penetrating orbitocranial gunshot injuries. This group found that anatomical location of injury, extent of injury and GCS score at presentation were the most important predictors of neurologic recovery following penetrating orbitocranial injuries (51). The anatomical location of an injury as determined by imaging also has implications on patient outcome. Blackman et al. evaluated the anatomical location of injuries involving 92 patients presenting with acute traumatic brain injury. They defined several levels of injury progressing from the cortex of the brain to the brainstem, a depth of injury level. Images were classified according to five depth of lesion levels (cortical to brainstem). Functional outcomes in mobility, self-care, and cognition were evaluated in conjunction with the depth of lesion encountered on imaging. Patients with deeper (brainstem) lesions tended to have longer lengths of stay in rehabilitation, however were able to eventually become equal with patients who had more superficial lesions. The authors suggested that one may not be able to predict outcome in the early acute phase in the intensive care unit on the basis of standard brain imaging alone. Patients with deeper lesions tended to enter rehabilitation at a more impaired level, although may eventually reach a level of functioning equal to peers with more superficial brain injuries. They also suggest that it may take a longer period of time to reach this level of functioning than for less severely injured individuals (52).

While many studies have evaluated the Glasgow Coma Scale or compared a different scale to the GCS, some authors have suggested that the 15-point GCS may not add any additional prognostic value over more simplified triage scales. Gill et al. evaluated the performance of GCS scores in a level 1 trauma center from 1990 to 2002, relative to four clinically relevant traumatic brain injury outcomes (emergency intubation, neurosurgical intervention, brain injury, and mortality). They evaluated

a simplified 3-point scoring system (simplified verbal score: oriented = 2, confused conversation = 1, inappropriate words or less = 0; simplified motor score: obeys commands = 2, localizes pain = 1, withdrawal to pain or less = 0) with the total GCS and found that the simplified scoring system correlated well with the GCS for predicting outcome. This study suggests that the 15-point GCS may be needlessly complex for predicting neurological outcome (53).

While CT is most important in the acute triage of patients with traumatic brain injury, MRI is more helpful in evaluating the long-term sequelae of these patients. The value of MRI in predicting outcome of rehabilitation in patients with head injury appears promising in view of the relationship between MRI abnormalities and neuropsychological deficits (54). Post-traumatic seizures (PTS) and post-traumatic epilepsy (PTE) are well-documented sequelae of traumatic brain injury. Patients who have depressed skull fractures, acute intracranial hematomas, or seizures during the first week post-injury have an increased risk of developing PTE. Factors found to influence the likelihood of seizures include severe head injury (GCS 3 to 8), diffuse cerebral edema, acute SDH and depressed skull fractures (55). Information obtained through static neuroimaging techniques, and particularly MRI may help identify patients at increased risk for PTS or PTE (56, 57).

Mazzini et al. detected the risk factors for PTE in rehabilitation patients and found that the occurrence of PTE was significantly correlated with hypoperfusion in the temporal lobes, the degree of hydrocephalus, the evidence of intracerebral hematoma, and operative brain injury. Hypoperfusion in the temporal lobes was determined with single photon emission computed Tomography (SPECT), while hydrocephalus was diagnosed with MRI. This study sought to define the influence of PTE on late clinical and functional outcome. Findings revealed that the psychometric tests intended to explore memory, language, intelligence, attention, and spatial cognition did not show any significant difference between patients with and without epilepsy. PTE also was significantly correlated with a worse functional outcome 1 year after the trauma (58).

Pohlmann et al. identified clinical and neuroradiological variables in severe brain injury with predictive value for PTE and evaluated the influence of each risk factor for epilepsy. The authors found that of all patients with PTE in the study, 68.5 percent had their first seizure within two years after the trauma. Significant risk factors for PTE were focal signs in the first examination, missile injuries, frontal lesions, intracerebral hemorrhage, diffuse contusion, prolonged posttraumatic amnesia, depression fracture and cortical-subcortical lesions. The combination of the last three variables conferred a particularly high risk for PTE.

The authors concluded that the risk for PTE is clearly determined by variables that correlate with the severity, the extent of tissue loss and the penetrating nature of the brain injury. Combined seizure pattern, high seizure frequency, anti-epileptic drug noncompliance and alcohol abuse predicted poor seizure control (59).

While the use of MRI is well established in evaluating patients that present with PTE, some researchers have also studied the role of diffusion weighted MRI (DWI) in traumatic brain injury. As discussed earlier with cerebral edema, diffusion-weighted MRI (DWI) is very sensitive for areas of cytotoxic edema. Diffusion MRI is a sequence that has become very important in the imaging of acute and subacute stroke. It allows one to distinguish between cytotoxic edema that is present in cerebral infarction from vasogenic edema. In addition, the diffusion MRI helps to define at risk tissue and often is positive before the patient has CT findings to indicate a stroke. Schaefer et al. evaluated 26 patients presenting with diffuse axonal injury using diffusion weighted MRI. They found that the volume of lesions on diffusion-weighted MRI provides the strongest correlation with a score of subacute on modified Rankin scale at discharge (60). Goetz et al. evaluated 23 patients with traumatic brain injury using diffusion weighted MRI and specifically studied the role of the apparent diffusion coefficient (ADC). The ADC is a parameter used in diffusion MRI to distinguish between true diffusion restriction suggesting cytotoxic edema vs. "T2 shine-through," or anything that may have increased signal on T2 weighted sequences. These researchers found reported a correlation between injury severity and increasing ADC ( $p = 0.03$ ) but no correlation with either T1 or T2 weighted MRI, suggesting that the ADC used in diffusion MRI is a sensitive and independent marker of diffuse white matter tissue damage following traumatic insult (61).

Many of the studies discussing the use of MRI, and particularly diffusion MRI (DWI) have focused on subacute or chronic traumatic brain injuries. Some authors have also explored the use of MRI in the acute setting. Maeda et al. evaluated 10 patients with diffusion-weighted MRI, presenting in the acute setting with traumatic brain injury. Their study attempted to define the time frame for development of cerebral edema following acute brain injury. Within 3 hr post-trauma, diffusion MRI showed no remarkable pathology. Furthermore, the ADC values at 3 hr post injury were within the normal range (contused/normal brain =  $1.00 \pm 0.21$ ). At 6 hr post-injury, diffusion-weighted MRI demonstrated a low signal intensity core in the contusion and a high signal intensity rim in the peripheral area of contusion. The ADC value at 6 hr increased in the contusion proper (contused/normal brain =  $1.26 \pm 0.13$ ) and decreased in the peripheral area (contused/normal brain =  $0.58 \pm 0.19$ ). These findings indicated that early cellular swelling in the

peripheral area of contusion begins within 6 hr following injury. The authors also propose that the delayed occurrence of contusion-induced cellular swelling suggests that the cerebral blood flow does not decrease to ischemic levels immediately following injury (62).

Static imaging techniques may also be used to follow patients with brain injury for potential delayed complications. As discussed earlier, hemorrhagic or non-hemorrhagic contusions may occur in the brain due to blunt forces. The frontal and temporal lobes are particularly vulnerable to contusions secondary to the underlying bony ridges. Delayed bleeding may occur into these regions of perfused yet injured brain. These delayed complications may lead to neurological deterioration from edema, increasing mass effect, and herniation. Delayed hemorrhages into the orbital-frontal regions may also lead to neurological deterioration due to elevated intracranial pressure. Early diagnosis and aggressive therapy in these patients could potentially improve outcome (63). Several authors have examined the sequelae of delayed intra-cerebral hemorrhage and the role that static imaging plays (64, 65). Delayed intra-cerebral hemorrhage often occurs between 3 hr and 10 days after the inciting traumatic insult, particularly within the first 3 days. Thus, if these potential lesions are deemed clinically significant, static imaging performed within this time interval is likely to detect these delayed complications. There have been case reports of patients presenting with delayed hemorrhages as long as 168 days post-trauma (66). These occurrences are the exceptions rather than the rule. These delayed lesions may present with non-focal symptoms such as headache or vomiting. Thus, delayed intracerebral hemorrhage may be considered in the differential diagnosis in these patients if there has been a recent history of trauma.

## CONCLUSION

This chapter has focused on the predominant static imaging modalities used in the evaluation of traumatic injury of the brain. In addition, the dominant injuries seen in clinical practice have been described, and their appearances on imaging have been reviewed. These injuries and their sequelae have been discussed in terms of clinical outcome.

In summary, imaging technology is rapidly progressing. There are advances being made daily in the fields of imaging physics, computers, computed tomography, and magnetic resonance imaging. These modalities become the tools that may be used by imagers and clinicians to evaluate, diagnose and treat traumatic injuries of the brain. What does not change, however, is the pathophysiology of brain injury. Thus, it is of paramount importance to learn the mechanisms, anatomy, physiology, and evolution of the different manifestations of traumatic brain injury.

## Functional Neuroimaging of TBI

*Joseph H. Ricker*  
*Patricia M. Arenth*

### INTRODUCTION

New technologies, as well as advances in existing technologies, have changed how both healthy and injured brains are evaluated in research and clinical settings. In combination with traditional neuromedical examination and psychometric testing, functional neuroimaging is providing a means through which additional information about brain structure, function, and recovery may be obtained. Enthusiasm for functional neuroimaging can be readily appreciated, yet it must be balanced by the need for empirical evidence and a healthy level of caution.

Increasingly, clinicians are using advanced imaging techniques (e.g., SPECT, PET, fMRI) with persons having traumatic brain injury (TBI), however, clinical application of most of these techniques still remains investigational, within the context of this population (1). The present chapter provides an overview of several functional neuroimaging procedures and their applications in the context of TBI. This chapter will also address many limitations of these procedures, with implications for exercising caution if they are utilized in clinical evaluation.

### RESTING AND ACTIVATED FUNCTIONAL NEUROIMAGING

In functional neuroimaging, one can dichotomize the available techniques into two broad categories: “resting”

or “activated” (2). Resting paradigms are those that acquire functional images during nonactivated (i.e., “static” or baseline) conditions. Resting studies, by design, have no explicit or systematic requirements of the participant other than those required to successfully acquire a technically valid image, such as having the participant lie still, minimizing head movement, and eliminating extraneous stimuli (3). Although participants do not overtly engage in any specific task, there is no systematic way to “control” random or volitional covert mental activity during the image acquisition. There have been several studies that have applied resting functional neuroimaging across multiple populations, most of which have examined chronic glucose uptake (with positron emission tomography, PET), and resting cerebral blood flow (using PET or single photon emission computed tomography, SPECT). These studies will be discussed later in context.

In contrast to resting paradigms, activation studies require participants to systematically receive sensory input (e.g., a visual array) or engage in an activity (e.g., motor or cognitive) in order to elicit changes in brain physiology that are correlated with a specific stimulus or event in time (4). These tasks are usually administered in adherence to a strict protocol, typically with some form of overt response required in order to provide an objective correlate of the participant’s active engagement in the task. Because of the physical properties of the dependent

**FIGURE 12-1**

An Example of O-15 PET Combined with an Activation Paradigm. The participant is being asked to recall a previously learned list of words while being scanned. Regions of increased blood flow (indicated by the arrows) within the frontal lobes are associated with increased cerebral activity known to mediate retrieval of newly learned information

variables examined (e.g., briefer half-lives of radioisotopes, or transient changes in hemodynamic response), activation studies have much briefer time sampling windows than resting studies. Some technologies are even able to image changes across time in a relatively continuous manner (e.g., magnetoencephalography and event-related functional MRI). Given this improved level of control, activation studies permit examiners to make more accurate inferences about the cerebral activity correlated with the motor or cognitive process in question. Figure 12-1 presents an example.

### **SINGLE PHOTON EMISSION COMPUTED TOMOGRAPHY (SPECT)**

SPECT is an approach to functional imaging that is based on the concept that regional changes in brain activity or chemistry can be measured indirectly via externally placed gamma radiation detectors (referred to as “cameras”), which detect the regional accumulations of tracer flow or receptor-binding isotopes. There is an emphasis on imaging changes in regional cerebral blood flow (rCBF), but relatively specific neuroreceptor imaging studies are also possible using SPECT (5).

The dependent variable in SPECT derives from the well-established principle of increased cerebral activity

correlating with increased blood flow. That is, when neural activity in a region of the brain increases, related energy requirements also increase. Because the blood supply carries glucose and oxygen to the brain, the flow of blood to the active area increases (6). The radioisotopes themselves are absorbed into glial cells that are proximal to the active neurons, but these isotopes are not immediately excreted. Thus, the absorbed radioisotopes remain in greater concentration in the more active areas. Through normal radioactive decay, the isotope emits annihilated radioactive particles (i.e., photons), which are then detected by the external cameras. Computer-based reconstruction permits external representations to be derived that correlate with differences in blood flow.

SPECT is more widely available than PET or FMRI. In addition, many of the radioisotopes that are typically used with SPECT can be ordered and delivered in advance, thus precluding the necessity of an on-site cyclotron and chemist, as required for PET. SPECT has application in examining resting blood flow, but has more limited utility in imaging a change in blood flow from one point in time to another. SPECT can be used to image change in resting blood flow from one well-defined event to another (e.g., from pre-ictal to ictal state), but it is not appropriate for use in mapping blood flow changes that change rapidly over time (such as those encountered in most states of cognitive activity), or for making direct inferences about brain metabolism (4) due to the time require for radioactive decay of the isotopes: The most commonly used radioactive isotopes for SPECT are absorbed by the brain within 2 min, but may have half-lives of several hours. The effect of this is that after the tracer has been administered, the resulting images that may be acquired can remain the same for the next several hours.

SPECT is not as diverse as other imaging techniques, such as PET, but novel ligands are under continuous development. The compound 123-I-para iodoamphetamine (IAMP) provides a unique look at immediate and delayed perfusion. Other compounds such as 99m-Technetium-HMPAO are also being used for the same purpose. Recent technologic advances have provided for multiple-headed scanners, which offers improved spatial resolution.

As with all assessment tools SPECT has several sources of potential measurement error. Unlike PET, SPECT imaging requires that regional counts be normalized to an area that is ostensibly free from injury. Thus, *relative* flow values in SPECT are often based upon a region such as the thalamus or cerebellum. While such assumptions might be valid for some populations with focal lesions (e.g., stroke), they might not be valid for populations whose neuropathology is more diffuse, such as occurs in TBI. In addition, SPECT resolution currently does not yet approach that of PET imaging. Color SPECT

imaging software can produce visually striking – but potentially misleading images, thus reliable and valid interpretation is best accomplished through quantitative pixel counts (7). It must also be noted that although SPECT *can* be used quantitatively, this is not the case in most clinical settings. Visual inspection of SPECT maps is a subjective, qualitative process, and interpretation may vary from clinician to clinician (8).

### SPECT STUDIES OF BRAIN INJURY

Resting brain SPECT studies of individuals acquired months (or sometimes years) after moderate and severe brain trauma have demonstrated decreased cerebral blood flow, primarily within prefrontal cortex (9–10). In most of these studies, decreased blood flow and metabolism were generally beyond what might be expected based solely on findings from structural scans (i.e., CT and MRI). The presence of decreased resting blood flow or metabolism is not, however, in and of itself evidence of compromised or nonfunctional brain tissue (11).

Numerous investigations have demonstrated that SPECT is superior to CT and structural MRI in the detection of the presence and extent of trauma-related lesions. SPECT has been applied to mild brain injury and has demonstrated regionally decreased blood flow in the presence of normal acute CT scans, but there is much variability across individuals (i.e., no pathognomonic profile emerges). Positive SPECT findings have also sometimes been demonstrated in cases of below average neuropsychological test scores in cases of mild brain trauma, but it should be noted that SPECT findings are usually not very predictive of neuropsychological test performance (12–13).

In spite of advances in technology and data analysis, the utility of SPECT in characterizing specific injury states or predicting outcome remains controversial. SPECT has been shown particular utility when correlating neuropsychological parameters with the effects of brain injury (14–15), but caution must be exercised given that SPECT findings are routinely positive in a variety of medical and neurological disorders (16–19), learning disabilities (20), as well as in substance use and emotional disorders (e.g., 21–30). Some investigators have noted that when used in a *prospective* design, a negative SPECT scan is a good predictor of a favorable outcome after brain injury, and that SPECT overall correlates well with the severity of the initial trauma (31). Still, there are relatively few well-controlled prospective studies of SPECT (and for that matter, PET and fMRI) being used in differential diagnosis, prognosis, and intervention (2, 32). The use of normative data (8), rather than subjective impressions of SPECT images, will greatly facilitate such developments.

SPECT has been shown to be of use in research studies following brain injury, but there is no particular SPECT profile that is solely pathognomonic for any level of traumatic brain injury (2, 33). The Therapeutics and Technology Subcommittee of the American Academy of Neurology (34) rated SPECT as an *investigational* procedure for the study of brain trauma. More recently, the American College of Radiology (ACR) (1) has rated SPECT as inappropriate (a rating of 2 on a scale of 1 to 9, with 1 indicating “least appropriate”) in clinically evaluating postconcussion symptoms. In spite of the absence of evidence supporting routine use of SPECT in brain injury, SPECT appears to be used frequently in clinical and forensic contexts as a means of supporting a diagnosis of brain injury. With increasing evidence and appropriately designed studies, however, and greater specificity of diagnostic criteria (particularly with mild head injury), SPECT is likely to be of improved clinical utility in the future (32, 35–36). For example,  $^{99m}\text{Tc}$  SPECT has been used recently to examine the therapeutic effects of hyperbaric oxygen on recovery after TBI (37). SPECT has also recently been found to be predictive of post-traumatic amnesia acutely after TBI (38) and useful in assessing the efficacy of intraventricular shunt placement after TBI (39).

### POSITRON EMISSION TOMOGRAPHY (PET)

Like SPECT, positron emission tomography (PET) is a radioisotope-based imaging technology. PET studies typically utilize intravenous tracers such as  $^{18}\text{F}$ -fluorodeoxyglucose (FDG) for the quantification of “resting” (i.e., nonactivated) regional brain metabolism (40). An exception is Xenon, which is an inhaled isotope. As they are catabolized, annihilation particles are emitted and are detected by an external scanner.

Resting blood flow changes (41) and dynamic changes associated with motor or cognitive activity (11) can be accomplished through the use of tracers such as oxygen-15 ( $\text{O-15}$ ) labeled water. Radiolabeled ligands that bind selectively within dopaminergic, serotonergic, and other endogenous neurochemical systems have been developed and are seen as having great potential for future research (36). Genetically mediated transporter markers (e.g., for dopamine transport) are also available (42).

PET has been widely used as a research tool since the 1970s, but requires a cyclotron to be present on site for most radioisotopes and remains a very expensive procedure. Thus, its application to persons with traumatic brain injury has been minimally investigated. PET has the capability of demonstrating specific biochemical or physiologic processes associated with cerebral blood flow and metabolism. As with SPECT, clinical data from PET

imaging are typically portrayed visually in the form of the spatial distribution of radioisotopes projected on to actual or standardized anatomic MRI templates.

### PET STUDIES OF BRAIN INJURY

Acute O-15 PET studies of human brain trauma have shown that significant changes in regional (but not necessarily global) hemodynamics occur, such as lower contusional and pericontusional blood flow and flow-to-volume ratios (43). There is also heterogeneity in regional glucose metabolism (44). In addition, cerebral hyperglycolysis is a pathophysiological response that occurs in response to injury-induced neurochemical cascades and can be demonstrated via FDG-PET (45–46).

Several studies have demonstrated PET's ability to detect brain abnormalities that are not visualized on CT or standard MRI sequences in cases of moderate and severe brain injury (2). In addition, functional imaging data exist to suggest that there can be regions of physiological dysfunction beyond the boundaries of static lesions (e.g., contusions) seen with structural imaging. This has been demonstrated for many years using both FDG-PET (47) and Cobalt-55 PET (48). Such changes are seen acutely and occur more in grey matter relative to white matter (49). Acute metabolic changes often begin to resolve within the first month following injury, regardless of injury severity, but the correlation between the extent of change in disability and the changes in brain metabolism are minimal (46).

Although PET would appear intuitively to lend itself well to the many clinical issues that emerge after brain trauma, there are surprisingly few studies that have actually attempted to directly relate functional imaging findings with cognition after TBI. In most of these studies, the findings from neuropsychological and other assessments have been obtained at points in time that were quite disparate from the time at which imaging occurred. For example, one frequently cited paper (50) described FDG-PET and neuropsychological test scores among a selected group of 9 individuals that had experienced mild head trauma. Their CT and MRI findings were negative, but PET imaging demonstrated a variety of regions of decreased FDG uptake, some (but not all) of which corresponded to decreased cognitive testing scores. Such findings have little generalizability, however, given that subjects were specifically selected for inclusion based upon their outcome criteria rather than criteria selected a priori. In addition, scanning and the neuropsychological evaluation were separated in time by an average of 11 months, thus essentially negating the reliability of any correlation between PET and cognitive findings.

In more carefully designed studies, it has been noted that localized abnormal cerebral metabolic rates in

frontal and temporal regions correlate with both subjective complaints and neuropsychological test results obtained during the chronic phase of recovery (51). In moderate and severe TBI, resting PET studies have demonstrated frontal hypometabolism, with related decreased performance on neuropsychological tests that are mediated by frontal lobe functioning (52). Recently, through the use of PET, an association between post-TBI anosmia and orbitofrontal hypometabolism has been demonstrated (53).

As described earlier in this chapter, activation studies are likely to be far more sensitive to the functional effects of brain injury or disease, as such paradigms introduce *in vivo* cognitive challenges (54). The first published PET study (55) to apply a cognitive activation paradigm with individuals that sustained brain injury demonstrated cerebral blood flow changes in the left prefrontal cortex among individuals with TBI during a free recall task when compared to controls, but blood flow increases were noted in more posterior brain regions in TBI subjects during both free and cued recall. The change in allocation of neural resources during tasks with greater cognitive load may suggest increased cognitive effort among individuals with TBI (and thus greater blood flow within prefrontal cortex during task performance). In addition, it was demonstrated that during recognition tasks, both the controls and the individuals with TBI performed at comparable behavioral levels (and within normal limits), yet the individuals with TBI still demonstrated increased change in regional cerebral blood flow relative to the controls. This suggests that after brain injury, individuals must exert more cognitive effort than controls to attain the same level of overt behavior. Subsequently, a different group of investigators also demonstrated comparable findings in a larger sample of individuals with TBI, again using O-15 PET and a verbal memory task (56).

### FUNCTIONAL MAGNETIC RESONANCE-BASED IMAGING (FMRI)

Techniques based on magnetic resonance imaging (MRI) capitalize on the presence of hydrogen in all of the body's tissues. When the nuclei of hydrogen atoms encounter a strong magnetic field, they align in parallel to that field's direction. In MRI, radiofrequency (RF) pulses are presented at an angle that is at 90° relative to the magnetic field. This causes roughly 1 percent of the hydrogen nuclei to realign and begin spinning in a different direction (a condition called "excitation"). When the RF pulse is then stopped, the nuclei return to their original alignment and spin (57). During the process of returning to previous resting status, an electrical signal is emitted from nuclei that is detectable by the scanner and allows reconstruction of static anatomic images.

Functional MRI (fMRI) is a variant of structural MRI. The primary difference, however, is that the dependent variable of interest in fMRI is the change in intensity of electrical signal emissions related to increases in blood flow (that are presumably caused by changes in neural activity). Thus, the focus of fMRI is on regional changes in brain activity rather than anatomic structure alone. As with O-15 PET, during fMRI specific stimuli or tasks are presented to the individual within the scanner in an attempt to elicit or increase brain activity. When neural activity increases in a brain region, there is a corresponding increase in blood flow to that region. In fact, this blood flow may increase by over 50 percent (58), beyond metabolic needs. This excess of flow to the region results in a localized surplus of oxyhemoglobin relative to deoxyhemoglobin in the cerebral venous and capillary beds. Oxyhemoglobin is naturally diamagnetic, while deoxyhemoglobin is paramagnetic (i.e., becomes readily magnetized within a magnetic field). With increased neural activity and concomitant increased blood flow, there is a net increase in diamagnetic material (oxyhemoglobin), and a net decrease in paramagnetic material (deoxyhemoglobin). This results in an increased signal intensity that can be detected externally, and is represented as higher signal intensity on T2\* (“T2-star”) weighted scans. This change in signal intensity is referred to as the blood oxygen level dependent—or “BOLD”—effect (59).

As compared with other neuroimaging techniques, fMRI utilizes the body’s natural physical responses to high-strength magnetism, thus no exogenous radioisotopes or contrast agents are required. Anatomic resolution of fMRI is also superior to that of SPECT or PET. In addition, there are numerous activation paradigms that can be carried out in fMRI, and it allows for greater flexibility in paradigm with reference to repeatability and brevity of the overall scanning session in comparison to other techniques (2).

As with any imaging procedure, however, fMRI can be impacted by numerous variables, particularly in clinical populations such as TBI. Consideration must be made for head movement, normal high frequency noise within the scanner, morphologic brain abnormalities (e.g., frontal or temporal lobe resection secondary to trauma), claustrophobia, anxiety, boredom, or actual onset of sleep while in the scanner.

Although most contemporary MRI scanners can be adapted to perform fMRI, this technique is still investigational in most clinical populations, including brain injury (1). Thus, fMRI is primarily a research tool at this time and its availability is generally limited to academic medical centers. A single fMRI session generates a large volume of data, which necessitates considerations for computer hardware, data storage and data security. At present, fMRI protocols do not actually “automatically” or “objectively” yield brain maps, nor are there normative values for fMRI scans or activity levels. Resulting images

must therefore be carefully and skillfully reconstructed, and this reconstruction process should be considered as much of an art as science. The approach that one takes in reconstructing and displaying the data in the form of brain images data will impact the display, and potentially the interpretation, of the end product.

## FMRI STUDIES OF BRAIN INJURY

At the time of this writing, there are very few fMRI studies of individuals with TBI, although there are several centers with active funding and ongoing protocols that will address this significant dearth in the scientific and clinical literature.

In the first fMRI studies of individuals with TBI (60–61), the investigators examined individuals with a very recent history of mild brain injury (i.e., within the previous 30 days). The individuals with mild TBI demonstrated intact behavioral performance on a verbal working memory task, but they did show right hemisphere lateralized fMRI activation in response to increased working memory load, as compared to healthy controls. In subsequent fMRI investigations of working memory following moderate and severe TBI (62–63), increased blood flow and more widespread dispersion of cortical activation was noted during working memory tasks. This again suggests that increased cognitive effort is reflected in increased brain activation on fMRI. In a study of working memory and response inhibition, fMRI was used to demonstrate increased recruitment of cerebral resources following severe diffuse TBI, particularly during response inhibition or when task difficulty was increased (64). This greater expenditure of effort to achieve overtly normal behavioral performance has also been demonstrated in an fMRI study of simple psychomotor execution (i.e., finger-tapping) among individuals with TBI examined several years after injury (65). One recent case study (66) has demonstrated correlations between changes in fMRI activations and improvement in cognitive status following rehabilitation of an individual with severe TBI, a compelling finding that warrants replication.

Although fMRI represents a very advanced approach to brain imaging vis-à-vis cognitive functioning when compared to SPECT or PET, it has not reached a sufficient threshold of evidence for routine use at any level of injury severity after head trauma. Given the paucity of fMRI research in TBI, the ACR has not fully evaluated fMRI and continues to classify this procedure as investigational in the examination of any level brain injury.

## FUTURE RESEARCH

The past few years have seen tremendous advances in functional neuroimaging technologies and approaches to

data analysis. In addition, there have been exploratory studies in several clinical populations, including TBI. In spite of these advances, these techniques remain investigational in most clinical applications (67). As with any technology, the transition from “investigational” to “routine” will not occur overnight, nor will it occur solely from the publication of a handful of case studies or small investigations drawn only from highly selected cases. It will occur after much additional, well-designed, systematic research (68). This should not be misinterpreted as a fatalistic statement, however. It is, in fact, the expectation of the authors that functional neuroimaging technologies will eventually demonstrate sufficient sensitivity and specificity to warrant routine clinical application, particularly among individuals with much potential to be helped by rehabilitation.

## Electrophysiologic Assessment Techniques: Evoked Potentials and Electroencephalography

*Henry L. Lew  
Eun Ha Lee  
Steven S. L. Pan  
Jerry Y. P. Chiang*

**V**arious behavioral measures have been used to identify cognitive deficits as well as to predict functional outcome in traumatic brain injury (TBI). However, results among these studies have often conflicted (1, 2). Recently, advances in computer technology have facilitated electrophysiologic data acquisition and faster processing speed. As a result, electrophysiologic techniques have resurfaced as potentially powerful clinical measurements. As clinicians, we encounter persons with a variety of lesions in the nervous system. We are often expected to establish early diagnosis and treatment, as well as to provide continued monitoring of the recovery process. In this chapter, we summarize the potential applications of somatosensory evoked potentials (SEPs), brainstem auditory evoked potentials (BAEPs), conventional electroencephalography (EEG), P50, and P300 as objective measures in evaluating cognitive function, as well as their efficacy in predicting outcome in persons with TBI.

### **SOMATOSENSORY EVOKED POTENTIALS**

The evoked potential (EP) is an electrophysiologic response of the nervous system that occurs as a result of repeated sensory stimulation (3). Different from conventional EEG,

which shows continuously varying brain activity, EPs are averaged responses, which are temporally related to the incoming stimuli (4). Many EP measurements have been tested for their efficacy in clinical evaluation and in predicting functional outcome (5–7). Some tests provide reliable prediction of ominous outcomes (8, 9), while others prognosticate favorable outcomes (6, 7). SEPs seemed to belong to the former category (6, 9–13).

SEPs are responses of the nervous system to various sensory stimuli, including electrical, tactile, vibration, or painful stimulation. Among these stimuli, electrical stimulation has been most popular due to its ease of use. Short-latency SEP (SSEP) is a part of the SEP occurring within 50 msec after peripheral nerve stimulation in either upper or lower extremities (14). SSEPs are relatively independent from level of consciousness, while middle or long latency SEPs are influenced by cognitive status to a larger degree. Due to its reliability and stability, SSEP is commonly used for clinical evaluation and prognostication in TBI (4, 10). An example of normal SSEP from stimulation of median nerve is illustrated in Figure 13-1.

For traumatic coma in adults and adolescents, bilaterally absent cortical SEP responses predicted a 95 percent probability of non-awakening from coma (10, 15). Beca and colleagues studied SEPs within 4 days of coma onset in children with severe brain injury (16), and found that

FIGURE 13-1

Normal SSEP waveforms from stimulation of left median nerve at the wrist

absent SEPs had very high positive predictive values (92–100 percent) for unfavorable outcome. In children with TBI, the likelihood of awakening from coma despite bilaterally absent SEP response was approximately 7 percent (10, 15). In a recent study by Lew et al. (6), bilateral absence of cortically recorded median nerve SEP within 8 days of severe TBI (Glasgow Coma Scale  $\leq$  8) was strongly predictive ( $p < 0.005$ ) of the worst functional outcome, namely, death or persistent vegetative state. In the above study, specificity and positive predictive values of absent SEP response for death or persistent vegetative state were as high as 100 percent at 6 months post-TBI.

In addition to SEP, there have been efforts to combine other evoked potential studies using so called “multimodality evoked potentials.” Shin et al. performed BAEP and SEP in TBI patients, and compared the results with clinical outcome (11). Although neither of the electrophysiologic measurements showed significant correlation with the cognitive level at a one-year follow-up, SEP increased the predictive value of initial clinical parameters including Rancho Los Amigos Scale or age. As for visual evoked potential (VEP), it has been utilized independently to evaluate visual impairment such as post-traumatic vision syndrome after brain injury (17, 18).

Several factors must be taken into consideration during the interpretation and analysis of the SEP waveform. For example, peripheral neuropathy of the nerve being stimulated may prolong the latency of cortically recorded potentials. Evoked responses recorded from the brainstem and cervical spine should be reviewed to rule out concurrent spinal cord injury. To distinguish central pathology from peripheral pathology, central conduction time (from the brainstem or Erb’s point to the cortical level) can be used (19). Increased level of sedation may reduce the amplitude of cortical SEP. Therefore, when the SEP amplitude is too small, it is prudent to repeat the test after removal of sedation (10). All things considered, decisions regarding continuation of life support should not depend totally upon SEP testing, but instead rely on overall

FIGURE 13-2

Normal brainstem auditory evoked potential waveform

clinical status, together with other laboratory findings and, most of all, family input.

### BRAINSTEM AUDITORY EVOKED POTENTIALS

Brainstem Auditory Evoked Potentials (BAEPs, also known as BAER, brainstem auditory evoked response) represent the electrophysiologic response of the central nervous system to repeated click stimuli, and is characterized by a pattern of 5 neurogenic waves (20). The BAEP wave I originates from the cochlear nerve, and wave II arises from the cochlear nucleus. Waves III, IV, and V originate from the superior olivary complex, lateral lemniscus, and inferior colliculus, respectively. An example of normal BAEP waveform is illustrated in Figure 13-2.

Prolongations of interpeak intervals between I–III, III–V, or I–V have been reported in patients with TBI, (11, 21–24). The most ominous finding is complete absence of a repeatable waveform. In a study on comatose children and adolescents with traumatic brain injury, BAEP abnormality was found to be about 40 percent of the 62 patients tested (25). In a meta-analysis, it was concluded that normal BAEP obtained within the first week of TBI onset had a very good prognostic value for awakening from coma (26), while EEG did not have much clinical utility. However, another independent study showed that the presence of BAEP in post-coma unawareness patients did not have any significant prognostic value, because the presence of normal BAEP in these patients may merely suggest that the brainstem had been spared despite significant injury above the brainstem (27).

In mild TBI, prolongation of BAEP wave I and III latencies had been observed soon after concussion, and prolongation of BAEP interpeak intervals (between wave I and V) had been noted from the first day of TBI (28). In other studies of persistent post-concussion syndrome, no significant BAEP latency delays were found (29). In more severe cases of TBI, prolonged interpeak interval persisted for several weeks (28, 30, 31). It should also be

noted that when more rigorous normative values were applied (abnormality defined as greater than 2.5 SD, rather than 2.0 SD, from the mean), no abnormalities in BAEP were noted after mild TBI (32). Also, in a group of amateur boxers ( $N = 47$ ) who supposedly had repeated concussions, no differences in BAEP results were observed when compared to other athletes with low risk of TBI (33). There have been several studies on BAEP to determine its correlation with dizziness. In patients with post-concussion syndrome, the BAEP alterations were not associated with dizziness or abnormal vestibular function (34). In another study involving patients with mild head injury, significantly prolonged BAEP latency was observed. However it was not correlated with outcome after 3 months (35).

The value of BAEP for hearing screening has already been established in newborns because of its objective nature and ease of use (36, 37). Due to co-existing cognitive problems, it is sometimes difficult to detect hearing dysfunction in TBI patients, especially in the early stages of recovery (38). This may result in delays in audiological, surgical, and rehabilitative interventions. Review of literature from 1975 to 2001 showed that the incidence of hearing problems for various degrees of TBI varied from 7 to 50 percent (25, 39–43). A recent review of inpatient records from a TBI unit showed that 17 percent of moderate to severe TBI patients showed abnormal behavioral audiograms after the injury (44). If hearing screenings with BAEP were performed prospectively on all moderate-to-severe TBI patients, the incidence could be higher than 17 percent. In a study on 40 TBI patients (22), BAEP results were compared with behavioral audiometry, and the authors concluded that BAEP was more diagnostic than pure tone audiometry in the evaluation of brainstem dysfunction. In conclusion, the utility of BAEP in TBI may be limited to evaluation of brainstem dysfunction and hearing impairment (45).

## ELECTROENCEPHALOGRAM

Conventional electroencephalogram (EEG) measures electrical activity generated by the brain via surface electrode recording. An example of ongoing EEG is illustrated in Figure 13-3. Traditional EEG studies typically involve subjective and qualitative analysis, although efforts are being made to objectively quantify the EEG data, such as Fourier Transform (FT) of the frequency bands. With advances in computer-based signal processing technology, quantitative EEG (QEEG) analyses may gain wider use in evaluating TBI patients (46).

### Conventional EEG

There are four basic components in EEG waveforms. Alpha waves (8–12 Hz) are seen in the awake but relaxed

FIGURE 13-3

Continuous electroencephalography recording by surface electrodes

state, while beta waves (12–30 Hz) are observed in the fully awake state. Delta waves are the slowest waves (less than 4 Hz), which are related to nondreaming deep sleep. Theta waves (4–8 Hz) also are associated with hypnotic or meditation states of consciousness. These waves are affected by age and recording sites. The pathologic brain wave patterns include focal or generalized spikes observed in patients with convulsive disorders. Other pathologic patterns vary from overall slowing to altered proportion of waves. Burst suppression pattern is characteristically seen during the induction stage of anesthesia. It is typically shown as a mixed pattern of high-voltage bursts and low-voltage suppression period, which are also related to anoxia, coma, and brain damage (47, 48).

EEG patterns have been empirically used to assess the severity of TBI and to predict their functional outcome (49). In 1973, Bricolo (49) reported that EEG is a useful evaluation tool for comatose TBI patients. They found that subjects with “spindle patterns” had relatively favorable prognosis, and patients with monophasic or slow disorganized electric activity patterns without response to environmental stimuli had much higher mortality rate. Synek (50) studied the EEG patterns of patients with cerebral anoxia or head injury, and concluded that those who responded to external stimuli were usually associated with good outcomes. Some other favorable EEG patterns included normal activity, rhythmic theta activity, frontal rhythmic delta activity, and spindle pattern. On the other hand, epileptiform activity, nonreactive, low-amplitude delta activity, and burst suppression patterns with interruptions of isoelectricity were associated with poor prognosis. Needless to say, patients with complete isoelectric EEG activity had the highest mortality.

Although EEG analyses may provide some prognostic information for patients with severe TBI, there are issues with their application in mild TBI. Jacome et al. (51) found no EEG abnormality in 24-hour ambulatory EEG monitoring of mild TBI patients. One and a half decades later, Voller et al. (52) did a combined EEG/MRI study. Again, no EEG abnormalities were observed in mild TBI patients. Even in patients with structural lesion per MRI, no focal change in EEG was noted. Based on the aforementioned studies, conventional EEG analysis is not highly regarded as either a diagnostic or prognostic tool in evaluating the patients with mild TBI.

### Quantitative Electroencephalography

Quantitative electroencephalography (QEEG) is based on highly sophisticated computation of EEG signals. The fundamental element of QEEG is spectral analysis, which decomposes the complex EEG signal into various component frequencies. The amount of alpha (8–12 Hz), beta (12–30 Hz), delta (0–4 Hz), and theta (4–8 Hz) component activity contained in the EEG signals are quantitatively isolated and stored in digitized format for further analysis. Topographical mapping of different frequency bands (sometimes referred to as BEAM, brain electrical activity mapping) can be made based on the results of spectral analyses. QEEG has clinical value in certain neurologic abnormalities such as epilepsy, cerebrovascular disease, and dementia (53). However, experts in neurophysiology have not completely reached their consensus regarding the clinical utility of QEEG in mild head injury, moderate head injury, or post-concussion syndrome (53–56).

Due to the availability of digital recording and computer-based real-time quantitative analyses, many researchers have devoted their time and efforts to exploring QEEG as a tool for evaluating TBI patients. Bricolo et al. (57) first studied comatose TBI patients by spectral EEG analysis. They suggested that interhemispheric frequency band asymmetries were associated with poor outcome. In contrast, patients with spontaneous EEG power spectrum variability and persistence or return of EEG activity within the alpha or theta frequency were correlated with favorable prognosis. (58, 59).

Comparing the predictive values between QEEG and Glasgow Coma Scale (GCS) in severe TBI patients, Karnaze et al. (60) showed that altered spectral patterns were correlated with better survival, and its predictive value was equivalent to, but not significantly higher than that of GCS. Thatcher et al. (61) compared QEEG, GCS, brainstem auditory evoked potential (BAEP), and Computed Tomography (CT) in outcome prediction of 162 comatose TBI patients. EEG phase pattern was demonstrated to be the most prognostic, followed by EEG coherence, GCS, and brain CT, respectively. Alster et al. (62)

also demonstrated that spectral EEG analyses were more predictive of brain injury outcomes than GCS and BAEPs.

Thatcher et al. (63) compared QEEG patterns between patients with mild TBI and age-matched controls. An overall classification accuracy of 94.8 percent was reported. Mild TBI subjects showed increased coherence and reduced phase in frontal and temporal areas, decreased alpha band amplitudes in the parieto-occipital territories, and reduced spectral power difference across anterior/posterior cortical regions. Tebano (64) also performed spectral EEG analysis in persons with brain injury. Their results showed that mild TBI patients had a shift in peak alpha frequency band toward lower frequency values. Twelve years later, Cudmore (65) also demonstrated that EEG coherence pattern differentiated controls from patients with mild TBI. Increased alpha/theta ratio was observed in mild TBI patients (66), possibly due to reduced theta activity, with relatively stable alpha activities.

In summary, these studies imply that QEEG findings may be better than conventional EEG in studying mild TBI patients. However, inter-research comparison and meta-analysis are problematic due to lack of standardized techniques and inconsistent inclusion/exclusion criteria. In addition, QEEG analyses are derived from vast amount of data points over various recording electrodes, and researchers typically use multiple analyses to derive the results. Consequently, type I error is a major concern, and multiple inter-electrode comparisons may yield some “statistically significant” but not “clinically meaningful” results.

### PAIN-RELATED POTENTIAL (P250)

Deep brain stimulation (DBS) of various brain regions (e.g., mesencephalic reticular formation or the thalamic center median-parafascicular (CM-Pf) complex) has been used to evaluate or even promote recovery from the persistent vegetative state (PVS). To monitor clinical utility of DBS, the late positive wave of cortical potentials elicited by painful stimuli (pain-related potential, P250) has been investigated (67–69). In chronic vegetative state, the depressed P250 was temporarily enhanced by DBS. A persistent enhancement of the P250 was also correlated with better clinical outcome (67). The P250 may provide objective and quantitative information regarding the level of cortical responsiveness to painful stimuli in persons in low level neurological states following brain injury.

### P50

The P50-evoked response is the event-related potential (ERP) response around 50 msec to auditory stimuli (P50 ERP). This potential is recorded at the scalp, and reflects the cholinergically dependent, hippocampally mediated,

and pre-attentive process of sensory gating to auditory stimuli (70, 71). Traditionally, paired auditory stimuli are used for P50 study. The procedure is as follows: First, hearing threshold (in dB SPL) is determined, and the auditory stimuli are presented at 25–45 dB SPL above the hearing threshold (72). Employing the International 10–20 System of Electrode Placement (73), the P50 potential is recorded at Cz-A1 with a ground electrode at A2. Pairs of auditory stimuli (1 msec duration, 20Hz–12kHz) are presented with certain intra-pair (around 0.5 sec) and inter-stimulus (around 10 sec) interval. An overall grand average is obtained for both the conditioning and test P50 responses. The P50 latency and amplitude can be identified by computer algorithm (72, 74).

The P50 ratio (in percentage) is the amplitude ratio of the test P50 to the conditioning P50. Examples of P50 suppression and nonsuppression are illustrated in Figure 13-4. It is used as an index for auditory sensory gating (72). P50 suppression is defined as a P50 ratio of  $\leq 40$  percent, and P50 nonsuppression is  $\geq 60$  percent. P50 ratio between 40 and 60 is considered as an indeterminate P50 suppression (72). Arciniegas et al. reported that the P50 ratio was significantly increased in TBI (75). Interestingly, the P50 ratios of different TBI subgroups, categorized by duration of post-traumatic amnesia (PTA) did not show significant difference from one another. Those TBI subjects with similar level of cognitive impairment at the time of testing demonstrated similar amount of abnormal P50 suppression despite varying severity of initial brain injury. In another study (72), the frequency of P50 nonsuppression was investigated in patients with persistent posttraumatic attention and/or memory impairment. Preliminary analysis showed that the majority of TBI subjects have discernable P50 response, and that P50 nonsuppression is common among TBI patients with subjective symptoms of attention and memory

impairments, providing some evidence that clinically impaired auditory gating is variably correlated with P50 nonsuppression.

Regarding the source of P50 potential, it has been suggested that the generator is located at the hippocampus (74, 76, 77). Sensory gating process may facilitate stimulus selection and information processing, which are important for attention and memory function (72). It was suggested that impaired sensory gating cause attention and memory impairments after TBI (78), and that abnormal P50 findings may be a useful marker for cholinergic dysfunction (72, 75, 79, 80). In summary, these studies suggest that the P50 response may be useful not only for evaluating cognitive dysfunction, but also for monitoring pharmacological interventions in TBI.

### EVENT-RELATED POTENTIALS/P300

Event-related potentials (ERPs) are cognitive potentials recorded over the scalp. They have been regarded by psychophysicists as indicators of information processing, which may not be fully appreciated by measuring behavioral performance alone (6, 81, 82). In the active ERP paradigm, the subject is asked to discriminate a rare/target stimulus (typically with occurrence rate of 20 percent) from an interrupted series of frequent/nontarget stimuli (80 percent occurrence rate) (83). When averaged appropriately, the target stimuli generate a prominent positive peak (P300) approximately 300 msec after stimulus onset (83–85). The P300 response reflects active attention, working memory, and the ability to detect novel stimuli among a series of similar signals (81, 84, 86, 87). Amplitude of P300 reflects the amount of cerebral activity required to process information and maintain working memory as the controlled environment is updated with incoming sensory input (86). Studies have shown that the P300 latency is a reliable indicator of stimulus classification speed, which is independent from the response selection processes (88, 89). Traditionally, simple auditory and visual tasks such as tone and color recognition have been widely employed in ERP testing due to its ease of use (83, 86, 90, 91). Although these tasks are rather primitive when compared with other paradigms (e.g., word recognition, affect recognition), simpler tasks have the advantage of generating larger amplitudes and shorter latencies, which in turn simplify the data analysis process. An example of normal auditory P300 response is shown in Figure 13-5. The waveform was recorded at an Cz electrode, using an active oddball paradigm with pure tones as stimuli.

Not surprisingly, P300/ERP studies have been applied to patients with cognitive impairments (92) and psychiatric disorders (93, 94). For comatose patients who are unable to participate actively in the testing process, the passive ERP paradigm can be used (6, 95–98). Several brain

FIGURE 13-4

P50 suppression and nonsuppression (72)

**FIGURE 13-5**

Normal auditory event-related potential (ERP) waveforms from pure tone (1000 Hz versus 500 Hz) discrimination task

injury studies utilized simple tones as stimuli (7, 95–99), which yielded P300 responses in about 30 percent of apparently comatose patients. Preserved P300 seemed to predict the emergence from coma (95, 99, 100) and higher chance of recovery (90 percent or higher) in long-term follow-up (95, 99, 101). However, the absence of P300 did not exclusively prognosticate ominous outcome (6).

Based on recent data published by various researchers (6, 101, 102), it was apparent that preserved P300 component was associated with good clinical outcomes, while it was coincidentally noted that the N100 component also correlated with favorable outcome. In one study (101), investigators recorded auditory P300 potentials using three different passive paradigms both in normal subjects and in patients with severe consciousness impairment after TBI. Results showed that the N100 latency was longer, with significantly depressed amplitude in TBI patients than in normal subjects. It suggested that cognitive processing of exogenous sensory stimuli may still take place, albeit with some delay, when the patients' level of consciousness appeared to be severely impaired. Although the N100 response was thought to be associated with passive perception of incoming sound (103), there is evidence to suggest its involvement with alertness and stimulus processing (81). Based on the above-mentioned studies, it is possible that both the N100 and P300 components are associated with active information processing (101, 102, 104).

To increase the ecologic validity of the ERP task, recent studies employed speech stimuli such as patients' names (6, 101, 105). From a theoretical standpoint, a person's own name would generate a more robust ERP response. By comparing three different speech targets (subject's own name, the word "mommy," and a meaningless speech sound), a recent study demonstrated that the subject's name was indeed a viable target for eliciting cognitive ERP (102).

ERP testing has also been used to monitor effects of caffeine, nicotine, alcohol intake, and various psychostimulants. Caffeine and nicotine increased the P300 amplitude and shortened the latency, while acute alcohol consumption decreased the amplitude and prolonged the latency (81). Anderer et al. compared the pharmacologic effects of various drugs in healthy subjects. While methylphenidate and citalopram enhanced P300 in various cortical regions, lorazepam and haloperidol depressed P300 component (106). From a theoretical perspective, ERP might be a useful tool in evaluating the pharmacologic effect of various so called "cognitive enhancers" after brain injury.

In summary, ERP may be valuable in investigating residual cognitive function of patients with TBI because of its noninvasive nature (107) and superior temporal resolution (108). Also, using multi-channel recording, ERP may contribute to localization of certain brain activities based on dipole theory. With advances in computer technology, ERP may complement behavioral testing in the comprehensive evaluation of cognitive function.

## CONCLUSION

So far, we have discussed use of various electrophysiologic measurements for persons with TBI. SEP is a reliable prognosticator for ominous outcome after severe TBI. Combining ERP with SEP increases the power for predicting a favorable outcome. P300 and P50 are valuable in evaluating pharmacological effects of various drugs on cognitive function. The utility of BAEP in TBI is limited to evaluation of brainstem dysfunction and hearing impairment, rather than actual cognitive function. Although conventional EEG and QEEG have their inherent limitations, they may gain wider use as technology improves and more standardized studies are performed.

Neuro-imaging studies, such as MRI (magnetic resonance imaging) or fMRI (functional MRI) have been used to obtain structural information along with electrophysiologic information (109–112). While ERP measurement can provide high temporal resolution for evaluation of cognitive processing, fMRI detects regional changes of brain activity in response to specific task performance. However, most of these combination studies (using imaging and electrophysiologic measurements) have been performed on psychiatric patients, and have been rarely applied to persons with TBI. As for future research, the addition of electrophysiologic and neuro-imaging studies may provide comprehensive, objective, and valid assessments of cognitive status in persons with TBI, and may be useful in prognostication of long-term functional outcome.

## Prognosis After Severe TBI: A Practical, Evidence-Based Approach

*Sunil Kothari*

*It seems to be highly desirable that a physician should pay much attention to prognosis. If he is able to tell his patients when he visits them not only about their past and present symptoms, but also to tell them what is going to happen, as well as to fill in the details they have omitted, he will increase his reputation as a medical practitioner and people will have no qualms in putting themselves under his care.*

*Hippocrates*

Like diagnosis and treatment, prognosis is a fundamental responsibility of all clinicians. This is especially true after a traumatic brain injury, when uncertainty about the future compounds the suffering already experienced by patients and families. Indeed, families have identified information about prognosis as one of their most important needs in the aftermath of a traumatic brain injury (1–3). Unfortunately, this need often goes unmet, as families report they were rarely provided adequate prognostic information (2,3).

Providing patients and families with this information can help in several ways. Knowing what the future might hold allows families to gain some cognitive control over a situation they otherwise feel powerless to affect. Moreover, there is a symbolic importance to prognosis: patients and families want to believe their condition is

understood (4). Simply knowing that the clinician understands their condition can alleviate anxiety. Given the importance of prognosis for patients and families, some authors have even suggested that prognostication is an ethical *duty* for clinicians (4).

Despite its clear importance, clinicians often neglect prognosis. Some reasons for this neglect apply only to the delivery of *poor* prognoses: a lack of training in the delivery of “bad news”, the emotionally demanding nature of providing a poor prognosis, a fear of extinguishing hope, and the fact that a poor prognosis highlights the limits of professional help (4). Other barriers can affect *any* act of prognosis: the belief that prognostication is arrogant or hubristic, a lack of facility in probabilistic reasoning, and the difficulty in extracting clinical guidelines from a large body of literature (4).

Because of this difficulty in developing guidelines based on the research literature, health care professionals often rely on their own clinical experiences in formulating prognoses. However, such an approach is of limited value: not only is a clinician’s personal experience subject to selection bias, it is also prone to significant cognitive distortion (5,6). Many studies have shown that a clinician’s “subjective” estimation of prognoses is often far less accurate than those derived from well designed studies (7–9).

Yet, providing prognostic information based on these studies can be difficult for TBI professionals. The

literature is vast, with hundreds of studies reported, all varying in focus, design, and quality. Also, most of the studies were designed or reported in a way that makes it difficult to derive *clinically* useful guidelines. Often, they report only general associations (e.g., “outcome is related to the length of coma”). Even when these associations are quantified, it is done in a way that limits their applicability to individual cases (for instance, by using regression equations).

The purpose of this chapter is to address these obstacles and thereby derive accurate and useful guidelines from the relevant literature. It is hoped that this information will enable TBI professionals to make the most accurate prognoses possible, both to inform their own clinical decisions as well as to provide the desired information to patients and families. Of course, other reviews of this topic exist (10–24), including several excellent ones that have recently been published (25, 26). The review presented here differs from the others in three important ways. First, an attempt was made to review *all* available and relevant studies. Second, this is the first review to apply an evidence-based approach to this area. Finally, the primary aim was to develop guidelines that will be *clinically* useful.

The chapter is divided into five major sections:

- a summary of findings
- guidelines for communicating prognostic information
- a brief review of recent developments in the field
- an appendix on guidelines for evaluating studies on prognosis
- an appendix describing the methodology of the literature review

The core of the chapter is contained in the next two sections, which summarize the findings of the evidence-based review and provide guidelines on communicating this information to patients and families. The third section briefly describes developments in the area which will likely assume greater importance over the next several years. The first appendix provides a guide for evaluating future studies on prognosis. The second appendix provides a detailed description and justification for the methodology guiding this review. To maximize the usefulness of this chapter as a future reference, all the important information is summarized in the figures and tables. Therefore, after an initial reading of the entire chapter, readers can then simply refer to the tables and figures to review the essential information. This chapter does not address topics relevant to prognosis after TBI that are covered elsewhere in the textbook (see Figure 14-1).

## SUMMARY OF FINDINGS

### Clinical Utility: The Concept of a “Threshold Value”

The primary purpose of this chapter is to provide clinicians with information that is not only evidence-based but also *practical*. The nature of the studies in this area makes this difficult, for several reasons. First, most of the relevant studies do not *directly* address issues of prognosis. Instead, they often have simpler aims, such as providing a description of the possible outcomes after TBI as well as the factors associated with these outcomes. As a result, the findings are reported in such a way that only the broadest generalizations are possible (e.g., that the initial Glasgow Coma Scale (GCS) score is correlated with outcome after a TBI). Although this knowledge does represent an advance in our understanding of TBI, it does little to help clinicians who are trying to prognosticate for individual patients. Even when these associations are quantified, it is in a form that is not clinically useful (e.g., as correlation coefficients).

This was a limitation even of those studies that directly addressed prognosis. For example, the relationship between a potential predictor variable and an outcome might be expressed as a path coefficient or the percentage of variance explained. Yet, both clinicians and laypeople are more used to thinking about, for instance, probabilities (e.g., “what are the chances that he will ever work again?”). Unfortunately, there is no straightforward way to translate results expressed as path coefficients,  $R^2$ , log-likelihood’s, correlation matrices, etc., into prognoses that are meaningful to the clinician, let alone the family. For most clinicians, our knowledge begins and ends simply with the awareness that certain variables are associated with outcome (e.g., GCS, pupillary abnormalities, etc.), without knowing how to apply that information to individual cases. There were a handful of studies that actually did provide practical guidelines for clinicians (e.g., by using simple formulas, prediction trees, or scores from specially designed scales), but they did not meet the other inclusion criteria of this review.

To maximize the clinical utility of studies that did meet the inclusion criteria, the results were interpreted

through the use of threshold values. These are values of a predictor variable above or below which a particular outcome was especially unlikely. For example, several studies reported that no one with a duration of PTA over three months achieved a good recovery as defined by the Glasgow Outcome Scale (GOS) (Figure 14-2). Thus, three months would be considered a threshold value for the duration of PTA, at least in terms of excluding the possibility of a good recovery on the GOS (Figure 14-3). Conversely, several studies found that no one who had a duration of PTA of *less than* two months ended up severely disabled (by GOS criteria); two months would then be the threshold value for excluding the possibility of severe disability.

As “milestones” in a patient’s recovery, threshold values can be useful to clinicians. For instance, as the length of a patient’s PTA extends beyond three months, rehabilitation clinicians can counsel family members about realistic expectations for the future. On the other hand, if two months have not yet elapsed since the injury, clinicians can give hope to families even if the patient is still in PTA.

Studies that reported their results in a way that allowed the determination of threshold values were especially important for this review. Unfortunately, less than a third of the included studies did so. In some cases this

was because the variable in question did not turn out to have a threshold value. This occurred when, regardless of the score or value, a prognostic factor was associated with all possible outcomes. For instance, for any initial GCS value between 3 through 8, all the outcomes on the GOS are possible, so there are no threshold values for this variable. With other factors, such as PTA, it does make sense to speak of threshold values. Even in these cases, however, only a minority of the studies were designed or reported so that one could determine what those threshold values actually were. The guidelines in this chapter relied heavily on these few studies, since they were the ones that provided the most useful information for clinicians.

Because of the limited number of studies involved, it was important to provide independent verification of the validity of their conclusions. This was done by determining if the results were consistent with the findings of the other, excluded, studies. For example, excluded studies were reviewed to determine if any of them reported a significant number of cases of good recovery on the GOS when the duration of PTA extended beyond three months (one of the threshold values derived from the included studies). If the excluded studies also converged on the same threshold values, one could be more sure of the validity of the original values. In fact, the results of the excluded studies were consistent with almost all the derived threshold values; the few exceptions were not clinically significant and are discussed in more detail below (in the sections on individual predictor variables).

The threshold values that were chosen were those that allowed one to exclude either a good recovery on the one hand or a severe disability on the other; no attempt was made to determine similar threshold values for moderate disability. This was motivated by the belief that, for most family members, it is the GOS categories of severe disability and good recovery that are of most interest in the subacute period. Families want to know how long they can still hope for a good recovery (and may not be as concerned, during that time, about whether the alternative is moderate disability or severe disability). Conversely, it is reassuring to families to hear it is unlikely the patient will be severely disabled (even if neither they nor the clinician knows whether the eventual outcome will be a good recovery or moderate disability).

Of course, interpreting threshold values is not unproblematic. There is a degree of statistical uncertainty for all calculated threshold values. For example, even if no one with a duration of PTA greater than three months had a good recovery in a particular study, such an outcome is still *statistically* possible. This statistical uncertainty can be quantified using confidence intervals. The lower end of the confidence interval would be zero (in a study where no one had the outcome of interest), while the upper end would represent the largest number of people who could have had the outcome of interest. The use

- DEAD
- VEGETATIVE STATE (“alive but unconscious”)
- SEVERE DISABILITY (“conscious but dependent”)—unable to live alone for more than 24 hours: the daily assistance of another person at home is essential as a result of physical and/or cognitive impairments.
- MODERATE DISABILITY (“independent but disabled”)—independent at home; able to utilize public transportation; able to work in a supported environment.
- GOOD RECOVERY (“mild to no residual deficits”)—capacity to resume normal occupational and social activities, although there may be minor residual physical or mental deficits.

**FIGURE 14-2**

*Glasgow Outcome Scale*

A value of a predictor variable above or below which a certain outcome is especially likely or unlikely.  
 Example: *If post-traumatic amnesia (PTA) lasts more than three months, a person is very unlikely to achieve a “good recovery” on the Glasgow Outcome Scale (GOS).*

**FIGURE 14-3**

*Definition of Threshold Value*

of confidence intervals in this context is further explained in the second appendix.

There were also instances where two or more studies differed in the threshold values they identified (for instance, excluding the possibility of a good recovery after a PTA of two months in one study but not until a PTA of three months in another). As discussed below, a decision was made to err on the side of conservatism in these situations by choosing the value (larger or smaller, depending on the outcome), which minimized the possibility of an inaccurately pessimistic prognosis. So, in this example, one would choose three months of PTA as the threshold value in order to avoid discounting the possibility of a good recovery in those patients whose PTA lasted between two to three months.

### Brief Comment on Methodology

The inclusion criteria are summarized in Figures 14-4 and 14-5. The second appendix provides a detailed review and justification for selecting these criteria. For present purposes, it is noted that the review focused on studies of adults who had sustained a moderate or severe TBI (either closed or penetrating). The predictor variables represented the information most likely to be available to rehabilitation clinicians: initial Glasgow Coma Scale score (GCS), length of coma, duration of post-traumatic amnesia (PTA), age, neuroimaging findings, and results of early neuropsychological testing. The outcomes of interest (assessed at 6 months or later) were vocational reentry, return to independent living, or the classification on the Glasgow Outcome Scale (GOS). The use of the GOS as the primary outcome of interest requires justification; this is provided in the second appendix.

Out of the hundreds of articles reviewed, there were only 35 studies that met all the inclusion criteria: 12 using neuroimaging predictors (27–38) (Table 14-1), 24 using clinical predictors (27, 29, 30, 33, 38–57) (Table 14-2), 2 focused on the elderly (58, 59) (Table 14-3), and 2 on

Outcomes studied should be relevant and meaningful to a layperson (e.g. family member) asking about prognosis.

Predictor variables should represent information easily accessible to rehabilitation clinicians.

The population studied should be similar to the population encountered by rehabilitation professionals.

The studies must meet minimal methodological criteria in terms of patient selection, follow-up, statistical analysis, etc.

**FIGURE 14-4**

*General Guidelines for Inclusion of Studies*

penetrating brain injury (60, 61) (Table 14-4) (the numbers add up to more than 35 because some studies investigated more than one prognostic factor). No studies that used early neuropsychological testing as a predictive variable met all the inclusion criteria. Neither did any studies that focused exclusively on moderate TBI. More importantly, of all the studies that were included, only a third allowed for the determination of threshold values. In particular, eight of the closed head injury studies reported threshold values with acceptable confidence intervals (0–12 percent): one for MRI, one for length of coma, two for length of PTA, and four for age. In what follows, the results of the studies are reviewed by predictor variable. The conclusions are summarized in Figure 14-6.

### MRI

*Summary* Two studies (32, 34) met the inclusion criteria, both using information from Magnetic Resonance Imaging (MRI) obtained within two weeks after injury. Both found the depth of the lesions correlated with outcome. Specifically, they discovered that lesions in the cortex or the white matter were not associated with worse outcome, whereas brain stem lesions were strongly associated with poor outcome. One study (34) also determined a

#### *Population*

1. Publication after 1983
2. Setting in North America, Western Europe, Australia, New Zealand, or Israel
3. Setting in either acute care or inpatient rehabilitation
4. Moderate and/or severe TBI (penetrating and/or closed)
5. Exclusively or primarily adult TBI

#### *Predictors*

6. Predictor variables: GCS (total), length of coma, PTA, age, neuroimaging (CT or MRI), and/or early neuropsychological testing.

#### *Outcomes*

7. Outcomes: GOS, vocational re-entry, and/or independent living
8. Outcomes assessed at 6 months or later

#### *Methodology*

9. Sample must represent consecutive admissions (whether done prospectively or retrospectively) or a random/neutral sampling of consecutive admissions
10. Sample size > 25
11. Follow-up greater than 80 percent
12. Statistical analysis performed (or, if not, enough information provided to analyze oneself)

**GCS:**

- Lower scores associated with worse outcomes
- No threshold values

**Length of Coma:**

- Longer duration associated with worse outcomes
- Threshold values:
  - Severe disability unlikely when less than two weeks
  - Good recovery unlikely when greater than four weeks

**PTA:**

- Longer duration associated with worse outcomes
- Threshold values:
  - Severe disability unlikely when less than two months
  - Good recovery unlikely when greater than three months

**AGE:**

- Older age associated with worse outcomes
- Threshold values:
  - Good recovery unlikely when greater than 65 years

**NEUROIMAGING:**

- Certain features (e.g., depth of lesions) associated with worse outcomes
- Threshold values:
  - Good recovery unlikely when bilateral brainstem lesions present on early MRI

a lower brainstem lesion made a good recovery), the confidence interval was too large to be included. There were, however, some differences in the findings of the two studies. The study by Wedekind (32) found that lesions in the basal ganglia and corpus callosum, as well as the total lesion burden in the brain, were associated with a worse outcome; the later study (34) did not find these associations.

*Discussion* The advantage of conventional MRI (relative to CT scanning) is that it allows for better visualization of lesions, especially those in the brainstem. As a result, MRI is ideally suited to study the centripetal model of brain injury severity (62) which claims that the stronger the forces to which the brain is subjected, the more severe the injury and the deeper the lesions. The findings of these two studies (as well as others that did not meet the inclusion criteria) are consistent with this hypothesis: depth of lesion is associated with worse outcomes because it is a marker of brain injury severity.

*Conclusions* If an MRI from the first several weeks after a TBI is available, the depth of the lesions (and, possibly, the total lesion burden) are associated with worse outcome. In particular, the presence of bilateral brainstem lesions makes the possibility of a good recovery very unlikely.

**CT**

*Summary* Ten studies (27–31, 33, 35–38) met the inclusion criteria; all but one were conducted in the acute care setting. However, even the study from the rehabilitation setting made use of the acute care CT scan. Almost half of the studies used scales that included several different imaging variables, making it difficult to isolate how individual variables contributed to outcome (two of the

**FIGURE 14-6**

*Summary of Studies of Nonpenetrating TBI*

threshold for the possibility of a good recovery: no one in their study with bilateral brainstem lesions made a good recovery (95 percent CI: 0–8 percent). Although the second study (32) reported a similar finding (i.e., no one with

studies used the Traumatic Coma Data Bank (TCDB) classification, one the intracranial severity score of the Abbreviated Injury Scale (AIS), and one a scale especially designed for the study). Nonetheless, certain patterns emerged.

Every study that looked at the presence of subarachnoid hemorrhage (SAH) as a variable found that it was associated with worse outcome. In addition, all but one of the studies that examined the presence of cisternal effacement or midline shift found they correlated with worse outcome. Finally, although the presence of epidural or subdural hematomas was correlated with worse outcome in the studies that included them as predictor variables, no more specific conclusions could be drawn, given the variation in how they were graded.

The two studies that used the TCDB classification reported threshold effects, although they differed in what they found. One study (31) found that no patient whose scan was classified as a “level VI” category (the worst rating) achieved a good recovery or moderate disability. The other study (36) found that no one with a “level I” scan (the best rating) did worse than moderate disability. However, the confidence intervals around both values were unacceptably large. In addition, neither study confirmed the finding of the other, rendering the reported thresholds unsupported across studies.

*Discussion* Since the acute care CT scan (or a report) is often available to rehabilitation professionals, it would have been helpful if the CT findings yielded more definitive prognoses. Unfortunately, although it is known that certain lesions are associated with worse outcomes, the nature of the relationship is such that more specific prognoses cannot be made. It may be that the use of more quantitative measures of CT lesions would yield better prognostic information, but this has not yet been demonstrated. Overall, all of these findings are consistent with those of the excluded studies.

*Conclusions* The presence of SAH, cisternal effacement, significant midline shift, EDH, or SDH on an acute care CT scan are all associated with worse outcomes. More specific conclusions about the implications of the lesions cannot be drawn, because each one individually can be associated with the full range of outcomes after TBI.

### Initial GCS

*Summary* Of the studies that met the inclusion criteria, ten (38, 41, 42, 45, 46, 48, 50, 53, 56, 57) examined the relationship between GCS and outcome. As mentioned earlier, studies that used only a subset of the GCS (e.g., motor score) were excluded because, although rehabilitation professionals should have access to the initial GCS score, the individual subscores would be much less available. All but

one of the studies found an association between lower GCS scores and worse outcomes. Although the studies measured the GCS differently (e.g., admission, post-resuscitation, highest in the first 6–24 hr, etc.), none of them discovered threshold or cut-off values for outcomes. In other words, any particular initial GCS score could potentially be associated with any outcome (although the chances of having a good outcome diminish as the GCS score is lower).

*Discussion* Although providing a general idea of the severity of the injury, the GCS by itself does not yield definitive prognoses. This is true even when the accuracy of the GCS is increased by varying the timing and content of measurement. Even the most accurate of the methods did not improve accuracy enough to allow for more specific prognoses. Also, rehabilitation professionals are often limited in which GCS score they have access to (and often don't know exactly when it was obtained). For both these reasons, it did not seem worthwhile to look more closely at the accuracy of different ways of obtaining the GCS. All of these findings are consistent with the rest of the literature (that is, the studies that were excluded).

*Conclusions* Although the initial GCS score is associated with outcome and lower GCS scores are associated with worse outcomes, one cannot draw more specific conclusions solely from the GCS score.

### Length of Coma

*Summary* Of the studies that met the inclusion criteria, there were six (27,39,41,44,53,55) that studied the relationship between the length of coma and outcome. Four of the six defined the length of coma as that period of time until the patient started following commands. The other two studies did not specify how coma duration was measured. All but one found a relationship between the duration of coma and outcome (the longer the duration of coma, the worse the outcome). In addition, one of the studies (53) reported its data in such a way that it was possible to determine a threshold value for excluding the possibility of a good recovery. Specifically, they found that no subject made a good recovery whose length of coma exceeded fourteen days (53).

*Discussion* Although the duration of coma has been defined several different ways (e.g., when GCS is 9 or above, when the eyes open, etc.), all the studies that reported their method of measurement used the time to follow commands. This was also the predominant method of measurement in the rest of the literature. Therefore, the rehabilitation clinician using the length of coma for prognostic purposes should follow the same guidelines. Only one study (53) reported a threshold value with an acceptable confidence interval. However, the

value of 14 days they found seems too short. For instance, the Tate study (44) reported instances of a good recovery even after a month of coma. Other studies, excluded in the review, also converge on approximately one month as a cut-off point (beyond which the chances of a good recovery are small) (63–65). In these studies, it appears that, on average, only 7–8 percent of patients will make a good recovery who are not following commands beyond one month.

*Conclusions* The longer the duration of coma (as measured by the time to follow commands), the more likely a worse outcome. In particular, a duration of coma greater than four weeks makes a good recovery unlikely.

### PTA

*Summary* Of the studies that met the methodological criteria, seven (27,44,50,51,53,55,57) investigated the relationship between the length of post-traumatic amnesia (PTA) and outcome. All but one found the two were associated (the longer the duration of PTA, the worse the outcome). Only two of the studies reported how they measured PTA (53,55); both of these studies relied on the Galveston Orientation and Amnesia Test (GOAT) to mark the end of PTA (i.e., a score of greater than 75 on two consecutive days). Two of the studies (50,53) reported their data in such a way that it was possible to determine threshold values for excluding the possibility of either a good recovery or a severe disability. Specifically, one of the studies found that no subject had an outcome of severe disability until their duration of PTA exceeded two months (CI 0–3.6 percent) (50). Similarly, the Katz study (53) found that only 2 percent of individuals with a duration of PTA less than two months was severely disabled (CI 0.3–8.8 percent). Although both studies converged on the period during which a severe disability was unlikely, they varied in when they were able to exclude the possibility of a good recovery. The longest reported duration of PTA before one could exclude a good recovery was three months (CI 0–11 percent) (53).

*Discussion* The duration of PTA has long been considered one of the most powerful prognostic factors available to the rehabilitation clinician (66). Besides its power, the duration of PTA has other advantages that make it especially useful. For one, the duration of PTA lends itself to the identification of threshold values. Also, many of these thresholds are crossed while the patient is in inpatient rehabilitation, allowing the rehabilitation professional an opportunity to substantively address issues of prognosis during the rehabilitation stay. In addition, because these thresholds are often reached in rehabilitation, the rehabilitation professional has much more control over the measurement of this variable.

In general, the studies that reported thresholds converge on a duration of PTA of 2–3 months when the prognosis becomes much clearer. For instance, both the Bishara (50) and Katz (53) studies agreed that the possibility of severe disability was very unlikely when the duration of PTA was less than 2 months. Also, both the Bishara (50) study (whose confidence interval was too wide to include) and the Katz (53) studies converged on 2–3 months as the duration of PTA before the possibility of a good recovery becomes very unlikely. A review of the studies on PTA that did not meet the inclusion criteria revealed findings consistent with this value.

*Conclusions* The longer the duration of PTA, the worse the outcome. In particular, it is unlikely that a person will have an outcome of severe disability if the duration of PTA is less than two months. Conversely, it is unlikely a person will have a good recovery when the duration of PTA extends beyond three months.

### Age

*Summary* Of the studies that met the inclusion criteria, seventeen (27,29,30,33,38,39,40,42,43,45,47,49,50,52–55) investigated the relationship between age and outcome. All but two (39,50) found the two were associated (the older the patient, the worse the outcome). There were differences in whether increasing age was seen as a continuous risk factor or whether the risk increased at certain ages (“inflection points”). Four of the studies (33,49,52,53) reported threshold values of an age above which a good recovery was extremely unlikely. However, there was variability in the exact age found to represent this cut-off point. Among patients with a severe TBI, two studies found that no patients had a good recovery after the ages of 55 (CI 0–4.1 percent) (49) and 60 (CI 0–6.9 percent) (52). Another study found that, although there were some patients with a good recovery after the age of 65, the probability was low (6 percent) (CI 2–14 percent) (33).

*Discussion* Age is a powerful prognostic factor. Although the risk for adults appears continuous, the prognosis worsens significantly after the age of 65. This is discussed in more detail in the next section. A review of the excluded literature is consistent with these findings.

*Conclusions* Older patients have a worse outcome after a severe TBI. In particular, in patients over 65, the chances of a good recovery after severe TBI are unlikely.

### Special Populations: Elderly

*Summary* There were two studies (58,59) meeting the inclusion criteria that examined prognostic factors in patients over the age of 65. Both studies found the initial

GCS was associated with outcome: the lower one's GCS score, the worse the outcome. One study (59) found that no subject with an admission GCS <8 had a good recovery at long-term follow-up (CI 0–8.2 percent). This is consistent with the studies mentioned previously (49,52) that also found no subjects over 65 who had a good recovery after a severe TBI.

The other study on the elderly (58), however, found that a subset of those with an admission GCS less than eight did have the potential to achieve a good recovery. Specifically, they reported that those patients who regained consciousness within 72 hours had the potential to achieve a good recovery (3 percent in their series) (CI 0.6–8.9 percent). This finding is consistent with the results of the other study mentioned previously (33) that found some patients over 65 who achieved a good recovery (6 percent in their series, with CI 2–14 percent).

*Discussion* The importance of TBI in the elderly is growing. This is not only because the incidence of TBI rises in the elderly but also because the percentage of the population over the age of 65 is growing. Although there may be confounding factors (e.g., co-morbidities), it is now clear that age is an independent risk factor in this population (67). There are many potential reasons for this, ranging from the nature of the injuries in the elderly (e.g., subdural hematomas) to changes in the brain as one ages (e.g., decreased functional reserve, less elasticity of blood vessels, etc.). These issues are discussed in more depth in the chapter on TBI in the elderly (Chapter 21).

For our purposes, the main point is that a good recovery after a severe TBI in a person over 65 is very unlikely. The increased likelihood of poor outcomes is also found in the other severity categories. In fact, several writers have noted that, in terms of outcome, a moderate TBI in the elderly resembles a severe TBI in a younger person (58, 68, 69). Even the outcomes of mild TBI in the elderly are much worse, with many never returning to their premorbid functional status (70).

*Conclusions* In patients over the age of 65, the lower the admission GCS, the worse the outcome. In particular, older patients who have sustained a severe TBI (GCS less than eight) are unlikely to achieve a good recovery.

### Special Populations: Penetrating Injuries

*Summary* There were two studies (60, 61) that met the inclusion criteria which investigated prognostic factors in civilian patients with penetrating missile wounds. Both studies found the GCS was associated with outcome: the lower one's GCS score, the worse the outcome. Both studies also found that CT findings of bilateral injury or trans-ventricular injury were associated with worse outcomes. One study (60) found that no patients who had a

post-resuscitation GCS score <8 had a good recovery at long-term follow-up (CI 0–4.4 percent). The other study (61) only included patients with GCS scores of 3–5. No one in their series achieved a good recovery at long-term follow-up (CI 0–1.6 percent).

*Discussion* Penetrating injury differs from closed brain injuries in many ways, as discussed elsewhere in this textbook (Chapter 18). In terms of outcome, the early mortality rate after penetrating injury is much higher than that of closed head injury (71). Among the survivors, however, there are proportionally fewer people who are left vegetative or severely disabled (71). Although many prognostic factors have been studied in penetrating injuries (71), only the GCS is readily available to rehabilitation clinicians. Unlike closed head injury, where a range of outcomes is still possible with a GCS of 3–8, in penetrating injury it is very unlikely that patients with an initial GCS in this range will have a good recovery. These findings are consistent with those in the excluded studies; only one study reported any patients who achieved a good outcome with an initial GCS of 6–8 (8 percent) (72). However, they also found no one achieved a good recovery with an initial GCS of 3–5.

*Conclusions* In patients with a penetrating missile injury, lower GCS scores and CT findings of bilaterality or trans-ventricular injury are associated with worse outcomes. Moreover, those patients with a post-resuscitation GCS score of 8 or less are unlikely to achieve a good recovery.

### Special Populations: Moderate TBI

The focus of this chapter is on severe TBI because it is with this group of patients that the most uncertainty exists about long-term prognosis. In contrast, outcomes after moderate TBI are much clearer (10,19): more than 90 percent of individuals with moderate TBI will achieve either a moderate disability or good recovery. This information is certainly useful for clinicians counseling family members, especially by reassuring them the odds are heavily in favor of at least independent living, if not a return to previous function.

There are certain risk factors associated with the poorer outcomes: lower GCS scores (e.g., 9 or 10), older age, and abnormalities on the CT scan (10,19). When these are present, patients are more likely to have a moderate disability (or, infrequently, even a severe disability) rather than a good recovery. This information can be used to adjust the content and tone of prognostic information provided to family members.

Although the prognosis after moderate TBI is good, it is here that the limits of the higher categories of the GOS are most obvious. Studies have shown that even individuals with a good recovery often have neurobehavioral

problems that contribute significantly to the morbidity of moderate TBI (10,19). It is important to communicate this information to the family, although initially it may be in the most general of terms (e.g., “most people are able to at least live on their own after this type of brain injury, although they may have some other problems”).

### Neuropsychological Testing

Although early neuropsychological testing (performed within one month after injury or at the resolution of PTA) was originally included as a potential predictor variable, none of the studies reviewed met the methodological criteria, mainly because of limited follow-up. Still, because neuropsychological testing is so widely used in the rehabilitation setting, the findings of some of these studies (64,73–77) are reviewed here. Almost all the studies found an association between selected test results and long-term outcome, even when adjusted for demographic and injury severity variables (64). The specific tests found to be predictive varied between the studies, however, limiting the utility of the findings. Another feature of the studies that reduced their applicability was the use of statistical analyses that cannot easily be utilized in the clinical setting (e.g., correlation coefficients, principal components analysis, etc.).

Even when the findings were reported in a clinically useful way, the studies were still not helpful. This is because early neuropsychological testing, even when correlated with outcome, is not a particularly powerful predictor. In the language of the rest of the chapter, there were no threshold values that were found for neuropsychological test scores. For instance, one study (75) found that a normal score on one of ten tests identified as predictive still had less than a 50 percent chance of predicting productivity at one year or beyond. Even an impaired score, which was a more powerful prognosticator, predicted lack of productivity in only 70 percent of people. The utility of testing is further diminished by the fact that only a subset of patients are able to be tested subacutely; therefore, the results of these studies are not relevant to the significant number of patients who are not testable during inpatient rehabilitation.

In fact, this distinction between those who are testable or not (rather than the test scores themselves) turns out to be the most powerful predictor in these studies and one that could potentially serve as a threshold value for prognosis. In one of the two studies that examined this relationship (75), only 6 percent of patients who were unable to complete any test during inpatient rehabilitation were productive at one year. In the other study (64), only 6 percent of those who were not testable at one month were employed a year later. In contrast, being testable was not as predictive in either study, correctly classifying only about 40 percent–80 percent of those who

would be productive at one year. Although the inability to be tested in the subacute setting appears to be a potentially valuable prognostic variable, it does not provide significantly more information than the better supported use of length of coma or duration of PTA.

Indeed, it is likely that the findings in these studies were confounded by the length of coma or PTA. For instance, the first study was designed so that people were only tested when they emerged from post-traumatic amnesia. Thus, being testable was a marker for the length of PTA. The primary reason that patients who are not testable during inpatient rehabilitation do poorly is that they have a prolonged PTA. Assuming that most patients are discharged from inpatient rehabilitation about 2–3 months after their injury, those patients who are not testable during this period must have had lengths of PTA greater than 2–3 months, which was the threshold value identified in the previous studies. Similar considerations apply to the other studies (63,64). There was one study that did adjust for PTA duration; it found that neuropsychological test performance made a contribution to the prediction of productivity beyond that made by the duration of PTA (76). The exact improvement in predictive power made by the tests was not reported, however, and is unlikely to be clinically significant.

In conclusion, it is likely there is an association between early neuropsychological test performance and long-term outcome. More specific conclusions cannot be made because of the methodological limitations of the studies, the lack of consensus on which tests are most important, and because, even with the most robust results, there are no threshold values for test performance. The only statement that can be made with some confidence (within the constraints of the methodological limitations already discussed) is that not being testable early on is a poor prognostic sign for a productive long-term outcome. This subject is more extensively reviewed elsewhere (77).

### Summary

The 35 studies were almost unanimous in finding that age, initial GCS score, length of coma, duration of PTA, and neuroimaging findings are correlated with outcome (Figure 14–6). However, this represents information that TBI clinicians already know. Of much greater interest is the existence of threshold values for several of the variables; these allow the clinician to formulate more fine-grained prognoses in individual cases. Specifically, age, length of coma, and duration of PTA all provide valuable information the clinician can use to mark milestones when either a severe disability or a good recovery are unlikely. These results are based on a small number of studies (less than a third of the total), however; this must be kept in mind when using this information in clinical situations. On the other hand, the fact that these results were consistent

with those in the excluded studies increases one's confidence in the findings. In essence, the results are at least consistent with almost *all* the published literature.

There was only one minor exception to the general agreement between the included and excluded studies: the maximum length of coma after which a good recovery is extremely unlikely. The original review found a value of two weeks. However, as mentioned above, there were several excluded studies that found a significant number of individuals with a good recovery after two weeks of coma. These other studies seem to converge on the value of one month of coma as the time after which a good recovery is very unlikely. Because of the wish to err on the side of preserving hope, one month of coma was adopted as the final threshold value for length of coma (Figure 14-7).

Finally, the statistical uncertainty involved must be kept in mind. The upper limits of the confidence intervals for the threshold values averaged approximately 7 percent. This means that, on average, up to 7 percent of individuals could have outcomes that are considered unlikely (e.g., up to 7 percent of patients with a PTA greater than 3 months may have a good recovery on the GOS). This underscores the point that one should use terms such as "unlikely" or "very unlikely" rather than, for instance, "never" in talking with families. One may even want to convey the associated degree of uncertainty in quantitative terms.

### Applying the Guidelines

The final guidelines are presented in Figure 14-7. They are based both on the results of the initial review as well as, for length of coma, the findings of the excluded studies. Also, only findings supported by more than one study were included; this meant the results of the MRI study were not part of the final guidelines. There are a few final points about applying these principles. The first is simply to recommend the use of the different sources of information at different times in the recovery process. For

*Summary of Evidence-Based Guidelines for Prognostication After Severe TBI\**

example, if someone older than 65 years has a severe TBI, one knows fairly early that the chances of a good recovery are low, especially if they do not regain consciousness within a few days. For those under the age of 65, however, one will probably need to wait until the duration of coma is known (especially when it is less than two weeks or greater than 4 weeks). Later, because of its predictive power, the length of PTA should be used as the primary source of information.

This sequential use of different variables is important not only because the later variables are more powerful than the earlier ones. It is also necessary because there is not always a strong correlation between the variables (e.g., between the length of coma and duration of PTA). For instance, based on clinical experience, one can have a duration of coma of less than two weeks (which would imply a relatively good prognosis) with a protracted PTA of greater than 2–3 months (which implies a worse prognosis). In these cases, the prognosis based on the duration of PTA should be used as the primary source of information. It is also important to keep in mind some sense of the trajectory of recovery and adjust one's predictions accordingly. In someone who is still minimally conscious at two months, for instance, it is extremely unlikely they will become fully conscious and clear from PTA within the following month. Thus, one does not always have to wait until the passage of a full three months to infer that the likelihood of a good recovery is low.

Finally, it is also important to modify one's predictions based on the presence or absence of significant focal lesions. Although it is true that almost all the studies "correct" for the presence of focal lesions (by including both those with and without such lesions), knowledge of a significant focal lesion can help with prognostication in individual cases. Someone with a left anterior lesion and significant language deficits will likely have a worse outcome than patients who have similar lengths of coma, PTA, etc., but who don't have the same focal lesion. On the other hand, it has been shown that patients who primarily have diffuse axonal injury usually do worse than those whose primary lesions are focal (53). If the predominant underlying pathology is known, clinicians can use this information to modify what they tell patients and their families. In summary, application of the principles presented here involves the sequential use of the predictor variables, modified by knowledge of the larger trajectory of recovery as well as the presence or absence of significant focal lesions.

### COMMUNICATING PROGNoses

*Patients and their families will forgive you for wrong diagnoses, but will rarely forgive you for wrong prognoses.*

*David Seegal*

### Barriers to Communication

Formulating a prediction constitutes only part of the clinical act of prognosis; this information must then be communicated to patients and families. Clinicians' reluctance to communicate this information is just as responsible for the neglect of prognostication as is the difficulty in developing a prognosis in the first place. There are many reasons for this reluctance. Many health care professionals believe that patients and families don't want prognostic information (4). Yet, studies have shown that professionals significantly underestimate patients' and families' desire for this information (78–82). One study found that 88 percent of patients wanted prognostic information (83). Another study showed that, even when patients had not explicitly asked for prognostic information, they wished the clinician had discussed it with them (84).

Although none of these studies were specifically related to TBI (most were in oncology), there is no reason to believe the findings would be any different in brain injury. As mentioned earlier, families have identified information about the future as one of their greatest needs in the aftermath of a TBI (1–3). Of course, it is true some patients or their families sincerely do not want prognostic information (85). It may even be true that these preferences may vary by one's ethnic or cultural group (85). Therefore, one of the key steps in communicating prognoses is to find out how much information the patient or the family wants.

Another reason that rehabilitation professionals may be reluctant to discuss prognosis is the fear that families will interpret any discussion of uncertainty as evidence of the clinician's lack of competence (86). There is some support for this concern: one study found that the presentation of probabilities in discussing possible outcomes undermined patients' confidence in their physicians (87). In addition, there is evidence that clinicians themselves are unable to tolerate uncertainty (88); this is likely to contribute to their avoidance of prognosis.

Rehabilitation professionals may also believe that communicating a poor prognosis to patients or families causes too much pain, thereby extinguishing hope that might be needed to actively engage in rehabilitation. Yet studies in other contexts at least partially belie this concern. One study found that, although communicating a poor prognosis did result in short-term distress among cancer patients, they experienced less anxiety, more peace of mind, and better adjustment in the long-term (80). It might even be the case that not being told about a poor prognosis interferes with the grieving process by making it much more ambiguous (since one is not sure whether a loss has occurred). There is evidence this "ambiguous grief" results in more emotional distress than grief where the loss is both clear and acknowledged (89).

Finally, avoiding a discussion of prognosis can itself cause distress: the anxiety associated with uncertainty often compounds the suffering families experience. Of

course, like everything else in medicine, the benefits of communication must be weighed against the risks; however, in most cases, it is probable that more is gained by open communication (4). This is not to say that minimizing distress and fostering hope are unimportant. Rather, it is to highlight the fact that the avoidance of prognosis is unlikely to achieve these goals. There are better means by which to foster hope; some of these ways will be discussed shortly.

Not only are clinicians concerned about the distress they might cause families, they themselves feel distress in communicating poor prognoses (4). Clinicians (especially physicians) might feel unprepared to deal with the emotions the patient or family might express. Also, it has been argued that conveying a poor prognosis reminds clinicians of the limits of their abilities (since they are powerless to change the outcome) and this also reduces their willingness to have these discussions. Finally, the fact remains that most clinicians (again, especially physicians) are simply not trained in "how to break bad news" (78). Their reluctance stems from not knowing *how* to proceed (compounded by their apprehension in publicly performing a skill they have not mastered).

It is hoped the guidelines presented here (summarized in Figures 14-8–14-10) will help allay some of this anxiety and improve the frequency and quality of communication of prognostic information. Several general guidelines for communicating prognostic information are presented in Figure 14-8; these guidelines will structure the discussion to follow.

### Guidelines for Communicating Prognoses

*Begin with the Patient and Family* Although most patients and families want prognostic information, this is not universally true. Even those who want to discuss prognosis may differ in the amount of information desired as well as how its delivery is timed. Thus, if patients or families don't explicitly ask to discuss prognosis, it is important to ask if they are interested in the information. If so, one should explore in more detail what they are interested

- Begin with the family's desire for information as well as their current beliefs.
- Ensure that the meaning and content of the outcomes are understood.
- Present quantitative information in a manner that can be understood (see Figure 14-9).
- Foster hope.
- Pay attention to the process of communication (see Figure 14-10).

**FIGURE 14-8**

*General Guidelines for Communicating Prognostic Information*

- Try to use “natural frequencies” when communicating probabilistic information (e.g., “Eight out of ten people with this type of injury will make a good recovery”)
- Present information both qualitatively as well as quantitatively (e.g., “This is a very good chance of a good recovery”)
- Attempt to “frame” information in both a positive and negative manner (e.g., “That is the same as saying that two out of ten people with this type of injury will not make a good recovery”)
- When possible, consider presenting the information visually.
- Ask person to restate, in their own words, their understanding of the information provided

FIGURE 14-9

*Guidelines for the Communication of Quantitative Information*

- Find a quiet, comfortable room without interruptions
- Sit close and speak face to face
- Have the family member's support network present, if wanted
- Present the information at a pace the family can follow
- Periodically summarize the discussion to that point
- Periodically ask family member to repeat or summarize what was said
- Keep the language simple but direct, without euphemism or jargon
- Allow time for questions

FIGURE 14-10

*Guidelines for the Communication Process*

in (for instance, in terms of possible outcomes). It is also helpful to begin by asking the family members what they already know and what their current perceptions are. This enables the clinician to build on the knowledge they already have or, if appropriate, correct any misinformation that might distort their understanding of the information to follow. Starting with the patient or family's desires and beliefs not only ensures that the discussion addresses their needs, but it also draws them into the conversation early (and thus hopefully makes it easier for them to articulate their concerns). It also gives them some sense of control in a situation where they often feel powerless.

**Ensure Understanding of the Outcomes** It is important that families clearly understand the nature of the outcomes discussed. This is especially important when one is using studies that rely on the GOS. The names of the GOS

categories can be confusing. In particular, the terms moderate and severe disability may imply a far worse prognosis than might actually be the case. Most families would not necessarily consider someone who can live independently and use public transportation moderately disabled, even if they can't work. Or, a person who might be independent in mobility and self-care might not be considered severely disabled, even if they were unable to live independently for cognitive reasons. Given this ambiguity, it is best to avoid the GOS category names altogether, and simply describe concretely what the outcomes might be. It is also important to mention some of the limitations of the GOS. Families should be aware that patients who achieve a good recovery might still have significant emotional or behavioral issues. At the same time, they should also know that the category of severe disability does not automatically preclude a good quality of life. One study found that almost half of individuals classified as severely disabled by the GOS at one year were satisfied with their lives (and close to a third who had made a good recovery were dissatisfied with their lives) (90). Finally, it is important to stress to families that most of the studies on prognosis followed patients for only a year, on average, and that there is evidence for continued gains well beyond that time (15).

**Present Statistical Information in an Understandable Manner** Prognostication is not only about the range of possible outcomes but also the likelihood of their occurring. Therefore, the ability to convey the numerical aspects of the information accurately is crucial. However, there are significant barriers to effective communication of quantitative information. The level of numerical literacy (“numeracy”) in the general population is low (91). Even the understanding of the most elementary ideas of probability cannot be taken for granted. In one study, only half the respondents were able to predict the results of tossing a fair coin 1000 times. The same study found that only 16 percent of respondents correctly answered all three of a set of basic numerical questions (92). These findings have been reproduced in other studies (93).

People had the most difficulty with concepts such as relative risk (94), odds, rates (where the numerator is fixed at 1 and the denominator varies) (95), and proportions where the denominator was anything other than 10 or a 100. One common problem is that people often pay attention only to the numbers and not the form they are in. That is, they believe that the expression with the highest number must represent the highest probability, regardless of whether it is expressed as a rate, proportion, percentage, etc. In one study, subjects rated a health problem as riskier when told that it affects 1,286 out of 10,000 people compared to one that affects 24.14 out of 100 people (96). Other times it is not clear why people are having difficulty. For instance, in another study, half the

respondents believed that 2.6/1000 was a larger number than 8.9/1000 (94). Converting between proportions and percentages was particularly difficult (92,97). In summary, there is a significant chance for confusion when the likelihood of outcomes is communicated by concepts such as rates, proportions, etc.

However, the most common way of communicating prognostic information, both in studies and in clinical practice, is through the uses of percentages (e.g., “there is a 70 percent chance he will be able to go back to work”). Yet the comprehension of even such a seemingly straightforward concept as percentages cannot be taken for granted. One study that assessed the understanding of the phrase “there is a 30 percent chance it will rain tomorrow” found that two thirds of the subjects misinterpreted the statement (for instance, believing it meant that it will rain just 30 percent of the day or in 30 percent of the area) (98). The problem here has less to do with numbers and more with an understanding of the referent class—what the percentage is about (e.g., believing that it refers to a portion of the day or the geographic area instead of the likelihood of any rainfall). Even when it seems clear to professionals what the referent class should be, patients can be confused. In one study where patients were told “your risk of developing breast cancer is 10 percent”, one subject asked “10 percent of what?” (99). Besides confusion about the referent class, there are other logical or conceptual difficulties that people can have with percentages. For example, a study found that some people thought the risk of developing and dying of breast cancer was higher than the risk of simply developing breast cancer (100).

In addition to the conceptual issues, problems even arise with the numerical aspects of percentages. In looking at cumulative risks (which required addition), many subjects in one study ended up with totals greater than 100 percent (100). In another study of people who were “highly educated”, 20 percent of the respondents were not able to state which represented the larger risk: 1 percent, 5 percent, or 10 percent (93). Thus, when communication about prognoses involves the use of percentages, it cannot be automatically assumed that patients or families understand this information.

The difficulty in understanding numerical information is further compounded by the quantified uncertainty associated with any prediction. That is, not only is the primary outcome itself expressed as a probability (e.g., “your son has a 70 percent chance of living independently . . .”), but this estimate itself is subject to uncertainty (“ . . . and we know this with 90 percent certainty”). Having to process two different levels of numerical uncertainty can overwhelm families and patients and, thus, ironically, end up disempowering decision-making rather than enabling it (87). These expressions of uncertainty can also undermine confidence in the clinician (87), as discussed earlier.

In the end, the numbers themselves may not even be used in decision making. Several studies have found that people immediately code numbers they hear into qualitative or ordinal categories such as high, medium, or low probability or even simply “likely” or “not likely” (86,94,96). Moreover, there is evidence the categories people use were better predictors of their decision making than the actual numbers they were given (94,96). Others have found the form of the information (numerical vs. qualitative) did not affect decision making (101). These findings raise the issue of whether professionals should be communicating numeric values to patients and their families in the first place, rather than using qualitative statements such as likely, unlikely, probable, etc.

In fact, studies have shown that about a third of people would prefer that information about the likelihood of future events be given in qualitative terms rather than numerically (102,103). The problem with qualitative information, however, is that there is a wide variation in the interpretation of the terms, both among patients as well as professionals. One study found that the range of values patients associated with the word “frequent” was 30 percent to 90 percent (102). A report on the understanding of these terms by professionals finds that, for example, the range of values associated with the term “unlikely” was .05 to 90 percent (104). A study that compared the understanding of clinicians and patients found that they differed by an order of magnitude in the numerical associations they made to the same qualitative terms (105). These findings suggest that any use of descriptive terms would need to be supplemented by numeric information, even for those patients who prefer that information be presented qualitatively.

In addition to numeric and qualitative *verbal* communication, there is evidence that graphic displays may also aid in communicating numeric information (106). However, very few studies have directly examined which format might be the most effective. One study that did investigate this question found that a row of ten human stick figures (shaded and unshaded to represent the percentages involved) was the most easily understood graphic and preferred by most of the subjects (99). This is an area needing further study.

So far the discussion has focused on how the quantitative content of information is presented, whether descriptively, numerically, graphically, etc. Yet, non-quantitative aspects of the message can also affect a person’s perception of how likely an event is to occur. For example, one could state that a patient has a 10 percent chance of having a good outcome or a 90 percent chance of having a poor outcome. Almost universally, people perceived a good outcome as being more likely when presented with the “positive” statement (“10 percent chance of good outcome”) than when presented with the “negative” statement, despite both being numerically equivalent. These

findings are the result of “framing” effects, the most widely studied of which has been the “positive/negative” or “loss/gain” frame, as in the example above. A recent review found that, while framing effects did exist, their effect on patients’ understanding was much less than that of the “innumeracy” described earlier (107). Still, the existence of framing effects has implications for how prognostic information might be communicated in TBI, as will be seen below.

Although the discussion so far has primarily been about patients and families, it should be pointed out that professionals, especially physicians, often have the same problems in handling quantitative information. Studies have found that physicians are subject to positive or negative framing effects in their treatment decisions: when the same numeric data were presented in a positive frame, physicians were more likely to undertake the treatment (108). Other studies have demonstrated that the way in which the results of clinical trials are reported will affect physician prescribing practices, even when the results themselves are identical (108). For instance, physicians are more likely to prescribe medications if efficacy is presented as a relative risk reduction instead of an absolute risk reduction (109,110). With regards to the qualitative use of probability terms, there is just as much variability in physicians’ understanding of these terms as is found with laypeople (104). Finally, there is widespread acknowledgement of the difficulties most physicians have in understanding other statistical concepts, including concepts used routinely in journal articles and even clinical practice (111,112).

*Practical Suggestions for Presenting Statistical Information* Given the significant barriers to the communication and comprehension of numeric information, what is the best way for a professional to proceed? One solution would be to minimize the occasions in which this information would need to be presented. Clinicians could avoid these discussions during those periods of the recovery process when there are a wide range of possible outcomes. Because each of these outcomes will be associated with a different likelihood of occurring, a discussion would involve the presentation of many different probabilities, further compounding the difficulties patients and families have with quantitative information. One of the advantages of threshold values is that they minimize the cognitive demands on comprehension. To tell a family that it is extremely unlikely the patient will be severely disabled or, alternatively, that it is now extremely unlikely they will have a good recovery, is comprehensible and requires minimal numeric abilities to understand. During periods before these milestones are reached, clinicians could avoid discussing the probabilities of particular outcomes and rely on more general statements such as “All we can say at this point is that there is a chance that she

will be able to return to work; we will know more later, as further information becomes available”.

Some families, however, will request detailed information even before milestones are reached. Or, even after a threshold has been crossed, they are interested in the likelihood of a moderate disability on the one hand and either a severe disability or good recovery, on the other. In these cases, there are some general principles that a TBI professional can follow to maximize the chances of comprehension (Figure 14-9). The first suggestion addresses the issue of what form the numeric information should be communicated in. As mentioned earlier, most people have significant difficulties with odds, rates, risks (especially relative risks), etc. Even percentages can be confusing for many people (100). The form of communicating numeric information that seems least susceptible to misunderstanding is the use of natural frequencies (98,99,112). In essence, a natural frequency describes the number of people out of an easily comprehensible set (e.g., 10 or 100) that have the outcome of interest. For instance, rather than state “There is an 80 percent chance your son will have a good recovery in a year”, one would say “Out of 10 people like your son, eight of them will have a good recovery in a year” (98,99,112).

As professionals, we are so used to converting one expression into another that we may no longer perceive the differences between these two formulations. There are, however, two important differences between using natural frequencies and using percentages. First, from a numeric point of view, people have more difficulty with percentages than they do with proportions (as long as the denominator is either 10 or 100 and is kept constant). This is not the only issue, however. To see why, compare the two expressions: “Your son has an 8 out of 10 chance of having a good recovery” and “Out of 10 people like your son, eight of them will have a good recovery”. Even though both formulations use proportions, people have much less difficulty with the second formulation.

This is because the second formulation specifies the referent class. By making it explicit that one is talking about people, the ambiguity that might result in questions such as “80 percent of what?” can be avoided. It also relevant that the referent class refers to persons instead of outcome categories. There is increasing evidence from cognitive psychology that people are better able to handle computations if they involve persons rather than abstract concepts (98,112). This was also seen when physicians were asked to solve questions of probability involving diagnostic testing (112).

Another suggestion to improve the communication of quantitative information would be to present the information through different routes; not just numerically, as just discussed, but also qualitatively and visually. Because most studies show that people are equally divided in how they wish to receive information, it would make sense to

rely on more than one modality. And the fact that people might have difficulty even in their preferred modality justifies presenting the information in at least two different ways. So, in the example cited, after the information was presented numerically, one might say “This is a very good chance for a good recovery”.

In addition, given the known effects of framing on the perception of information, one can consider framing the information both positively and negatively. One might say “This means that 2 out of 10 people in his situation will not have a good recovery”. Although framing information both positively and negatively might ensure better understanding of the actual likelihood, it could be argued that clinicians should rely mainly on positive framing so as to maximize hope (see below). Finally, as with any other medical interaction, it is helpful to ask the patient or family members to state, in their own words, their understanding of the information.

*Fostering Hope* The recommendation to foster hope may seem out of place in a discussion of *techniques* for communicating prognostic information. However, hope is an important part of this process. Of course, hope is most relevant when there is uncertainty. When the eventual outcome is fairly clear (e.g., PTA duration of several days), hope is less relevant precisely because of the certainty of the outcome. In contrast, when the outcome is uncertain (and an undesired outcome is possible), hope becomes correspondingly more important. Fostering hope has many advantages. For one, it may help patients and families to mobilize their energies and resources to engage fully in rehabilitation. In addition, when the prognosis is likely to be poor, even a little hope may “cushion the landing” and allow family members more time to process and come to terms with the probability of a poor outcome. Finally, based on clinical experience, most families seem far more upset with clinicians who offered them little or no hope when the outcome turned out well than those who offered some hope when the outcome was poor.

Of course, there are risks to offering hope, most notably the fear it might prevent family members from adequately preparing for a poorer outcome than they expect. However, the standard advice to families to “hope for the best but plan for the worst” (113) should allow most families to prepare for an undesired outcome without losing hope. When the concern about lack of adequate preparation persists, the clinician can always engage the family in another conversation, trying to shift their perspective. Overall, it appears that the benefits of offering hope in prognosis outweigh the risks (at least in most situations).

It was the commitment to fostering hope that was partly responsible for the emphasis on threshold values in this chapter. For instance, the interest in the longest period of PTA before one can reasonably exclude the possibility of a good recovery was motivated by the wish to

preserve justified hope as long as possible. Likewise, being able to tell family members that the chances of severe disability were unlikely if a patient emerged from PTA within a particular time frame helps to allay fears about the possibility of an especially “bad” outcome. The disadvantage of threshold values is that one has to wait until the milestones are reached before one can provide families with more precise information. One way to minimize the frustration of families during the period before a threshold value is crossed is to describe concretely what the potential outcomes are. This is much more helpful and reassuring than saying “we’ll just have to wait and see what happens”. Knowing what the outcomes might be gives families some sense of control (if only cognitive), while preserving hope for a favorable outcome.

Another way in which to convey hope involves framing the information in a positive way by presenting the likelihood of the favorable outcome rather than the unfavorable outcome (e.g., by saying “he has an 80 percent chance of a good outcome” instead of “he has a 20 percent chance of a poor outcome”). One could also accentuate the positive aspects of less favorable outcomes. For instance, one could point out that someone with a severe disability may still be independent in mobility and self-care. Or that there is not a strong correlation between disability category and quality of life. Or that people with traumatic brain injury are usually fairly healthy. In addition, emphasizing that improvement continues beyond the first year (the end point for many of the studies discussed) is another way of providing encouragement. Even the uncertainty in the prognosis can help to foster hope; by carefully highlighting this uncertainty, one can salvage a little hope even when the prognosis is particularly poor. One could even provide a rough numerical estimation of this uncertainty, based on the confidence intervals discussed earlier (e.g., “Although it is possible that up to 5 percent of people in his condition could have a good recovery, it is extremely unlikely”). Finally, it is important to reassure the family they will not be abandoned and that the clinician will be available to them during the long period of recovery (if true).

*Optimizing the Process* There have been several good reviews on improving the process by which this information is communicated, especially in the case of “bad news” (78–80). Some of these guidelines are summarized in Figure 14-10 and are self-explanatory.

## RECENT DEVELOPMENTS

*Predictions are difficult, especially about the future.*  
Yogi Berra

This chapter has focused on “classical” predictors of outcome after TBI. This was motivated by the wish to focus

on variables that are easily accessible to rehabilitation professionals. In addition, there is a much larger body of literature available for these variables than for more recently discovered prognostic factors. Still, rehabilitationists should be aware of these recent developments as they are likely to affect clinical practice over the next several years. Several of the most promising of these prognostic variables are discussed below: magnetic resonance spectroscopy (MRS), serum 100b assays (s100b), and apolipoprotein E (APO E) status. The one other modality that might have been included here is the use of evoked potentials in prognostication; however, this topic is covered elsewhere in this book (see Chapter 13).]

### MRS

Magnetic Resonance Spectroscopy (MRS) is a noninvasive modality that provides information about the neurochemical status of the brain. As such, it provides physiological information that appears to correlate more strongly with neuronal dysfunction than the structural information provided by conventional MRI. MRS allows one to measure the quantity of compounds thought to be markers of neuronal damage, whether from inflammation, impaired energy metabolism, neuronal death, myelin breakdown, etc. Examples include N-acetyl-aspartate (NAA), choline (Cho), and creatinine (Cr). Changes in the quantities of these compounds (or the ratio between them) correlate with the extent of cellular damage after neural insult.

Although this modality has been studied in many neurological disorders, its use in TBI is just beginning (114). Studies have already shown, however, that people with TBI and controls differ in the amount of these various compounds and that the relative concentrations correlate with *concurrent* neuropsychological performance (115) or GOS category (116). Other studies have demonstrated that certain variables (e.g., decreased NAA/Cr, decreased NAA/Cho, and increased Cho/Cr) correlate with other markers of injury severity (such as GCS and PTA) (117). Even more importantly, studies have shown that concentrations of these compounds seem to correlate with later outcomes, such as GOS at 6 months.

Several studies have found that MRS studies performed in the subacute period (approximately 6 weeks post-injury) correlated with outcome at 6 months or longer. For instance, either total gray matter NAA (118,119) or white matter NAA/Cr (120) correlated with both neuropsychological outcome (118,119) as well as outcome on the GOS (118,120), at 6 months. Other studies found that MRS scans done in the acute period also correlated with long-term outcome. One study found the NAA/Cr ratio acquired about two weeks after injury correlated with outcome on both the GOS and DRS at six months (121).

Besides the general finding that MRS variables correlate with later outcomes, several studies found

threshold values that seem to discriminate between various possible outcomes. One study reported values of gray matter NAA above which no one had less than a good recovery and below which no one had a good recovery (118). Another study found minimal overlap in the white matter NAA/Cr values between those subjects with severe disability, moderate disability, and good recovery (121). Finally, several studies investigated the improvement in accuracy gained by using MRS data instead of traditional clinical variables. For instance, one study in children found the presence of early (one week) lactate correctly classified children into either a good recovery/moderate disability or a poor recovery 96 percent of the time (versus about 80 percent accuracy with traditional clinical variables) (122). Another investigation also found that early (one week) MRS variables improved accuracy over clinical variables from 72 percent to 84 percent (123).

Although the results of these studies are promising, several caveats must be kept in mind. First, all of these studies were exploratory and met few of the methodological criteria used in this chapter. In addition, although several of the studies demonstrated that acute MRS variables were more accurate than other acute variables (such as GCS, pupillary abnormalities, etc.), no study has compared the accuracy of MRS variables to the even more powerful clinical variables that are available later (e.g., duration of PTA). Despite these current limitations, MRS is potentially a powerful aid to clinical prognostication after TBI.

### Serum 100b

Many serum markers have been proposed as prognostic factors after traumatic brain injury. These include serum 100b protein, neuron-specific enolase, interleukin 6, cleaved tau protein, and glial fibrillary acidic protein. Of these, the most promising work has involved serum 100b protein (S100b), which is found predominantly in astroglial cells. After a brain injury, increased levels of this compound are found in the blood as damaged glial cells release serum 100b across a disrupted blood-brain barrier. The protein is released immediately and peaks early; as a result, most investigators believe that only very early values (within hours after a TBI) are helpful in prognostication. As with MRS, serum 100b has also been studied in other neurological disorders such as anoxic brain injury.

Studies in traumatic brain injury have shown that early S100b levels correlate with the severity of injury (124,125) as well as the extent of abnormality seen on neuroimaging (125–129). More importantly, there are now many studies that suggest that early S100b values help predict long-term outcome as measured by the six month GOS category or neuropsychological test performance (127–133). Other studies have demonstrated that early S100b values are also correlated with outcome at

one year, both on the GOS (134–136) as well as on quality of life measures (134).

Most of these studies reported cut-off values for S100b levels that help distinguish between favorable (usually moderate disability/good recovery) and unfavorable outcomes (usually severe disability or death). They also reported the sensitivity, specificity, vegetative state, and positive and negative predictive values of the different cut-off values chosen. In general, the values chosen had high specificities (over 90 percent) and moderate sensitivities (around 70 percent). In other words, when S100b values are higher than the threshold levels chosen, there is a 90 percent chance of an unfavorable outcome. On the other hand, serum values below the cut off values are not as helpful because as many as 30 percent of patients with values below the threshold can still have an unfavorable outcome. Of course, the values chosen can be adjusted to increase either the sensitivity or specificity (but always at the expense of the other). Most of the studies being discussed compared the accuracy of predictions based on S100b levels with those based on other variables such as GCS, imaging abnormalities, etc. In almost every case, the S100b value was the most powerful predictor of outcome (137). Finally, although the discussion so far has focused on severe injuries, there is interest in using S100b values to predict which patients are at the highest risk of developing persistent post-concussional symptoms after a mild TBI (138–141).

Although all of these results are encouraging, they are still preliminary. As with the studies on MRS, almost none of the studies met the methodological criteria used in this review. In addition, the studies that reported the relative superiority of S100b compared the accuracy of S100b levels to values of *isolated* acute care variables rather than to a *combination* of these factors (which are known to be more powerful). Another significant concern about the use of S100b assays is the accumulating evidence that there are significant extracranial sources of S100b. These include soft tissue and bone, which are often damaged by the same incidents that result in TBI (142). As a result, there is a concern that previous studies may not have adequately controlled for these extracranial sources of S100b; this issue is still being debated. Finally, since the serum 100b level must be drawn within a short period after the injury, it is only of use to the rehabilitationists if they have access to results from the acute care setting. Despite these concerns, S100b values are potentially a powerful aid to prognostication after TBI.

### Apolipoprotein E

Apolipoprotein E plays a number of different roles in the human brain, many of which are not completely understood (143). Although its role in Alzheimer's disease has been known for a long time, there is now evidence this

lipoprotein can affect outcome after TBI. Early studies suggested that possession of the E4 allele was associated with a worse outcome after TBI. One study found this allele over-represented in patients who were still vegetative after one year and that presence of the E4 allele was a better predictor of outcome than the duration of coma (144). In another early study, patients with the E4 allele were more than twice as likely to have an unfavorable outcome on the GOS as those without the allele, even when adjusted for age, CT findings, and initial GCS (145). A different study found that, although the risk of severe disability was not associated with the presence of the E4 allele, the chances of having a good outcome were lower in the E4 group, even when controlling for age or duration of unconsciousness (146).

Despite these early findings, more recent studies have demonstrated either a smaller effect of the E4 allele or no discernible effect. Although a recent study reported a lower FIM motor score in carriers of the E4 allele, the difference was clinically small and was not found in the cognitive FIM score (147). Other studies found no association between the presence of the E4 allele and GOS outcome at 6 months (148,143). However, in the latter study (143), this may have been a result of the population studied (South African blacks); all the previous studies were done in caucasian populations and it is known that the impact of the E4 allele varies by race, at least in Alzheimer's disease.

Thus, the results of the studies done so far have been inconsistent. It seems fairly clear that the E4 allele does modify some end-points such as hematoma size (149), performance on a few neuropsychological tests (150, 151), or the development of late post-traumatic seizures (148). Its effect on more global outcome measures, however, is less pronounced. More importantly, the effect is not large enough to significantly improve clinical prognostication. Rather, the value of these findings will more likely be in identifying targets for intervention in the pathophysiology of TBI.

### Neural Networks

All the advances discussed above involved new types of information or data that were not previously available. But there is also some interest in different ways of analyzing already available information. All the studies discussed in this chapter used traditional statistical methodologies such as linear regression or decision trees. The use of newer statistical methodologies holds out the hope that more accurate predictions can be made than with conventional statistical methods. Probably the most promising of these new methods are neural networks. A neural network is a system of mathematical models that attempt to model the way the human brain processes information. One of its most distinctive features is that it "learns by experience".

That is, given a large data set and “training rules” about data relationships, the neural network can respond in novel ways to new inputs (such as data that were not used in the original “training”). The use of neural networks in clinical medicine is growing (152,153) and its use in TBI is being explored (154).

Two primary issues surround the use of neural networks in prognostication. The first is accuracy: does the use of the neural networks result in more accurate predictions than more traditional models? The evidence from other fields is mixed (152) and a study on TBI found no difference in accuracy between a neural network analysis and one based on logistic regression (154). The other issue surrounding the use of neural networks is ease of clinical use. The concern is that neural networks are “black boxes” because there is no way of making explicit how they generate their predictions. All one can know are the data inputs and the resultant outputs. In more traditional methods, the algorithm used is explicit and its conceptual bases understandable, even if its numeric aspects are not. It has been suggested that this lack of transparency would limit the use of neural networks by clinicians (153). Despite these concerns, the use of neural networks in outcome prediction after TBI holds promise and bears further investigation. Other statistical methods are also being evaluated; readers are directed elsewhere for more information (155,156).

### CONCLUSIONS: SUGGESTIONS FOR FURTHER RESEARCH

There is still much work that needs to be done on prognosis after traumatic brain injury. For one, it would be helpful if a larger group, such as a task force, reviewed the literature in order to see if they could replicate the results of this chapter. Having a group of individuals involved, rather than a single author, might improve the quality of the criteria used, the scope of the literature search, as well as the classification of the studies. In addition, a larger group could expand the grading system that is used to include different levels of strength of evidence (as is common in most evidence based reviews). At the time of this writing, it appears that the American Congress of Rehabilitation Medicine has assembled a task force that may pursue these goals.

In addition to reviewing already existing studies, it is important that more studies be conducted in an attempt to confirm the findings of this review. However, these studies should be designed so as to build on the strengths of the current literature and to compensate for its weaknesses (in scope or design). This is crucial given how few studies formed the basis of the recommendations presented here. Most generally, it would be important for future studies to incorporate the concept of threshold

values to maximize their clinical utility. It would also be important to focus on those variables that have already shown promise as being clinically useful (such as the duration of coma or PTA, magnetic resonance spectroscopy, etc.) rather than those that are clearly not powerful enough to aid in clinical prognostication (such as initial GCS or CT imaging). It is noted that the utility of neuropsychological testing is still unclear, given the limitations of the studies done to date. It would be useful to have better studies in this area to determine the value of such testing.

In addition to selecting appropriate variables, it would be important for future studies to address shortcomings in the outcome measures used previously as well as to study more relevant populations. With regard to outcome measures, given the clear limitations of the Glasgow Outcome Scale, more studies should be conducted with newer, more promising measures such as the Community Integration Questionnaire. The duration of follow up should be longer as well, given what is now known about the possibility of clinically meaningful recovery that can occur a year or more after an injury. In terms of setting, more studies are needed that are based in inpatient rehabilitation (thus circumventing the problems that arise when attempting to extrapolate from the acute care setting to patients in rehabilitation).

Finally, it is important that studies be conducted that attempt to identify what types of prognostic information patients and families want. There have been very few studies that have explicitly addressed this issue (see the discussion in Appendix II). Yet, because prognostication is ultimately a *clinical* act (one directed at and meant to benefit patients and families), it is crucial that future studies on prognostication (as opposed to studies on outcomes more generally) be designed around the explicit needs of patients and their families.

### APPENDIX I: EVALUATING AN ARTICLE ON PROGNOSIS

This section discusses some general guidelines that readers can use when evaluating individual studies on prognosis; these are summarized in Figure 14-11. Interested readers are referred to more detailed discussions of these issues (157–165). In general, three main principles guide the critical evaluation of an article on prognosis: the *quality* of the study, its *relevance* to one’s own practice, and the *utility* of the findings. A study can be methodologically sound but inapplicable to one’s practice, for instance if the study population is not similar to one’s own. Or the reverse can happen: the study is relevant to one’s practice but, because of problems in design, one cannot rely on the study’s results. Finally, a relevant and methodologically sound study may still not be helpful because

<p><b>Outcomes</b></p> <ul style="list-style-type: none"> <li>• Is the outcome clinically important?</li> <li>• Is the outcome measure validated?</li> <li>• Is the outcome measure described well enough that it can be easily applied?</li> <li>• Did an appropriate amount of time elapse before the outcome was measured?</li> </ul> <p><b>Predictor Variables</b></p> <ul style="list-style-type: none"> <li>• Are the predictor variables described well enough that they can be easily applied?</li> <li>• Are the predictor variables easily accessible?</li> <li>• Do the predictor variables have high reliability?</li> </ul> <p><b>Sample</b></p> <ul style="list-style-type: none"> <li>• Is the population described well enough to determine if they are similar in relevant aspects to your own (including the site)?</li> <li>• Was there any bias in the selection of subjects (for instance, an inception cohort vs. a convenience sample)?</li> <li>• Was the sample large enough?</li> <li>• Was there minimal loss to follow up?</li> <li>• Were the characteristics of those who were lost to follow up compared to those who completed the study?</li> </ul> <p><b>Results</b></p> <ul style="list-style-type: none"> <li>• Were the findings reported in a form that is useful for clinicians (e.g. absolute risk)?</li> <li>• Was the precision of the estimates provided (e.g. confidence intervals)?</li> <li>• Was there an evaluation of validity (replication of findings in same sample)?</li> <li>• Have the findings been confirmed in other studies (reproducibility)?</li> <li>• Are the findings believable on biological grounds?</li> <li>• Do the findings represent an advance over already available prognostic tools?</li> </ul>
---

**FIGURE 14-11**

Guidelines for Reading an Article on Prognosis

the results are reported in a way that makes it difficult to apply to clinical practice.

These principles of quality, relevance, and utility guide the questions that one should ask about the various components of the study: outcomes, predictors, sample, and results (Figure 14-11). It is also important to assess the statistical analysis performed, although this issue is only briefly addressed here. Many of the criteria listed in Figure 14-11 will be familiar: they are identical to the inclusion criteria for this review. The second appendix provides a detailed review of these criteria; therefore, they will not be discussed here. Rather, the focus will be on the new criteria listed. The following discussion is organized according to the topics mentioned earlier (outcomes, predictors, sample, results).

## Outcomes

The outcomes must be of clinical relevance, one that would matter either to the clinician, the patient, or their family. Whatever outcome measure is used, it should be well described so clinicians can apply it to their own patients. The outcome should also be easy to measure in clinical practice. It should also be a measure that has either already been validated or, at least, has had some assessment of validity performed in the study itself. Finally, the outcome should be measured at an appropriate time (at least 6 months after a TBI).

## Predictors

Many of the same criteria apply to the study's choice of predictor variables: they should be well described, have high reliability, and be easily accessible or easily performed by the clinician.

## Sample

The sample should also be well described, so readers can decide if the subjects are similar to their own patients. In assessing this, it is also important to keep in mind the nature of the treatments received by the study population and whether one's own patients receive similar treatments. The study should be prospective, utilizing an inception cohort, rather than retrospective (e.g., a case-control design). The sample size should also be adequate. The size of the sample not only affects the precision of the estimates (e.g., the width of the confidence intervals) but also ensures the sample obtained is representative of the population. In addition, many of the statistical analyses performed require a sample of a certain size for the results to be valid (e.g., for multivariate analyses).

There should also be minimal loss to follow-up. Although most authors recommend the loss to follow-up should be no greater than 15–20 percent, the real issue is the number of people lost to follow-up relative to the number of people with the outcome of interest. One way of evaluating this would be to examine what would happen if everyone lost to follow-up ended up in each of the outcome categories. For instance, a 15 percent loss to follow-up in which the outcome categories were equally likely (e.g., 50 percent “good” and 50 percent “bad”) would not affect the results significantly. Even if you assume that all of those lost to follow-up either had a good outcome or a bad outcome, the percentages would shift only slightly (e.g., to 57 percent and 43 percent in either direction), not enough to affect prognostication. On the other hand, in a study in which no one achieved a certain outcome (e.g., severe disability), a 15 percent loss to follow-up would be significant if all 15 percent were severely disabled. Finally, it would be ideal if the

characteristics of those lost to follow-up were compared with those who remained in the study.

## Results

The results have to be reported in a way that is clinically useful, so they can be used to formulate a prognosis for individual patients. In general, absolute risks or simple percentages are more useful than measures such as relative risk, likelihood ratios, odds, etc. There should also be some report of the precision of the estimate provided (e.g., the width of the confidence interval). Ideally, there should also be some assessment of the model's validity: both by replication of the findings in the original sample as well as, more importantly, replication at other sites. Although this assessment of validity represents the ideal, it is rarely met in studies of TBI. An exception that illustrates the importance of replication was a study done in the acute care setting (166). This study applied a previously published model (167) to their own patient population. Although the model was reported to be 100 percent accurate in the original study, the second study found it to be only about 65 percent accurate in their patient population.

Finally, the results of the study should be interpreted in the larger context of the available literature. Do the findings make sense based on what is known of the pathophysiology and natural history of TBI? Have other studies confirmed the findings? Do the findings provide for more accurate prognoses than is already possible?

## APPENDIX II: METHODOLOGY

### Methods

Extensive literature searches (based on the inclusion criteria described below) were performed on Medline, PsycInfo, and the personal database of a colleague of the author (which has over 20,000 TBI specific articles); the search covered the period from 1983 through 2004. Hundreds of articles were retrieved and their bibliographies then reviewed for further references. All the articles were then reviewed to determine whether they met the inclusion criteria. The inclusion criteria were developed after extensive discussions with various professionals (including, for instance, neurosurgeons and biostatisticians), as well as family members and survivors. The general principles that guided the selection of the inclusion criteria are presented in Figure 14-4. The inclusion criteria themselves are listed in Figure 14-5. The sections that follow explain the rationale for the criteria chosen.

### Population

*Severe TBI* Patients with moderate and, especially, severe TBI make up most of those admitted to inpatient

rehabilitation. Therefore, the original plan was to focus on both of these groups. However, there were no studies meeting the inclusion criteria that focused only on moderate TBI. Even among the studies that met the inclusion criteria, only a few included patients with moderate injuries and, even then, they only comprised a small percentage of the total number of patients. Moreover, these studies had other eligibility criteria that excluded many of the moderately injured patients (e.g., by only including patients who had been admitted to an ICU). For these reasons, this chapter focuses on patients with severe TBI. This seems appropriate given the limited evidence available for patients with moderate injuries, the generally good outcomes in this group (10), and because patients with severe injuries are the ones for whom prognostication is often the most difficult. Studies on civilian penetrating brain injury were evaluated separately from those on closed brain injury, given the substantial differences between these two populations.

*Subacute Period After TBI (Acute Care and Rehabilitation)* The focus of this chapter is on prognostication during the subacute period, which was defined as the period from the initial stabilization of the patient after the injury (usually in the first week) to approximately three months after the injury. It was felt that this period was of most concern to rehabilitation clinicians working with TBI. Certainly, there are other periods in which the question of prognosis is relevant. Most obviously, there is a great deal of concern about prognosis in the acute setting, early after a TBI. Similarly, survivors and family members often continue to have questions about "final" recovery many months or even years after a brain injury, during the chronic phase.

In this chapter, however, the focus is on prognostication during the time that lies between these two periods. There are various reasons for this focus. For one, the literature on prognostication is enormous, and it would be impossible to survey all of it in a single chapter. Besides, at least with regard to prognostication in the acute stage, there has already been a comprehensive evidence-based review (168). In addition, the focus in the immediate aftermath of a TBI is mostly on mortality rather than on broader outcomes. Rehabilitation professionals are less likely to be involved during the period immediately after the injury, although they often play a more important role after the patient is stabilized. Although rehabilitationists are the primary clinicians during the chronic phase (after approximately 6–12 months), the questions that arise during this period are often easier to answer because much more information is available by then.

In contrast, there is relatively little information during the subacute period, which is one reason why prognostication is so difficult then. At the same time, the need for prognostic information is greatest during this period.

Families have often been so focused on issues of survival during the acute care stage that they are just beginning to think about the long-term implications of the injury. This is especially true after patients are admitted to inpatient rehabilitation. In many ways, then, this period represents a pivotal point after a TBI and providing information about outcomes is one of the clinician's most important obligations during this time (2).

The question then arose as to whether to limit the review to only those studies done in the inpatient rehabilitation setting or to also include studies done in acute care. The populations are clearly different. The primary issue is that only a subset of all TBI patients admitted to acute care eventually goes to inpatient rehabilitation. Many patients die in the acute care setting. Of those patients that survive, some have improved to the point that they do not require inpatient rehabilitation and can be discharged with outpatient services. At the other end of the spectrum, many survivors of TBI have not made enough neurological progress to meet the criteria for admission to inpatient rehabilitation and are therefore often discharged to long-term care facilities or home. Thus, there is a concern that the acute care population would not necessarily be representative of patients seen in rehabilitation.

Despite these concerns, studies done in the acute care setting were included in this review. Since both acute care and inpatient rehabilitation usually occur during the subacute time period, it was felt that studies from both settings were needed to adequately represent this phase. Also, rehabilitation professionals often first encounter patients in the acute care setting and are often asked by other clinicians or family members about long-term prognosis early after a TBI. Additionally, despite differences between the two populations, the variables affecting prognosis seem to be similar; in fact, there were no appreciable differences in the findings of the studies done in the two settings.

The most important reason for including the acute care studies, however, is that there were only five studies conducted in the inpatient rehabilitation setting that met the inclusion criteria. Given the limited number of well designed rehabilitation studies, the choice was either to include acute care studies or to liberalize the inclusion criteria so more studies based in rehabilitation could be included. It was decided that well designed studies of prognosis from the acute care setting would be more useful than methodologically weaker studies based in the rehabilitation setting.

*Studies Published After 1983* Beginning in the early eighties, changes in pre-hospital, neurosurgical, and ICU care have resulted in a steady decline in mortality from TBI (169–171). Whether functional outcome has also improved is less clear. There has been some concern that

although mortality has declined, the survivors are disproportionately severely disabled. Recent reports don't support these fears, however, and it now appears that functional outcomes have improved along with survival (172,173). Because of these changes in care, it was decided to exclude studies published before 1984, under the assumption that the care patients received before that time differed from current care in ways that directly impact outcome. Specifically, it is assumed that studies done before the early eighties would underestimate survival and function. Although acute medical and surgical care continued to improve after the early eighties, most of these changes have been relatively minor compared with those of twenty years ago. The primary changes over the past fifteen years have been the adoption of the new standards by an increasing number of non-academic centers (170,173).

*Setting: North America/Western Europe/Australia/New Zealand/Israel* Although there is some documented variation in TBI care *within* the United States (as well as between the U.S. and Europe) (174), care in the countries listed above was similar enough to justify grouping them together (175). Even though care in the excluded countries may be similar to that in the countries above, there is no evidence to support this. Because variations in care are likely to affect outcomes, studies originating in countries other than those listed were excluded.

*Age: Adult* Since pediatric TBI is discussed elsewhere the studies included in this review focused exclusively or predominately on *adult* TBI. Also, because age is such a powerful predictor of outcome, also included were studies on the elderly.

*Subpopulations* In general, studies that included a wide range of patients were preferred, since this would most closely resemble the typical patient population seen by most rehabilitation clinicians. In addition, beyond a certain point, it becomes difficult for clinicians to use a different set of guidelines for minor variations in pre-injury, injury, or post-injury factors. Some groups are so distinctive, however, that studies that focused exclusively on them were included. The most notable examples in this review were the studies on the elderly and those with civilian penetrating injuries. A few studies that focused on other subsets of the TBI population were included only if that subset made conceptual sense and was easily identifiable by a rehabilitation professional. For instance, included were studies that limited themselves to patients who regained consciousness in acute care as well as one that focused on TBI patients who did not sustain other injuries. However, studies that focused only on those patients with, for example, traumatic subarachnoid hemorrhage or a history of elevated intracranial pressure,

were excluded under the assumption that this information was often not readily available and did not reflect conceptual categories that rehabilitation professionals routinely use.

### Predictor Variables

The review is limited to the following predictor variables: age, initial Glasgow Coma Scale score (GCS), length of coma (LOC), duration of post-traumatic amnesia (PTA), and early neuroimaging (CT and MRI). There are several reasons for focusing exclusively on these predictors. First, these variables are among the most powerful predictors of outcome available. More importantly, they represent pieces of information that are either easily available to most rehabilitation clinicians (e.g., age, initial GCS, etc.) or can be prospectively determined in the rehabilitation setting (e.g., duration of PTA). Although there are other variables that can also have a significant impact on outcome (e.g., pupillary abnormalities, hypoxia, premorbid functioning, etc.), this information is often not readily available (for instance, because of the limited availability of medical records). Thus, studies that rely on utilizing this information may not be particularly useful for rehabilitation clinicians providing subacute prognostication.

Only those studies that used the *total* GCS score were included. Although there are compelling reasons for the use of just the motor score in prognostication (176), rehabilitation clinicians do not often have available to them a patient's GCS subscores. There were also many studies that combined the variables selected for this review with other variables to create a single predictive model (for instance: age, pupillary abnormalities, and GCS motor response). Although the clinical utility of these models is dependent on the *combination* of variables (some of which are not readily available to the rehabilitation clinician), the studies making use of these models were included because they provided evidence that the variable of interest (e.g., age in the example above) was, after a multivariate analysis, associated with outcome.

Although neuropsychological testing during inpatient rehabilitation was originally included as a predictor of interest, none of the studies on early neuropsychological testing met the methodological criteria. Although not discussed as part of the evidence based review, the studies that have been done are briefly reviewed in the body of the chapter.

### Outcomes

*Outcome Measures* One of the central issues in prognostication is to be clear about the outcome of interest. There are many outcome measures available: survival, physical impairment, ability to perform activities of daily living, cognitive and behavioral status, return to work,

independent living, quality of life, etc. (177,178). The outcome one chooses depends on the question(s) one is asking and whether these questions are being asked for research or clinical purposes. In particular, the interests of professionals (especially researchers) and families do not always coincide. For instance, there is evidence that the outcomes of most interest to family members, at least during the rehabilitation phase, have to do with broad conceptual categories such as independent living and return to work (179,180). Besides the intrinsic importance of these categories, there is a symbolic importance associated with them (181). That is, given the importance our culture places on employment and independent living, these roles come to symbolize our membership in the community at large. Even the concern with other outcomes (e.g., physical impairment, cognitive decline, etc.) is interpreted mainly by their impact on these more holistic functional categories (179,180).

Unfortunately, most studies do not use measures of these types of outcomes, for several different reasons. First, these outcomes are so broad that they can include a wide range of patients within a single category. For instance, the category of severe disability in the GOS would include both a minimally conscious patient as well as someone independent in basic activities of daily living who is unable to live alone because of cognitive deficits (182). These measures are also insensitive to changes that can occur beyond the first 6 months to a year, making them less useful in studying the longer term natural history of TBI (178,183). Third, the psychometric properties of these global outcome measures often are not as good as those of more fine-grained research measures. For example, there are concerns about inter-observer agreement in the clinical use of the GOS (15). Another concern with the GOS is the fact that what is documented is the rater's subjective impression of a person's abilities rather than actual outcome. For instance, the measure documents the rater's beliefs about a person's ability to work rather than actual employment (which may account for the finding that ratings on the GOS may not be as strongly correlated with measures of employment as one would expect) (177).

The broadness of categories such as return to work or independent living can obscure the underlying mechanisms that mediate the outcome. Although this is sometimes seen as an advantage of these measures (so that they "integrate" the effect of many deficits into a final outcome such as work) (184), this characteristic can also lead to the loss of valuable information. For instance, is the person unable to live independently because of executive dysfunction, impulsivity, or physical impairment? Or because of factors that have nothing to do with the brain injury (e.g., other disabling physical conditions, financial resources, family support, etc.) (25)? By collapsing these distinctions, the use of these outcome measures can obscure the underlying deficits that

actually prevent people from living independently or returning to work.

There is also evidence that, at least early on, both patients and family members overestimate the contribution of certain outcomes to eventual quality of life (such as independent living) and underestimate the importance of others (such as social relationships). During the chronic phase of TBI, most studies show that emotional and behavioral issues are far more important to family members than, for instance, residence or occupational status (180,185–187). Even for patients, there is evidence the GOS categories do not correlate well with their own ratings of their quality of life (90). The broad categories of return to work, independent living, or the GOS are simply not designed to identify sequelae such as quality of life, social relationships, behavioral disturbances, etc.

However, although they will likely change their minds later, the fact remains that it is still these broad categories of functional outcome that families and patients are concerned with during the subacute period. To prognosticate about outcomes that are not yet relevant to them can lead to dissatisfaction and the perception that their needs for information are not being met. And since prognosis is ultimately a clinical act that tries to address the *current* needs of families and patients, their preferences have to be considered. For this reason, this review was limited to those studies that focused on return to work or independent living, either directly or through the GOS.

Despite its other limitations, the GOS actually seems to be one of the most useful measures of these sorts of outcomes. This is because the GOS utilizes outcome categories that correspond to those used by lay people, making results expressed in terms of its categories useful to clinicians. For instance, in discussing that their loved one will likely be “moderately disabled” in a year, the clinician can explain that the patient will likely be able to live independently but will have residual deficits precluding their being able to return to competitive employment. This outcome is understandable to family members since they, too, think in terms of independent living or employment.

In this respect, the GOS contrasts to measures such as the Disability Rating Scale (DRS) that either report a numerical score that has no real meaning to a layperson or is divided into categories (e.g., partial disability, moderately severe disability, etc.) that also have no clear conceptual correlates. Although it is true that information about living situation and employment can be extracted from the DRS, the data needed to do so is rarely reported in the literature (it is usually only the total score that is reported). The relatively clear meaning of the GOS categories is also an advantage relative to the results of neuropsychological testing. For most family members, a decline on a neuropsychological test is of little relevance except as it has an impact on “real-world” outcomes such as independent living.

Despite its advantages in addressing the needs of patients and families, there are still the many methodological limitations of the GOS mentioned earlier. There are newer measures that retain many of the advantages of the GOS while avoiding some of its limitations (e.g., the Community Integration Questionnaire). Unfortunately, there were no studies using these measures that also met all the other inclusion criteria. This fact reflects one of the primary reasons for the use of the GOS in this review. Because it is the most widely used measure in the TBI outcomes literature, including the GOS as an outcome measure significantly expanded the number of studies that could be included in this review. In fact, to exclude studies that used the GOS would have limited this review to less than a handful of studies (that met all the other criteria listed).

*Outcome Measured at 6 Months or Later* For several reasons, this review is limited to studies that assess outcome no earlier than six months after injury. Waiting *at least* six months is uncontroversial given the well-known clinical observation that, for most individuals, significant improvement occurs during the first six months after an injury. It could be argued, however, that since recovery clearly continues after six months, it would be better to wait a longer period of time, for instance, at least a year. Indeed, there is growing evidence that some individuals can continue to have meaningful recovery even many years after their injury (188–190). Nonetheless, there are compelling reasons to include studies that assess outcome as early as six months. First, studies have shown that, despite continued improvement, it was rare for an individual’s GOS category to improve after six months (191). More practically, if only studies that assessed outcome beyond six months were included, well over half of the studies would have been excluded, further limiting what is already a small evidence base.

### Methodological Criteria

The methodological criteria adopted are, for the most part, self-explanatory. The review is limited to studies with consecutive admissions (or a random sample of consecutive admissions) to minimize the possibility of systemic bias (which might arise from sampling based on any other criteria). Likewise, the requirement of at least 80 percent follow-up minimizes the biases that might be encountered with high rates of drop-out. Historically, TBI outcome studies have been characterized by high rates of loss to follow-up (1/3 to 1/2 of the original sample); the implications of this for the validity of studies on outcome have been recently reviewed (192). Unfortunately, almost no studies analyzed the characteristics of those lost to follow-up to see if they differed substantially from those who were included. In the interest of having more than

1–2 studies to review, it was decided that an analysis of patients lost to follow-up would not be required of studies to be included.

The criterion specifying a minimum sample size was adopted from the AANS acute care prognostication review (168). Finally, the studies were reviewed to ensure that some form of statistical analysis was performed on the data of interest. If not, the study was still included if enough information was provided for the statistical analysis to be done by a knowledgeable reader. This was an issue for some of the older studies, where the distribution of outcomes was occasionally reported only in a descriptive manner. However, there was no attempt to screen studies based on the statistical models employed. The most commonly utilized models in this area are regression models and decision trees. The features and limitations of these approaches are detailed elsewhere (193–200).

There are some potential criteria not utilized in this review, either because they were not applicable or because they would have greatly limited the number of studies available. Most notably, a study was included even if it did not adjust for confounding factors (because so few did so). However, those studies that performed an univariate versus a multivariate analysis (or something else to adjust for confounding factors) are noted in the tables. More importantly, the fact that the studies that did not adjust for confounds came to the same conclusions as those that did increases the confidence in the findings of the review.

### Threshold Values and Confidence Intervals

It cannot be automatically inferred that a particular outcome is impossible, just because no one over or under a particular threshold value had the outcome of interest in a particular study. This is because there is always a degree of statistical uncertainty, even when the outcome of interest does not occur. For example, even if no one with a duration of PTA greater than three months had a good recovery in a particular study, it might still be *statistically* possible that a certain percentage of them could have achieved that outcome. This possibility can be quantified by confidence intervals. In a study where no one had the outcome of interest, the lower end of the confidence interval would be zero, while the upper end would represent the largest number of people who could statistically be expected to develop the outcome of interest. The width of this confidence interval will depend on the sample size.

For instance, if no one out of a sample of 87 people achieved a good recovery on the GOS, the 95 percent confidence interval would be approximately 0 to 3 percent. That is, the findings are compatible (with 95 percent certainty) with up to 3 percent of that group achieving a good recovery. If, instead, no one out of a sample of only

17 people achieved a good recovery, the confidence interval would be much wider (approximately 0–16 percent). Therefore, the most that one can infer from the smaller study (with 95 percent certainty) is that anywhere from 0 to 16 percent of similar people could have had the outcome of interest. It is also important to keep in mind that a study in which no one had a particular outcome is not necessarily stronger evidence for a threshold value than a study in which some subjects had the outcome. It all depends on the width of the confidence interval. For instance, a study with a large sample (e.g., 150) that reported that 4 percent of subjects had a good recovery would actually have a smaller confidence interval (1–9 percent) than a study with a smaller sample (e.g., 27) in which no one achieved a good recovery (CI 0–11 percent).

Unfortunately, none of the studies that reported threshold values reported the associated confidence intervals. Therefore, the author calculated the confidence intervals for all the threshold values. However, only those threshold values with a 95 percent confidence interval of no greater than 0–12 percent are reported. This figure represented a balance between the limits of tolerability of error and the wish to include as many studies as possible.

## Neuroimaging Correlates of Functional Outcome

*Erin D. Bigler*

### **NEUROIMAGING CORRELATES OF FUNCTIONAL OUTCOME**

How do neuroimaging findings best predict outcome once the brain has been injured? The answer is complicated. Even though many trauma-induced abnormalities can be identified by neuroimaging and such findings represent one of our best objective measures of brain injury, there are numerous variables (in addition to simply identifying neuroimaging abnormalities) that have to be considered. For example, imaging—even functional imaging—represents only a particular moment in time, yet predictions of outcome typically involve statistical statements of much broader timeframes involving the future, including the lifetime of the individual injured. Likewise, the recovery process is dynamic and ever changing, particularly in the first year of injury. A host of injury variables apply, including: the type of brain injury, the severity of injury, the brain regions most likely affected, the age at time of injury, as well as, the issues involving cognitive reserve and individual differences. Since the advent of contemporary neuroimaging the type, degree, location, and a host of other indicators of brain imaging abnormalities have been examined in an attempt to answer this question.

The chapter that follows will provide an update on this topic, by first offering an overview of the history of lesion-location research in predicting functional outcome

from traumatic brain injury (TBI), followed by typical injury characteristics observed in neuroimaging of TBI that are predictive of functional outcome, along with current methods for establishing the best predictor of outcome and future implications of the clinical utility of neuroimaging in evaluating functional outcome from TBI. Because of rapid changes in technology and how brain scans can be analyzed (1), only a few studies have actually systematically addressed this issue with a mixture of qualitative and quantitative analyses in using neuroimaging to predict functional outcome (2–10). Basically, these studies demonstrate that presence of abnormalities in structural imaging are associated with more negative outcome, particularly when the abnormalities are shown to be chronic. This chapter will review these studies along with other clinical associations and methods for the use of structural imaging findings in the prediction of functional outcome in TBI.

### **HISTORICAL PERSPECTIVE AND AN INTRODUCTION TO THE PROBLEMS OF PREDICTING FUNCTIONAL OUTCOME BASED ON STRUCTURAL NEUROIMAGING**

Clinical neurology, as did much of medicine, developed from a ‘signs and symptoms’ approach, where a particular neurological symptom (i.e., paralysis) had a clinical

presentation (i.e., hemiplegia) that specified a particular pathophysiology (i.e., corticospinal tract damage potentially localized), depending on what other signs and symptoms were present. The motor system analogy is used here, because it was the first to be comprehensively examined resulting in established functional outcome using lesion-localization methods of neuropathologists and clinicians. Likewise, motor impairment has been the system most extensively examined from a traditional structural as well as functional neuroimaging perspective (see Figure 15-1) (11, 12) where clinical outcome has been related to underlying brain pathology. For example, using neuroimaging techniques, identification of damage within the corticospinal tract (see Figure 15-2) typically leads to some type of motor impairment as shown in Figure 15-3; where this patient had left-side hemiplegia as a result of shear injury at the level of the internal capsule. Accordingly, knowing the location of the lesion within a dedicated neural pathway (i.e., corticospinal) for a specific function (in this case, motor) leads to a predictable functional outcome (impaired motor skills).

Extensive mapping of sensory-perceptual and some language based pathologies were the next to show lesion-location specificity and prediction of functional outcome depending on a signs and symptoms approach, particularly with primary sensory systems (13). Mapping of language function, however, turned out to be far more

FIGURE 15-1

Three images of the cortical activation related to a simple unilateral finger movement showing how functional imaging techniques can isolate motor cortex. *Left:* The cortical regions showing an increased hemodynamic response with respect to the rest period. Such hotspots are located over the primary motor cortex. *Center:* The spatial distribution of the estimated cortical current density distribution occurring over a reconstruction of the cortex 100 ms before the movement occurs. The cortical current density distribution is obtained by high-resolution EEG recordings with 128 electrodes. *Right:* The current density distribution is relative to the same time instant (100 ms before movement) but is estimated from the MEG recordings in the same subject. This demonstrates the focal nature of somatomotor function. Used with permission from Babiloni et al. (12). Accordingly, cortical damage outside this system does not impair direct motor functions of the hand

problematic than initially anticipated in light of what were thought to be well known “language” centers of the brain such as Broca’s and Wernicke’s areas. It became apparent that language was less dedicated to precise locations that could be consistently identified between individuals and was more loosely distributed than the more ‘hard-wired’ sensory and motor systems. So, instead of showing discrete lesions that consistently impaired language, studies generally found more extensive regions wherein damage anywhere within some boundary would result in language impairment. This is nicely demonstrated in Figure 15-4 taken from the work of Bates et al. (14), mapping out left-hemisphere lesions in right handed individuals that produce language impairment (deficits in word fluency and auditory comprehension). Figure 15-4 also shows that no uniform area that when damaged produced the same disturbance in language in all subjects, but rather damage across a broad range of the left hemisphere resulted in impaired language function. There were areas where the likelihood of language impairment was maximized, but this illustration also demonstrates individual differences in brain organization once outside of primary motor and sensory systems. The more distinct 1:1 correspondence between pathology and

FIGURE 15-2

(Left, A) Diffusion tensor imaging (DTI) tractography is used to isolate the corticospinal tract (upper arrow), demonstrating its descent from motor cortex, down through the midbrain region (lower arrow). Arrows represent where injuries to this direct motor pathway resulted in the motor impairment and paralysis seen in the case presented in Figures 15-3 and 15-6. Although the fibers that comprise the corticospinal tract involve only a very small region of the brain, damage anywhere along this pathway will result in some type of functional impairment in motor abilities. (Right, B) Colorized DTI scan image in coronal plane used to identify tract orientation used to perform the tractography to isolate the corticospinal tracks. Blue represents tissue aligned in vertical orientation which was the source to extract the fiber pathways depicted in A. Adapted from Lazar et al. (22) and Lainhart et al. (118) used with permission

FIGURE 15-3

MR imaging showing residual small, focal shear lesions involving the basal ganglia (arrows in B, D, and E) and internal capsule (B, bottom arrow) in the right hemisphere (scans are in radiological perspective, with right on the viewer's left) that result in impaired motor function on the left side of the body (refer to C). In F, the patient has no difficulty placing blocks while blindfolded to successfully complete the Tactual Performance Test. In contrast, impaired motor performance is present in the left hand demonstrated by paralysis and posturing as shown in C. This figure demonstrates the impact of a strategically placed lesion (shown in red in A) to result in functional impairment. B, D and E represent the axial, sagittal and coronal views with arrows pointing to the focal lesions. The figure in A contains the 3-D reconstruction of the brain with the ventricle in blue, showing the location of the focal damage. Figure 15-6 (also from this patient) demonstrates atrophy of the cerebral peduncle, a consequence of damage to the corticospinal track and some focal hemorrhaging (petechial in nature) that occurred at the level of the midbrain

function as found in dedicated motor and sensory systems is less apparent once function is defined by some element of cognition or behavior. In general, widely dispersed neural regulatory systems underlie complex behaviors and therefore, structure-function relationships predictive of functional outcome outside of primary motor and sensory deficits are more difficult to establish (15). Nonetheless, general statements can be made about neuroimaging defined damage to certain brain regions or neuroregulatory centers and functional outcome.

Also, because of neural mechanisms that relate to recovery and adaptation, small lesions strategically placed within dedicated neural pathways may have pronounced effects upon functional outcome of motor or sensory abilities, such as complete paralysis, blindness or loss of smell or auditory processing. In contrast, extensive lesions that do not damage such dedicated primary systems may have no or minimal effect upon such functions, even though the

FIGURE 15-4

This illustration demonstrates the dispersion of left hemisphere regions that disrupt language function after a focal cerebrovascular accident. Representative slices from voxel-based lesion-symptom mapping (VLSM) computed for fluency and auditory comprehension performance of 101 aphasic stroke patients. These maps are colorized depictions of *t*-test results evaluating patient performance on a voxel-by-voxel basis. Patients with lesions in a given voxel were compared to those without lesions in that voxel on measures of fluency (a-c) or auditory comprehension (d-f). High *t*-scores (red) indicate that lesions to these voxels have a highly significant effect on behavior. Dark blue voxels indicate regions where the presence of a lesion had relatively little impact on the behavioral measure. Only voxels that were significant at  $p = 0.05$  (controlling the expected proportion of false positive) are shown. Insert of brain depicts the level of each slice. Lesions within the insula (b) and deep parietal white matter (c) had the most impact on fluency, whereas injury to the middle temporal gyrus (d) produced the largest effect on measures of auditory comprehension. Used with permission from Bates et al. (14)

area of damage may encroach such regions. This is readily observed by comparing the case presented in Figure 15-3 to the one in Figure 15-5. In Figure 15-3 and in the additional imaging presented in Figure 15-6 the patient has distinct damage at the level of the internal capsule and basal ganglia on the right, as well as Wallerian degeneration at the level of the cerebral peduncle, reflective of generalized 'downstream' wasting of the corticospinal track. This is consistent with the left side motor involvement as shown in Figure 15-3. In contrast, the patient shown in Figure 15-5 received extensive focal damage to the left frontal region, which extends back towards motor cortex, but does not specifically involve motor systems, even though there is a small white matter (WM) lesion noted at the top of the internal capsule (see Figure 15-6). This patient had no motor deficits on a widespread neuropsychological battery of motor tasks, including the Tactual Performance Test on which the case in Figure 15-3 displayed distinct impairment. Additionally, even though there is extensive frontal

FIGURE 15-5

This case demonstrates extensive focal frontal pathology that resulted from a fall, that included frontal skull fracture and subdural hematoma that was surgically removed. Red represents the residuals from the coup injury or point of initial impact producing focal damage shown in the 3-D in A. Extensive frontal involvement is also depicted in the axial fluid attenuated inversion recovery images (FLAIR) images, but not only is the brain damaged in the region where focal impact occurred, but is damaged in a linear fashion directly opposite the point of focal impact, representing the contre coup injury as shown by the arrows. Unlike the case in Figures 15-3 and 15-6, this patient did not have paralysis, even though the focal frontal damage is very close to motor cortex (colored in green). Thus, extensive damage can occur to the cerebral cortex without causing functional impairment in motor function. Likewise, even though this patient had extensive left hemisphere damage, language function recovered to the point where he performed within normal limits, although probably below pre-morbid levels, even though some areas of damage overlap with the brain regions delimited in Figure 15-4 that would be expected to affect language

wasting in the patient presented in Figure 15-5, the patient had only minimal language deficits, despite considerable overlap of damage to frontal tissue that usually impairs language (see Figure 15-4). Other than subtly reduced word fluency and an occasional stuttering-like episode during conversational speech, the patient's performance on language tests was otherwise within normal limits.

Thus in attempting to predict functional outcome, a strategically placed lesion, albeit relatively small, may produce a distinct deficit if it involves a primary motor or sensory region of the brain. Oppositely, even large lesions such as that depicted in Figure 15-5 may not produce a consistent syndrome when damage is outside primary motor and sensory systems, due to individual differences in brain structure-function relationships. Neuroimaging methods have improved greatly over the last 20 years providing excellent macroscopic detection of brain pathology associated with TBI. As might be expected from the discussion in this section, while there are some generalities that can be established using lesion detection and localization methods to prognosticate about functional outcome (see Refs. 16, 17), there are also limitations when structural imaging is the only method used for predicting functional outcome.

Because contemporary magnetic resonance (MR) imaging so nicely depicts gross structural pathology, early neuroimaging studies were overly optimistic and assumed

FIGURE 15-6

This is the same patient (shown on the right) as depicted in Figure 15-3, but with additional views compared to a non-brain injured control subject on the left. The axial view at the level of the body of the ventricle demonstrates ventricular dilation as a result of hydrocephalus ex vacuo. This is also a reflection of generalized cerebral atrophy, which is also demonstrated by the nonspecific loss in size of the corpus callosum (CC) as shown in F. Uniform CC reduction, as seen in this case, probably reflects uniform reduction of white matter pathways in the brain following severe TBI. In H, the cerebral peduncle on the right (viewer's left) shows atrophy, an indication of corticospinal involvement and consistent with the motor impairment shown in Figure 15-3. Also, at this level note the dilation of the temporal horns of the lateral ventricle, typically an indication of temporal lobe damage as well (see Bigler et al., Ref. 86). The 3-D image at the top shows the brain in flesh tone and the ventricle in blue. Clearly there is generalized ventricular dilation in the TBI patient as seen in B

that distinct lesion-behavior connections could be established, relating the presence of certain lesions with a typical functional outcome (see Ref. 18). However, initial studies were disappointing in their ability to predict outcome from TBI. As imaging technology improved, part of the reason for these disappointing findings became obvious, because what constitutes a 'lesion' depends on the imaging methods used and their resolution to detect abnormalities, as well as the underlying diffuse nature of TBI even when the only clinically identifiable abnormality is a focal lesion. This problem is shown in the case illustrated in Figures 15-3 and 15-6. Although distinctly focal lesions are clearly identified, generalized cerebral atrophy is also present and manifested by ventricular enlargement, wasting of the corpus callosum, and prominence of the cortical sulci. Thus, whatever effects occur from the focal injuries, do so within the backdrop of generalized damages.

From the perspective of actually detecting an abnormality with MR imaging, different MR weightings have different sensitivity in detecting pathology, which then influences how imaging findings relate to functional outcome. The problem of differences in sensitivity in detecting abnormalities and their relationship to functional outcome is presented in Figure 15-7. In this figure what shows up as an abnormality changes as to the type of MR image sequence used. For example, the T1 image provides excellent anatomical detail along with clearly defined areas of abnormal signal depicting multiple regions of damaged tissue, including prominent areas of encephalomalacia together with cystic formations in the frontal region. Although on initial review this may seem to capture the extent of the underlying damage, other imaging sequences

FIGURE 15-7

Multiple imaging sequences were performed on this subject with severe TBI, showing how each imaging sequences is sensitive to different types of pathology. In each case, the additional identification of abnormal signal from the separate imaging sequences has been superimposed upon a 3-D reconstruction of the brain. The ventricle is represented by blue. At the top of each figure is the image sequence (i.e., T1) and the colorization (i.e., red) depicting damage identified. Quantitative data demonstrating widespread atrophy is provided in Table 15-1

\* TBI = traumatic brain injury.

demonstrate even greater pathology that simply cannot be ascertained from the T1 image. For example, the T2 images provide better delineation of abnormal CSF collections, conspicuously involving almost the entirety of the frontal region at the level viewed, better appreciated than the dark signal seen in the T1 images. However, neither the T1 nor T2 images fully depict the extent of disseminated white matter abnormalities, as shown in the fluid attenuated inversion recovery images (FLAIR) or the residual hemorrhagic lesions as shown by the gradient recalled echo (GRE) images. Not shown here are other methods that detect abnormalities such as MR spectroscopy, magnetization transfer and white-matter coherence determined by diffusion tensor imaging (DTI, 1, 19, 20) that would likely demonstrate even additional abnormalities if applied to a case like that shown in Figure 15-7. Finally, when a functional imaging tool is used, such as single photon emission computed tomography (SPECT; see Figure 15-7), further clarity of the extent of functional impairment is evident by the widespread perfusion defects, even in some tissue where more normal signal is observed on MR imaging. Thus, what is defined as abnormal is dependent on imaging sequences and technology used, where each imaging method has its own set of limitations. Without taking into consideration all of these abnormalities in the predication of functional outcome, functional outcome predicted strictly from neuroimaging becomes problematic.

Lastly, an even more potentially insurmountable limitation of contemporary neuroimaging in predicting functional outcome is that even with our best existing neuroimaging tools, microstructure cannot be imaged. Inferences can be made about neurochemical composition of tissue via MR spectroscopy (MRS, 4,21) and diffusion tensor imaging permits identification of aggregate white matter tracts (see Figure 15-2 and Ref. 22) and their 'coherence' where optimal white matter shows lower apparent diffusion and higher fractional anisotropic coefficients (see 23), but actual microstructure can not be imaged in vivo at this time. That is not to say that tremendous strides are not occurring in exploring methods of neuroimaging of microanatomy (see 24), but the application of such structural imaging techniques is just now being applied to the study of functional recovery from TBI and its predication. Because of these limitations with structural imaging, it is likely that many of the advances in predicting TBI outcome will come from the integration of structural and functional neuroimaging (25, 26).

At the microstructure level, post-mortem cases have clearly shown widespread histopathological abnormalities, particularly in moderate to severe TBI (27-29), especially involving axonal damage (27, 30, 31) and disrupted neurotransmitter systems, but also mild TBI where gross abnormalities based on visual inspection are either absent or minimal (32-36). Since in structural neuroimaging the

threshold detection of abnormal signal using current MR technology is approximately a  $\text{mm}^3$ , whatever abnormality can be visualized in structural imaging represents the sum total of all underlying microstructure pathology. Returning to Figures 15-3 and 15-6, while the focal deficits are clearly evident, there is generalized damage. Presence of generalized damage suggests widespread microstructure pathology affecting the brain in a nonspecific fashion. This is not only readily depicted in the case shown in Figures 15-3 and 15-6 but can be shown by comparing the volumes of different brain structures from a TBI patient to a normative comparison as presented in Table 1, which was taken from the patient shown in Figure 15-7. Using quantitative methods, surface area measurements or actual volumes can be calculated from any brain region of interest (ROI) and compared to normative data, or an appropriately matched control (see Ref. 37). For the case presented in Figure 15-7 the patient's quantitative imaging findings are compared to an age and head size (i.e., intracranial volume) matched control subject. As can be seen, in all comparisons, including all of the subcortical structures, atrophy has occurred. As shown by the comparisons in Table 15-1, there is not a region that was spared 'injury', either directly or indirectly, in this case of severe TBI. This observation of widespread damage, both at the macroscopic (which neuroimaging can detect), as well as microscopic level in TBI, has led to the concept of diffuse brain injury (DBI), and will be described next. DBI may be the single most important factor that complicates predicting outcome from structural neuroimaging studies.

### NEUROIMAGING OF TRAUMATIC BRAIN INJURY (TBI) AS A DIFFUSE BRAIN INJURY (DBI)

Graham et al. (29) discuss TBI in the context of underlying general neuropathology, often referred to as DBI (see also Refs. 31, 38, 39). This is a very important concept to understand in interpreting functional outcome from structural imaging and, as will be shown by the discussion that follows, ventricular dilation in combination with reduced brain volume are indicators of DBI (37).

As introduced above, hydrocephalus ex vacuo is a commonplace occurrence in moderate-to-severe (i.e., Glasgow Coma Score, GCS < 12) TBI. This occurs because ventricular CSF is under pressure, which in turn creates an outward pressure gradient within the ventricle, which under normal conditions is kept in balance by brain mass and CSF reabsorption, so that a constant equilibrium is maintained between brain and ventricle. However, following TBI induced neuronal cell loss, brain parenchymal volume is reduced but ventricular CSF pressure (provided that some type of occlusive hydrocephalus is not present) remains constant. With the loss of parenchymal

volume there will be a natural, passive expansion of the ventricle. This is illustrated in all of the clinical cases presented so far (see Figures 15-3, 15-5, 15-6, and 15-7).

One of the most straightforward ways to quantify ventricular dilation or hydrocephalus ex vacuo in TBI patients is to compare the ratio of total ventricular volume to total brain volume, the so-called ventricle-to-brain ratio or VBR. Because the margins between the ventricular cavity and brain parenchyma are distinct on CT and/or MR imaging, VBR can be readily calculated using either imaging technology (Bigler, 1999). From mid-adolescence to late middle life, the VBR is relatively constant at about 1.5, with a standard deviation of approximately 0.5 (40, 41). This type of quantitative analysis can then be applied to scan findings at anytime post-injury in demonstrating trauma related DBI. For example, the case presented in Figure 15-8, demonstrates the use of VBR to show acute effects of cerebral edema (another potential generalized insult to the brain in TBI) and then ventricular expansion as an indicator of generalized parenchymal volume loss and DBI (42). This case is particularly helpful in demonstrating these points, as the patient had MR imaging done prior to injury, depicting normal ventricular size based on quantitative analyses. Increased levels of cerebral atrophy, as measured by VBR or other indices of parenchymal volume loss, relate negatively to overall outcome (43).

FIGURE 15-8

Axial MR (A, B) taken prior to injury, compared to follow-up computerized tomography (CT, images C-F) imaging done on the day-of-injury (DOI, shown in C and D) and at different times post-injury. Note the compression of the ventricular system (smaller size) on the DOI scan, representative of generalized cerebral edema. The patient's pre-traumatic brain injury (TBI) ventricle-to-brain ratio (VBR), shown at the bottom, was well within normal limits (normal VBR ~1.5, standard deviation = 0.5), but on the DOI scan and the acute stage post-injury, VBR is significantly reduced, again another indicator of generalized cerebral edema. By four months post-injury (I, J) significant ventricular dilation has occurred and VBR has risen to approximately two standard deviations above the mean, reflective of generalized brain volume loss secondary to trauma induced generalized degeneration. This patient had a Marshall et al., (65) level III (swelling) clinical rating of the DOI CT scan (see Table 15-2)

VBR is related to all severity of injury measures in a rather linear fashion, as shown in Figure 15-9, including GCS, loss of consciousness (LOC) and post trauma amnesia (PTA) (44) and any adverse systemic effects such as hypoxia (42). Unmistakably, ventricular dilation of the nature observed in TBI results from DBI and is likely the best single measure of DBI. Based on this assumption, larger VBR reflects generalized atrophy and therefore represents a severity marker of neuropathological changes. Larger VBR is associated with worse cognitive outcome and greater neurobehavioral sequela of acquired brain injury (37).

Unfortunately, quantitative analyses are often not available to the clinician, so how does one best evaluate ventricular dilation and cerebral atrophy, short of quantitative analyses? Actually, this can be readily performed with a straightforward visual inspection of either CT or MR findings, since small ventricular size is the norm in the noninjured brain until after the sixth decade of life (41). Since this is more completely addressed in a following section, only brief mention will be made here. Even when substantial acute pathological changes are present in the initial CT scan done on hospital admission following TBI, the DOI scan provides baseline information

FIGURE 15-9

This illustration is from our ongoing traumatic brain injury (TBI) data base and represents 151 subjects with varying levels of severity of injury as defined by Glasgow Coma Scale (GCS). Plotting either brain volume, hippocampal volume, or the ventricle-to-brain ratio (VBR, a measure of global atrophy) results in linear and quadratic relationships that demonstrate brain or hippocampal atrophy is directly related to the severity of injury. Note that the relationship is best fit by a linear rather than quadratic function for whole brain volume (Blue color), the ventricle-to-brain ratio (Red color) or hippocampal volume (Yellow color). The hippocampal data is based on a subset comprised of 46 subjects. In each case there is a linear loss of brain parenchymal volume directly related to severity of injury. Accordingly, loss of tissue is a function of severity of injury. Similar plots are achieved if PTA or LOC are substituted for GCS. Adapted from Bigler et al. (119)

FIGURE 15-10

Day-of-injury (DOI) axial computerized tomography (CT) scans demonstrated multiple frontal hemorrhagic contusions and intraparenchymal areas of hemorrhage and edema, with compression of the anterior horns of the lateral ventricle. By four months post injury, follow-up CT demonstrates loss of density in frontal tissue, with corresponding dilation of the anterior horns of the lateral ventricle. However, the entire ventricular system is also showing expansion (hydrocephalus ex vacuo), reflective of generalized degeneration. By two years post-injury, fluid attenuated inversion recovery images (FLAIR) magnetic resonance (MR) imaging demonstrates generalized ventricular enlargement and extensive signal abnormality widely distributed across the frontal regions, bilaterally. This illustration demonstrates the utility of comparing DOI imaging to subsequent imaging studies and how this permits easy tracking of degenerative changes (i.e., ventricular dilation)

about preinjury ventricular size. As shown in Figure 15-10, this patient sustained a severe head injury as a consequence of an auto-pedestrian accident, and DOI CT findings demonstrated extensive frontal hemorrhagic lesions. Nonetheless, ventricular size can still be distinguished, even though generalized edema had developed by the time that the initial CT scan was obtained. On the DOI scan, small anterior horns of the lateral ventricular system can be readily identified, although somewhat effaced by the surrounding edema. In comparison, by the chronic stage, all follow up scans demonstrated ventricular dilation as well as changes in frontal parenchyma. Thus, clinicians should not only view the DOI imaging to identify acute pathology, but also as a benchmark for what the brain looked like before injury. Another way to view trauma induced atrophy, or DBI, is by viewing the midsagittal plane, where not

only the body of the lateral ventricle can be observed, but the corpus callosum (CC) as exemplified in Figure 15-6. Figure 15-6 compares the midsagittal MR view and a 3-D comparison of the ventricular system in the case presented in Figure 15-3 to show the diffuse nature of moderate to severe TBI as expressed by ventricular dilation and CC atrophy. Regardless of how it is demonstrated (i.e., simple visual inspection and interpretation, quantitative measures such as increased VBR, increased clinical atrophy ratings [see below] or thinning of the CC, etc.), presence of generalized cerebral atrophy is a predictor of cognitive, neuropsychiatric and neurobehavioral sequelae (2, 5, 6, 37, 45, 46).

What has just been discussed brings up another issue that demonstrates the complexities and challenges of establishing brain-behavior relationships in predicting functional outcome in TBI. For those who survive significant brain injury and ‘recover’ whatever function or make whatever type of adaptation possible, structural imaging will mainly highlight the lesion or damage, which is probably not where functional reorganization is or has taken place (26, 47–49). For example, in the case presented in Figure 15-5 where extensive cortical wasting, particularly of the left frontal region, had occurred, frontal damage originally resulted in a generalized expressive aphasia that lasted several months. However, after an extended recovery and rehabilitation period, this patient eventually recovered verbal abilities to the point of obtaining a verbal IQ score of 100 and a normal score on confrontational naming, performances that reflect general intactness of language. He still had some diminished word fluency, but the more significant changes were in personality, drive and temperament, not language. Obviously, the abnormalities that reflect absence of and/or nonfunctional tissue do not necessarily represent the regions of the brain that have adapted. Research in this area has shown that functional reorganization occurs in regions that have been spared or less damaged, often distributed in a fashion that cannot be fully predicted due to individual differences, and often in regions not traditionally associated with such functions (50, 51).

This issue of functional adaptation has been nicely demonstrated by Mathias et al. (52) who has studied reaction time and speed of processing in mild to severe TBI. If white matter is particularly vulnerable to brain injury, structurally identified by reduced CC surface area, this would suggest disrupted interhemispheric white matter projection and interhemispheric transfer of information. However, Mathias et al. (52) as well as others (53–55) have shown that the degree of CC atrophy only modestly, and in many cases nonsignificantly, relates to deficits in interhemispheric transfer observed in patients with TBI. In other words, the CC is critical for transfer and integration of information between the two hemispheres and is clearly vulnerable in TBI (see Figure 15-6), but despite presence of CC lesions and atrophic changes, for the most part TBI patients

recover the ability to carry on interhemispheric transfer of information and reaction time tasks, albeit slower than their non-TBI matched cohorts. Rarely do TBI patients have a lasting callosal syndrome (56). So, even though significant CC atrophy occurs in brain injury and is related to severity of injury, somehow the injured brain adapts and interhemispheric transfer of information occurs. When such adaptation occurs, using just structural neuroimaging as the basis for measuring the atrophy of the CC results in minimal power to predict impairment. The point here is that when some functional recovery has taken place, structural imaging of damaged tissue may not capture how the brain has adapted, it only measures the original region(s) of damage. Chapter 16 on functional imaging will have more to say about this problem, and the future of predicting functional outcome will probably come from the integration of structural and functional imaging.

FIGURE 15-11

Statistical parametric mapping (SPM, top black and white plots) of a voxel-by-voxel quantification of damage (shown in red in the 3-D brain representations) from a group of TBI subjects who had sustained frontal or temporal lobe contusions. VBM analyses where red represents decreased gray matter density in six TBI adolescents (mean age = 16 years old, standard deviation = 5.1) all with moderate-to-severe TBI (all had had GCS scores of 8 or below) compared to 18 control subjects of similar age (three control subjects per TBI patient within 2 years of age). Note the predominance of frontotemporal damage

In summary thus far, the mere presence of imaging abnormalities from trauma are not sufficient, by today's understanding of brain-behavior relationships to fully predict functional outcome. What may appear straight-forward (i.e., simply comparing 'lesions' to outcome) actually represents a very complex clinical question. Restrictions of current neuroimaging methods to fully integrate all levels and types of abnormalities from cerebral trauma into a prediction model, means that any one identified neuroimaging abnormality, by itself, often lacks robust relationship with functional outcome (57, 58). The exception here, as will be discussed later, is with brainstem abnormalities.

### Vulnerability of Frontal and Temporal Regions

The earliest post-mortem TBI studies demonstrating the most likely regions of contusion confirmed the predilection for frontal and temporal locations (59). More contemporary neuroimaging studies have clearly demonstrated the greater likelihood of frontal-temporal damage over damage to any other brain region in cases of TBI (60) and can be shown when voxel-based morphometry (VBM) is used to compare those with brain injury versus control subjects as presented in Figure 15-11. A dorsal view of a skull, with the skull cap removed, is shown in Figure 15-12, clearly demonstrating the location of the

FIGURE 15-12

Dorsal view of the open human skull (skull cap removed), where the skull cap has been removed. Top of the picture is just above the orbit. The general location of the base of the frontal lobe (jugum of the sphenoid bone) and location of the medial temporal lobe is outlined in bold letters. A: Frontal crest, B: Orbital part of frontal bone and anterior cranial fossa, C: Crista galli, D: Sphenoid, E: Petrous part of temporal bone, F: Anterior clinoid process, arrow points into the pituitary fossa or sella turcica, G: dorsum sellae above with clivus extending down, H: Foramen magnum, I: Middle cranial fossa, J: Posterior cranial fossa

anterior, middle and posterior cranial fossa. The ventral surface of the frontal lobe is situated in the anterior cranial fossa, the ventral surface of the temporal lobe in the middle cranial fossa and the cerebellum in the posterior cranial fossa. For slight movement and minimal impact, the three cranial fossa create protective factors to hold the brain in place. However, the soft, pliable brain is no match against the hard inner table of the skull once inertial forces exceed its tolerance limits. Mechanical deformation of the brain against bone, not only injures the parenchyma through mechanisms of compression and stretching (31), but increases the likelihood of contusion (61, 62). Using the integration of CT, that permits detailed identification of the bones of the skull, and MRI, that permits detailed identification of brain structures, the vulnerability of these regions is easy to appreciate because of how they are partially cradled and encapsulated by bone as shown in Figure 15-13. Thus, the undersurface of both the frontal and temporal regions become particularly vulnerable to mechanical deformation and/or contusion against bony structures as well as the anterior aspect of the temporal lobe against the sphenoid bone and the medial aspect of the temporal lobe against the sphenoid and petrous bones and clinoid process. Likewise, the basal forebrain sits just anterior to the clinoid process and the jugum of the sphenoid, both regions that have some potential for protrusion into the base of the frontal lobe. Likewise, more anteriorly, the frontal bone plate just above the nasal-orbital region, as shown in Figure 15-12, has several prominent ridges. Understanding this part of the

FIGURE 15-13

From left to right, fused spiral CT bone window imaging of the skull (shown in pink) interfaced with MRI in axial (T2), coronal (T1) and sagittal (T1). Bone is shown in pink to highlight how the brain is encapsulated by the cranium, particularly the anterior and middle cranial fossa. This patient sustained a moderate TBI with left temporal petrous bone fracture, that had healed by the time imaging was obtained. However, not the increased CSF in the anterior pole in the T2 Axial view shown on the left. Likewise, the coronal view in the middle demonstrates temporal lobe atrophy (temporal horn dilation, reduced size of hippocampus compared to the contralateral size of the hippocampus), reduced temporal stem. Quantitative analyses demonstrated overall reduced temporal lobe white matter volume, reduced since of entorhinal cortex, hippocampal and amygdala volumes

brain-skull interface becomes particularly important in understanding the behavioral significance of neuroimaging findings in TBI and the increased likelihood of inferior frontal and anteromedial temporal lobe damage (see 62), as clearly demonstrated by the VBM analysis shown in Figure 15-11.

Given that there is greater frontotemporal lobe damage associated with TBI, it is no surprise that the most common neuropsychological sequelae associated with TBI are those in the realm of memory and executive impairment (60). Since memory, particularly working memory, is central to all aspects of executive function, it may be that the single most important cognitive function typically disrupted by TBI is some aspect of memory (61, 63). Budson and Price (64) have recently reviewed the gross neuroanatomy associated with memory dysfunction as depicted in Figure 15-14. By comparing the illustration of the brain regions typically damaged in TBI, as shown by the VBM analysis presented in Figure 15-11, it should come as no surprise why some impairment in memory is such a common feature in TBI. Budson and Price (64) go on to provide more details as to key structures involved in various types of memory and that is presented in Figure 15-14. As can be seen major frontotemporolimbic regions and pathways are at the basis of the key structures that underlie memory function. What is of particular interest in linking TBI to neuroimaging findings and cognitive outcome, is that each structure depicted in Figure 15-14 has been shown to be affected by TBI and in the case presented in Table 15-1 and Figure 15-7, each of the areas key to memory function were damaged. Accordingly, Figure 15-14 can be used as a guide to the type of memory dysfunction that may result from a brain injury, depending of the location and extent of involvement of a particular brain region.

### NEUROIMAGING OF ACUTE INJURY AND PREDICTION OF OUTCOME

Although from the above discussion, it is easy to see why the effects of TBI are more complicated than just location of a lesion(s) that predicts neurobehavioral outcome, it is still important to understand how lesions begin and evolve following trauma, and how the earliest lesions identified by neuroimaging relate to functional outcome. Using acute imaging compared to sub-acute and chronic imaging and tracking lesions and atrophic changes may yield far more important predictive statements about outcome, than just a single static image, usually during the chronic stage, to predict functional outcome. Since the first neuroimaging study of someone with a brain injury is typically a CT scan on the day-of-injury (DOI), this Chapter will next overview the relationship between the DOI CT scan and functional outcome. The DOI scan serves another purpose as well (as introduced above) that

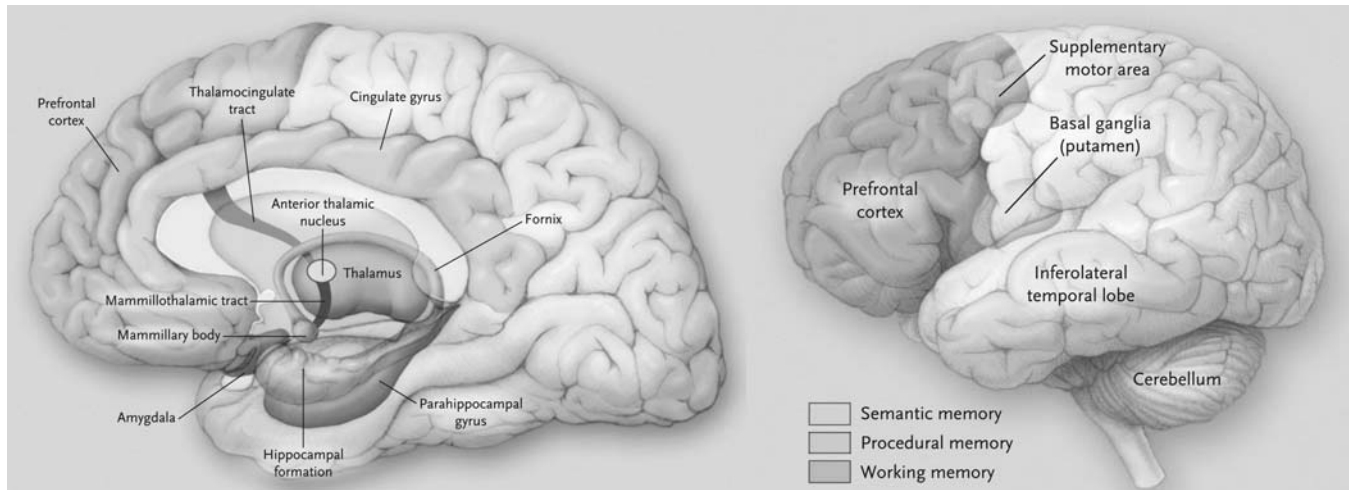

FIGURE 15-14

*Left:* The medial temporal lobes, including the hippocampus and parahippocampus, form the core of the episodic memory system. Other brain regions are also necessary for episodic memory to function correctly. *Right:* The inferolateral temporal lobes are important in the naming and categorization tasks by which semantic memory is typically assessed. However, in the broadest sense, semantic memory may reside in multiple and diverse cortical areas that are related to various types of knowledge. The basal ganglia, cerebellum, and supplementary motor area are critical for procedural memory. The prefrontal cortex is active in virtually all working memory tasks. Other cortical and subcortical brain regions will also be active, depending on the type and complexity of the working memory task. Used with permission of Budson and Price (64) and NEJM

of establishing a baseline to track changes overtime. Thus, comparing follow-up CT or MR imaging to the DOI scan (as in Figures 15-8 and 15-10) often provides more useful information relating to predication of outcome from brain injury; such comparisons will be the basis of the concluding topic.

Much of the interpretation of DOI CT scans has already been addressed in chapter 11 and therefore this section will concentrate not so much on lesion identification, but on the relationship between these lesions and functional outcome. Figure 15-15 summarizes the typical lesions seen on acute CT imaging in cases of cerebral trauma where CT imaging is positive. These types of abnormalities, as well as other common trauma related abnormalities, can be simply classified and rated, as shown in Table 15-2 based on the work of Marshall et al. (65). This guide can be used to establish severity of abnormalities as found in acute imaging, as will be discussed and elaborated upon in the next section, where acute imaging findings are used to predict functional outcome.

#### DAY-OF-INJURY (DOI) COMPUTERIZED TOMOGRAPHY (CT) AND PREDICTION OF OUTCOME

The scale established by Marshall et al. (65) attempted to characterize trauma induced acute abnormalities on a nominal rating scale grading computerized tomography (CT) abnormalities from not discernible (Grade I) to

diffuse (Grade IV), as well as whether a hematoma was present (Grade VI), or had to be evacuated (Grade V), along with presence of brainstem pathology (Grade VII). These classifications by Marshall et al. are more completely detailed in Table 15-2 and the different type of acute traumatic lesions seen on CT as presented in Figure 15-15, in turn result in distinct likelihood of frontotemporal atrophy as already shown in most of the previous examples given in this chapter, and specifically shown in Figure 15-16. The patient shown in Figure 15-16 sustained a moderate-to-severe TBI in an auto-pedestrian accident with bilateral temporal contusions and development of a subdural, which was evacuated. The neuroimaging done more than two years post injury demonstrates the frontotemporal locus of damage. This patient's initial DOI CT scan would have been rated a III by the standards outlined in Table 15-2.

In a comprehensive study that examined 240 consecutive admissions at a Trauma I hospital for head injury who survived sufficiently to progress to an inpatient rehabilitation unit, we were able to examine the predictability of CT findings based on the Marshall et al. (65) rating system to outcome at various stages during the recovery process (see Refs. 9, 66). For these 240 subjects the mean GCS was approximately 9, with an average of several days of unconsciousness and an average PTA of 2 to 3 weeks. Accordingly, as a group, these subjects generally sustained moderate-to-severe TBI and represented the typical course of outcome following inpatient rehabilitation. Using the Marshall et al. (65) classification method, the most common lesions present on the DOI CT scan were Level

FIGURE 15-15

The axial section of a computerized tomography (CT) scan of the head at the level of the lateral ventricles, obtained without the addition of contrast medium, revealed four types of acute post-traumatic intracranial hemorrhage (Left is on the reader's right side); an epidural hematoma (thick white arrow) and a squamous temporal fracture (which is not shown) on the left side, a laminar subdural hematoma (thick black arrow) on the right side, right-sided periventricular and frontal-lobar contusions containing an intraparenchymal hematoma (thin white arrow), and a subarachnoid hemorrhage (thin black arrow) in the right frontal region. These injuries were sustained in a fall. (Reproduced with permission from Mattiello & Munz, (120) and the *New England Journal of Medicine*. Copyright © Massachusetts Medical Society.) Had this patient received a Marshall et al. (52) rating, it would be a level IV (see Table 15-2)

II (some diffuse swelling and presence of some petechial hemorrhages or small contusions). In fact amongst these 240 hospitalized subjects, almost 60 percent of all CT scans were so classified, whereas about 13 percent had Level I findings, 17 percent had Level III findings, approximately 4 percent with Level IV and 3 percent with Level VII. About 17 percent had some type of mass lesion. Since this study was based on the initial or DOI CT scan, no one had a mass lesion removed at that point, therefore no Level V subjects were part of this study. Despite clear-cut findings of pathology on the DOI CT scan (i.e., > Level II),

FIGURE 15-16

This illustration demonstrates the vulnerability of frontal and temporal regions for focal brain injury following traumatic brain injury (TBI). The 3-D reconstruction shown in B, highlights the frontotemporal damage in red as identified in multiple planes of magnetic resonance (MR) and fused MR-single photon emission computed tomography (SPECT) imaging, where arrows point to regions of focal encephalomalacia. D is the fused SPECT image with the axial MR shown in C and H represents the coronal fused MR-SPECT, where distinct focal temporal lobe encephalomalacia is evident in G. L designates left, R designates R. For A and E, the inset shows the level for the fused MR-SPECT image

TABLE 15-2<sup>≠</sup>  
Descriptive Categories of Abnormalities Visualized on CT\* Scanning

LEVEL	DEFINITION
I	Diffuse Injury I (no visible pathology)
II	Diffuse Injury II
III	Diffuse Injury III (swelling)
IV	Diffuse Injury IV (shift)
V	Evacuated mass lesion
VI	Non-evacuated mass lesion
VII	Brain stem injury

No visible intracranial pathology seen on CT scan  
 Cisterns are present with midline shift 0-5 mm and /or: lesion densities present; no high- or mixed-density lesion >25cc; may include bone fragments and foreign bodies  
 Cisterns compressed or absent with midline shifts 0-5 mm; no high- or mixed-density lesion >25cc  
 Midline shift >5mm, no high- or mixed-density lesion >25cc  
 Any lesion surgically evacuated  
 High- or mixed-density lesion >25cc, not surgically evacuated  
 Focal brainstem lesion, no other lesion presenty

<sup>≠</sup> Based on Ref. 65.  
 \*CT = computerized tomography.

## Regional Cortical Vulnerability to TBI Predicts Neuropsychiatric Sequelae

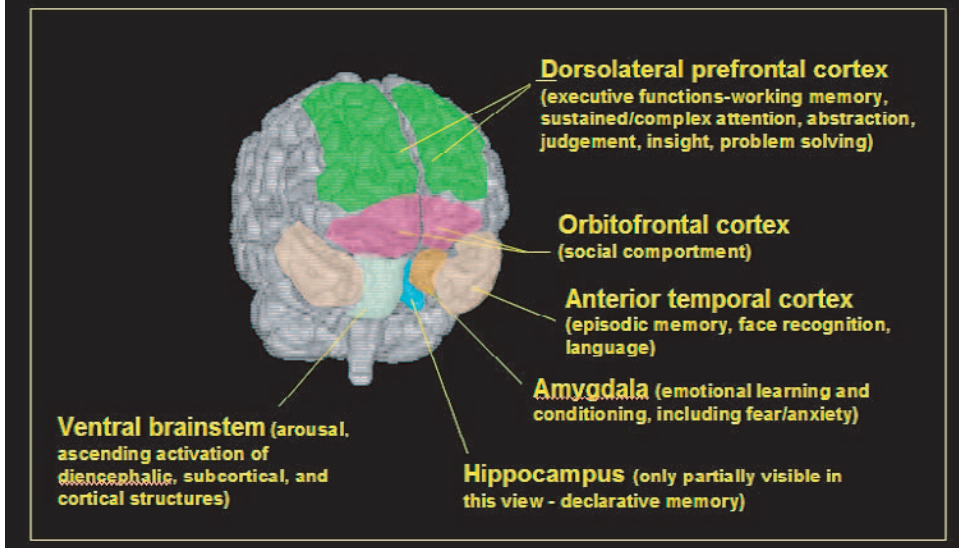

FIGURE 45-5

FIGURE 49-3

such findings were not very predictive of outcome at the time of admission to rehabilitation, rehabilitation discharge, or one year followup using the Functional Independence Measure (67, 68) or the Disability Rating Scale (DRS, 69), except for those with abnormal brainstem findings on CT. Presence of a brainstem lesion was a negative predictor at all time periods post-injury and distinctly predictive of those with the worst outcome (see also Ref. 70). Thus, the mere presence or absence of CT abnormalities on the DOI scan was by itself not much of a predictor of neurobehavioral and or neuropsychiatric outcome, except for those with brainstem lesions. This is consistent with other studies that have attempted to use the DOI CT as a functional indicator of outcome (8, 71–73).

We next examined how DOI CT findings related to more long-term MR imaging findings, using quantitative measures, exploring the relationship of atrophy (i.e., increased VBR) determined at 25 days or later post-injury to outcome. One of the nice factors using the VBR metric is that it automatically corrects for head size differences (74), so no further adjustment in the ratio score is need in comparing subjects of different age, sex or physical characteristics. It may seem intuitive that with greater rating of acute CT abnormality that more prominent VBR would be the outcome. However, this was not the case. It appears that a threshold effect was present, where once injury equalled or surpassed a Marshall et al. (65) Level II rating (see Table 15-2), significant cerebral atrophy resulted that was indistinguishable from the other CT ratings. Another way of saying this is that once a Level II CT classification had been reached, DBI effects had occurred that ultimately resulted in generalized cerebral atrophy, but the degree of cerebral atrophy was rather independent of the CT rating. Interestingly, in the Katz and Alexander (8) study, presence of scan abnormalities, in association with the length of PTA, was the best predictor of outcome (see also 75). Again, it may simply mean that it is not so much the magnitude of DOI CT scan abnormalities, but rather the mere appearance of abnormalities in conjunction with certain markers of brain injury severity, such as PTA, that become predicative of functional outcome. Regardless of DOI CT ratings, by one-year follow-up, increased VBR was associated with greater deficits in FIM and DRS outcome. Presence of any DOI CT lesion has been shown to be associated with greater likelihood of developing MRI identified cerebral atrophy and greater atrophy is a risk factor for worse outcome (43).

When post-traumatic atrophy is substantial, especially in cases where acute injury is a Marshall et al. (65) CT rating of Level II or greater, tracking changes from the DOI CT scan can be most informative, simply by viewing the progression of change in the ventricular system and prominence of cortical sulci in imaging studies (either

CT or MR; see Figures 15-8 and 15-10). Somewhere between 25 days post-injury and six months, the majority of atrophic changes that are likely to occur will have done so (see 40, 76), although degenerative changes may continue for up three years post-injury before the brain returns to its ‘normal’ age-related volume loss (see 77). Given these observations, if the clinician obtains the DOI CT and a follow-up CT or MR scans at least six weeks post-injury, presence of identified lesions or atrophic changes relate to poorer outcome. Suggested methods for easy clinical rating of these abnormalities will be offered in the next section.

In the study of TBI outcome, Dikmen et al. (78) have compiled a variety of measures they label as a “Functional Status Examination” (FSE, 78) that include the Glasgow Outcome Scale (GOS, 79), health and back-to-work questionnaires, psychosocial and emotional functioning, as well as two neuropsychological measures [i.e., Trail Making Test (80), California Verbal Learning Test (81)]. A single FSE composite score can be created from these different measures and then used to explore DOI CT relationships with outcome. Using the FSE, Temkin et al. (72) examined 209 adults with TBI all with CT abnormalities (i.e., 65, rating of Diffuse Injury II or greater) and only 20 percent of the cases reported no problems, which formed their ‘good’ functional status group, meaning that 80 percent had some residual impairment reflected in worse FSE composite scores. The majority of CT abnormalities in this ‘good’ outcome group where Marshall et al. (65) classification group II with regard to DOI CT abnormalities with the majority in the ‘good’ outcome group having GCS of 13–15, but minimal PTA. In contrast, the 80 percent in the Temkin et al. (72) study that had intermediate (i.e., some residual deficit) to poor FSE findings, also had Diffuse Injury II classification by Marshall et al. (65) standards as the most common rating with GCS also in the 13–15 range. They even had similar LOC duration but what distinguished this group with poorer outcome was longer PTA. Thus, long duration PTA and presence of at least a Marshall et al. rating of II, results in the worse functional outcome.

Katz and Alexander (8) examined 243 patients with TBI admitted to an inpatient rehabilitation unit and studied the global effects of abnormalities on either CT and/or MR imaging including petechial white matter hemorrhages, diffuse or localized edema, intraventricular or subarachnoid hemorrhaging, and cortical contusions. All imaging studies were based on clinical ratings of the scans and did not systematically employ the Marshall method for rating CT scans and included not only DOI scans but sub-acute scan information as well. Presence of scan abnormalities in association with duration of PTA was associated with greater deficit as measured by the GOS (79). Interestingly, focal lesions were not that predictive of outcome. Their study also addressed age where older

individuals (i.e., >40 years of age) demonstrated worse outcome even though imaging and injury severity characteristics were not different. Integrating these findings with the Bigler et al. (9) and Temkin et al. (72) studies, discussed above, since of all the injury severity measures (i.e., LOC, PTA, GCS), PTA is the most predictive of VBR (see Figure 15-9) and, since Temkin et al. (72) and Katz and Alexander (8) both demonstrated the importance of PTA in defining outcome, PTA, in relationship to imaging findings, may provide the best indicators of functional outcome. Consequently, worse functional outcome is expected when structural neuroimaging on the DOI scan demonstrates presence of a Marshall et al. (65) level rating of II or greater in conjunction with extended duration PTA or when chronic findings of focal or generalized cerebral atrophy are found on follow-up imaging more than 25 days post-injury.

### CLINICIAN BASED RATING METHODS FOR STRUCTURAL NEUROIMAGING IN PREDICTING FUNCTIONAL OUTCOME

#### Lobular Atrophy and Functional Outcome

For a variety of reasons, including the configuration of the brain within the anterior and middle cranial fossa, frontal and temporal regions of the brain are particularly vulnerable to injury (82), as explained above and exemplified in Figure 15-16. Scheid et al. (83) found the frontal lobes to have at least three times the number of microbleeds than any other brain region, with the temporal lobe coming in second place for most frequent location for injury. This was graphically depicted in the group VBM analysis presented in Figure 15-11 and in an individual case as presented in Figure 15-16, where neuroimaging studies were performed several years after significant brain injury where the patient initially sustained frontal and temporal lobe contusions, leaving the patient with chronic lesions as areas of focal encephalomalacia that also exhibited perfusion defects on SPECT imaging. Because of the critical nature of frontal and temporal regions in regulating memory, executive and emotional functioning, damage to these areas typically affects such functions. A simple lobular rating method has been shown effective in establishing the degree of atrophy in frontal and temporal regions (84) that can be used by the clinician to forecast functional outcome relationships. The ratings are based on T1 weighted MR images, but other weightings could also be substituted, including CT imaging. Figures 15-17 and 15-18 demonstrate this clinical rating method and Figure 15-19 presents actual TBI cases and their functional outcome associated with the clinical rating methods for identifying frontal and temporal lobe atrophy using the guidelines shown in Figures 15-17 and 15-18. In studies that have employed this

method presence of frontal and/or temporal lobe atrophy was chiefly associated with neuropsychological deficits in memory as well as associated deficits in executive function and presence of neuropsychiatric symptoms, particularly depression and anxiety (84, 85). Because these rating methods only require visual inspection of the imaging studies, they can be performed in the clinician's office and provide a useful index for establishing brain-behavior relationships and functional outcome in TBI. One reason for the importance of identifying temporal lobe atrophy is because of the relationship of hippocampal atrophy (86) and the susceptibility of the hippocampus to injury (87).

FIGURE 15-17

Anterior frontal lobe atrophy rating of T1-weighted axial images based on the method outlined by Victoroff et al. (117). In performing this rating, the frontal region has been isolated in red as shown in the axial view inset and the rating standards blown-up for the Standard #1 and #2 images. Presence of atrophy is visualized as a prominence in subarachnoid cerebral spinal fluid (CSF), which fills the widened sulci because of reduced gyral size. On the T1 image presented in this figure, CSF is represented by dark signal. Ratings focus on the cortex anterior to the frontal operculum (that is, anterior to the insula). Ratings assess the single image showing the lateral ventricles at the point of the longest visible antero-posterior connection or depending on the slice angle the image closest to the mid point of the genu of the corpus callosum where full view of the extent of the interhemispheric fissure can be viewed, example as shown. Atrophy is rated as follows: 0 = none or negligible (see Figure 15-19, control subject); 0.5 minimal, but less than seen in Standard #1; 1 = mild or moderate = equal to or greater than standard #1, or up to that equal to Standard #2; 2 = severe = definitely more than Standard #2. The key in making these ratings is to not focus on ventricular dilation, focal pathology of the frontal lobes or some other type of abnormality, other than the atrophy. The ratings can either be performed as a total frontal atrophy rating or by left and right. As shown in Figure 15-19, two clinical cases of severe traumatic brain injury (TBI) demonstrate the implementation of the rating in this figure and Figure 15-18

FIGURE 15-18

All of the clinical caveats given in the caption for Figure 15-17 also apply in rating the temporal lobe. Ratings are carried out on the T1 coronal image. Coronal images are used because they provide better visualization of medial temporal anatomy than axial images. Ratings assess the single image that is the first image, moving posteriorly, that definitely shows both temporal stems connecting the temporal and frontal lobes. This image usually shows the amygdalae and/or anterior aspect of the hippocampus (but neither the amygdala nor the hippocampus is rated). Ratings focus on gyral atrophy, attempting not to be influenced by the width of the Sylvian fissure (which might reflect parietal rather than temporal lobe atrophy). To get a total temporal lobe atrophy rating, both individual temporal lobe ratings can be summed. The rating following standards are used: 0 = none or negligible (see Figure 15-19); 0.5 = minimal, or up to that seen in Standard #1; 1 = mild or moderate = definitely more than standard #1, less than or equal to Standard #2; 2 = severe = definitely more than Standard #2. As an example, an actual rating of temporal lobe atrophy in a TBI patient is presented in Figure 15-19

### White Matter Hyperintensities (WMHs) and Functional Outcome

Damage to white matter may show up as a hyperintensity on several types of MR imaging sequences (i.e., T2, intermediate, etc.) and relate to functional outcome (88–91). While such hyperintensities do occur in the normal population, are related to aging (92) and by themselves may not signify pathology (92, 93), they are more frequent in patients who have experienced a head injury (94). There are simple rating scales that can be used by the interested clinician to classify WMHs, typically in periventricular (PV) and centrum semi-ovale (CS) regions of the brain; these are described in Figure 15-20 and several TBI cases with WMHs are shown in Figure 15-21. In the study by Hopkins et al. (94), WMHs in frontal and/or temporal regions were associated with greater deficits in memory and executive function compared to TBI patients without WMHs. Additionally, TBI patients with WMHs endorsed more symptoms of depression and anxiety. The qualitative rating method of WMHs is straightforward to perform, and can be readily done in the clinician's office if the proper image sequences have been obtained. Simply stated, presence of WMHs in frontal and temporal brain regions is

FIGURE 15-19

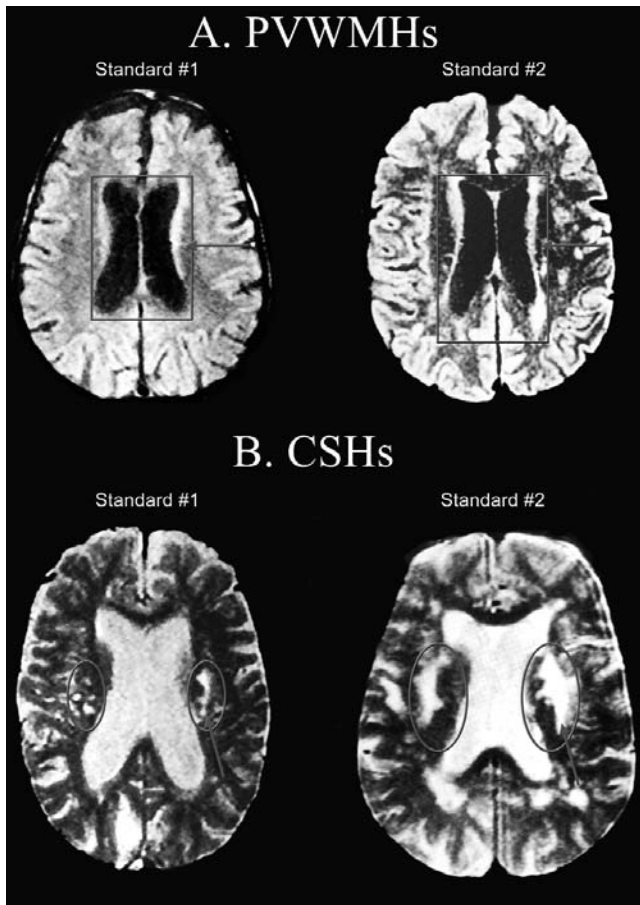

Using the rating method outlined in Figures 15-17 and 15-18, two different TBI patients, one with frontal atrophy (top right) and the other with temporal lobe atrophy (bottom right), were rated. For comparison, two non-brain injured age-matched controls are presented on the left, both received a 0.0 rating on their respective ratings. The frontal rating for atrophy (shown in A) was a 2, bilaterally. Note in comparison to the normal control, the prominence of the frontal sulci and inter-hemispheric fissure. For the temporal rating it was also a 2, but only on the left. It was 1 on the right. Both patients had poor outcome (impaired memory and executive function and at the time of imaging, both had received long-term antidepressant medication for mood management), particularly the one with such prominent frontal atrophy. These type of clinical ratings can be quickly performed on any patient and provide a meaningful qualitative rating for linking structural pathology to functional outcome. Adapted from Bergeson et al. (84)

associated with worse functional outcome in TBI. Since, the degree of WMH abnormality is related to severity of injury, and severity of injury is related to worse functional outcome, presence of WMHs becomes another rating index of severity of injury. The clinical cases using this method as shown in Figure 15-21, where all patients had significant residual neurobehavioral deficits in association with WMHs.

### Clinical Rating of Ventricular Dilation as a Predictor of Outcome

Ventricular dilation, specifically hydrocephalus ex vacuo, as previously discussed, was the first trauma induced

**FIGURE 15-20**

White matter hyperintensity rating methods are presented in this figure. (A.) *Method for rating periventricular white matter hyperintensities (PVWMHs)*: PVWMHs are defined as hyperintensities hugging the ventricle (“rims” and “caps”) on the proton density (intermediate echo) axial image. The proton density images were used in the original Victoroff et al. (117) standardization because these images exhibit good contrast between the ventricles and PVWMHs, although T2-weighted images can also be used. Ratings assess the single image showing the lateral ventricles at the first level (going superiorly) that is definitely superior to the lateral bulges of hyperintensity created by the heads of the caudate nuclei. 0 = none or negligible; 0.5 = less than or equal to standard #1; 1 = mild or moderate = definitely more than standard #1, less than or equal to standard #2; 2 = severe = definitely more than standard #2. Note that in Standard #2, the signal is brighter and more extensive going beyond, in some cases, the length of the ventricle (see double arrow). For the standard, Victoroff et al. (117) used the highlighted image in the figure, rating only the left (views are in radiological perspective.)

(B.) *Method for rating centrum semi-ovale white matter hyperintensities (CSHs)*: CSHs are defined as deep white matter hyperintensities definitely separated from the ventricle on the T2-weights axial image. Hyperintense T2 lesions may be seen with or without corresponding hypointense T1 lesions. When corresponding lesions less than 0.5 cm are seen on both T1

and T2, particularly in the periventricular white matter and basal ganglia, they are regarded as probable Virchow-Robin spaces. Lesions greater than 0.5 cm seen on both T1 and T2 are regarded as probable completed infarctions. Both are excluded from the ratings of CSHs. Thus the CSH rating encompasses all hyperintense T2 lesions that do not have a matching hypointensity on the T1 image, regardless of size, degree of hyperintensity, or shape. Ratings assess the single image showing the lateral ventricles at the point of the longest visible antero-posterior connection. When in doubt, ratings are made by reference to one side (the left side, viewer's right) of the standard scans: 0 = none or negligible; 0.5 = less than or equal to the left side of standard #1; 1 = mild or moderate = definitely more than standard #1, less than or equal to the left side of standard #2; 2 = severe = definitely more than the left side of standard #2. Again, as in A., the standard image is highlighted.

pathological change to be systematically investigated in TBI following the introduction of clinical CT imaging in the mid 1970s (see Refs. 95, 96). Ventricular dilation, as previously explained, is a sign of generalized cerebral atrophy where more dilation is associated with poorer outcome (2, 6). Unfortunately for the clinician, most of the work with ventricular dilation and outcome from TBI has been based on quantitative methods that require digital images along with hard and software for image analysis. However, a simple rating method can be performed, using data already presented in cases used in this Chapter. Since ventricular size is quite constant through the 6th decade of life (41, 97), this makes clinical rating relatively straightforward. Using a four-point scale, as discussed above with lobular atrophy and WMH ratings, where 0 represents ‘within normal limits’, .5 indicates slight dilation, 1.0 indicates mild to moderate and 2 represents moderate and beyond, ventricular dilation can be established by using the standards presented in Figure 15-22. Clinical ratings of 1 or higher are the ones most likely to be related to poorer outcome. Groswasser et al.’s (2) research suggests that this may be accomplished by just rating the III ventricle. Normal III ventricle size is rather slit-like (see Figure 15-23). Because of its midline position deep within the brain, III ventricle dilation may reflect atrophic changes of not only subcortical but cortical atrophy and may be very sensitive to parenchymal volume loss anywhere in TBI (98). Again taking from cases already presented in this chapter, Figure 15-23 shows the ease in viewing III ventricle

Similar ratings can be made using this scheme when fluid attenuated inversion recovery images (FLAIR) and various susceptibility weighted MR images as they too have sensitivity to white matter abnormalities and presence of hemosiderin (as a marker of shear injury) in white matter. Figure 15-21 shows white matter injury with the above ratings in two TBI cases. These ratings can also be applied to white matter abnormalities that are outside the traditional region of the centrum semi-ovale. For ease in classification these are labeled CSH+. An example of this is presented in Figure 15-21

FIGURE 15-21

(A) Axial proton density magnetic resonance (MR) scan showing periventricular white matter hyperintensities (PVWMH; see arrow) in a traumatic brain injury (TBI) patient in the frontal region on the right (scans are in radiological perspective). (B) T2 weighted image showing white matter hyperintensities (CSH+) in right frontal region (arrow). (C) Fluid attenuated inversion recovery images (FLAIR) image showing CSH+ in another region of the frontal lobe in the same TBI patient as shown in B. Presence of these types of frontal lesions relate to impaired functional outcome in TBI and likely reflect focal disruption of white matter pathways and are a clinical manifestation of diminished white matter integrity

FIGURE 15-22

Using scans from different figures in this chapter, a simple, normal 'Ventricular Size' rating can be established by using the four figures and a four point rating scale. Ventricule Part A is from the control subject in Figure 15-19A. Part B is from the subject in Figure 15-13, although this body of the lateral ventricle view was not actually shown. Part C is from Figure 15-6D and part D is Figure 15-19A (traumatic brain injury, TBI, patient). Similar to the ratings for focal atrophy of the frontal (see Figure 15-13) or temporal lobe (see Figure 15-14) regions, the ventricular rating is based on a 0, 0.5, 1 and 2 rating, where A represents 0, B represents a 0.5 (greater than A but equal to or less than B), C represents a 1.0 (greater than B but equal to or less than C) and 2.0 is anything greater than C exemplified by D. The presence of increased ventricular size in TBI is associated with worse functional outcome

size and its relationship to brain injury severity and outcome.

### Coup-Contre-Coup and Outcome

The coup-contre-coup phenomena in brain injury is a common form of injury (29) and actually represents another

FIGURE 15-23

Using scans from different figures in this chapter, a simple 'Ventricular Size' rating of the III Ventricle can be established. (A) Using the axial MR view from Figure 15-8, with a reversed gray scale image, the III ventricle region is outlined in red. This represents a normal III ventricle size. (B) View (not previously shown) taken from the case presented in Figures 15-3 and 15-6 and shows a mild dilation (III ventricle outlined in red). (C) This view was taken from the case presented in Figure 15-16 and demonstrates a mild-to-moderate dilation (particularly the more posterior aspect of the III ventricle as outlined in red). (D) This was taken from the case in Figure 15-7 and demonstrates a moderate-to-severe dilation of the III ventricle (outlined in red). Applying the four point rating scale for III ventricle dilation A would be rated as 0; B at 0.5; C a 1; and D a 2. In each, classification incorporates the figure as equal to or less than the Standard. Increased III ventricle dilation in traumatic brain injury (TBI) is associated with worse outcome

factor that complicates the prediction of outcome using neuroimaging findings. As previously discussed this is excellently demonstrated in the neuroimaging depicted in Figure 15-5. This patient fell some 20 feet, striking the left frontal region, resulting in depressed skull fracture and development of a subdural hematoma that had to be neurosurgically removed. The residual focal effects of the left frontal injury are readily detected by the presence of focal atrophy, highlighted in red in the illustration. However, only on the FLAIR image, can the contre coup damage be detected in the right parietal area, in the form of abnormal signal intensity, not atrophy, particularly in white matter. The right parietal damage is in a linear path directly opposite the point of left frontal impact, where the skull fracture occurred. Although beyond the scope of full discussion in this chapter, an obvious implication of a contre coup injury such as that shown in Figure 15-5, some 10 cm completely opposite the point of impact, means that tremendous bio-mechanical forces of physical energy were transmitted through the brain on this plane (see Ref. 39). With such impact forces of injury transferred through the brain there typically are widespread microstructural changes within the sectors subjected to acceleration/deceleration injury that are not detected by neuroimaging, but only pathologically identified microscopically (see Ref. 29). With regards to functional outcome in the presence of coup/contre coup injuries, the very nature of these multi-focal injuries in association with DBI factors, makes prognostication difficult. This may

be why in the Katz and Alexander (8) study presence of focal contusions was not strongly associated with outcome. When lobular atrophy is identified, as discussed above, additional imaging sequences should be obtained to explore whether contre coup injury is present and its relationship to functional outcome.

### TBI, Anterior Commissure and Basal Forebrain Damage

Over the last decade, the clinical importance of the basal forebrain in neuropsychiatric disorders has been clearly established (99, 100) and discussed earlier in this chapter. As the name implies, the basal forebrain is a region at the posterior base of the frontal lobe, cradled in the anterior cranial fossa, situated just above and anterior to the clinoid process of the skull, making it vulnerable to impact injury at the skull-brain interface in this region (101). The location of the anterior commissure (AC) is typically considered part of one of the superior boundaries of the basal forebrain. The AC is comprised of a small band of white matter tracts that course between the two hemispheres that interconnects mesial temporal and orbitofrontal cortices (102). Although not specifically investigated, it probably shares a similar vulnerability as does the CC (103) and as recently shown by Wilde et al. (43) the ventral aspect of the frontal lobe is particularly vulnerable to injury. As shown in Figure 15-24 (this is the same patient as shown in Figure 15-16), in comparison to a normal control, a TBI patient with severe injury clearly demonstrates AC atrophy, as shown by the dilation of the suprachiasmatic recess compared to the control subject. What is also evident in this illustration is that all of the area under the AC exhibits atrophy as well. This region contains the critical origins of cholinergic innervation for all of cerebral cortex (104). The AC has traditionally been considered part of the upper boundary of the basal forebrain, so atrophic changes at the level of the AC and below, probably reflect basal forebrain damage. The basal forebrain regions at the AC level comprise critical structures of the limbic system and the ventral striatum including the extended amygdala, the basal nucleus of Meynert and the midline septal nuclei (99, 100). These brain regions have been shown to be critical for maintenance of emotional regulation and given its vulnerability to injury; it is likely that basal forebrain damage contributes to the common emotional changes associated with TBI (62, 105, 106). Lastly, as shown by the VBM analysis depicted in Figure 15-11, one of the areas of greatest change in gray matter density in this cohort of TBI subjects analyzed was in the basal forebrain region.

### Medial Temporal Lobe Damage

As shown in Figure 15-13, the medial aspect of the temporal lobe butts up against the medial surface of the

FIGURE 15-24

The TBI case on the left is the same as shown in Figure 15-16 and Figure 15-23C. The control subject on the right is the same as shown in Figure 15-6A. The arrows shown in the control subject point to the anterior commissure (AC) in axial (top right) and coronal (bottom right) planes, that is easily identified by the distinct and unmistakable band of white matter fiber projections. In the coronal view, the region beneath the AC, in part, defines the basal forebrain. In comparison to the TBI subject, it is clear that there is a diminution in the size of the AC. Also note in the TBI patient dilation of the III ventricle (see Figure 15-23) and enlargement of the suprachiasmatic recess, indicating volume loss of brain parenchyma in this area. The suprachiasmatic recess is just to the left margin of the arrow in the bottom coronal view of the control subject and is situated just above the optic chiasma. This is also the region of the substantia innominata, where in the nucleus basalis of Meynert exists and other critical structures of cholinergic innervation (121, 122). This TBI patient also had an area of focal encephalomalacia of the frontal region (arrow), as indicated by increased focal CSF in that region. Damage involving atrophy of the AC and inferior frontal region, including the basal forebrain likely results in significant changes in memory and mood regulation, as was the case with this patient

middle cranial fossa, formed in part by the clinoid and sphenoid bones. The medial surface of the parahippocampal gyrus houses both the entorhinal cortex and subiculum, which input the hippocampus. Hippocampal atrophy following TBI has been one of the most replicated findings in quantitative analysis of temporal lobe

FIGURE 15-25

True inversion recovery sequence that highlights the distinction between white and gray matter and clearly shows the atrophy of the medial temporal lobe, expressed as reduced volume of the hippocampus (compare to control subjects at similar level) and temporal horn dilation. Loss of medial temporal lobe volume, and in particular volume loss of the hippocampus, gives rise to 'downstream' atrophy of the limbic projection system of the fornix, as shown in Figures 15-26 and 15-27

FIGURE 15-26

As labeled in the control subject, atrophy of the fornix, anterior commissure (AC), mammillary body (MB) and the mammillothalamic track can be readily identified in the TBI patient. The sagittal image is from a 3 Tesla scan and clearly shows ventricular dilation, thinning of the corpus callosum, marked shrinkage of the fornix, clear reduction in the size of the AC and MB with no ability to identify the mammillothalamic track. This patient sustained a severe TBI in a MVA, with his initial GCS rated at a 5

structures (63), but as shown in Figure 15-13, the atrophy of the medial temporal lobe and its underlying white matter pathways exhibits atrophy as well as the distinctly evident hippocampal atrophy. While memory outcome is one of the most replicated of the neurocognitive sequelae of TBI and relates to hippocampal atrophy (60), memory impairment following TBI could result from widespread medial temporal lobe damage as well (see Ref. 62). As shown in Figure 15-25, even though the hippocampus is clearly atrophic, so is entorhinal cortex and adjacent white matter. Since entorhinal cortex is the recipient of diverse inputs from all regions of cerebral cortex, the disruption of memory may have nonspecific factors associated with damage outside of the hippocampus, proper and this likely relates to only the modest relationship between hippocampal atrophy and memory outcome. Damage to the medial temporal lobe structures and the hippocampus, in turn disrupts input to the fornix, resulting in atrophy of the fornix, which may also be susceptible to mechanical deformation and shear/stretch effects as well (107), can be readily visualized in MR imaging as shown in Figures 15-26 to 15-27. Furthermore, fornix atrophy leads to reduced size of the mammillary body and the mammillothalamic tracks, as shown in Figure 15-26 and 15-27. Returning to Figure 15-14, all of these structures are critical to memory function and susceptible to injury in TBI.

FIGURE 15-27

Fornix in coronal perspective as it comes off of the posterior aspect of the hippocampus at the level of the splenium of the corpus callosum. This patient sustained a severe TBI in a MVA where her initial GCS was reported to be a 4. This illustration demonstrates the ease with which fornix atrophy can be identified

### THE INTEGRATION OF STRUCTURAL AND FUNCTIONAL IMAGING

The image of the brain generated by CT or MRI only represents gross brain structure. Although in the living individual structure is never devoid of function, neither CT nor MRI structural imaging provide a direct measure of function. However, as explained in Chapter 12 on functional imaging in this book, the principles of structural imaging can be applied to obtain functional measures of the brain. As already discussed, when structural changes are detected they merely depict where the macroscopic abnormalities are and not necessarily the totality of areas or systems that may be disrupted. However, structural imaging typically represents the very best method for projecting functional changes as nicely depicted in Figure 15-28 based on the studies by Lewine et al. (26, 49). As shown in this illustration, MR structural imaging is used as the format for demonstrating where SPECT and MEG abnormalities were found, both measures of functional impairment. As depicted in Figure 15-28, structural pathology in the inferior frontal region was obvious on MR imaging, likely from gliding-type contusions between the brain and the inner table of the skull, particularly the greater sphenoid and the bony protrusions of the interior surface of the frontal bone (i.e., crista galli). Despite the clarity of these distinct lesions, with relatively well demarcated boundaries as defined by the MR signal intensity returning to uniformity once outside the confines of the lesion, neural function was not normal in the 'normal' appearing tissue just outside of the well defined areas of damage. As such, these 'normal' areas, even though close to the lesion, do not exhibit abnormal MR signal and therefore, from strictly a structural imaging standpoint, would be interpreted as 'normal' brain parenchyma. However, when the perfusion defects of SPECT are superimposed, it is apparent that the area of dysfunction exceeds the distinct MR identified lesion boundaries. In other words, the actual area of 'damage' that disrupts function, as measured by SPECT imaging is greater than the lesion(s). More importantly, though, the SPECT abnormalities still do not encompass all the abnormalities as reflected in the MEG findings. Therefore, the true extent of the 'abnormality' will always be larger than the defined lesion. By integrating all three methods, MR, SPECT and MEG, a clearer picture of more generalized cerebral dysfunction involving a much larger area of cerebral cortex emerges. It may be that such integrated imaging methods will yield better prediction of functional outcome. Using the same type of techniques, essentially any imaging modality can be integrated with another, such as 3-D CT or MR images integrated with PET, MRS, quantitative EEG data and so forth. An example of this is presented in Figure 15-29 showing the presence of structural atrophy of the medial temporal area in

FIGURE 15-28

Data are shown for an 18-year-old male subject who suffered moderate head trauma in a motor vehicle accident at age 14. The subject had a Glasgow Coma Score (GCS) of 10 at the time of hospital admission. This patient sustained a moderate-to-severe traumatic brain injury (TBI) with post-injury neuroimaging being performed more than a year post-injury. The single photon emission computed tomography (SPECT) and magnetoencephalography (MEG) were co-registered with the coordinates of the magnetic resonance imaging (MRI), so that all three images could be reliably integrated where SPECT and MEG abnormalities are projected specifically on their corresponding regions on the MRI, as shown in the top row. This also permits the 'fusing' of all images, into a single integrated image showing all abnormalities in a single view. Normal SPECT perfusion is characterized by yellow-orange, more prominently observed toward the cortical surface, where gray matter is found. Blue represents less to absent perfusion, normal in regions of highly concentrated white matter (do to minimal metabolic activity in such regions) or in cerebral spinal fluid (CSF) filled spaces, because no perfusion occurs in such regions. Initial MR revealed by frontal and left temporal contusions and a left fronto-temporal sub-dural hematoma. At the time of SPECT/MRI/MEG imaging, the patient had a chronic post-concussive syndrome characterized by mild depression, frequent head aches, memory and attention problems, and general cognitive decline as characterized by low IQ and impaired processing speed and accuracy. MRI revealed focal bi-frontal and left temporal encephalomalacia, some generalized atrophy and ventricular dilation, and evidence of diffuse axonal injury. SPECT showed concordant hypoperfusion of right and left frontal regions and the left temporal lobe. SPECT also provided evidence of a mild generalized cortical atrophy and ventricular dilation. MEG revealed focal slow waves at concordant right and left frontal and left temporal regions. MEG also showed left parietal slow waves. MEG was the only imaging method to explicitly reveal parietal injury. (Reproduced with permission from Lewine et al., Ref. 26.)

FIGURE 15-29

The T1 coronal image of the TBI patient presented on the right clearly demonstrates bilateral hippocampal atrophy (arrows) clearly defined by the shrunken appearance of the hippocampi and the dilated temporal horns of the lateral ventricle. The Fluorine-18 dioxylucose (FDG) PET imaging fused with the structural MRI, as shown on the right demonstrates relatively normal cortical metabolic activity, except in the medial temporal lobe region and particularly in the bilateral hippocampal region. The hippocampus can be isolated in 3-D as shown below, where the control subject demonstrates the normal appearance of the hippocampus whereas in comparison to the patient's atrophic hippocampus. As would be expected, this patient exhibits significant deficits in short-term memory function, where some of his neuropsychological scores are below three standard deviations of where they were expected to be prior to injury

a child who sustained a severe TBI that resulted in bilateral hippocampal atrophy. Interfacing the PET imaging with the structural clearly shows significant defects in cerebral activation in the medial temporal region, that is actually asymmetric even though the appearance of the structural atrophy of the hippocampus and temporal lobes appear to be symmetric and bilateral.

### NEW TECHNIQUES AND INTEGRATION ACROSS TECHNIQUES: THE FUTURE OF STRUCTURAL IMAGING IN PREDICTING FUNCTIONAL OUTCOME

Only a brief statement will be made on this topic, which should be obvious to the reader at this time. Detection of structural pathology will only improve with the introduction of new hardware and software for structural image analysis (1, 108–114). More rapid and automated image analysis methods are being introduced on a regular basis (115). Accordingly, the prediction of functional outcome in TBI will only improve in the future, particularly as functional imaging measures are integrated with structural (116).

## SUMMARY AND CONCLUSIONS

Although predicting functional outcome from neuroimaging findings is a complex task fraught with many limitations, recent advancements in brain imaging have resulted in significant improvement and understanding of the relationship between structural neuroimaging findings and outcome. As a conclusion to this chapter, the following simplified outline is proffered as a clinician's guide in determining relationships between clinical neuroimaging findings and outcome. The rating begins with the DOI scan, typically a CT, compared to various CT and or MR follow-up scans, particularly more than 25 days post-injury.

1. If the DOI CT is a Level I according to the Marshall et al. (65) rating method (no discernible abnormality, as shown in Table 15-1) and there was minimal or no LOC or PTA and GCS was  $>13$ , structural neuroimaging will likely be interpreted as "clinically" normal and neither qualitative or quantitative analyses will be that predictive of functional outcome. In other words, a 'normal' scan does not necessarily mean normal or a good recovery but absence of abnormality, particularly with minimal PTA, tends to be seen in those with the best chance for good functional outcome.
2. If the DOI CT is a Level I but there is positive LOC and PTA, the patient should have follow-up MR imaging (a minimum of 25 days post-injury) that includes protocols sensitive to blood byproducts, white matter integrity and CSF filled spaces. Normal scan findings at follow-up imaging will be predictive of better outcome than found in those with positive follow-up scans. Those with MR abnormalities in follow-up who show enlarged VBR as a sign of generalized atrophy, presence of focal frontal or temporal lobe atrophy or generalized white matter atrophy (i.e., callosal atrophy) or WMHs will have worse outcome. Functional neuroimaging may be particularly important in understanding outcome at this stage.
3. TBI patients with Level II CT findings or worse generally are more likely to have abnormalities identified on follow-up MR imaging and the degree of VBR identified atrophy will relate to outcome. More atrophy (i.e., larger VBR), generally the worse the outcome. Focal atrophy of the frontal and or temporal brain regions will relate to deficits in short-term memory and/or executive function and likewise, will be associated with a greater likelihood for neuropsychiatric disorder, particular in the domain of mood and anxiety based symptoms.
4. Independent of DOI CT rating, in TBI cases where frontal and or temporal lobe atrophy is identified and/or presence of white matter lesions and/or blood

byproducts (i.e., hemosiderin) in these region, using the method outlined in this chapter for rating of lobular atrophy and/or WMHs [i.e., based on the Victoroff et al. (117) method] will be associated with greater deficits in one or all of the following functions: executive, emotion and/or memory. Where focal atrophy is present, review of the scans for potential contrecoup injury is recommended. Presence of contrecoup injury complicates the prediction of functional outcome.

5. Presence of brainstem lesions on DOI CT carries the worst prognosis for functional outcome.

## Functional Assessment in TBI Rehabilitation

*Marcel Dijkers*  
*Brian Greenwald*

**C**hronic disease and injury often result in difficulties performing day-to-day activities, because of physical, cognitive or emotional impairments.

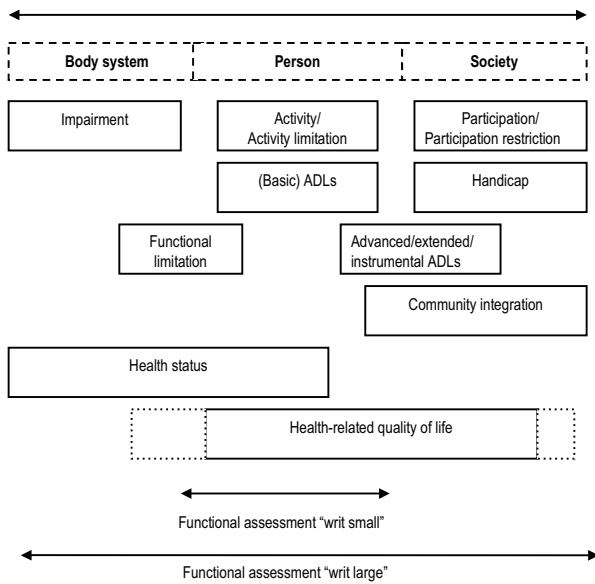

The process of determining the type and degree of such problems, or the ability to perform normal acts, activities and roles, is typically designated “functional assessment”. This is a misnomer, in that “assessment of function” or “functioning assessment” more clearly expresses the nature of this activity. Terms that overlap with “functional assessment” (FA) to a considerable degree are health status assessment, disability assessment or measurement, geriatric assessment, and others (1, 2). All of these activities aim to measure to what degree the person in his or her functioning deviates from “normal”, where normal may refer to typical for persons without disorder (either all persons, or persons of the same age, gender, education, etc.), or the person’s own pre-injury status.

Assessment in this context refers to quantification, where the exact position of the person on a continuum ranging from unable (complete lack of function) to very able (on a level with or even better than “average” or pre-injury) is determined and expressed in a number. This is the meaning of the term FA as commonly used in health care and rehabilitation practice and research. (From other perspectives, quantification is a more limited activity than assessment) (3). However, the term assessment has a second meaning, referring to evaluation or valuation: the

worth or meaning attached to the (amount of) function, by the person involved or by others. While the two types of “functional assessment” are strongly connected, the two are not synonymous. Whereas it is generally true that the value of a particular status increases with functional ability (being able to walk fast is more valuable than being able to walk only slowly), people may differ in how they value one ability compared to another (talking vs. reasoning), and in how they value one specific level of an ability compared to another level (4). These inter-individual differences come into play more, to the degree that the issue shifts from basic human functions (e.g. grasping) to more complex ones (holding down a job). Traditional methods of FA deal exclusively with the quantification issues (which are far from simple by themselves), and not with the valuation question. However, it is becoming increasingly clear that in order to assess with any level of adequacy what medical care and rehabilitation “produce”, issues of valuation need to be dealt with (5). In this chapter, the reasons for and some methods of capturing the subjective valuing of functional states will be discussed, along with more traditional “functional assessment” methodologies and measures.

### THE DISABLEMENT CONTINUUM

As suggested above, “functioning” may cover an extremely broad area, from simple functions involving a single body

**FIGURE 16-1**

Aspects of functioning on a continuum

system to complex activities that are dependent on multiple physical and cognitive skills and are implemented in social interactions according to established social and cultural patterns. In Figure 16-1, the World Health Organization's International Classification of Functioning, Disability and Health (ICF) is used as a framework to delineate various concepts and terms encountered in the FA literature.

The WHO defines impairment as “problems in body function or structure as a significant deviation or loss”; in spite of the word “body”, impairments include deficits in psychological functions (6) p.12. In a previous edition of the ICF, the International Classification of Impairments, Disabilities and Handicaps (ICIDH) (7) the same term was used; the taxonomy offered, however, did not make a clear distinction between deficits of structure and deficits of function at the impairment level. An FA instrument at the Impairment level often used in TBI care and research is the Glasgow Coma Scale (GCS) (8). At the level of the person, activity is characterized as “execution of a task or action by an individual”(6);p.14 its negative aspect, activity limitations, is defined as “difficulties an individual may have in executing activities”(6);p.14. The ICIDH used the term “disability” for this concept, which was defined very much similar to the current term “activity limitation”. Within rehabilitation, the prototypical measure of activity limitations is the Functional Independence Measure (FIM) (9), but many other instruments have been used, within and outside traumatic brain injury rehabilitation. Finally, the person-in-interaction with others may have participation restrictions, which are defined as “problems an individual

may experience in involvement in life situations”(6)p.14; the positive counterpart is characterized as “involvement in a life situation”;(6)p.14 In the ICIDH the term “handicap” was used for the negative aspect, which was defined in a manner quite different from the newer term. However, many of the measures developed to operationalize “handicap”, such as the Craig Hospital Assessment and Reporting Technique (CHART) (10) are now used as measures of participation restrictions, including in the traumatic brain injury (TBI) literature.

Human activities range from simple acts such as stretching a leg to complicated pursuits such as running a household, and it is difficult to define the three concepts of impairment, activity (limitation) and participation (restriction) in a clear and non-overlapping way. The ICF offers separate concepts for the three domains of the disablement continuum, but only two taxonomies: one for Impairments, and one for Activities and Participation, with guidelines for users of the latter as to how the theoretical distinction might be implemented in practice, using the taxonomy. In some instances, it is even not simple to place any one act or activity in one of the three ICF baskets. Many measures of “functioning” such as the Disability Rating Scale (DRS) (11) overlap two or three of the concepts – intentionally or because the developers were not aware that the indicators they combined belonged to distinct conceptual classes.

FA “writ small” deals with Activities/Activity Limitations, and rehabilitation and other specialists have developed many measures to quantify self-care, mobility, everyday communication and other types of activities. We will focus on a limited number of measures commonly used in TBI services and research, but try to give the readers an overview of the concepts and techniques useful in understanding and evaluating instruments, and selecting them for clinical and research applications. FA “writ large” also includes measuring Impairments and Participation (12), and instruments that quantify those aspects of the latter two that are of relevance to TBI are included here.

Many terms developed prior to or outside the ICIDH/ICF can be placed on the same disablement continuum, as shown in Figure 16-1. The core interests of rehabilitation, Activities of Daily Living (ADLs) (sometimes designated basic ADLs) coincide with Activities. Extended (Instrumental, Advanced) ADLs (measured using e.g. the Frenchay Activities Index (FAI) (13) or the Adelaide Activities Profile (AAP) (14)) are generally defined to straddle the Activity-Participation distinction; on the other side of the continuum, Functional Limitations typically represent activities such as grasping and lifting that cross the divide between Impairments and Activities. Measures of Functional Limitations used in TBI care and research include the TEMPA(15) which assesses upper limb function. Developed and applied

outside of TBI care are such UE measures as the CUE (16), and newer LE measures such as the WISCI (17). Community integration instruments, such as the CHART or, in TBI research more frequently, the Community Integration Questionnaire (CIQ) (18) quantify aspects of IADLs, and other facets of Participation, with emphasis on the social interactional components.

Health status, a term used by health outcomes researchers, typically is defined and operationalized as combining elements of Impairment and Activity Limitations, although some measures (such as the well-known Short-Form 36) (SF-36) (19) also includes indicators of Participation. The SF-36 now increasingly is used as a measure of quality of life (QOL). QOL has been defined in a number of ways;(20) most definitions and operationalizations of health-related QOL (HRQOL) overlap with Activities and Participation, and may even take in some aspects of Impairment. Many disease-specific HRQOL measures include symptoms, which typically are missing from Activity and Participation measures; however, many symptoms can be seen as Impairments, which suggests that HRQOL is somehow synonymous with “disablement”, the term the ICIDH’ authors used to represent the entire spectrum from Impairments through Handicaps.

### THE STRUCTURE OF FUNCTIONAL ASSESSMENT INSTRUMENTS

At the simplest level, FA measures consist of a number of separate items, each one of which refers to a narrow or broad ability or skill – for instance, lifting overhead, transferring into a bathtub, or making telephone calls. On each item from two to as many as seven different levels or categories of “ability” are distinguished, which have quantitative values from 0 (or 1) to the highest. The lowest category corresponds to no ability/cannot do at all/need maximum help, and the highest to independence, “normal”, or even above average. Additional metrics have been used, such as difficulty (21) and time needed (22). For measures of participation, metrics used include frequency of performing an activity (10), hours spent on an activity (23), share of activities performed (24), and others. The numbers a patient or subject receives on the constituent items typically are added together, and the total (with or without further arithmetical manipulation) reflects his or her functional status in the domain being measured. For some measures, the items all have the same number of steps and the same minimum and maximum value (e.g. FIM), but that is not necessarily the case – for instance, the Barthel Index(25) consists of some items with only two categories of ability, while the others items have three. Differential scoring of the categories from one item to the next can be used to express the relative

weight (importance) of the constituent skills for overall functioning, according to the instrument’s creator. A separate weighting step prior to addition can be used to achieve the same purpose.

The numeric values of the categories (item scale steps) represent measurement on an ordinal scale – they only indicate relative order along the able-not able (or not participating-participating) continuum, but the differences between scale steps are not equivalent, and the values chosen for them are arbitrary. As a result, adding up the scores for the items to obtain the total score is not an operation that is allowed, based on the rules of mathematics. Therefore, total scores do not reflect position along a continuum that has a true zero point, and constant distances between scale points. (These constitute the definition of a ratio scale, which is what is required for calculating means for a group, or percentage improvement over time). However, research has shown that if the item category values are chosen “reasonably”, the sum of ordinal items corresponds quite well to values on a true ratio scale, at least for intermediate levels of the continuum of total scores (26). Rasch analysis, a mathematical procedure based on Item Response Theory (IRT) has been used to transform a set of scores on ordinal FA items into a score on an interval scale (10, 21, 26). The theoretical assumptions and mathematical manipulations underlying Rasch Analysis-based FA instruments are beyond the scope of this chapter; good introductions to the technique and its application to FA may be found in Bond and Fox (27).

However, most FA measures used in TBI clinical services and research such as the GCS, DRS, and CIQ have never been subjected to Rasch analysis, let alone rescored on the basis of the findings of such an analysis. They may not be unidimensional, and increases from very low initial scores (e.g. a FIM total of 40) may be much easier to accomplish than apparently equally great increases (as expressed in score points) from medium or high starting points (e.g. a FIM of 90). As a result, one should be quite careful in interpreting FA instrument scores as applied to individuals, and to groups. Especially “percent improvement” and “change efficiency scores” should be considered as nothing but approximations of the mathematical precision they appear to offer. Calculation of means and all other operations that require interval scales (regression analysis, etc.) are somewhat less suspect, but the results also should be considered as approximations. Mathematical wizardry cannot make up for the basic problems created by ordinal measurement of skills and performances. In the years to come, more information on Rasch-analysis or IRT analysis of existing FA instruments will become available, and new instruments will be introduced that were developed using up-to-date IRT methods. We will be much more justified in treating the scores on those types of instruments as ratio scale numbers.

## ISSUES IN FUNCTIONAL ASSESSMENT

### Capacity and performance

Two aspects of functioning are commonly distinguished: capacity and performance (6). Capacity is what people can do under optimal circumstances – well rested, encouraged to their best, in a physical environment with minimal barriers. Performance is what they do in everyday life. People who can do self-care not necessarily always do it, for a variety of reasons. One of the most common reason is that their environment is not accommodating, or that the energy and time a task requires preferentially are spent on other, more worthwhile endeavors – whether that is work or watching one's favorite soap opera. Studies with spinal cord injury patients have shown that many for whom self-care is a "marginal" skill prefer to have a personal care attendant or family member perform their care, so that they can get out of the house and get to their job (28). There are no clear parallels for cognitive-communicative skills after TBI, although it is likely that people with limited short-term memory and impaired ability to focus may leave it to others to read a bus schedule for them and tell them what time they need to catch the bus to make it to an appointment, even though with sufficient time and effort they could figure that out by themselves.

At the Impairment end of the disablement continuum, functional limitations tests tend to be performance focused. The ASIA motor scale(29) is based on the patient's ability to contract key muscles, and the physician and patient are hardly interested in the patient's actual frequency of contracting those muscles. At the other end of the continuum, measures of participation or community integration without exception quantify performance. It is either impossible to test capacity (how could one test "ability to function as a brain surgeon"), or not of interest: actual performance is of importance as the long-term outcome of rehabilitative efforts, not potential. It is in the middle ground, the domain of Activities, that a discrepancy between capacity and performance is most likely to be relevant, and performance is modifiable with environmental and other interventions.

### Testing, observation and reporting on performance

Three methods are used to collect functional information. Testing involves requiring the patient or client (or research subject) to perform specific tasks or skills under the direct supervision of the test administrator, who times the test, assesses the amount of help from aids or aides that is needed, etc. This tends to occur in laboratory situations, but testing can also be done in the person's home or other setting where the activities involved are or should be performed (30). Depending on the degree to which the test situation approximates an optimal one, the resulting score

quantifies optimal capacity, or capacity in the situation that is considered most relevant to the uses to which the functional information is to be put.

Observation of actual behavior is the basis for quantifying what the person does do, rather than what he or she can do. Most functional assessments of Activity reported as part of inpatient or outpatient rehabilitation programs is observation based – at least in theory. For instance, the Uniform Data System (UDS) FIM admission and discharge scores are based on what the patient does in the first three days after admission or the last three before discharge. In practice, there is continuous pressure on the patients to perform at their best, especially in treatment with PTs and OTs, and the measure of performance turns into a measure of capacity. Research using the LORS, for instance, has shown that scores reported by therapists are systematically lower than those reported by nurses (31). Nurses presumably report on what they observe the patients doing when going about their life on the nursing unit, while therapists only see them during scheduled hours, where they cannot waste time observing what the patients do naturally – the therapists need to optimize the patients' performance.

A third way of collecting FA information is through report by the patient, or a proxy such as a family member. These reports can involve capacity (for instance, in the CUE(16)), but more typically address performance. Questions are asked about how the person performs the various activities included in the FA measure in his or her daily routine. Using a standardized branching questionnaire, trained interviewers can reach a high-level of inter-rater (inter-interviewer) reliability. This is how data are typically collected for follow-up assessments in the UDS, and other program evaluation approaches.

All three methods have their advantages and disadvantages, in terms of cost, personnel needed, required ability of the patient to cooperate with the data collection, etc. If capacity data are of interest, testing is the preferred method; for true performance data, interviewing is the only feasible approach. Problems arise when the data obtained by two methods need to be linked. For instance, a typical question (clinically and in research) is whether the person manages to maintain or even improve on the skills he or she was discharged with from inpatient rehabilitation. The hospital data are typically collected using observation, in an environment that tends to be more accessible than the typical residence, and with overt or covert pressure to perform one's best. The home follow-up data are normally collected using interviews, concern performance in a different environment, in which there may be no incentive at all to use all the abilities taught in rehabilitation. If a change in functional performance is noted, is this due to the change in data collection method per se, or due to changes in the environment, or even because of changes in the true underlying capacity (continued

neurological recovery)? This issue has hardly been studied, and we don't know enough about differences in scores for various data collection methods for various FA instruments to tease apart the various factors (32).

### The nature of the items

In an IQ test, the person tested completes multiple arithmetic, similarities, and other items which in themselves are not of interest to the test administrator. The IQ score that results is of interest, because it gives an (imperfect) indication of the person's overall cognitive abilities. The focus is on the underlying trait – intelligence. In FA, however, the items most likely have intrinsic meaning, to the person performing the assessment and to the individual assessed: they reflect activities that are of importance in and of themselves – whether it is stair climbing or the ability to communicate a simple idea. FA “tends to occur within a realistic setting that approximates the one in which the actual criterion behavior will occur” (2) p101. That does not mean that there is no underlying construct “functional ability” that is of interest – but the underlying ability is of concern mostly because it informs on the functional items that were part of the assessment, and possibly on those that were not part of it. Because the primary interest is in the items (tasks, activities) themselves, there always is a tendency to include in FA measures the full panoply of acts that are part of normal human functioning. The Patient Evaluation and Conference System (PECS) in one of its versions included 97 items, of which as many as possible were to be completed as applicable to the patient (33, 34). Such an extensive menu is feasible when various staff report on patient status within their area of expertise (speech and language, neuropsychology, chaplaincy, etc.) but not in situations where subjects are tested, or are required to report on their performance. Maintaining a balance between feasibility and inclusion of those functional tasks that are key to living has always been a balancing act for FA instrument developers. Measures that cover “all areas of life” (or at least all aspects of Activities and Participation) tend to select fairly broadly defined tasks (e.g. “dressing”), and limit the number to 10 to 20. Instruments developed for use by specific disciplines are apt to include more narrowly defined tasks (“putting on a pull-over”) and include a large number: The Klein-Bell ADL Scale contains 170 items to cover just six areas: dressing, mobility, elimination, bathing/hygiene, eating, and emergency telephone use (35).

When the focus of FA shifts from performance of individual tasks to the status of broad underlying abilities (“self care”; “motoric strength and coordination”), the need to include each and every possible item diminishes. Traditional psychometric methods can be used to show that the underlying construct can be measured with one set of items (indicators) as well as with another set,

and that the resulting total scores will have high correlations with one another. Some measures of functional limitations (the transition area between Impairments and Activities) do not attempt to “cover the waterfront”; they select activities that are representative of the entire universe of relevant items, and use those to score, for instance, upper extremity functioning. After all, once it is known how much difficulty a subject has picking up a can of soup, and how much picking up a ream of paper, it should be fairly clear how well she would do lifting a paperback book. To what degree this same reasoning applies at the other end of the disablement spectrum, Participation, is not yet known. The ICF distinguishes about 90 different aspects of “Participation”, in 9 chapters covering communication, mobility, domestic life, etc. Is it necessary to obtain information on all of these to get a complete view of someone's level of Participation? Or is it possible to extrapolate from three household tasks to all others, and also to know quite adequately how well the person does in the civic responsibilities domain? That depends to a large degree on whether Participation is a single unidimensional construct, or a large collection of items that all reflect Participation in some way, but do not even represent multiple dimensions. There presumably are key Participation components that no FA instrument would want to omit (work, social relations with family), but the need to, and opportunity for, collecting information on all others is still not known. These and other problems involved in measuring Participation are discussed in greater detail in Dijkers et al. (36).

The presence of an unidimensional continuum underlying functional tasks makes it possible, for those whose interest is more in the patients'/clients'/subjects' status on the construct rather than their performance on each of the individual items, to use computer adaptive testing (CAT) and related techniques to administer very short, targeted sets of items, matched to the individuals' ability (performance) level, that produce the same quantity and quality of information as the more expansive sets of items from which these sets are drawn (37–39). To date, application of CAT to FA has been more demonstration of concept than use in daily clinical and research practice.

### ISSUES IN MEASUREMENT: THE PSYCHOMETRIC CHARACTERISTICS OF FA INSTRUMENTS

Whenever we measure, error creeps into the resulting score, whether it is a small error in measuring simple concrete characteristics (for instance, the area of a room), or a large error in quantifying abstract concepts such as authoritarianism. FA is no exception, and the issue is not so much getting rid of the error (we never will be able to

that completely), but being aware of the amount of error our data contain, and being aware what it means for any conclusions we draw and actions we undertake based on those data. Metrology (the science of measuring) is a major concern in all science disciplines, and the developers and users of FA instruments have mostly relied on the methodologies for instrument development originating in psychology. “Psychometrics” is a very technical and for most clinicians very boring subject, but knowledge of some of the basics is necessary for the fruitful use of FA instruments.

Traditionally, two aspects of the data reflecting the results of measurement have had most emphasis, validity and reliability, but in clinical applications such issues as sensitivity and practicality are increasingly getting attention. In theory, reliability is an aspect of validity, but most people tend to think of them as separate characteristics of instruments (or, more properly, of the data produced by instruments), and the techniques for quantifying validity and reliability are separate. “Validity” refers to the question: is this instrument measuring what it purports to measure? If it is targeting characteristic X, do the numbers reflect X, and not Y, or a little X with a lot of Z? “Reliability” refers to the question: how reproducible is this measurement – if we repeated the measurement operation, with the same or a similar “ruler”, would we get the same result? As illustrated in Figure 16-2, an instrument can be very reliable without being valid. If it is not reliable at all, it by definition is not valid. The goal we are aiming for is instruments that are both valid (they measure what we want to measure) and reliable (they give results that are reproducible).

Over the years, a great many techniques have been developed to quantify validity and reliability, each applicable to different situations. Unfortunately, psychologists and social scientists have fallen into the habit of “inventing” new types of validity and reliability, by naming them after the techniques. However, there is no such thing as test-retest reliability or construct validity. There is only one validity and one reliability of each instrument, which are estimated using different techniques.

FIGURE 16-2

The relationship of reliability and validity

## Reliability

Estimating the reliability of measures is the easiest to understand. The estimates all are based on some form of repeat measurement. If two clinicians at the same time rate the ability of patient X on the FIM Grooming item, they should come up with the same number – or else one or both are wrong. We can estimate the reliability of the FIM grooming item *as used by these two clinicians* by having the two rate a few hundred patients, and calculate how often they agree – completely, or almost so. A statistical formula such as coefficient kappa (or weighted kappa) can be used to express the result. All these formulas are constructed in such a way that the result, the reliability coefficient, varies between 0.00 (no reliability whatsoever) and 1.00 (perfect reliability). “Interrater reliability” can be estimated based on a few raters to represent all possible raters, so that we can have an idea as to how reliable this one-item instrument is in the hands of the average clinician.

If the same patients are rated by the same clinician twice, we similarly can calculate “intra-rater reliability”, the degree to which she agrees with her earlier ratings. There are two scenarios for this – either the patients’ performance is videotaped, or the rater observes the patients twice. In the latter case, it is of course important that we are sure these patients have not changed in the mean time. In both instances, the clinician should “forget” about her rating the first time around – which is not that difficult if large numbers of ratings are to be made.

Functional status is a fairly broad and abstract entity (a “construct”, in psychometrical parlance), and it is unlikely that a single item such as Grooming can represent the entire construct. Typically, we select multiple indicators (items), and combine them to adequately operationalize the theoretical definition we may have. Use of multiple indicators has another advantage – any random measurement error involved with quantifying any one item is likely offset by the random error in another item. (For that reason, the more items there are in an instrument, the more reliable it will be, *ceteris paribus*, because the chance of random error being eliminated is increased. Any *systematic* error will just remain, however, and practical issues come into play if instruments are too long). Because each item in a FA instrument is a repeat measurement of the construct, like the two raters for Grooming are repeat measures, we can calculate the agreement between items, as yet another estimate of reliability. A number of formulas to estimate “internal consistency reliability” exist, the most frequently used of which is (Cronbach’s) coefficient alpha. “Split-half” and “parallel forms” reliability are related formulas. All of them take values between 0.00 and 1.00.

The minimal level of reliability a measure needs to have depends on the purpose to which the data are to be

put. A minimum of 0.90 for situations where decisions on an individual patient need to be made (discharge Mrs. Jones or extend her stay another week?) is often quoted, while 0.70 or 0.80 is a typical minimum required for group applications, such as in program evaluation and research. Longer instruments tend to be more reliable, but the trend is toward the use of short forms, such as the SF-12 and the CHART-SF rather than long ones, like their parents SF-36 and CHART. With better construction, new short instruments can offer reliability approximating that of older long ones. Another development is computer-adapted testing (CAT), in which only those questions that are targeted to the ability level of the person are being asked (39). For very simple instruments, paper-and-pencil adapted testing is possible (40, 41).

### Validity

Validity cannot be estimated in such a simple way as reliability can, except in one unusual situation: there is an existing instrument that we are certain is perfectly valid. In that case, we can administer the old instrument and the new one to a sample, calculate the correlation between the two scores, and use that correlation as the estimate of the validity of the new measure. The issue of course is: if there is a perfectly good measure, why is there a need to develop a new one? (The importance of having a shorter scale may be the only acceptable reason). Less powerful methods are used in the more common situation: there is no existing measure, or the existing ones are problematic in themselves.

“Face validity” is (in the eyes of most authorities) not a form of validity determination, but an answer to the question: does the instrument “on the face of it” measure what those completing it expect to see – does a measure of X have questions about X that patients recognize as such? Some instruments have no or little face validity, but are perfectly valid – for instance, the Minnesota Multiphasic Personality Inventory (MMPI). In the arena of FA face validity is hardly an issue, because the constructs quantified, or at least the activities that are used as indicators, have a fairly low level of abstraction. The closely related term “content validity” refers to a measure covering the entire construct the developer is targeting, in the eyes of experts. It is generally determined by having the experts draw up lists of necessary content for a measure of X, or checking the content of the draft measure. Of course, this presumes there is a clear description (by the authors) of the concept they would like to operationalize – it makes no sense criticizing a painted portrait on realism if you don’t know the person depicted. There are no standard formulas for calculating this validity aspect.

“Predictive validity” concerns the ability of a measure to predict a future state or event that is inherently linked to the characteristic being measured. A college

entrance examination is said to have predictive validity if it can be used to accurately predict who in four (five, six) years will graduate. A parallel in FA would be the ability of a measure to predict who will be successfully discharged home versus to a nursing home. One problem with predictive validity assessment is the fact that there are no hard and fast rules as to what should be the minimum level of success in predicting. We know that many factors affect successful independent living – the accessibility of the home, family and other support available, the person’s stubbornness and willingness to run risks of falling, etc. Does a FA instrument have adequate predictive validity if predictions based on it are correct 40% of the time? 50%?

“Known group validity” is based on differences in scale scores between two groups that are known to differ in the characteristic the instrument aims to measure. The average score of persons with TBI on a measure of physical functioning should be higher than the average of persons with SCI; in case of a measure of cognitive functioning, the situation should be reversed. If the data do not parallel these expectations, quite likely the instrument is not measuring what we think it is. Alternatively, a lot of systematic error (bias) is reflected in the data. A similar problem as mentioned above occurs with determining known group validity: how much of the variation in the functional status of the overall group should be explained by diagnostic category, TBI vs. SCI? If every person with TBI is known to have a higher physical functioning level than every person with an SCI, things would be easy: the variation explained should be 100%, and everything lower than that would mean less than perfect validity. However, the distributions for functioning ability of the SCI and TBI groups overlap, and the variation explained in a t-test reflects both the difference between group means, the standard deviations around those means, and the random and systematic error in the measure we use. Stating that a good functional measure should explain between 0% and 100% of variance is not very helpful in selecting or developing an instrument.

Lastly, “construct validity” concerns the relationships between the measurement data of a (highly abstract) construct and data for other constructs. Sometimes we have a basis in theory to predict that construct K should be strongly related to (yet not identical with) construct L, and be independent of construct M. (For instance, “ADL ability is related to community integration, but unrelated to political party preference”). If the data brings this out, the operationalization of K should be valid (and similarly the operationalizations of L and M). If the predicted association between K and L is minimal or absent, however, we don’t know if the problem is with the theory, or the operationalization of K, or the measurement of L. And it is an unusual theory that specifies the exact strength of the relationship between K and L, predicated

on perfect measurement of the constructs involved. “Strong” or “very strong” is the best we get, and those are not very good starting points for evaluating the level of validity of the instruments involved.

The above should make clear that the estimation of the validity of instruments always is less straightforward than the quantification of their reliability. Finding high values parallel to e.g. a 0.91 level of test-retest reliability just does not happen; validity coefficients are much lower, because all methods of validity estimation are roundabout. In practice, it is necessary to use all possible methods of estimating validity, and based on multiple findings “patch together” evidence supporting validity – which never will be iron-clad. Finding encouraging levels of the various types of validity distinguished here, in multiple studies, with patterns of correlations that make sense based on expert knowledge, is what typically occurs. Fortunately, in the case of FA, the construct being measured is fairly concrete, and the specialists involved have extensive knowledge of the determinants, correlates, intergroup differences etc. of various aspects of functional status, making the issue of assessing the quality of specific measures less problematic than the preceding list of issues might suggest.

“Ecological validity” does not concern validity proper, but the relevance of assessment data to real-life situations outside the testing situation. For instance, the Wisconsin card-sort test(42) is a measure of executive functioning (the ability to plan, initiate, execute, monitor and correct one’s actions) often used by neuropsychologists to assess persons with TBI. Like all neuropsychological tests, it is administered in a quiet office after the person tested has had a good night’s sleep and is still fresh, etc. How well do the results predict the patient’s ability to make breakfast for her children while testing the middle schooler on history and finishing her own make-up before leaving for work, with the TV competing for attention?(43) Testing executive functioning in situations that resemble the real world would provide data that are more “ecologically valid”, but the standardization of testing might suffer. Standardization of testing has always been a keystone of psychometric methods of assessing reliability and validity of neuropsychological instruments, and of quantifying the abilities of individual patients or clients – they are capacity measures. However, standardized environments tend to be dissimilar from the settings where people perform self-care, communicate, do work and all other things captured under the umbrella of functioning. Testing in a standardized environment almost always means in an optimal environment – and the results tend therefore to be more indicative of capacity than of performance.

### **Sensitivity.**

It is easy to see that if a FA “measure” has just two categories: “able” and “unable”, it lacks sensitivity: it

cannot reflect fine distinctions in ability/performance, and it cannot be used to record minor but clinically significant changes. Sensitivity refers to the ability of an instrument to capture distinctions that are clinically relevant or small enough to be of importance in research, across the full extent of the range of ability of the cases to be measured. When sensitivity is discussed in relation to change, the term responsiveness is frequently used.

Floor effects and ceiling effects are one issue in sensitivity. The first terms refer to the lowest measurable level of performance on an FA instrument being higher than what is the status of the least able person to be measured. All individuals who have ability equal to the lowest measurable level or lower are clumped together and given the corresponding score. Vice versa, a ceiling effect means that the highest measurable level is lower than the level of at least some of the more able patients/clients. It should be noted that very often measures are developed for one population, in which they have no floor or ceiling effects, but then applied to another, in which they do. For instance, the FIM was designed to quantify functional status of rehabilitation inpatients, and any patient who achieves the maximum score on discharge was probably an inappropriate admission. However, a few years after onset of TBI many persons will score at the maximum of the Motor FIM subscale. The FIM was never designed to distinguish between people with minimal deficits that do not affect functioning, other mere mortals, and Superman. Thus, “lack of responsiveness” sometimes is a problem for which the instrument user is responsible, not the instrument developer.

Quantification of responsiveness is not done using formulas resulting in simple coefficients ranging from 0.0 (not responsive at all) to 1.0 (maximum responsiveness possible). All methods are mostly useful for comparing responsiveness of one measure with that of another, allowing one to select the most responsive one. A variety of indices are used, including effect sizes (the mean change between time 1 and time 2 divided by the standard deviation at time 1), the standardized response mean (the mean change between time 1 and time 2, divided by the standard deviation of change scores), receiver operating characteristic (ROC) analysis, and many others. Discussion of these indices is beyond the scope of this chapter; the reader is referred to the extensive literature (44–46). A particular subgroup of these indices involves a rating, typically by the patients themselves, that from time 1 to time 2 they have improved (or deteriorated) a little or a lot, or stayed the same; any FA score changes should correspond to these subjective “transition ratings” (47, 48), or else it lacks responsiveness.

### **Other psychometric characteristics**

Beyond validity, reliability and sensitivity, there are a number of other characteristics of a FA measure that are

relevant to its use in clinical, program and research applications, most of which have to do with practicality:

- **Language:** this is especially relevant to self-administered measures, such as the CIQ (18), but may also be an issue with observational and other measures. Both the reading level and a translation in a language the user is familiar with are of concern
- **Training required:** many observational FA instruments and test-type measures require the user to be trained, and sometimes certified (30), in order to produce reliable data
- **Time and equipment required:** measures that take inordinate time on the part of the subjects or the administrator, or that use special equipment (in some test-type measures such as the Tufts assessment of motor performance (TAMP) (49)) may not be suitable outside research applications

## USES OF FUNCTIONAL ASSESSMENT

The origin of FA (writ small) in medical rehabilitation is in attempts by clinicians to express quantitatively the deficits patients had on admission to rehabilitation, and to monitor progress, or at least determine discharge status, so that there was some “proof” of the effectiveness of treatment, beyond the patient’s simple report that he or she now could do things that were impossible or difficult before admission. The fore-runners of instruments such as the Barthel Index (BI) (25) were simple checklists for recording (lack of) problems with performing self-care and mobility activities (2). From these simple early efforts, measurement instruments of sometimes great sophistication have grown. In addition, the range of applications of these instruments has expanded tremendously, so that we now can describe uses in the care of individual patients, treatment programs as a whole, reimbursement, and research. The type of information needed in these various applications is somewhat different, and even when the basic instrument used is the same (the FIM is the “workhorse” of medical rehabilitation, and is used almost throughout all these types of applications), ideally there would be differences in scoring or other details.

### Uses in care of individual patients

Decisions on admissions to inpatient and outpatient programs are often based on a formal FA, to see if the person has the types and degrees of deficits that the program is qualified and authorized to treat, either in general or for the specific person in question. The “baseline” assessment therefore often is communicated to the third party payor, who may use it to approve program admission and a certain duration or intensity of treatment. The pre-admission

or admission assessment is frequently the basis for a prognosis, which is communicated to the patient and the payor, and ideally underlies goal setting. Many programs use an FA instrument such as the FIM to set goals, either for classes of patients or for individual patients. Software applications have been developed to assist case managers to make such predictions; they are based in large part on a data base that contains the data on many previous patients with the same rehabilitation diagnosis, age, gender and co-morbidities.

Goal setting ideally is more individualized than the limited number of constituent items and/or outcome levels of standard instruments allow. Several methodologies have been developed to allow more or less “customized” selection and quantification of goals, which then are the basis for treatment plan development. Results can be monitored to see if goals are reached (in the time span planned), or need to be modified based on new or initially unknown complicating factors. Goal Attainment Scaling (GAS) is a method originally developed in the mental health arena(50) that has been applied in medical rehabilitation, mostly for research purposes, it seems (51, 52).

In GAS, the client and therapist together set multiple goals, and for each determine the most likely outcome level, as well as two levels of lesser accomplishment, and two of better accomplishment. For instance, for the goal mobility, the target level could be “household walker – can ambulate 50 feet without walker, and without difficulty”. Lower levels could reflect use of supports and/or lesser distance (scored as –1 and –2); higher levels greater distance and/or outdoors mobility (scored as +1 and +2). Each of the several goals (walking; bathing; doing dishes, etc.) is given an importance weight reflecting patient/client valuation. To calculate the overall outcome of treatment, the outcomes for the various goals are summed, after weighting by the importance factors. Thus, the GAS and derivative methods incorporate to some degree the individual valuation of functioning components, but do so only for those actions and activities that display major deficits, rather for all domains of functioning. The end result of the outcomes operationalization reflects success in terms of the goals set, not client functioning in terms of deviation from “normal”. For that reason, these types of instruments may be more useful in clinical applications than in research on the determinants and consequences of functional deficits. Appropriate use of functional measures for goal setting must take into account premorbid function, patient resources (financial assets, family and community support), and known prognostic information. The Canadian Occupational Performance Measure (COPM) (53, 54) uses a methodology very similar to GAS. Ironically, much less is known about the reliability of individualized instruments such as the GAS and COPM than about the measurement qualities of standardized instruments such as the FIM.

Decisions on treatment termination should be based on a number of factors, that include not just functional status (achievement of treatment goal, plateauing) but also family factors, carry over and continuation or generalization of functional skills learned in therapy.

Treatment monitoring using a FA measure is applied in many rehabilitation programs, even if the goals have been set without patient input or without subjective a-priori weighting. Team rounds often exist of the reporting by “most responsible/ knowledgeable therapies” (nursing for bladder; speech for expression, etc.) of the current status of the patient on the numeric items offered by the FA instrument used in the facility. Even before powerful desk-top or hand-held computers existed, various facilities had developed computerized systems for collecting and displaying functional status information – e.g. the Rehabilitation Indicators project (55) and the PECS (33, 34, 56). Even if weekly or less frequent team meetings do not employ formal quantification, the status of the patient with respect to various skills and other aspects of Impairment, Activities and (in outpatient programs) Participation is typically discussed. Almost all rehabilitation programs quantify status on discharge, because that information is needed to document program results, and subsequently is used in program evaluation. While increasingly treatment termination decisions are based on “external” criteria (e.g. a maximal length of stay approved by a third party payor), ideally they are founded on either the accomplishment of goals, or plateauing of the patient in terms of overall functional ability. In both instances, measurement of patient status should be performed using an instrument that has minimal error so that (lack of) change can be reliably determined.

FA information may also be used to communicate about progress and outcomes of treatment with persons who are not part of the team. Patients themselves, their family members, referral sources, and payors have a keen interest in the functional aspects of the patient’s status, especially where it concerns Activities and Participation. One additional use of FA for individual cases is long-term monitoring of a patient’s status. Especially in the case of progressive diseases, this type of information is important to make decisions on new treatments, changes in patient environments, etc. In fact, this use of FA has led to a designation of functional status information as a sixth (after the standard four and pain) vital sign (57).

The foregoing issues suggest that the choice of an appropriate validated FA measure for the individual with TBI depends on a number of factors including: time after injury, rehabilitation setting, and goals of rehabilitation. When clinical improvement is seen, and goals and maybe even the rehabilitation setting (inpatient acute and subacute, etc.) are changed, the measurement tools should be reevaluated. The use of a scale that is insensitive to the improvement that is expected, or not measuring the progress toward an individual’s goal, should be avoided.

### Uses in program administration.

Most rehabilitation programs have as their overall goal something along the lines of: to improve quality of life by reducing impairments and increasing activities and participation level. Program evaluation aims to assess to what degree a program indeed accomplishes what it sets out to do – improve functional status of people with disablement. Basic questions are: do patients change for the better (program effectiveness), and if so, are resources used optimally in accomplishing this (program efficiency).

While change from admission to discharge from a program is common, it is unfortunately not easy to offer proof that the program deserves credit. For instance, a person with TBI may score higher on a post-test than on a pre-test for a number of reasons that have nothing to do with the selection, timing, quality and quantity of services received: natural recovery, improved test-taking ability, and many others (58). All rehabilitation programs face the same problem, and one solution that has been found is to compare outcomes between programs, under the assumption that not *all* change in *all* programs can be explained by causes other than treatment received, and the “excess” change in the best programs is truly the result of interventions. Longitudinal evaluation of a program’s outcomes is facilitated by creation of a minimal data set for all programs that includes demographics, time since injury and measures of injury severity, in addition to specific scales of functioning, selection of which depends on program type and time of follow-up (59). The Uniform Data System (UDS) in which most inpatient rehabilitation facilities in the US participate, as well as some subacute facilities and nursing homes that offer rehabilitation, is one such data aggregator.

Comparisons between programs is fair only, of course, if their inputs (admission status) are the same; it may be much easier to bring an admit FIM score of 50 up to 100 for someone with SCI than for a patient with TBI. Thus, UDS and other aggregators produce reports that compare like with like, in terms of diagnostic group, co-morbidities, age, and other factors considered relevant to chances of program success. The focus tends to be on functional status change over time, as the key indicator of effectiveness. Because the better programs may achieve a certain level of change using much fewer resources than poorly organized ones, length of stay (LOS) is typically used as a gross indicator of resource use. Functional status change per day then is an indicator of program efficiency. (It may be worth repeating here that a number of assumptions, including interval-level measurement of functional status, are made that may not stand up to scrutiny). There are other methods of evaluating a program’s effectiveness, e.g. by evaluating what percentage of the patients did achieve the goals that were set at admission. It is natural that a small percentage of patients

do not progress as well as anticipated, e.g. due to inter-current illness. But if a large percentage fails to make the standardized or individualized functional goals set for them, the program is either selecting the wrong types of patients, or staff and programs are ineffective. Shifts in program admission policies, management or processes may be needed. Unfortunately, routine program evaluation data tend to be insufficient to indicate where exactly the problem is and how it can be fixed; additional studies are needed to obtain that information. However, routine outcome data can and should be communicated to stakeholders, including current and future patients, third party payors, and the local community. The Centers for Medicare and Medicaid Services (CMS) has started to post comparative functional outcomes for nursing homes on its website, and it is to be expected that similar “report cards” including functional FA information will be published in the future for many other facilities that offer rehabilitation of some type.

Choosing appropriate functional measures for the evaluation of a TBI program should be based on what point of the rehabilitation spectrum the program serves. Measures of impaired structure/function would be appropriate for acute inpatient care, with coma scales used for low level patients. Activity measures are most appropriate for acute or subacute inpatient care; Participation measures are needed to assess the effectiveness and efficiency of outpatient services in the community.

The Commission on Accreditation of Rehabilitation Facilities (CARF) (<http://www.carf.org>) is a widely recognized not-for profit accrediting organizations and programs, including TBI programs. It currently offers accreditation in seven categories of brain injury services, including inpatient hospital rehabilitation, residential services, and home and community-based services. Accreditation is based on documenting adherence to standards as well as a surveyors’ evaluation. Depending on the level of care different criteria need to be met. Ensuring patient and family education as well as considering future rehabilitation needs are required components. Outcome measures include appropriate functional assessment during and after treatment. Patient and family satisfaction measures also play an important role.

In addition to program evaluation (which is a CARF-required activity) and accreditation, FA data are used in a variety of activities centering on improving program services quality. Whether they are called outcomes management, continuous quality improvement (CQI), or total quality management (TQM), they all involve considering the organization delivering services as a system, with parts and subsystems that all should be studied continuously to reduce inefficiencies, improve administrative and clinical procedures, and reduce risks and adverse events (3). FA information almost by definition plays a key role in making decisions in programs that deal with individuals with TBI or other disabilities. For instance, an

admission-to-discharge increase in functioning less than a specified minimum could be an indicator threshold violation that triggers an in-depth investigation whether a problem (opportunity to improve processes) exists. FA information could also function as a monitor that is collected routinely to indicate functioning of the program(s) – a vital sign for the organization.

Effective 2002, CMS has, under its Prospective Payment System (PPS), paid inpatient rehabilitation facilities (IRFs), fixed amounts for each patient discharged, rather than reimbursing (adjusted) charges, costs of operations or some other formula used in earlier years and still used by other payors. The fixed amounts are based in part on the functional status of the patient on admission, combined with diagnostic category (stroke, TBI, SCI, etc.) and age category. For functional status a minor variation on the FIM is used, which is embedded in the IRF-Patient Assessment Instrument (IRF-PAI). The combination of diagnosis, IRF-PAI functional status category and age defines a group whose rehabilitation requires unique resources, as acknowledged in the payment amount for each case (60). (This payment is further adjusted for comorbidities (“tiers”), salary levels in the region the facility is located, etc.). The PPS has given facilities financial incentive to hasten if not improve outcomes. Facilities need to ensure they are doing functional assessment accurately to document patient impairment.

The National Committee on Vital and Health Statistics (NCVHS) has recommended capturing and classifying functional status information as part of routine health care transactions, so that administrative databases could be mined and used for a variety of purposes, including monitoring overall population health, health care management, public health planning, predicting costs and financial management, and policy development (61). At the moment, only limited information on functioning is available, mostly through Medicare files, on special populations: those receiving inpatient rehabilitation (IRF-PAI), nursing home residents (Minimum Data Set – MDS), and people receiving home health (Outcome and Assessment Information Set – OASIS). The Subcommittee on Populations of the National Committee on Vital and Health Statistics which investigated these issues suggested that, with modifications, the ICF might be a useful taxonomic system (a “uniform code”) to base such data collection across the continuum of care on. The uniform code would not prescribe *how* to measure functional status, but only specify *what* data elements need to be reported. (In this sense, it would be comparable with e.g. the ICD, which does not specify *how* to diagnose a particular disease, only *what* the disorders of interest are and how they are related to one another). A German group under the guidance of Stucki and associated with the WHO has begun the development of ICF “core sets” – listings of selected Impairments, Activity Limitations and Participation Restrictions

that are of particular relevance to the care and management of a particular diagnostic group (62–64). The ICF allows coding the severity of Impairments, Activity Limitations and Participation Restrictions,(65) but these are very “primitive” methods that do not operationalize measurement. Presumably, productive use of the core sets, especially in applications beyond clinical care, requires a system or systems of functional assessment.

### Uses in research

Program evaluation typically does not address what was done for individual patients (the “black box” aspect of rehabilitation) to explain changes in functional status and link those interventions to outcomes. It also does not systematically address alternative explanations for outcomes, and has no hard evidence for the effectiveness of traditional or innovative treatments. This is where research comes in. Per end June, 2005, Medline contained over 27,000 records classified under “Activities of Daily Living”, which is used to classify papers on ADLs, (chronic) limitations of activity, independent living, and self care. Functional assessment papers are also indexed under other headings – for instance, “geriatric assessment” added another 2,000 plus unduplicated records. Of this total, only a small number addresses clinical application at the level of the individual (presumably less than 5%) and a slightly larger number (maybe 10%) concerns the program level uses of FA measures. Most published research concerns either the development of FA instruments, including assessing reliability, validity, sensitivity, and practicality characteristics, or the use of FA measures to evaluate the effects of rehabilitation, describe the natural course of disablement, assess the financial and social impact of disability, etc.

Because functioning is the central interest of rehabilitation providers and researchers, and their patients/clients, it is to be expected that much of their research uses FA information as either the “independent” (predictor) variable, or the “dependent” (outcome) one, or both. The same holds true with respect to TBI rehabilitation: FA measures, whether specific to individuals to this diagnostic group (CIQ,(18, 66) Disability Rating Scale (DRS),(11)) or generic (FIM) are used in a large percentage of the published research. In this literature one also finds application of very specialized measures (e.g. of functional communication) that will not be covered here. It is worthwhile to remember, though, that before any use is made of its results, this research needs to be assessed in terms of the applicability of the FA instruments selected, and their psychometric qualities.

### SUBJECTIVE VALUATION OF FUNCTIONAL PERFORMANCE

A major criticism of most of the FA measures used in TBI clinical care, program evaluation and research is the fact

that they do not reflect the subjective view of the person involved. “Normal functioning” may be a laudable goal, but not if that functioning detracts from the person’s subjective QOL. For instance, O’Neill et al. found that persons with TBI may do better holding down part-time rather than (normative) full-time jobs. (67). Several studies have shown that measures of participation account for much more of the variance in life satisfaction or well-being measures than do measures of impairment or activity limitations (68–71). Thus, the nature of the fit between functional activities and the person’s values, preferences and abilities needs to be considered and reflected in some way in FA instruments, especially in Participation measures. Corrigan noted that outcomes can be defined from three perspectives: that of the person with TBI, that of the healthcare professionals treating the injury, and that of society (72). The latter two perspective presumably are reflected, to some degree, in the FA measures commonly used. However, the point of view of the insider, the person with TBI, to date has not been investigated with any degree of the attention it deserves.

This case has been made most fervently by Brown and Gordon (5). They argue that in the measurement of social constructs, value judgments are involved, and the values of the insiders (here: persons with TBI) and the outsiders (persons without disability: clinicians, researchers) may be different. Power imbalances occur in measurement whenever the outsider’s values and preferences are incorporated into the means-ends chain leading from interventions to immediate outcomes to ultimate outcomes, with few, if any, mechanisms for tapping into the values and preferences of the insider. Such power imbalances are of concern because the insider’s perspective can vary significantly from that of the outsider.

While most instruments designed to measure aspects of “functioning” have concentrated on the “how independent” and “how much” of acts, actions and roles, a few have explored additional dimensions. GAS and the COPM, mentioned above, are semi-structured approaches by which rehabilitation service recipients formulate individualized goals for therapy and provide perceptions of the adequacy of their performance, their satisfaction with performance, and the importance of each goal to their lives. An importance-weighted sum of outcome serves as the key evaluation measure.

Given their open-ended nature, GAS and COPM goals specified can reflect performance in the domains of Participation and Activity, and even inclusion of Impairment aspects is possible. The choice of goals reflects individual valuation, as does the importance rating. A number of other instruments with standardized content have included importance ratings, such as the MACTAR (73) and many instruments traditionally classified as quality of life measures (74).

Three approaches to measuring participation with attention to both its objective and its subjective

dimensions have been developed. Based on the (draft) CIQ-2, Johnston et al. derived a version in which subjects expressed their opinions and feelings about their participation (75). Each CIQ-2 question about objective aspects of everyday life was supplemented by three questions:

- “How satisfied or dissatisfied are you” with the activity? A 7-point rating scale was offered.
- “Would you like this to change?” Four response categories were offered: no; yes, want more; yes, want less; and yes, want a qualitative change.
- “How important would this change be to you?” Five response categories were offered.

A similar addendum was created by Cicerone et al. for the original CIQ (76). CIQ scores had no correlation with the Quality of Community Integration Questionnaire, and fairly weak correlations with the Satisfaction with Cognitive Functioning, suggesting that satisfaction with the underlying cognitive skills needed for participation not necessarily translates into satisfaction with participation per se, which may be restricted by non-cognitive impairments in the person, or societal barriers.

Similar conclusions were reached in a third study that evaluated a participation instrument we developed that incorporates both objective and subjective elements, the POPS (described below). Brown et al. found that persons with and without TBI rated the importance of the 26 items included in the POPS largely the same (23). At the individual item level, there was a fairly strong relationship between the level of involvement (PO), and desire for change (PS); those individuals (particularly those with TBI) who did little or nothing of an activity almost never wanted to do less, and more often wanted to do more. The PO total score was only weakly correlated with the PS total score (0.22 for the TBI group; 0.16 for the comparison group), again indicating that satisfaction with participation (as reflected in desire to change) is not predicted very well by overall level of participation in those activities that “society” typically declares part of the repertoire of its adult members – the normative view reflected in objective participation instruments.

Subjective measures of the type described have a number of shortcomings, according to critics. First, they typically involve the multiplication of two factors, one an importance rating, the other a satisfaction rating or a desire for change indicator. The critics claim that no measurement model applies to such a procedure, and that therefore the resulting item scores and total scores have no meaning, or at least cannot be considered reliable or valid. The measurement model of classical test theory and that of IRT only recognize simple items each measured on an ordinal scale as input to measurement instruments that operationalize constructs on a (pseudo) interval scale. Another criticism of individualized measures is that if

individuals can determine (by exclusion or even nomination) which particular activities should be included in a measure, and with what weight, the “content” of the construct varies from person to person, and performing averaging and other statistical manipulations makes no sense. However, if the *content* in all instances judged (by the researcher) to be relevant to the construct, there is no problem. Personal construct psychology adherents see this as a strength of the methodology, rather than a weakness.

## SELECTION OF A FUNCTIONAL ASSESSMENT MEASURE

The selection of a FA measure to apply in a clinical, administrative or research situation is not straightforward. A first step always should be determining what one wants to measure: Activity (Limitation) only, or aspects of Impairment and Participation (Restriction) in addition? While there are a few instruments such as the Disability Rating Scale that cover all three domains, they do that often poorly, and using two or three separate instruments may be preferable. A second question is: what aspect of functioning is of interest, capacity or performance, and consequently what type of administration should be selected: testing in a laboratory or other setting, observation, or report by the patient or a proxy. This limits choices, and one’s options might be even more restricted if the population one deals with has particular characteristics that make application of the most common instruments impossible – e.g. intubation. The resources available for administration – a special laboratory, administrator training, time of administrator and subject – typically play a major role. Lastly, metrology characteristics – reliability, validity, sensitivity - should inform the selection, although in some situations the choice of instruments is so limited that one needs to accept a measure with less than stellar characteristics.

The following sections offer thumbnail descriptions of some of the more common FA measures used in TBI rehabilitation and outcomes research, or in similar applications on broader groups. The information offered is necessarily limited. The TBI Model Systems of Care maintain a website, COMBI (Center on Outcome Measurement in Brain Injury) (<http://www.tbims.org/combi/list.html>) that in mid-2005 contained information on 27 instruments commonly used in TBI clinical services and research, including most of the ones listed below. (The ones covered are marked with an asterisk). For each instrument, the following are offered: the actual instrument (subject to copyright restrictions); a syllabus containing administration and scoring instructions; information on administrator training and testing required; a description of the psychometric qualities of the instrument, based on the published literature; and frequently asked questions. The various sections are kept up-to-date by experts, frequently the individual(s)

who created the instrument involved. This resource is highly recommended to anyone needing more information on any of the measures listed below.

## IMPAIRMENT/FUNCTIONAL LIMITATION MEASURES

### Glasgow Coma Scale

The most commonly used and universally accepted TBI impairment instrument is the Glasgow Coma Scale (GCS) (8). The GCS was designed as a brief measure of the depth of coma that can be applied in the acute care setting. Three physical exam parameters are assessed: best visual, verbal, and motor responses. Eye opening is scored 1 to 4, verbal response is scored 1 to 5, and motor response is scored 1 to 6. Total scores, which can range from 3 to 15, typically are stratified into three levels: severe (GCS 3–8), moderate (GCS 9–12), and mild (GCS 13–15) (77). Of the three subscores, the GCS motor score has been found to be the most sensitive to long term outcome (78).

The GCS has been found to be a strong predictor of outcomes including as measured by acute care costs and mortality (79–86). In much research on outcomes of services provided in rehabilitation or the community, the GCS is used as a basic indicator of injury severity. Control for severity by using GCS as a covariate allows a better assessment of the impact of (experimental) treatment. However, it should be realized that the GCS score can be falsely low in the presence of drugs, alcohol, hypoxia or hypotension. Conversely it can be falsely high in the presence of an undetected expanding hematoma. Determining a GCS score may be difficult when a patient is intubated. Meredith published a study validating the accuracy of deriving a verbal score for intubated patients based on eye and motor subscores (87).

## ACTIVITY/ACTIVITY LIMITATION MEASURES

### Barthel Index

The Barthel Index (BI), developed in the fifties by Mahoney and Barthel(25) at one point in time was the major FA instrument in use in rehabilitation in the USA. It was improved upon and supplanted by the FIM, and now mostly has historic significance. However, clinicians and researchers in the United Kingdom, Australia and elsewhere still use the BI and modifications of it. The BI consist of 10 physical functioning items. Feeding, dressing, toilet transfer and stairs are scored on a 3-point scale: can do alone (10 points), can do with help (5), and cannot do at all (0). Grooming and washing/bathing are scored on a two-point scale: can do alone (10 points), can do with help or cannot do at all (0). Bladder control and

bowel control are on a three-point scale: incontinent (0), accidents (5) and unimpaired (10). Chair/bed transfer is also on a three-point scale, but independence gets 15 points, help needed either 10 or 5 (if much help is needed). Lastly, walking 50 yards is on a two-point scale: 15 points if independent, 0 if needs help. If the person cannot walk, wheelchair propulsion is substituted, which has a maximum score of 5 for ability, with or without help. The highest BI score possible is 100, the minimum is 0, and intermediate points are interpreted as percent of maximum. Alternatives and extensions of the BI have been created that add items, make the scoring more sensitive, or otherwise improve on this rather crude but simple instrument (2).

### \*Functional Independence Measure

The Functional Independence Measure or FIM, the dominant FA (writ small) instrument in US and international medical rehabilitation for the last 20 years was created, as part of an effort to develop a uniform system to track rehabilitation data, to improve upon the BI (9). It maintained all the BI items, splitting some, and added tasks reflecting status in the socio-cognitive domain. Initially the FIM for all its components used four-point rating scales, but early on, at the request of clinicians who wanted greater sensitivity, these were replaced by seven-point scales, reflecting a range from total assistance (score 1) to complete independence (score 7). Some recent scholarship suggests that in practice, clinicians cannot reliably distinguish the seven categories, and that a four-category scale may be more useful (88). Extensive manuals have been published to guide raters in how to apply the rating scale in each domain, and how to handle unusual situations, such as: should the motor items be scored with or without the patient's orthosis in place (89).

There are 18 items in the FIM, 13 covering ADLs, bowel/bladder care, and mobility, and 5 reflecting everyday communication and cognition. Some applications calculate a single FIM total score by summing over the 18 items, resulting in a total between 18 (total lack of functional ability) to 126 (normal or almost normal), but a more common algorithm, that has considerable research support(26, 90) uses the 13 motor items to calculate a motor subscale score, and the 5 remaining items to calculate a (socio)cognitive subscale score. More fine-grained subscales have been distinguished in various studies,(91) but for "routine" applications the two-subscale method is satisfactory. Typical administration of the FIM is by observation for inpatient rehabilitation status, and standardized interview for follow-up. However, self-administered versions have been used, and one study even used testing on the entire instrument (92). Testing on individual items is commonly done in research.

Many studies have reported on the internal consistency, test-retest or interrater reliability, validity and other

psychometrics of the FIM, which characteristics have generally been found to be satisfactory, for the motor component more so than for the socio-cognitive one. A quantitative summary of the research up to 1995 is provided by Ottenbacher et al (93). A criticism of the FIM sometimes reported is that it has ceiling effects, either in all diagnostic groups, or in selected ones. However, it should be kept in mind that it was designed for quantifying functional status in acute rehabilitation inpatients; within that population, almost all persons are not at ceiling, although there are exceptions, e.g. for SCI patients on the socio-cognitive scale. Use of the FIM in routine rehabilitation practice follows the rule that if a patient is not observed performing a particular task, that task should be coded 1. For instance, many rehabilitation programs do not ask patients to do a tub transfer on admission, and stairs may never be attempted by some diagnostic groups on admission or discharge. This coding instruction causes “missing information” to coincide with “total assistance”, causing serious distortions when these clinical data are used in research and other applications (60).

A separate version of the FIM has been developed for children, specifically those under 7 years of age, who for developmental reasons do not score maximal on the FIM items, even in the absence of disablement. The WeeFIM has the same 18 items, and the same 7 item categories for each, but the scoring instructions take developmental issues into account (94–96). Among TBI researchers, dissatisfaction with the limited coverage by the FIM of communicative, cognitive, and behavioral disturbances after brain injury lead to the creation of a “FIM-annex”, the \*Functional Assessment Measure (FAM), which offers an additional 12 items in these domains (97). The 30-item FIM+FAM has been subjected to limited testing of psychometric qualities, but appears a satisfactory measure (98).

### **PARTICIPATION/PARTICIPATION RESTRICTION MEASURES**

“Social disability”, “social adjustment”, “social integration”, “community integration” and “handicap” have been the organizing concepts for a number of measures that quantify participation in household and other productive activities, other social role performance, social relationships and similar activities now captured in the rubric “Participation” (36). Of the major “Participation” scales that are found in the (TBI) rehabilitation literature, the Craig Hospital Assessment and Recording Technique (CHART) (10), the Community Integration Questionnaire (CIQ) and the Mayo-Portland Adaptability Inventory (MPAI) (99) are based, to varying degrees, on the handicap concept of the ICDH, the forerunner of the ICF. Three measures based on ICF concepts to date have not

or only on a limited basis been used in published studies with individuals with TBI: Life-H(100); POPS(23) and the Participation Measure for Post-Acute Care (PM-PAC) (101).

#### **\*Craig Handicap Assessment and Reporting Technique (CHART)**

The Craig Handicap Assessment and Reporting Technique was designed to provide a simple, objective measure of the degree to which impairments and disabilities result in handicaps in the years after initial rehabilitation (10). The original CHART, developed in 1992, included domains to assess five of the WHO dimensions of handicap: physical independence, mobility, occupation, social integration, and economic self-sufficiency. Orientation (ability to orient self to one’s surroundings) was added later (102). The revised CHART consists of 32 questions and employs up to seven questions in each of the six domains to quantify the extent to which individuals fulfill various social roles. The items focus on observable criteria and have been worded to minimize ambiguity and promote a consistent interpretation.

Each of the subscales of the CHART has a maximum score of 100 points, which indicates that roles within the domain are fulfilled at a level equivalent to that of the norm: an able-bodied person. High subscale scores indicate less handicap, or higher social and community participation. The CHART was designed to be administered by interview, either in person or by telephone, and takes approximately 15 minutes. Participant-proxy agreement across disability groups has provided evidence in support of the use of proxy data for persons with various types of disabilities. The CHART has been found to be an appropriate measure of handicap that can be used with individuals having a range of physical or cognitive impairments, including individuals with TBI. The instrument has been used for research by the developers,(103–108), and others,(109, 110).

A short form of the CHART (\*CHART-SF) was developed using regression analysis and related statistical methods to select items, followed by rescoring so as to create the same 0–100 ranges as the original CHART displays. The Short Form has 19 items (instead of 32); its metric properties and equivalence to the CHART have not yet been evaluated.

#### **\*Community Integration Questionnaire (CIQ)**

The Community Integration Questionnaire constitutes a measure of rehabilitation outcome after TBI which reflects the values and goals of individuals who have a disability. Willer and his associates developed the CIQ using the following design criteria: brevity; suitable for use in an in-person or telephone interview, conducted with the person with TBI him/herself (preferably), or with a proxy; focus

on behaviors rather than feeling states; no biases resulting from age, gender or socioeconomic status; sensitive to a wide variety of living situations; and value neutral (18, 66, 111). Factor analysis was the basis for selecting from a larger pool of items 15 questions addressing home integration (H), social integration (S), and productive activities (P). These questions focus on involvement in roles and household chores, frequency of activities; one addresses the nature of leisure partners: family, friends with or without TBI. The CIQ has been used extensively in research on individuals with TBI, (67, 76, 108, 109, 112–117) as well as those with other types of acquired brain injury.

Dijkers reviewed the psychometric evidence available for the CIQ, and concluded that there were concerns with respect to reliability and validity; sensitivity and score distributions were problematic, and age and gender biases were prominent (24). He embarked on the development of an updated version (known as CIQ-2), which sought to rectify these problems, while maintaining as much of the old measure as possible. Items were added that broadened the scope of household and social activities, as well as travel and mobility; nature of companions and of the organization where the person works or goes to school were added. The final instrument, consisting of 37 questions, has not yet been published. A preliminary version was used in one published study that incorporated a modification that added a subjective participation component (75).

### **Participation Objective, Participation Subjective (POPS)**

The Participation Objective, Participation Subjective (POPS) measure developed by Brown et al. (23) differs from typical participation instruments in several ways:

- It focuses solely on activities, not on non-activity indicators related to community functioning, e.g., income, whether one's companions are largely disabled or able-bodied. The 26 items range from sexual activity to work, and from paying bills to speaking to strangers.
- It generates two measures: the PO, comprising an "objective" measure of participation, and the PS, comprising a subjective measure.

Subjective assessment (the PS measure) incorporates the preferences of the person by gauging the individual's satisfaction with his/her level of engagement in each activity, weighted by his/her rating of the activity's importance. These product scores are averaged across the 26 items to calculate a total score. In addition, there are five subscores more-or-less paralleling the ICF Activity domains: Domestic life, Interpersonal interactions and relationships, Major

life areas (work, school, etc.), Transportation, and Community, recreational and civic life.

The PO gauges performance in terms of frequency or duration of engagement in activity in real environments, not in terms of degree of impaired functioning. Total score and domain subscores are calculated using an algorithm that takes into account the importance ratings that persons with TBI and non-disabled individuals gave to these items, reflecting "societal" values rather than individual ones. (23).

### **Participation Measure for Post-Acute Care (PM-PAC)**

The Participation Measure for Post-Acute Care (PM-PAC) was designed to measure "participation outcomes of rehabilitation services provided in outpatient or home-care settings" From the literature and existing instruments the developers created or adopted a final set of 33 items in seven domains derived from the ICF: mobility; role functioning; community, social and civic life; domestic life; economic life; interpersonal relationships; and communication. (101). Items were written to "reflect a person's degree of perceived limitation in a particular life situation regardless of cause or means". Most items use a 5-point degree of limitation (not at all to extremely) response scale, but duration and degree of satisfaction are also used. Factor analysis and item response theory models were used to assess the dimensionality of the various subscales; some items needed to be reassigned, but in general the results indicated useful subscales ranging from three to nine items each, in which the "limitation", duration and satisfaction items combined well. Further research, including development of computer adapted testing (CAT) versions, is planned.

## **MEASURES THAT CROSS-CUT ICF DOMAINS**

### **\*Level of Cognitive Function Scale (LCFS)**

The Rancho Los Amigos Level of Cognitive Function Scale (Rancho or LCFS) was designed to describe the typical stages of behavioral recovery following a severe TBI during inpatient rehabilitation (118). The Rancho consists of a single 8-level ordinal item in which each category corresponds to increasingly complex behaviors. (With just a single item, the LCFS differs from the other FA instruments discussed here, and technically is not a "scale"). The simplicity of the scale has brought it into wide use by healthcare providers and payers.

The Rancho has been shown to have a modest degree of validity and reliability (119). Scores on admission to rehabilitation correlate with 24-hour GCS score, length of coma, and duration of posttraumatic amnesia. In addition, the LCFS correlates with the DRS and the FIM and FAM cognitive items (120). Given the

correlations between measures of severity and disability, it is not surprising that the Rancho score on admission to rehabilitation is associated with vocational outcomes (121, 122). When applying the Rancho scale, it should be recognized that it was devised only as a descriptor. Recovery from severe brain injury is not linear. In addition, patients may vary in their Rancho level depending on the time of day and other circumstances. The Rancho is not a particularly sensitive measure of recovery and it should not be used to measure recovery. Patients may skip levels or never go beyond a particular level, despite ongoing progress.

Thus, the Rancho scale is best used as it was initially designed, as a simple descriptive scale. It can offer some advantage in pre-admission screening and communication with healthcare providers/ payers. It can also alert rehabilitation teams to treatment issues they are likely to face.

#### **\*Disability Rating Scale (DRS)**

Rappaport's Disability Rating Scale (DRS) has 8 items that address the three original World Health Organization categories of impairments, disability and handicap (7). The first three items of the DRS (eye opening, communication ability, and motor response) are slight modification of the Glasgow Coma Scale(8) and reflect impairment ratings. Cognitive ability for feeding, toileting, and grooming items reflect level of disability. Handicap is addressed with two items, ability to live independently and employability. Each of the areas of functioning is rated on a scale of 0 to either 3 or 5, with the highest scores representing the higher level of disability. The maximum score is 29 (extreme vegetative state); a person without disability would score zero. The DRS rating must be obtained while the individual is not under the influence of anesthesia, other mind-altering drugs, recent seizure, or recovering from surgical anesthesia.

The DRS is fairly easy to use and can generally be completed in under 5 minutes. It can be scored from direct observation, via clinical interview, or by telephone interview (123). No significant technical training is required to administer the scale. Subjective assessment by clinicians is required for cognitive capacity of self-care, rather than actual observation of self care items. This subjective rating is also used for rating employability and independent living potential. The DRS is more reliable than the Level of Cognitive Functioning Scale (119). It has been used to predict ability to return to employment based on admission and discharge DRS scores (122–124). The DRS has been shown to be an effective scale to track progress across the continuum of clinical services and the course of functional recovery (11, 123).

Many studies have reported good reliability and validity coefficients for the DRS (106, 119, 120, 122, 123, 125–127). Limitations of the DRS include its assessment

of general functioning rather than specific functional changes, its lack of utility in patients with only physical disability, and its poor sensitivity to functional evaluation of mild or very severe impairment (DRS Score >22), where small functional changes may not be reflected in scores (120). Therefore, the DRS is more useful when used in conjunction with more detailed measures of function. For patients with Functional Independent Measure (FIM) scores >25, the FIM may have more sensitivity to changes in rehabilitation than the DRS (128). Subjectivity of rating cognitive capacity may also limit its use in mild or severe injuries. In addition, the DRS falls short in assessing patients with severe apraxia, aphasia, or aphonia as well as those who are "locked in" or have tracheostomies.

#### **\*Mayo-Portland Adaptability Inventory (MPAI)**

The Mayo-Portland Adaptability Inventory (MPAI), developed from a modification of Lezak's Portland Adaptability Inventory, was designed to assist in the clinical evaluation of people during the post-hospital period following TBI, and to assist in the evaluation of rehabilitation programs designed to serve this population. The MPAI can be completed by professional staff, people with TBI and/or their significant others. In the most recent version, MPAI-4, items represent the range of physical, cognitive, emotional, behavioral, and social problems that people may encounter after TBI. MPAI-4 items also provide an assessment of major obstacles to community integration that may result directly from TBI, as well as features of the social and physical environment. The three subscales (Ability, Adjustment, and Participation) have good psychometric properties.

The MPAI-4 and its predecessors have been used in a number of studies initiated by the co-developer and his associates (99, 129–133). Unfortunately, the MPAI has found no use outside this group.

#### **\*Glasgow Outcome Scale (GOS)**

The Glasgow Outcome Scale is a ordinal, single-item instrument used to describe outcome after TBI globally (134). It was commonly used before instruments such as the DRS and GCS were introduced. As a brief outcome scale it has been replaced by the DRS, which offers greater sensitivity to small changes or differences. However, the GOS it is still used occasionally, especially in neurosurgical studies of outcome after TBI. The five categories of the original scale are: dead, vegetative, severely disabled, moderately disabled, and good recovery. The \*Extended Glasgow Outcome Scale (GOS-E), an expanded version of the scale, divides each of the latter three categories in two, creating eight categories and increasing sensitivity of the instrument. A structured interview was introduced

to rectify a second problem of the GOS: fairly low interrater reliability (135). Adequate interrater reliability and content validity have been demonstrated for the GOS-E, and compared to the GOS, the GOS-E has been shown to be more sensitive to change in mild to moderate TBI (136). The validity of the GOS-E is also superior to that of the original measure (137).

*Kelly A. Ojdana*

### 1. INTRODUCTION

Rehabilitation needs and long-term planning for persons with severe traumatic brain injury (TBI) are covered in depth in other chapters of this volume. Here we consider one important aspect of long-term planning, namely longevity.

It is well known that mortality after severe TBI is exceptionally high in the acute post-injury period. It is perhaps less well known that long term mortality (2 years or more post-injury) is also increased, by comparison with the general population. It follows as a mathematical consequence that the life expectancy is reduced.

There are many studies of short-term survival after TBI. Detailed long-term data, however, and resulting research studies, are relatively sparse. The largest group studied on a long-term basis appears to be in the California Disabilities Database, which includes approximately 4,000 persons with disability secondary to TBI.

In this chapter we review what is known about life expectancy in TBI and present some new findings. Section 2 gives a brief review of key actuarial ideas needed for a discussion of life expectancy. Section 3 discusses the causes of death for which the risk is increased after a serious TBI, and reviews the literature. It is not always recognized that persons with TBI are subject to excess mortality risk from some of these causes. In section 4 we review the literature on life expectancy after TBI, focussing on recent research.

After this we discuss the factors that best predict life expectancy (section 5). It will be seen that, as in other types of chronic disability, the severity of motor dysfunction is the most important predictor of reduction in life expectancy. Later, in sections 6 and 7, we present some new findings on life expectancy and long-term decline in function after TBI. We discuss the effect of quality of care on life expectancy in section 8, the estimation of life expectancy in individual cases in section 9, and offer some conclusions in section 10.

### 2. TERMINOLOGY

It will prove helpful in the later sections to be familiar with the following terms:

- **Survival time:** the actual number of years lived by a given patient or member of a study population. A patient alive at the end of a study period is said to have a **censored** survival time as of that date.
- **Life expectancy:** the **average** survival time in a large group of similar persons. Note that this is not a prediction about any individual's actual survival time, as some survival times will be much longer and others much shorter than average.
- **Median survival time:** the time after which exactly half of a large group of persons are still alive. If all

the survival times are known (uncensored) and ordered from smallest to largest, the median is the middle value.

- **Exposure time:** the total number of person-years lived by all the members of a study population during the study period.
- **Mortality probability:** The chance of dying in a given period (e.g., a year). Like all probabilities, this number is between 0 and 1 inclusive.
- **Mortality rate:** The number of deaths in a study population divided by the number of person-years of exposure time. This is always larger than the mortality probability over the same period. Except in very high-risk populations, where the mortality rate could be greater than 1.0, however, the difference between the two is small.
- **Standardized mortality ratio (SMR):** the ratio of the observed number of deaths in a study population to the expected number, where the latter is what would arise from a suitably chosen reference group (often the age- and sex-matched general population in a given country). For example, an SMR of 2 means that the study population has twice the death rate of the reference group, after adjustment for age and sex differences. For further discussion, see Kahn & Sempos (1).
- **Relative risk (RR):** the ratio of the mortality rate in a study population to the mortality rate in the reference population. Unlike the SMR, the expected number is not standardized to the age and sex distribution in the reference population. The RR is often termed the **mortality ratio (MR)** in the actuarial literature.
- **Excess death rate (EDR):** the difference between the death rate in a study population and that in the reference population.
- **Life table:** a standard table summarizing mortality information about a group. Life tables are constructed for entire populations (2–6) or for suitably large subgroups (7–11). The table derives entirely from a set of age-specific mortality rates, and gives the life expectancy at every age. The median survival time can be easily computed from table entries (12, 13).

### 3. CAUSES OF DEATH AFTER TBI

It is clear from the published literature that there is an increase in long-term mortality in persons who have suffered a severe TBI. The published studies are, however, not entirely consistent on which causes of death account for the excess.

In the very short term, the primary cause of death is the brain damage itself. One of the largest studies was that of Sekulovic and Ceramilac (14), who summarized

autopsies of 499 deaths occurring within 30 days of traumatic brain injury. They found that 78% of the deaths were due to injury to brain stem, brain edema, or brain compression. Of the remainder, the most frequent cause was pneumonia.

The definition of “longer term” varies among the studies. For example, Baguley et al. (15) considered patients who had been released from the hospital into rehabilitation facilities, while Shavelle et al. (16) considered one year or longer post injury.

The published studies make clear that, even in the long-term, death rates from many different causes are elevated for persons with TBI by comparison with the general population. These causes are considered below.

- **Epilepsy.** We refer here to post-traumatic epilepsy, rather than post-traumatic seizures. Post-traumatic epilepsy refers to recurrent long-term episodes often observed in persons with TBI, while the term post-traumatic seizures is generally applied to events in the first post-injury week.

The classic studies of World War II veterans with TBI first documented the increased mortality risk from post-traumatic epilepsy (17). Later studies similarly addressed World War I veterans and reported the same finding (18, 19). This was confirmed in Roberts’ long-term follow-up of patients in England during the 1960’s and 70’s (20, 21) and in Rish et al.’s study of veterans from the Vietnam war (22). More recently Shavelle et al., in their study of Californians with long-term mental disabilities from TBI, estimated a standardized mortality ratio (SMR) for seizures of 24 by comparison to the general population (16). Even patients with less severe disabilities were subject to an increased risk.

The literature shows that epilepsy is more common in penetrating head injuries, such as gunshot wounds, than in non-penetrating injuries (23–27). One might expect that the severity of epilepsy would be greater, and therefore the mortality risk higher, for those with penetrating injuries. There does not appear to be any available evidence on this, however.

- **Suicide.** Roberts (20) found an increased suicide rate (SMR = 3) over the long term. A similar finding, and one documented in greater detail, was reported by Teasdale & Engberg (27). The latter authors, in their large study of Danish patients with TBI, found a suicide rate approximately four times that of the general population. They point out that persons with certain psychiatric conditions may be prone both to have accidents causing TBI and to commit suicide, though it seems unlikely that this could explain most of the association. A recent study by Pentland et al. (150) also found an increased proportion (1.3% of all deaths) due to suicide.

No increase in the suicide rate was observed by Walker and Blumer (28) or Shavelle et al. (16).

- **Respiratory infections and pneumonia.** Many studies document the increased risk of death due to these causes in patients with severe TBI. This is especially marked in persons who have become nonambulatory. Shavelle et al. (16) reported an approximately ten-fold increase in the mortality rate from respiratory causes, and Pentland et al. (150; Figure 2) found it to be the leading cause of death in this population after cardiac diseases. It appears that it is primarily the immobility, not the brain injury per se, that increases the risk; for example, a similar finding is reported in patients immobilized by spinal cord injury (29, 30).
- **Meningitis** was reported as an increased risk by Roberts (20), but not by other researchers (15, 16, 22).
- **Diseases of the circulatory system** are the leading cause of death in Western countries, and in the long-term the risk of death appears to be even higher in persons with severe TBI. Shavelle et al. (16) reported an approximately tripled mortality rate from these causes, by comparison with the general population, which by itself indicates a substantial reduction in life expectancy. Not surprisingly, the increase was largest among patients who had become nonambulatory. Weiss et al. (19) also found a long-term increase in the death rate from diseases of the circulatory system.

There are at least two mechanisms that could contribute to the increase in circulatory disease, and related deaths. First, persons confined to a wheelchair often take little exercise, and this alone increases the long-term risk of circulatory disease (31–35). Secondly, paraplegia appears to increase the risk of embolisms that travel from the lower body to the brain or lungs, and are often fatal. We are not aware of any studies that quantify these effects after TBI specifically, but a similar pattern of increased mortality has been observed in persons immobilized from spinal cord injury (29, 30) or cerebral palsy (59).

As with others who are immobile, persons suffering a TBI have an increased incidence of morbidity due to deep vein thrombosis, pressure sores, sepsis and urinary tract infections (36–48). However, there do not appear to be any studies documenting increased long-term mortality due to these causes. Of the 135 deaths described in Table 17-1 below, only one was due to any of the above (urinary sepsis).

Walker et al. (18) suggested that an injured brain makes the entire body more vulnerable to the stresses of aging. Lewin et al. (21, p. 1535) doubted Walker's hypothesis, pointing out that in their own study only a small number of causes of death appeared to be elevated

**TABLE 17-1**  
*Causes of Death for Persons Injured at Ages 10 or Older Who Died 5 or More Years Later*

CAUSE OF DEATH (ICD-9 CODES)	NUMBER	%
Cancer (140–239)	9	7
Seizures (345, 436, 780.3)	14	10
Circulatory (390–459, except 436)	26	19
Respiratory (460–519)	15	11
Digestive (520–579)	6	4
Urinary/kidney (580–599)	4	3
Choking/suffocation (910–915)	3	2
Other external (800+, except 910–915)	13	10
All other causes, including missing	45	33
Total	135	100

in their TBI population. As noted earlier, however, the much larger study of Shavelle et al. (16) found increased mortality from most major causes other than cancer, which may support the view of Walker et al.

Table 17-1 shows causes of death for persons injured at ages 10 or older, who died 5 or more years after injury. The data are from the California Disabilities Database over the period 1988 to 1999 (49).

Excluding the “All other causes” category, the largest category was circulatory diseases. The comparatively small proportion of cancer deaths reflects the increased number of premature deaths to other causes; for example, there were more deaths due to respiratory diseases and seizures than to cancer.

#### 4. RECENT LITERATURE ON LIFE EXPECTANCY

There is an abundant literature on short-term survival after TBI. The focus here is on the major recent studies on long-term survival. For a detailed history of studies prior to 1979 see Roberts (20, chapter 4).

- Walker and Erculei (17, 50) studied 364 World War II head-injured men from injury to 15 years later. The authors found a death rate 3 to 4 times greater than expected. They analyzed the frequency and severity of seizures, noting that men with post-traumatic seizures did not, on average, survive as long as those without seizures.
- Walker et al. (18) analyzed survival data through 1965 on 574 German World War I head-injured men. This ambitious study included a contemporary

control series of 581 unwounded veterans receiving meritorious medals. They constructed life tables and found a roughly 4-year reduction in life expectancy in the TBI group, with a larger reduction for those with epilepsy.

- Roberts (20) followed 469 patients who were amnesic or unconscious for a week or longer after a severe head injury. His analysis concentrated on the 366 who were discharged alive from hospital. He found that the chance of dying in the first 20 years after injury was elevated only in those injured at ages 5 to 25, and concluded that the effect of TBI on life expectancy was a 5-year reduction (20, p.146).

It appears from Roberts' Table 5.3 that some 80–90% of these persons could walk unassisted. If so, his conclusion would not apply to the most severely injured patients who were wheelchair-dependent or even bedridden. It has sometimes been inferred, incorrectly, that the Roberts' estimated 5-year reduction applied regardless of the severity of disabilities. Roberts himself evidently did not hold this view, as he reported that persons with the most extreme disabilities rarely survived ten years (20, p.142).

- Rish, Dillon and Weiss (22) studied 1127 Vietnam veterans who survived one week or longer after a penetrating head injury. The all-cause SMR over the 15-year study period exceeded 4 during years 1–3, ranged from 2 to 4 during years 4–11 and 13 post-injury, and was (probably because of the small sample size) less than 1 for years 12, 14 and 15. The authors concluded that the study population may have "approached the norm."
- Corkin, Sullivan and Carr (51) studied 190 World War II veterans with penetrating head injuries and a matched set of 106 with peripheral nerve injuries. They reported that head injury coupled with epilepsy reduced life expectancy compared to the control group, but that head injury alone did not.
- Walker and Blumer (28) studied 244 World War II head-injured men with post-traumatic epilepsy and found a death rate several times higher than in the general population.
- Strauss, Shavelle and Anderson (52) studied 946 children and adolescents aged 5 to 21 who suffered a TBI, following the subjects for up to 9 years. They constructed life tables stratified by a crude mobility scale (none, poor, fair/good). The resulting reductions in life expectancy, compared with the general population, ranged from very large (40 years) in persons with the most severe disabilities to quite small (2 years) in those who retained good mobility.
- Baguley et al. (15) studied 476 patients injured from 1986 to 1996. During the average follow up time of 5 years there were 27 deaths, compared to 6.7 expected, giving an SMR of 4.0. The difference was

highly statistically significant, again demonstrating that life expectancy after TBI cannot be considered normal.

- Shavelle and Strauss (53) computed excess death rates for persons with TBI, beginning two years after injury. The population studied was the largest in the literature, with 2629 subjects and 268 deaths in the 1988 to 1997 study period. As in their previous studies, these authors found that excess death rates were relatively small for ambulatory persons, but much larger for those who had become nonambulatory.
- Brown et al. (151) followed up on 1,448 persons with TBI, of whom 164 (11%) were described as having moderate to severe injuries. They found that persons with mild TBI exhibited a small but statistically significant reduction in long-term survival. For those with moderate or severe TBI, long-term survival of those who survived the first six months was similar to those with mild TBI. A difficulty in interpreting this last finding is that the "moderate to severe" range presumably contained a mixture of persons with extremely severe disabilities (for whom the life expectancy is without question markedly decreased) and persons with much less severe disabilities. The overall effect therefore depends on the relative proportions.
- Harrison-Felix et al. (152) followed 2178 persons with TBI who completed inpatient rehabilitation in one of 15 National Institute on Disability and Rehabilitation Research-funded TBI Model Systems of Care. They estimated an average reduction in life expectancy of 7 years. In a follow up publication jointly written with the present authors (153), they indicated a general approach to estimating the life expectancy of an individual of a given age, sex, and score on the Disability Rating Scale. For example, according to the Model Systems data the life expectancy of a young adult with an "extremely severe" disability is 50% of normal. This again indicates how life expectancy after TBI varies greatly according to the severity of the injury.

While some of the studies — most notably, those of subjects without epilepsy — did not report a substantial reduction in life expectancy in some groups, this may be because persons in those groups were less severely disabled. There can be no question that mortality is markedly increased among the most severely disabled patients, a pattern well documented also in cerebral palsy (54–65) and spinal cord injury (19, 30, 66–70). In discussions of life expectancy of persons with TBI, therefore, it is important to consider the severity of disability.

Persons with more severe injuries are much more likely now than in the past to survive the early high-risk period (22). Other things being equal, it may therefore be

that the more recent studies have a higher proportion of severely disabled persons. This would have obvious implications for the comparison of older and newer studies.

## 5. FACTORS RELATED TO SURVIVAL

The best predictors for survival in the *short* term are clinical measures such as the patient's Glasgow coma scale and duration of post-traumatic amnesia. The concern in this chapter, however, is with factors predictive of long-term survival.

For persons with TBI as well as in the general population, age is of course the most obvious determinant of life expectancy. Apart from age, the key factor is the severity of disability, especially motor dysfunction. This can be measured by simple functional items such as the patient's ability to walk, use hands, and self-feed. Other factors (such as preserved cognitive function or epilepsy) have a relatively small effect once motor function has been accounted for.

We now consider the factors that have been considered significant for life expectancy, citing the available evidence.

- **Age.** The increase in mortality of persons with TBI with age has been documented in many studies (52, 53, 71–74).
- **Sex.** In the general population, mortality of males at most ages is appreciably higher than that of females (2–6). For example, in the U.S. general population males age 30 to 60 have about twice the risk of death as females (2). Similar sex-differences have also been observed in persons with TBI (35). As would be expected, the difference is most marked in persons with milder disabilities and all but disappears at the most severe end of the spectrum. For example, no sex difference was found in the survival of persons in the permanent vegetative state (75).
- **Time since injury** is certainly an important factor in the short-term. The mortality risk declines steadily during the first two years after injury as the patient's condition stabilizes. In the much longer term, however, there is no clear evidence of a trend, once severity of disability is taken into account. For example, mortality rates of persons 5 years post-injury do not seem markedly higher than otherwise comparable persons 10 years post-injury (49).

Because mortality after severe TBI is so high shortly after injury, it has sometimes been suggested that individuals vary greatly in their "toughness": only the tough survive the initial post-acute period, and these individuals are likely to survive much longer. No doubt individuals do vary to some extent in their abilities to survive major trauma. A more

plausible explanation, however, is the well-known "healthy survivor" effect: persons with the most severe injuries die first, and the remainder have better survival because their injuries are, on average, less severe. This explanation is consistent with our finding that after the first few years, mortality rates are fairly constant over time once mobility and other factors are taken into account.

- **Mobility** is the most powerful predictor of long-term survival after TBI. Using the extensive California Disabilities Database, Strauss, Shavelle and Anderson (52) found a large difference in survival based on an overall mobility scale (none, poor, fair/good). The risk of death for persons with no mobility was approximately four times higher than those with fair or good mobility, even after adjustment for several other factors.

Shavelle and Strauss (53) subsequently computed age-specific mortality rates for three levels of ambulation (walks well alone; walks with support or unsteadily alone; does not walk). The age-specific mortality risks relative to the general population ranged from as low as 1.3 to as high as 17. Additional research indicates that, as would be expected, still more precise discrimination can be made based on more refined measures of motor function (49). Similarly, Baguley et al. (15) found that Functional Assessment Measure score was associated with survival.

- **Feeding ability.** Strauss, Shavelle and Anderson (52) found a sharp contrast in survival between four groups of persons: those requiring a feeding tube (RR = 6.6 compared to the best group), those fed orally by others (RR = 2.9), those who could finger feed (RR = 2.1), and those who could use utensils (the best group, with RR = 1 by convention). The inability to self-feed is an indirect measure of neurological compromise. It seems likely it is this compromise that causes the increased mortality, and the inability to self-feed is primarily a marker for it.
- **Need for ventilator support, oxygen, and/or frequent suctioning; history of respiratory problems.** We recently investigated the effect of these factors (49). Each was much more common in persons who could not walk and who required a feeding tube than in persons who were higher-functioning. In the former group, the univariate effect — that is, when no adjustment for mobility, etc. was made — was statistically significant and large: the relative risks for the factors ranged from 2 to 6. However, once age, sex, mobility and feeding were accounted for the (multivariate) relative risk was less than 1.2 for each factor.
- **Deficits in cognitive function and ability to communicate** are strongly correlated with severity of motor dysfunction. Although cognitive and communicative

functions are strong univariate predictors of mortality, their effects are modest when motor function is taken into account (49, 52). The same finding has been documented in persons with cerebral palsy (61, 62).

- **Epilepsy.** Many authors have found that epilepsy was strongly associated with reduced survival (17, 19, 50, 51). However, as others have suggested, this was likely because the presence of post-traumatic epilepsy is highly correlated with the extent of brain damage (17, 22). That is, epilepsy served as a marker for injury severity. Nevertheless, epilepsy is an independent risk factor for increased mortality. We recently confirmed this, and additionally found that in those who cannot walk, the relative risk of death for persons with generalized tonic-clonic seizures is 1.2 compared to others (49). In a separate study of people with minimal physical disabilities, Strauss et al. (76) similarly documented the increased mortality associated with recent seizures.
- **Calendar year.** The question is whether survival rates have improved over the years for a patient of given age and severity of disability. This would be termed a *secular trend*. The available data does not reveal any evidence of such a trend in recent (1980+) years (15, 49, 52). This may seem paradoxical because (i) as noted in other chapters of this volume, advances in rehabilitation have improved functional outcome after TBI, and (ii) as documented above, functional outcome, specifically mobility and feeding skills, are key factors associated with life expectancy. Thus it may well be that among patients with similar *initial* injuries, survival now is better than in previous decades because functional outcome is better. The cited research (15, 49, 52), however, looked at a different issue: comparison of survival now and in the past of patients who have the same *functional outcome*.

Several other factors should be mentioned as possible predictors of survival:

- **Poor education.** This factor was noted by Corkin, Sullivan and Carr (51). They suggest many reasons for the increased risk of death, including subsequent occupation and access to health care. To our knowledge other researchers have neither confirmed nor disproved this.
- **Depth of brain injury.** Weiss et al. (19) found that, as expected, the survival was poorer in persons with deeper (greater than 3 cm) brain injuries, although the difference was not statistically significant.
- **Penetrating versus closed head injuries.** Baguley et al. (15), in comparing the literature, concluded that there was no evidence of a difference. After controlling for

functional abilities we too could find no difference, though the power of this comparison was low (49). Zafonte et al. (77) also found no difference in functional outcome at one year post-injury. On a related point, we found no difference in survival (49) between those who suffered skull fractures (ICD-9 codes 800–804) versus intracranial injuries (850–854). Finally, it may be that the effect of epilepsy is different in penetrating versus closed injuries, though evidence on this does not appear to be available.

- **Duration of unconsciousness.** Neither Shavelle and coworkers (49, 52) nor Weiss et al. (19) found this to be a significant factor. Lyle et al. (78) found that duration of coma was associated with both recovery and survival to 2 years, but it is not clear if this result would hold true if attention was restricted to those alive at 1 year post-injury, and if the functional outcome — e.g., mobility — was accounted for.
- **Glasgow coma scale (GCS) and the duration of post-traumatic amnesia (PTA).** Again, these factors are measures of the severity of the injury, are highly correlated with short-term survival, and therefore have a relationship to subsequent longevity. We are not aware of any evidence, however, that either of these factors is associated with subsequent long-term survival given the functional outcome one year post injury.
- **Maladaptive behaviors** — such as drug use, other substance abuse, suicide attempts, assault, aggression, self-injurious behavior, and lack of safety awareness — are much more common in those who have suffered a TBI or other central nervous system trauma than in the general population. For example, several studies report an association between CNS trauma and criminal behavior, especially violent crime (79–81). Such behaviour is also more frequent in persons with TBI than in others with comparable levels of functioning whose disabilities are due to cerebral palsy, autism, and other conditions (32).

These behaviors, with the exception of safety awareness, were *positive* factors for life expectancy when considered in isolation (49). That is, for example, persons who abused drugs had a *lower* mortality rate (and thus higher life expectancy) than those who did not. This is not surprising as those who could exhibit the behaviors were much less severely disabled, on average, than those who could not. In fact, these factors had a small *negative* effect on survival once functional abilities were taken into account (49).

Maladaptive behaviors in general have all been shown to be associated with increased mortality. For a review of the epidemiological data, see Harris & Barraclough (82). As these authors show, a major component of the increase is deaths due to unnatural causes, including accidents, suicide and homicide.

It may be that the reduced life expectancy of relatively high-functioning persons with TBI in part reflects an increased rate of unnatural deaths associated with behavioral problems.

- **APOE 4.** It is also possible that the APOE 4 allele plays a role. As noted by Baguley et al. (15) in citing Teasdale et al. (83) and Friedman et al. (84), patients with the APOE 4 allele are more likely to suffer unfavorable outcome after severe traumatic brain injury. Recent research (85, 86) on this issue has found that the presence of the APOE 4 allele is associated with poorer memory performance and rehabilitation outcome after TBI. Research by Liberman et al. (87), however, did not show a consistent influence of APOE genotype on outcome. We are not aware of any data on the independent effect of this allele on long-term survival.
- **Quality of care** is addressed separately in section 8.
- **Other factors relevant to life expectancy in the general population** are also relevant for persons with

TBI. These include pre-injury health status and history of smoking, alcohol and drug abuse, obesity, etc. Scientific literature on the effect of most of these factors is available.

- There are **factors uncommon in the general population** that can affect the mortality risk of persons with TBI. Examples are difficulties with chewing and swallowing, contractures, pressure sores (for persons with limited mobility), bowel and bladder dysfunction, frequency of infections, and psychological factors (attitude to the disability, depression, aggressive behavior, etc.). For many of these factors, published studies of the effect on mortality are not available.

## 6. NEW ESTIMATES OF LIFE EXPECTANCY IN TBI

Tables 17-2 and 17-3 show our most recent findings (49). These represent a refinement of the data presented in our

**TABLE 17-2**  
*Female Life Expectancy by Age and Severity of Disability*

AGE	PVS <sup>a</sup>	CANNOT WALK		SOME WALKING ABILITY <sup>d</sup>	WALKS WELL ALONE <sup>e</sup>	GENERAL POPULATION
		FED BY OTHERS <sup>b</sup>	SELF FEEDS <sup>c</sup>			
10	12	27	46	55	61	70.0
20	11	26	40	48	54	60.2
30	10	22	33	41	46	50.5
40	9	16	26	31	36	41.0
50	7	11	19	23	27	31.7

<sup>a</sup>Permanent vegetative state: No purposeful motor or cognitive function. Requires a feeding tube.

<sup>b</sup>Does not feed self, must be fed completely (either orally or by a feeding tube).

<sup>c</sup>Can feed self with fingers or utensils, with assistance and/or spillage.

<sup>d</sup>Walks with support, or unsteadily alone at least 10 feet but does not balance well.

<sup>e</sup>Walks well alone for at least 20 feet, and balances well.

**TABLE 17-3**

20	11	26	40	44	49	54.7
30	10	22	33	37	41	45.4
40	9	16	26	28	32	36.2
50	7	11	19	20	23	27.4

<sup>a</sup>Permanent vegetative state: No purposeful motor or cognitive function. Requires a feeding tube.

<sup>b</sup>Does not feed self, must be fed completely (either orally or by a feeding tube).

<sup>c</sup>Can feed self with fingers or utensils, with assistance and/or spillage.

<sup>d</sup>Walks with support, or unsteadily alone at least 10 feet but does not balance well.

<sup>e</sup>Walks well alone for at least 20 feet, and balances well.

earlier publications, and take account of age, sex, and walking and feeding ability. For comparison, life expectancies in the permanent vegetative state (PVS) and the U.S. general population are also shown. As can be seen, the remaining life expectancy decreases both with age and with severity of injury.

At the most severe end of the disability spectrum, the permanent vegetative state (PVS), the life expectancy is at most 12 years, and no significant differences were found between the sexes. The PVS analyses are specific to persons with acquired injuries, including TBI and near-drowning, and who will require gastrostomy feeding for life. The corresponding figures (not shown) for persons with congenital conditions, degenerative diseases, or who require a ventilator are lower still.

Persons in the minimally conscious state (MCS) – a group that has received recent attention in the clinical literature (88–90) – have slightly higher cognitive function than those in the PVS. A study of infants who were immobile and in the MCS (“IMCS”) found that their survival was only slightly better than those in the PVS (91). Thus, once again, mobility is seen to be a more important predictor of survival than cognitive function. A subsequent analysis of 2,534 children and adults who were in the IMCS gave the same finding (49).

The nonambulatory group covers a wide range of functional abilities. At the low end of the range are persons in the vegetative state, and those who are immobile and require gastrostomy feeding. At the high end are persons who feed themselves, and have reasonable self care skills, even though they cannot walk. Tables 17-2 and 17-3 include a simple stratification on the basis of self-feeding, an important predictor of life expectancy. Further distinctions can of course usefully be made.

It should be pointed out that there are persons whose residual TBI is so mild that they do not require services (e.g., occupational and physical therapy) on an ongoing basis. These persons would not be in the California data base, and their life expectancies may be higher than any group described above. In the best case, where the effects of the TBI are minimal, the life expectancy is of course essentially normal, or even better than normal (if, for example, the person was a nonsmoker, took regular exercise, maintained a good weight, etc.).

Persons in the highest functioning group of the table — those who can walk well alone and balance well — nevertheless have disabilities severe enough to require ongoing services. The aggregate life expectancy is reduced by 4 to 9 years compared to the general population. As expected, the difference is smallest for the oldest persons. Note that there is no sex difference in life expectancy in the most severely disabled category, but a substantial difference among the higher functioning groups.

The TBI figures in Tables 17-2 and 17-3 do not take account of whether the person needs a feeding tube. This

need is uncommon in the higher-functioning groups, but about half of the persons over age 10 who cannot walk and cannot feed themselves do require a feeding tube, and their life expectancy is lower. Also not considered are specific fine and gross motor skills and cognitive ability, all of which affect life expectancy to some extent.

*Technical Note* The scientific methods underlying the study of life expectancy are well-documented in the actuarial, epidemiological and statistical literature; see, for example, Singer (91), Kahn and Sempos (1), Collett (92), Schoen (93) and Anderson (12). Full details on the specific methods used to compute the results in Tables 17-2 and 17-3 are described elsewhere (75, 94, 95). A brief summary follows:

- The analyses were based on data from 1,723 persons at all ages (PVS) and 3,598 persons over age 10 (TBI).
- A data set of person-months was constructed — PVS: 56,229 person-months; TBI: 285,424 person-months. Each person-month was associated with the subject’s age, severity of disability, etc., and an indicator variable for whether the person died in that month.
- Logistic regression was used to compute the annual mortality rates. The following factors were used:
  - **PVS analyses:** age, time since injury, etiology, and need for feeding tube.
  - **TBI analyses:** age, sex, time since injury, and the walking and feeding categories listed in the table.
- The PVS analyses provided mortality rates for all ages. The TBI analyses provided rates at the starting ages and a model was used to compute rates at subsequent ages. A life table or survival curve was then constructed, with the life expectancy obtained directly in the former case, and as the area beneath the curve in the latter.

## 7. LONG-TERM DECLINE IN FUNCTION

In the short term, patients with TBI often regain some functioning in the first year post-injury (96–98), but the rate of recovery slows thereafter (28, 99, 100). An exception is the elderly, who have a low rate of recovery even in the first year (101–104).

It appears that, over the long term, patients with TBI will lose functional abilities faster than those in the general population:

- Lewin et al. (21) reported progressive intellectual deterioration in their patients, more so than would occur in the general population.
- A relevant comparison may be with persons who have suffered repeated (“chronic”) TBI, as contrasted to acute TBI. Chronic TBI can result from boxing

(105, 106) and possibly from “heading the ball” in soccer (107–110). It is an often-progressive neurological condition with many of the same pathological characteristics as Alzheimer’s disease (110–112).

We investigated this issue of long-term decline in our TBI database, concentrating on one important functional measure: ambulation.

Figure 17-1 shows the long-term prognosis for a group of 100% who initially could walk with support (crutches, braces, etc.) two years post-injury. Of these, roughly 15% died within the next 8 years, 20% lost the ability to walk, 55% did not change, and 10% could walk well alone. That is, of those still alive twice as many declined in functioning as improved.

FIGURE 17-1

Long-term change in ambulation for adults aged 40 and over

*Technical Note* The curves for the cohort, including the survival curve, were computed using the Aalen-Johansen estimator (113). This statistical method was developed as an extension of the usual Kaplan-Meier (114) estimator to address the case of multiple live states (115). Day (116) showed that, in statistical parlance, the estimator is consistent and more efficient than the extended Kaplan-Meier estimator proposed by Strauss and Shavelle (117). The latter has previously been used to produce similar diagrams involving improvement or decline in function of persons with developmental disabilities (62, 118).

## 8. QUALITY OF CARE AND LIFE EXPECTANCY

Quality of care is a rather vague term that is frequently raised in discussions of life expectancy. It seems to cover a variety of issues, including:

- The expertise of the caregivers, ranging from highly qualified professionals to relatively unskilled (and

low paid) staff. A complicating factor is that caregivers are often family members, who generally do not have formal qualifications but in some cases become highly skilled carers.

- The accessibility of physicians and emergency services.
- The quantity of care and equipment provided, which is often a reflection of the funds available.

The effect of quality of care on life expectancy surely depends on what is being compared. If, for example, it is good care versus negligent or even deliberately substandard care, the difference in life expectancy will doubtless be large. This comparison, however, is generally not of interest. The most relevant comparison is between:

- The normal, standard care available in most Western societies, and
- The care expected given that the patient has a carefully prepared and well-funded life care plan.

It might be argued that the care embodied in (b) represents the best case in practice, as one cannot forecast exactly what care the patient will receive, or will choose to receive, in the coming decades.

The issue is evidently a complex one and we do not attempt to draw any definitive conclusions. Nevertheless, these observations may be helpful:

- Some states or countries provide services to persons with disabilities as an entitlement. For example, California provides annual person-centered individual program plans plus provision of all indicated care. In such cases it may not be clear what is the difference, if any, between (a) and (b) above.
- Strauss et al. carried out a series of studies in California that compared mortality in large long-term state facilities, private group homes, and the patient’s own family home (119–127). The authors found that mortality rates in the group homes and in family homes were comparable. Mortality rates in the state facilities, however, were generally lower, corresponding to modestly higher life expectancies. Reasons for the difference, which are related to quality of care, include round the clock supervision, continuity of care, centralized record keeping, and immediate access to medical attention (127).
- It is sometimes asserted that quality of care is the most important determinant of life expectancy. If the comparison is between (a) and (b) above, this assertion is incorrect: the most important determinant is undoubtedly the severity of the disability. For example, literature from many countries documents that young patients in the permanent vegetative state have mortality rates up to 500 times larger than in the general population (75, 128–136). If quality of

care is as important a determinant of mortality risk, then death rates under “standard” care would have to be 500 times higher than they would be under option (b). This is an extremely large ratio; to put it in perspective, heavy smokers are subject to mortality rates that are only 2–3 times that of the general population (137, 138).

- Researchers at The Dartmouth Atlas Project have found that more care (beyond what is reasonable and necessary) does not significantly prolong the life span of persons in the general population (139–142). Their website also provides an annotated list of 387 additional references supporting this conclusion (143).
- Finally, it may be noted that life insurance companies offer reduced premiums to persons with favorable risk characteristics, such as having ideal weight and being a nonsmoker. To our knowledge, (i) they do not give discounted rates to physicians or to the wealthy, both of whom have access to high quality health care, and (ii) life annuity underwriters do not routinely adjust for quality of care when pricing their structured settlements.

## 9. ESTIMATION OF LIFE EXPECTANCY IN INDIVIDUAL CASES

Life expectancy is an important factor in assessing the lifetime cost of future care for an individual with TBI. As we have seen, a sensible discussion requires, at a minimum, some familiarity with both the basic actuarial concepts and the relevant scientific literature. In practice, however, persons concerned with life expectancy assessment often lack this background, and as a result erroneous views are frequently advanced. We discuss some of the more significant issues below.

Much unnecessary confusion arises from the misuse of the term life expectancy when survival time is intended.

- For example, a terminally ill patient may ask the treating physician about life expectancy, but usually neither is interested in averages. Even in cases where the survival time will be limited to a few months or years, it is impossible to predict it with accuracy (144, 145). This forces the physician either to refuse to opine, and appear unhelpful, or to offer what is known about the average survival time in such cases. Even if the quoted average is appropriate, however, the patient’s actual survival time will likely be very different and the doctor will appear to be “wrong” (146, 147).
- In the legal arena, on the other hand, predictions of actual survival time are generally not required. For example, it is impossible to predict the survival time

of a normal 70 year-old male: according to government statistics 10% of such males will die in the next 4 years while another 10% will live well into their 90’s (2). But the *average* survival time — i.e., the life expectancy — is given by standard government life tables and is widely accepted by courts as the basis for compensation. It may be argued that the same reasoning should apply to persons with reduced life expectancy, including those with TBI.

- We note that if one insists upon making a prediction of survival time, then either the life expectancy or the median survival time is a possible choice. The latter has the useful interpretation of being the time at which the patient is as likely as not to be still alive. In the case of persons at high risk, such as those who are immobile and tube fed, the life expectancy is higher than the median (75).

A common misconception is that if a person’s current mortality risk is low then the life expectancy is nearly normal.

- The argument runs, for example, that although a given patient has severe epilepsy he is unlikely to die of it, and therefore “on the balance of probabilities the epilepsy will not reduce his life expectancy.” This argument again reflects confusion of life expectancy and survival time. In a very large group, *some* of the individuals will die of epilepsy, even though they are not the majority, and this reduces the *average* survival time — i.e., the life expectancy.
- An illustration of this point is the comparison of males and females. Males have life expectancies about 6 years shorter than females. It would thus be a mistake to argue that because a given 10 year-old boy is in perfect health and is currently subject to an extremely low mortality risk his life expectancy is the same as that of a 10 year-old girl.
- Further, the effect of even a moderate additional mortality risk on life expectancy is often underestimated. For example, if a 10 year-old girl has a medical condition that raises her mortality risk by only 5 deaths per 1000 persons per year for life, the result is a life expectancy reduction of 11 years.

It is often asserted that “Published studies are all based on large groups and it is impossible to predict the life expectancy of an individual.”

- Confusion of life expectancy and survival time aside, the assertion is essentially that because a scientific analysis cannot take account of *every* factor relevant to life expectancy of a given individual, *nothing* scientific can be said about an individual’s prognosis for survival.

- If this were true then standard government life tables would be irrelevant to an individual, and economists and others have been wrong to refer to them. It would also mean that life insurance actuaries and medical directors, who routinely decide whether to offer insurance to individuals and at what price, have no basis for making such decisions.

Frequently the view is expressed that high quality medical care will ensure a normal life expectancy. This is incorrect, as was discussed in the previous section.

The life expectancy literature on cerebral palsy, spinal cord injury and other conditions is extensive, and the comparison with these conditions to TBI may be helpful.

- The comparison with *cerebral palsy* (59–65) may provide a useful lower bound to the life expectancy in TBI, as persons with TBI appear to be subject to similar or slightly lower mortality risks than those with comparably severe cerebral palsy (52).

For example, the life expectancy of a 15 year-old male with cerebral palsy who can lift his head when lying on his stomach but cannot roll over or sit independently, and who is fed orally by others, has been estimated to be 22.8 additional years (62). This may therefore be a reasonable approximation to, though perhaps a slight underestimate of, the life expectancy of a similar TBI patient.

- Similarly, comparison with the *spinally-injured* patient, though imperfect, may be useful. For example, the life expectancy of a young paraplegic has been well documented to be reduced by 10 years or more (66–69). Such persons are unable to walk, but generally have unimpaired cognitive function, no bulbar dysfunction, and have normal upper body function and self-care skills with their hands. They therefore compare favorably in most respects with persons with TBI who have lost the ability to walk. (Some caveat is necessary here because spinally-injured patients are more at risk of certain medical conditions, including spinal degeneration and bowel and bladder problems.)
- For a person with TBI who is cognitively near-normal and ambulatory but still has some permanent difficulties with motor function, there is still some modest reduction in life expectancy. This may be seen by comparison with *uninjured persons who live a sedentary life style*, whose life expectancy may be argued to represent an upper bound in many cases. A permanently sedentary lifestyle is known to lead to increased risk of heart disease and other conditions (148, 149), and can be shown to lead to a reduction of about 4 years.
- Finally, if the patient has only minimal physical disability but suffers from *mental disorder or severe*

*behavioral problems*, the literature on excess mortality in such conditions may be applicable (82).

### Taking Account of Multiple Factors

Although ambulation and self-feeding are valuable predictors of expected longevity, there are other factors with some relevance. Some of these were discussed in section 5, and in addition there are refinements to mobility and self-care (can the subject roll over, sit or stand without support, carry on conversations, dress and bathe himself, etc.). Further, there are factors, such as bulbar dysfunction and hospital admissions for pneumonia, that must have some predictive value but for which there appears to be no relevant mortality data.

How can all these factors be incorporated into an estimate of a given individual's life expectancy? It is evidently not feasible to take them all into account in a scientific analysis. The rational approach is to work with the available data as far as possible – perhaps taking account of key factors such as mobility and self-care skills – and then to consider other factors for which data are not available. It may then be reasonable to argue for an adjustment, either upwards or downwards, to the evidence-based estimate. The input of a clinician can be very helpful in describing these factors and their effect on the individual's prognosis.

An alternative view is sometimes expressed: that the scientific approach should be abandoned because such an analysis cannot take account of *every* factor. Instead, a life expectancy is chosen on the basis of, for example, clinical introspection. It seems to us that this position is untenable: the existing mortality data should at least provide a *starting point* for any rational discussion.

## 10. CONCLUSIONS

An individual's *life expectancy* is the average number of additional years of life in a large group of similar persons. In many cases it can be estimated with some precision. Life expectancy should be distinguished from the individual's actual *survival time*, which is impossible to predict with accuracy, even in the uninjured general population.

We have seen that mortality is increased after TBI, many causes of death being more common than in the general population. These include pneumonia and other respiratory diseases, seizures, accidents (including choking), and – importantly – diseases of the circulatory system, related to immobility.

The key predictors of survival are mobility and self-care skills (notably, the abilities to walk and to self-feed). The life expectancy of persons who walk and self-feed is only modestly reduced by comparison with the general population, whereas nonambulatory persons with minimal

self-care skills suffer a much greater reduction. An extreme case is a gastrostomy-dependent patient in the permanent vegetative state, where the life expectancy is 10 years or less.

To estimate a given individual's life expectancy one can use the literature and existing data to account for some key predictors. Subsequently, it is reasonable to consider additional factors, which have not been taken into account, and to argue for a further adjustment. The alternative approaches of simply assuming that general population figures apply, or of proposing an estimate solely on the basis of clinical intuition, lack scientific justification and are in our view untenable. The existing population data must surely provide at least a starting point.

Finally, we note two factors relevant to life expectancy that have been insufficiently studied. The first is the prospect for improvement in function after the first few post-injury years. Although it is sometimes stated that almost all the meaningful recovery in function occurs during the first two years, it is a matter of clinical observation that substantial improvement sometimes occurs considerably later. There have been cases of persons emerging from the vegetative state after three or more years, although remaining with severe motor and cognitive dysfunction. It appears that there are no studies documenting the frequency of these late recoveries, or the degree of improvement that may occur.

Second, little is known about the decline in function of persons with TBI in old age. For example, if a young adult suffers a TBI and after several years is able to walk unsteadily and to carry on conversations with somewhat slurred speech, what can be expected in the subsequent decades, and what is the expected pattern of decline in old age? Further research on these questions would be valuable.

## TBI: Pathology, Pathophysiology, Acute Care and Surgical Management, Critical Care Principles, and Outcomes

*Eli M. Baron  
Jack I. Jallo*

**T**raumatic brain injury (TBI) accounts for more than 50,000 deaths in the United States yearly and accounts for nearly 50 percent of all injury deaths (1, 2). TBI remains the leading cause of both injury death and disability among children and young adults (1). Recent observations suggest a decline in both TBI-related hospitalization and TBI-related deaths (2). This is largely due to a 40% decline in TBI related deaths in motor vehicle accidents, attributed to both the increased use of seat belts and an increase in use of safety equipment (3). Nevertheless, there remains a substantial social and economic burden related to TBI, with 1.5 million Americans sustaining a TBI yearly and 250,000 Americans being hospitalized yearly for TBI (4, 5). Of these, 80 to 90,000 people yearly experience long-term disability (6). Costs of acute hospitalization in 1997 to 1999 ranged from over \$8000 on average for moderately injured patients to over \$33,000 on average for patients with TBI requiring critical care (5). In 1995 the total direct and indirect costs of TBI in America was estimated at \$56.3 billion (7). Further, at least 5.3 million Americans (~2% of the population) live with TBI related disabilities (6). Thus TBI presents an enormous medical and socioeconomic burden and is certainly one of the leading public health problems in the United States.

A recent study reviewing the hospital discharge data over the year 1997 revealed motor-vehicle crashes, falls,

and assaults as the leading causes of injury for TBI-related discharges (27.9, 22.5, and 7.3/100,000 respectively). Rates were highest for American Indians and Alaska Natives (75.3/100,000) and Blacks (74.4/100,000), reflecting lower socioeconomic status. The age-adjusted rate for males was about twice as high as for females (91.9 versus 47.7/100,000 respectively). For both sexes, the rates were highest among those aged between 15 and 19 years and  $\geq 65$  years, reflecting increased risk taking in the younger population (e.g. drinking and driving, driving without seatbelts, etc.) and confirming that TBI is a very important health problem among the elderly (8). Another larger study confirmed an alarming increase in the rate of fall related TBI deaths in the elderly from 1989–1998 (9). A decline of nearly 50% in terms of hospitalization has been observed since 1980, that has been attributed in part to injury prevention and to changes in hospital admission practices where more patients with mild TBI are managed in outpatient settings (6, 10).

An emphasis has been made regarding the mortality rates in severe TBI falling from the 50% range in the 1970's to the 30% range in the 1990's, with a concomitant increase in the number of good to moderately disabled survivors (as opposed to those severely disabled or vegetative). This has been proposed to be due to multiple factors including improved rescue systems, enhanced emergency care in trauma facilities, rapid surgical treatment and improvement in critical care (11). One controversial area

regarding improvement in mortality statistics is intracranial pressure (ICP) monitoring and its role in the management of severe brain injury. ICP monitoring has become a cornerstone in the modern day management of severe head injury. Much emphasis has been made in terms of classifying the resultant brain injury resulting from the initial traumatic insult as primary brain injury and subsequent insults as secondary injury. Secondary injury results from entities such as hypotension, hypoxia and ICP elevation. ICP monitoring may allow clinicians to intervene earlier in terms of treating ICP elevations, which are associated with an increased mortality. A basic understanding of injury mechanisms, morphology, pathophysiology, clinical presentation, therapeutic options and expected outcomes is necessary for the clinician involved in the rehabilitation of those sustaining TBI. The present discussion focuses on the diagnosis and management of the adult with traumatic brain injury with a review of head injury morphology, pathophysiology, surgical indications, ICP monitoring, ICU care, and outcomes.

### HEAD INJURY MORPHOLOGY

Head injuries can be classified as blunt or penetrating injuries. Blunt TBI includes motor vehicle accidents and falls, and is responsible for the majority of TBI in this country. *Coup* and *contrecoup* injuries respectively refer to damage resulting from blunt trauma, where coup injuries occur adjacent to the area struck by an object and countercoup injuries occur on the opposite side, usually due to resultant acceleration of the brain after being subject to a force and striking the calvarium or skull base of the opposite side. Penetrating injuries include bladed weapons and both low velocity and high projectiles such as handguns and assault rifles. The majority of injuries are either homicides or suicides, although accidental firearms injuries contribute significantly to this number. Injury resulting from gunshot wounds occurs as a result of energy transfer from the projectile to impacted tissue. Initially, injury starts by the direct crushing and lacerating of tissues as the missile enters the skull and brain, taking with it bone and tissue fragments. A pulsating temporary cavity, with lower intracavitary pressures is formed, where the cavity may be many times larger than the diameter of the bullet. This may generate pressure waves radiating to locations away from the bullet path, causing stretching and tearing wounds (12). Penetrating injuries also carry with them a theoretically increased risk of infection, especially if bone and particulate matter enter the neural substance. Despite recent advances in neurosurgical and critical care, the prognosis for patients sustaining gunshot wounds to the head remains dismal, with an overall mortality rate of patients presenting to hospitals alive being near 60% (12).

Head injuries are further classified by their pathologic and morphologic descriptions. Skull fractures are frequently seen with head injury. The more severe the injury, the more likely the presence of skull fractures. In one series of patients sustaining TBI, 3% of emergency room attendees, 65% of neurosurgical ICU admission and 80% of fatalities sustained skull fractures (13). Skull fractures are an important entity since they carry a much higher association with intracranial hemorrhages than TBI without the presence of skull fractures (13, 14).

Skull fractures can be associated with a variety of trauma related complications. They can be a source of infection and pathologic communication with the exterior. Cerebrospinal fluid rhinorrhea results from a fracture in the cribriform plate. Otorrhea results from fractures within the mastoid air cells or temporal bone (14). These entities carry a 2–9% risk of associated meningitis (15, 16). Depressed skull fractures carry a long-term risk of late posttraumatic seizures of 31% (17). Temporal bone fractures can be associated with seventh nerve damage and/or hearing loss.

Basilar skull fractures are associated in general with greater forces than simple cranial vault fractures. Classic signs of these include raccoon eye's, representing cribriform plate fractures and Battle's sign, representing ecchymoses over the mastoid process associated with an ipsilateral skull fracture.

Cerebral contusions most commonly occur in the frontal and temporal poles adjacent to bony surfaces of the skull base, resulting from the brain striking these upon traumatic acceleration (Figure 18-1). Gliding contusions of the

FIGURE 18-1

Axial noncontrast CT scan demonstrating bilateral frontal contusions

grey white junction represent considerably greater forces acting on the brain with associated rotational/ acceleratory vectors (14). Clinically, contusions can range from asymptomatic lesions to massive pulped areas of brain with resulting herniation. Cortical lacerations occur with penetrating injuries including depressed skull fractures.

Epidural hemorrhages usually occur in the middle fossa via laceration of the middle meningeal artery, although they can also occur in the anterior and posterior fossae. They are usually lenticular shaped and are bounded by suture lines where the pericranial layer of dura attaches to the skull (Figure 18-2). Epidural hemorrhages are most commonly associated with an overlying skull fracture (14). Though classically described with an associated lucid interval prior to clinical deterioration, only about half of patients undergoing surgical intervention present this way. These are important injuries to identify; if detected early they are usually associated with a good outcome and have a mortality of less than 10% (18).

Acute subdural hemorrhages are usually associated with a much poorer prognosis than epidural hemorrhages. This is because they often represent much more severe underlying brain damage (19). They usually result from torn bridging veins or from associated contusions hemorrhaging into the subdural space. Subdural hemorrhages tend to follow the shape of the convexities and tend to cover the entire hemisphere (Figure 18-3) (13). The present discussion pertains to acute subdural

hemorrhages in traumatic settings. Chronic subdural hemorrhages represent a different pathophysiologic condition where an initial small subdural hematoma enlarges secondary to transudative forces or repeated small hemorrhages because of associated chronic membranes. These tend to occur in older adults and are also most commonly related to an initially tearing of bridging veins.

Trauma is also the most common cause of subarachnoid hemorrhage. Often this occurs locally over convexities affected by coup type of injuries or the frontotemporal poles affected by contrecoup injuries (Figure 18-4). Subarachnoid hemorrhage from trauma can also occur in the interhemispheric fissure and in the basilar cisterns. At times it can be difficult to discern from aneurysmal subarachnoid hemorrhage, but usually the history is very suggestive of the etiology. Traumatic subarachnoid hemorrhage can result in hydrocephalus, defined as abnormal ventricular expansion with associated raised intracranial pressure (13). Hydrocephalus can also occur secondary to TBI in cases without frank intraventricular hemorrhage.

Diffuse axonal injury is a pathologic term referring to changes occurring in the brain post TBI as a result of rotational forces. The term shear injury is often used synonymously. These terms refer to classic pathologic changes including focal lesions in the corpus callosum, focal lesions of various sizes in the posterolateral quadrants of the

**FIGURE 18-2**

**FIGURE 18-4**

Axial noncontrast CT scan demonstrating a small amount of left convexity traumatic subarachnoid hemorrhage. Note its appearance as hyperdensity adjacent to the ipsilateral sulci (arrow)

brainstem next to the superior cerebellar peduncles and microscopic evidence of widespread damage to axons (13). Though MRI imaging may hint at it, the diagnosis is a tissue based one. Diffuse axonal injury is the most commonly cited cause, in the absence of hemorrhages or ICP elevations, of prolonged depressed consciousness and of severe disability in brain injured individuals. Three grades for diffuse axonal injury are widely used: Grade 1 abnormalities refer to scattered axonal bulbs through out the white matter of the brain; Grade 2 requires the presence of a corpus callosum lesion; in Grade 3 there is the additional lesion in the dorsolateral quadrant(s) of the rostral brain stem; Grade 3 lesions nearly always result in patients being in coma or a vegetative state until death (14).

## CONCUSSION

The term concussion has been used to describe the brain injury phenomenon often resulting in very disabling symptoms following a mild to moderate TBI where no hematoma or other intracranial pathology is seen on imaging. Symptoms include headache, nausea, vomiting, difficulty concentrating, retrograde and/or anterograde amnesia and personality changes, among others. Numerous clinical definitions of this term have been used with some requiring a loss of consciousness and others not.

Even with a mild TBI, there can be widespread neuronal dysfunction and axonal injury, with the possibility of delayed axotomy occurring, all potentially contributing to the post concussive syndrome (see below)(20).

## PATHOPHYSIOLOGY AND MOLECULAR BASIS FOR INJURY

### Primary Injury

The events that occur at the moment of injury, although possibly preventable are not reversible. Brain contusions and hemorrhages, however, represent potentially avoidable causes of death and disability when evacuated promptly. These are often seen together.

### Secondary Injury

Secondary neuronal injury after TBI has received much attention with new mechanisms being elucidated and previously described mechanisms being better understood. At a macroscopic level, secondary phenomena include edema, ischemia, necrosis, elevated intracranial pressure and inadequate cerebral perfusion. At a cellular level, energy failure occurs in association with a cascade of events that contribute to secondary injury such as elevated levels of intracellular calcium, release of excitatory amino acids, generation of free radicals, and breakdown of the cellular cytoskeleton and membrane with vascular dysfunction eventually leading to cell death (21).

### Excitatory Amino Acids

The first event in this sequence is thought to be the release of excitatory amino acids; this mechanism of injury has been termed excitotoxic injury. Following brain injury, excitatory amino acids are released from injured cells. Of the excitatory amino acids, glutamate has been studied the most. Glutamate acts postsynaptically at five subtypes of receptors. These receptors are named based on the agent that specifically activates them. The NMDA (N-methyl-D-aspartate) receptor complex is an ion channel that allows passage of calcium and sodium ions. When activated by glutamate, the NMDA receptor allows calcium ions to enter the cell. Large influxes of calcium ions into neurons stimulate calcium dependent enzymes with activation of proteases, kinases, phospholipases, and nitric oxide synthase. If unchecked, these processes can eventually lead to cell death with breakdown of the cytoskeleton, free radical formation, alterations in gene expression and protein synthesis, and membrane dysfunction. Blocking the NMDA receptor improves neuronal survival in vitro and in animal models of neuronal injury (21). NMDA blockers failed to show efficacy in

recent human trials for TBI. This has been thought to be due to glutamate excitotoxicity occurring immediately at injury time but afterwards glutamate has important normal functions, such as promotion of neuronal survival. The administration of numerous NMDA antagonists in human trials may have been in the time period where glutamate had resumed its normal critical functions, rather than earlier when they would have possibly prevented excitotoxicity (22).

### Free Radicals

Free radical formation is an important part of many mechanisms of secondary injury. The most common free radicals studied are superoxide ( $O_2^-$ ), hydrogen peroxide ( $H_2O_2$ ), hydroxyl (OH), and nitric oxide (NO). Free radicals are atoms or molecules possessing an unpaired electron in the outer orbit making them highly reactive. Free iron is a key catalyst of free radical mediated injury and is readily available in injured and contused brain tissue. Free radicals damage endothelial cells and injure the brain parenchyma. This results in disruption of the blood brain barrier and is partly responsible for both vasogenic and cytotoxic edema. Once initiated, free radical injury is a self-perpetuating process with increasing damage generating more free radicals. Cells attempt to minimize injury caused by free radicals by binding them with free radical scavengers such as vitamin E, ascorbic acid, superoxide dismutase, and others. Nevertheless, these coping mechanisms may be overwhelmed in areas of significant brain injury or ischemia. Pharmacological free radical scavenging agents have been effective in reducing neuronal damage in animal models of brain injury (21). Unfortunately, a human trial of a free radical scavenger (polyethylene glycol – superoxide dismutase) in severe head injury did not demonstrate an improved outcome (23). More recently, the cannabinoid dexamabinol has been proposed as a neuroprotective treatment for head injury. Mechanistically, dexamabinol most likely works as a noncompetitive NMDA antagonist in vitro and in vivo. It blocks NMDA stimulated calcium influx in primary neuronal culture, and head injury related calcium influx in rats. In addition, it is a potent free radical scavenger (24). Recently, however, a very large multicenter, Food and Drug Administration double-blind, randomized, placebo-controlled trial of dexamabinol vs. placebo failed to demonstrate efficacy of the drug in humans (25).

### NITRIC OXIDE

Nitric oxide, a ubiquitous second messenger has been implicated in a variety of cellular processes including vascular relaxation, neurotransmitter effects, and cytotoxicity. Nitric oxide is formed by the conversion of

L-arginine to L-citrulline and nitric oxide via nitric oxide synthase (NOS). The mechanism of nitric oxide cytotoxicity is unclear, but is closely intermingled with NMDA, calcium, and free radical mediated injury. Inhibitors of nitric oxide synthase have been found to reduce neuronal injury in animal models of brain injury. A host of other mediators of secondary brain injury are under investigation including: catecholamines, adenosine, cytokines, opioid peptides, and thyrotropin releasing hormone (21).

## PHYSIOLOGIC RESPONSE TO BRAIN INJURY

### Brain Edema

The cellular mechanisms of secondary brain injury described above contribute to brain edema, and subsequently to elevations in intracranial pressure, decreased cerebral perfusion, and cerebral ischemia. Brain edema has been traditionally described as either vasogenic or cytotoxic. *Vasogenic edema* results from disruption of the blood brain barrier. The blood brain barrier is maintained by tight junctions between endothelial cells that line the vessels of the brain. Injury to these cells allows extravasation of fluid and proteins into the interstitial space of the brain parenchyma. Disruption of endothelial cells may be primary, resulting from the initial impact or subsequent hemorrhage, or secondary resulting from free radical generation, cytokines, and other secondary mechanisms of injury. *Cytotoxic* or *cellular edema* is edema of the cells themselves in contrast to vasogenic edema which is edema of the interstitial space. Cytotoxic edema results from failure of cellular ion homeostasis and membrane function. As previously mentioned, secondary injury at a cellular level results in loss of ion homeostasis and membrane dysfunction. The time course of brain edema is variable. It is thought, however, that vasogenic edema occurs early after injury and cytotoxic edema occurs in a more delayed fashion. Brain edema after traumatic brain injury is often maximal at 24 to 48 hours (26).

Edema of the brain is an important marker for injury and is also a cause of secondary injury. This is because the brain is confined by the skull, which acts as a closed container. Intracranial pressure is determined by the volume of three elements in the skull: the brain parenchyma volume, the blood volume, and the cerebrospinal fluid (CSF) volume. An increase in the volume of any of these elements will result in an increased intracranial pressure after compensatory mechanisms are exhausted. As intracranial pressure rises, there is an initial passive release of CSF into the spinal canal. There is also an innate compliance of the craniospinal axis that allows for an increase in intracranial contents without an initial increase in intracranial pressure. Once the compensatory reserve is exhausted, there is a precipitous rise in intracranial pressure (Figure 18-5) (21).

FIGURE 18-5

Pressure volume curve of the craniospinal axis demonstrating a precipitous rise in intracranial pressure associated with exhaustion of compensatory mechanisms. At a pressure of 10 mmHg a volume of  $x$  can be added with little change in ICP (represented by points A to B). Adding the same volume when the ICP is about 25 mmHg results in a much larger change in ICP (points C to D)

### Intracranial Pressure and Cerebral Blood Flow

Intracranial pressure in an adult is ordinarily under 15 mmHg. Sustained elevations in intracranial pressure above 20 mmHg are poorly tolerated by the injured brain and have been associated with increased mortality (27, 28). Sustained elevation in intracranial pressure may result in cerebral ischemia if cerebral perfusion is hampered and, if severe, can result in brain herniation. Brain herniations may occur across the falx and involve the cingulate gyrus, across the tentorial hiatus and involve the uncus, or through the foramen magnum and involve the cerebellar tonsils. Cerebral ischemia results from inadequate cerebral perfusion. The ideal degree of cerebral perfusion in the injured brain is unknown. In the uninjured brain, cerebral blood flow is tightly regulated by myogenic, humoral, and neural mechanisms to maintain a constant flow despite changes in systemic arterial pressure and intracranial pressure. This autoregulation functions over a broad range of systemic arterial pressures ranging from a lower limit of 65mmHg and an upper limit of 140mmHg to maintain

cerebral blood flow at approximately 50ml/100gms/min. If blood flow falls beneath 25ml/100gms/min then electrical activity is lost and the EEG is flat, below 12ml/100gms/min brain stem evoked responses are lost and below 10ml/100gms/min brain failure results with loss of ion homeostasis and eventual cell death (21).

### Cerebral Perfusion Pressure

It is of paramount importance that an adequate cerebral blood flow be maintained to the injured brain. Unfortunately, there is no simple technique that allows for reliable, continuous bedside measurement of cerebral blood flow. As a result, the concept of cerebral perfusion pressure is invoked when discussing cerebral blood flow to the injured brain. Cerebral perfusion pressure (CPP) is defined as the difference between mean arterial pressure (MAP) and intracranial pressure (ICP):  $CPP = MAP - ICP$ . The concept of autoregulation can be extended to discussions of cerebral perfusion pressure in the uninjured brain. Autoregulation in terms of perfusion pressure has a lower limit of 50mmHg and an upper limit of approximately 140mmHg. With a perfusion pressure below 50mmHg, cerebral arterioles are maximally dilated and perfusion cannot match the brains metabolic needs. If this state persists brain ischemia follows. As previously noted, the brain poorly tolerates ischemic conditions which aggravate secondary injury. With a perfusion pressure greater than 140mmHg, cerebral arterioles are maximally constricted and blood flow increases passively with perfusion pressure (Figure 18-6) (21).

FIGURE 18-6

Autoregulation curve of the brain. Below a perfusion pressure of 50 mmHg and above a pressure of 140 mmHg blood flow passively correlates with perfusion pressure

Discussions of cerebral autoregulation are generally predicated on the brain's physiologic responses to changes in systemic arterial pressure. However, these discussions assume that the physiologic responses that are in effect in an uninjured brain are also in place after brain injury. This has been a topic of debate and study. Up to one-half of severely head injured patients will have some autoregulatory impairment. It appears as though the autoregulatory curve is shifted to the right with an increase in the lower limit at which autoregulation is effective (21). Patients with severe head injury probably require a CPP of 60mmHg to 70mmHg to maintain autoregulation of cerebral blood flow and prevent ischemic complications. In one study, outcome was shown to be significantly worse in patients with a CPP less than 60mmHg (29). Additionally, Rosner et al. (30) demonstrated more favorable outcomes when CPP was kept above 70mmHg. Current recommendations are to maintain cerebral perfusion pressure at 60mmHg to 70mmHg(31). Targeting CPP beyond 70 mmHg may increase the risk of adult respiratory distress syndrome, offsetting potential benefits from this therapy (32).

### CLINICAL PRESENTATION AND MANAGEMENT

Head injury can present in a variety of manners and often requires a high index of suspicion to be diagnosed. While loss of consciousness or altered consciousness, headaches, anisocoria, nausea/vomiting/dizziness and/or witnessed obvious traumatic injury to the head usually prompt a clinical workup, often TBI presents more subtly. All patients with a loss of consciousness or posttraumatic disturbance in sensorium should undergo CT scanning of the brain. Particular attention should be paid to intoxicated individuals, even without obvious signs of external injury. Subdural hemorrhages can easily be missed in patients intoxicated with alcohol, who may have suffered unrecognized head injuries. Further, stimulant drugs may result in TBI related agitation being overlooked. The widespread availability of CT scanning should result in a very low threshold for imaging.

Head injury can be classified as mild, moderate and severe. This is conveniently done with the aid of the Glasgow Coma Scale (GCS)(Table 18-1). Initially intended as a tool for clinicians to communicate their assessment of a patient's level consciousness in an objective matter (33), the GCS has been widely adapted as a head injury scoring system and has also proven to be an effective prognosticator with regard to clinical outcomes. Mild TBI is classified as GCS 14–15, moderate as GCS 9–13 and severe as GCS 3–8 (19).

In the field patients should have their airway status, breathing and circulation addressed first. Hypotension and

hypoxia in the field are proven secondary injury insults that are associated with poor outcomes, with hypotension being considerably more detrimental than hypoxia (34); both of these must be prevented if possible. Endotracheal intubation may be necessary in the field. Patients should have a GCS score assessed and pupillary exam prior to any sedation or paralytic being administered if possible. This can be done accurately by emergency medical personnel (35). Even if the patient has focal or lateralizing signs, such as a decreased sensorium and an enlarging pupil, current recommendations do not support ICP directed measures in the field, with the possible exception of hyperventilation in the intubated patient in neurologic extremis. Every effort to have TBI patients transported to the nearest facility possessing CT scanning, neurosurgical expertise and ICP monitoring capabilities, should be made(35). This can be most easily expedited in areas where neurotrauma systems are established. The spine should also be immobilized as there is a 4 to 8 percent association of cervical spine injury with TBI(36).

Upon arrival in the emergency room, the Advanced Trauma Life Support (ATLS) protocol, as per the American College of Surgeons, should be followed. This protocol stresses a systematic approach to trauma injury, where airway, breathing and circulation are assessed first. The assessment of the circulatory system should include attention to all sites of external bleeding including scalp lacerations which may be a source of exsanguination. Efforts should be made to control bleeding. In terms of fluid resuscitation crystalloid vs. colloid remains controversial. A recent large prospective randomized trial compared

saline to albumin in the intravascular resuscitation of critically ill patients. Similar outcomes were seen in both groups in terms of mortality and length of stay. Seven of the study population constituted patients with TBI. Mortality was increased in the subgroup with TBI receiving albumin with a relative risk of 1.62 over the group receiving normal saline (95 percent confidence interval, 1.12 to 2.34;  $P = 0.009$ ). The authors cautioned, however, that “such subgroup differences frequently occur by chance and the rate of death from any cause over a 28-day period is not considered the most appropriate outcome measurement with which to assess treatment effects in patients with brain injury (37).”

Once fluid resuscitation is addressed, a neurologic assessment is made in terms of GCS score, pupillary exam and lateralizing signs. This is preferably done prior to any sedation or paralytic being given. A lateral c-spine and chest x-ray should be performed. A CT scan is then performed as rapidly as possible in any patients with a suspected or confirmed loss of consciousness, skull fracture or abnormal neurologic/GCS exam. CT scanning has become the diagnostic procedure of choice for the initial assessment of intracranial injury. It accurately shows acute blood and identifies most skull fractures. Any coagulopathy requires correction in patients with acute blood on their CT scans.

Patients with mild traumatic brain injury who are neurologically normal with a negative head CT may be discharged home safely (38, 39). Other patients, especially those with altered mental status or collections on their CT scans should be admitted for observation and possible serial imaging. Patients with isolated skull fractures and normal neurologic exams can possibly be discharged to home, although this is controversial and must be assessed on a case to case basis (40–43).

## SURGICAL TREATMENT OF HEAD INJURY

Operative therapy is indicated in patients where intracerebral collections are exerting significant mass effect. Traditionally this has been defined as greater than 5 mm of midline shift (19). Midline shift is measured on axial CT scan images in terms of displacement of the septum pellucidum from the midline at the level of the foramen of Monroe. A line is drawn at the midline of the skull in the sagittal plane and then a perpendicular line is extended to the septum pellucidum, which is measured and recorded as shift (Figure 18-7). Mass effect is also evaluated in terms of correlation of local effect of abnormal collections on more normal appearing adjacent brain. Similarly, the basilar cisterns are evaluated for compression.

Numerous surgical criteria for a variety of commonly seen TBI related pathologies have been proposed (18). Epidural hemorrhages greater than 30 cc in volume

**FIGURE 18-7**

Midline shift measurement: the septum pellucidum is measured at the level of the foramen of Monroe. This scan demonstrates 1.9 cm of left to right shift

should be evacuated regardless of whether the patient is symptomatic. Those patients with a GCS score less than 9 with associated papillary dilation and an epidural hematoma should undergo decompression as soon as possible. Epidural hemorrhages less than 30 cc in volume and less than 1.5 cm in thickness, with less than 5 mm midline shift, may be managed by close observation and serial imaging in patients without focal deficits. Similarly, patients with acute subdural hemorrhages greater than 1 cm in thickness or subdural hemorrhages associated with greater than 5 mm of midline shift should undergo emergent evacuation. Smaller subdural hemorrhages may require evacuation in patients with neurologic deficits, in those deteriorating neurologically and in those with raised intracranial pressures. Both types of acute hemorrhages are best evacuated either through a craniotomy or craniectomy.

Intracerebral contusions may also be life threatening. Patients with intracerebral contusions with progressive neurologic deterioration referable to the contusion or resultant refractory intracranial hypertension should be treated operatively (Figure 18-8). Comatose patients with frontal or temporal contusions greater than 20 cc in volume with a midline shift of 5 mm and/or cisternal compression on CT scan, and those with a contusion

**FIGURE 18-8**

Axial noncontrast CT scan demonstrating life threatening left frontal intracerebral contusion which necessitated surgical evacuation.

greater than 50 cc in volume should be treated operatively. These numbers are general guidelines: patients with relatively good neurologic exams and contusions in eloquent cortex may be carefully watched, with medical treatment of ICP elevations if needed (18). Contusions are often associated with numerous other pathologic findings on CT scan such as significant cerebral edema with resultant cisternal compression and traumatic subarachnoid hemorrhage. In patients with severely contused frontal lobes with significant mass effect and resultant medically refractory intracranial hypertension, bifrontal decompressive craniectomy may be life saving; nevertheless, decompressive craniectomy for refractory ICP elevations remains a controversial area as discussed below.

Open depressed skull fractures greater than the thickness of the skull with evidence of dural laceration should be operated on acutely to lower the risk of infection. Nonoperative management may be an option for depressed skull fracture if there is no clinical or radiographic evidence of dural penetration, no evidence of significant intracranial hematoma, depression less than 1 cm thickness, no frontal sinus involvement, no gross cosmetic deformity, no evidence of wound infection, pneumocephalus or gross wound contamination. All open skull fractures, regardless of whether managed expectantly or surgically, should be treated with antibiotics. Closed skull fractures can be managed nonoperatively.

## ICP MONITORING AND THE TREATMENT OF ELEVATED ICP

Per the Guidelines for the Management of Severe Traumatic Brain Injury (44), ICP monitoring is appropriate in patients with GCS scores post resuscitation  $\leq 8$  with a head CT demonstrating hemorrhages, contusions, edema or compressed basilar cisterns. ICP monitoring may also be appropriate in patients with GCS scores post resuscitation  $\leq 8$  with a normal head CT and 2 of the following: age  $> 40$ , motor posturing, or a systolic blood pressure of  $< 90$  mmHg. These recommendations are largely based on the landmark paper by Narayan et al. (27) which defined which patients are likely to develop ICP elevations. There is a clear association between (abnormally) elevated ICP's and mortality (28, 45). While no significant prospective study to date has demonstrated that ICP monitoring leads to decreased mortality or improved clinical outcomes, there is considerable evidence favoring its use in the management of patients with severe TBI based on retrospective series and trauma data bank studies (46–49). Nevertheless, there remains some controversy regarding the efficacy of ICP monitoring based therapy vs. empiric therapies for head injury (e.g. empiric mannitol administration)(50–52). Despite this controversy, it has become a mainstay in the critical care management of patient's with severe TBI and may also be appropriate in some cases of moderate TBI.

Ventriculostomy (external ventricular drain) insertion is the ICP monitoring procedure of choice in adults with severe TBI. It permits both monitoring of pressure via transduction of a continuous fluid column from the ventricles and also permits CSF drainage (Figure 18-9). Other monitoring technologies such as fiberoptic monitors are also acceptable but do not permit cerebrospinal fluid drainage and are subject to measurement drift (53, 54).

A threshold of 20–25 mmHg can be used to define an elevated ICP. ICP elevation presenting as a change from lower more normal pressures must always prompt a search for a potential surgical mass lesion via a repeat head CT. Elevation of the head of the bed to 30 degrees promotes jugular venous drainage and lowers ICP (55). Preventing hyperthermia can also lower ICP. While a large recent trial found systemic hypothermia ineffective in improving outcomes in TBI (56), animal models have shown it to be neuroprotective and it may play a future role in TBI management. In patients where ICP management is of concern, a mechanical airway should be in place, allowing hyperventilation and sedation/paralysis to be used as needed. Steroids have not shown to be of benefit in reducing ICP elevations and are not recommended for use in TBI. Recently, the results of a very large randomized control trial where 10008 adults with head injury and a Glasgow coma score (GCS) of 14 or less within 8 h of injury were randomly allocated 48 h

**FIGURE 18-9**

18-9(a): Ventriculostomy catheter: a silicon catheter used for measurement of ICP and ventricular drainage. 18-9(b) Axial noncontrast CT scan demonstrating ideal placement of a ventricular catheter at the foramen of Monroe

infusion of corticosteroids (methylprednisolone) or placebo were published. Compared with placebo, the risk of death from all causes within 2 weeks was higher in the group allocated corticosteroids (1052 [21.1%] vs 893 [17.9%] deaths; relative risk 1.18 [95% CI 1.09–1.27];  $p = 0.0001$ ) (57). Based on the results of this trial a recent Cochrane review on the topic concluded that steroids should no longer be routinely used in people with traumatic head injury (58).

Mannitol is a very effective drug for lowering ICP and is a mainstay in this regard. It works by dehydrating the brain, especially areas of cerebral edema and by altering cerebral rheology. Unfortunately it loses some of its efficacy with time and has some potentially serious side effects including renal failure and pulmonary edema.

Mannitol is optimally given as a slow intravenous bolus. The dose is 1 mg/kg for immediate maximum effect and duration (19). High dose therapy is preferred in the presence of acute intracranial hematoma prior to surgery (59). Smaller doses are used as maintenance therapy for ICP elevation. Mannitol's effects may be augmented by other diuretics such as furosemide. A Foley catheter must be present to help monitor mannitol's diuretic effect. Serial serum osmolalities should also be measured, where osmolalities should be kept below 320 mOsm to reduce risk of renal failure (44).

While hyperventilation was advocated in the past to lower ICP, current recommendations are more modest in terms of its use. Hyperventilation works to lower ICP by causing cerebral vasoconstriction. This reduces ICP but can also exacerbate cerebral ischemia. Hyperventilation also loses efficacy with continued use. Current recommendations are for avoidance of the use of *prophylactic* hyperventilation in the first 24 hours after severe TBI. It is reserved for treatment of patients with established ICP elevations (e.g.  $PCO_2$  30–35 mmHg) and more aggressive hyperventilation is for those patients with refractory ICP elevation and those in neurologic extremis (44, 60).

Sedation with short acting benzodiazepines such as midazolam and analgesic agents such as morphine maybe useful additional agents to manage elevated ICP. Similarly, paralytics maybe useful in the management of refractory ICP elevations. Barbiturates are considered the last line medical therapy for otherwise medically refractory intracranial hypertension. They require electroencephalogram monitoring in order to confirm burst suppression. Barbiturates have serious side effects including cardiac depression and increased infection risk. Because of barbiturates' cardiac effects, most centers use pulmonary artery catheters for hemodynamic monitoring.

In cases of medically refractory ICP elevation or in cases of significant intraoperative brain swelling decompressive unilateral or bilateral craniectomy with duraplasty has been advocated. In the operating room this decision maybe made for technical reasons (e.g. the brain is swelling so rapidly that traditional closure of the dura and bone is impossible). The use of this procedure to treat medically refractory ICP elevation is controversial. Various studies have found improved outcomes and decreased mortality in patients undergoing a craniectomy for refractory ICP vs. those medically managed (61–63). It remains to be proven, however, whether decompressive craniectomy is beneficial over maximal medical treatment.

In the presence of ICP elevation an attempt should be made to increase cerebral perfusion pressures to at least 60 mmHg in adults. CPP is defined as the difference between mean arterial pressure and ICP. In the presence of elevated ICP, cerebral autoregulation maybe deranged. Thus elevating CPP maybe critical for brain tissue at risk for ischemia. Nevertheless, it is important to remember

that ICP elevation is itself detrimental; therefore ICP elevation should never be simply treated by elevation of CPP alone. Rather, its cause should be investigated and concomitantly treated.

### CRITICAL CARE AND ADDITIONAL NEUROMONITORING TECHNOLOGIES

A brief discussion of some of the issues regarding TBI related neurocritical care is warranted. As stressed above, ICP monitoring has become a mainstay in the modern management of severe TBI. Efforts should be made to maintain CPP above 60 mmHg in patients with elevated ICP's. Knowledge of patients' hemodynamic and volume status can be very useful in the maintenance of appropriate blood pressures for CPP directed therapy. Thus a central venous catheter should be placed for central venous pressure monitoring. In patients' undergoing treatment with barbiturates, pulmonary artery catheterization is warranted. Current recommendations are for maintaining euvolemia. Intravenous fluids should be isotonic solutions such as normal saline. Dextrose containing solutions are avoided as hyperglycemia has been shown to be associated with worse outcomes in TBI (64).

Similarly, glucose abnormalities must be avoided as secondary insults. Electrolytes should be followed with at least daily laboratory studies. Particular attention should be paid to sodium values. Syndrome of inappropriate antidiuretic hormone, diabetes insipidus and cerebral salt wasting have all been described in association with TBI—all are potential sources of secondary brain injury (65).

Seizures are another potential source of secondary insult. *Early post traumatic seizures* are those that occur within the first 7 days after a TBI and *late posttraumatic seizures* are those that occur later. Early posttraumatic seizures are more common in younger people and their risk of occurrence is increased in the presence of hematomas, contusion, prolonged unconsciousness and focal neurologic signs. They are usually focal seizures with or without secondary generalization. Late posttraumatic seizures are associated with penetrating injuries, early seizures, intracranial hematomas/contusions, GCS score less than or equal to 10 and depressed skull fractures. They are usually generalized convulsive seizures(17). Current recommendations are for *prophylactic* treatment of seizures in the TBI patient undergoing craniotomy or at risk for seizures with phenytoin or carbamazepine for 1 week (17, 44, 66, 67). If late seizures do occur, they should be managed by a neurologist in accordance with standard approaches to new onset seizures(44).

Infection in the ICU setting represents a very common source of morbidity and mortality in the TBI patient population. Urinary tract infections are the most common ICU associated infection. Their most effective means of

prevention is avoiding prolonged use of catheters. Secondary to the need for mechanical ventilation for a majority of these patients, and also their reduced airway protection mechanisms, pneumonia in the severe TBI patient population is the second most common nosocomial infection and the most common infectious cause of death (68). Several authorities have recommended early tracheostomy in these patients to promote pulmonary toilet, reduce infections and decrease length of stay in the ICU (69, 70). Aggressive attention to suctioning and maintaining the head of the bed elevated while administering tube feeds to minimize aspiration risk are mandatory as is strict hand washing (68). Immobile patients should be rolled every two hours to minimize the risk of skin breakdown. Early removal of patients' cervical collars may further avoid another source of decubitus ulcers (71). Perioperative antibiotics should be administered for trauma craniotomies (68). Additionally, antibiotic coated ventricular catheters may reduce infection rates in patients needing prolonged monitoring (72).

Nutrition should be initiated early in the critically ill TBI patient. This is preferably through a small intestine tube, with feedings starting within 2 to 3 days of injury (73, 74). Caution must be exerted when inserting nasal feeding tubes, as anterior skull base fractures may allow passage of the tube intracranially (75, 76). Nutritional needs in the TBI patient have been estimated to increase 40 percent over that calculated for uninjured people of similar age, sex and height. This is due to numerous factors including hormonal factors, cytokines and movement occurring post TBI. Despite high protein intake and appropriate caloric provision, during the early period post TBI, positive nitrogen balance cannot be achieved. A nutritional goal in the ICU should be the maintenance of adequate caloric and protein intake in an effort to improve nitrogen balance (77). Every severe TBI patient should have a formal nutrition assessment by an appropriately trained dietician. Markers such as prealbumin, nitrogen balance and liver function tests should be followed regularly. Gastrointestinal prophylaxis should also be routinely used in order to minimize the risk for stress ulcers.

Deep venous thrombosis is a common complication in the critically ill TBI population, with as many as 53.8% of patients experiencing this complication (78). Patients should have sequential compression boots and subcutaneous heparin used whenever possible. The safety of both subcutaneous heparin injections and low molecular weight heparins started early (within 24 to 72 hours) in severe TBI has been demonstrated (79, 80). Deep venous thrombosis should also be considered as source of fever. In cases of established thrombosis where anticoagulation is contraindicated, inferior vena cava filter placement should be considered.

Additional neuromonitoring technologies are used in selected centers. These include jugular bulb venous

saturation monitoring, cerebral blood flow monitoring and regional tissue oxygen tension monitoring, among others. Jugular venous oxygen saturation monitoring is intended to detect increases in oxygen consumption (decreased jugular oxygen saturation) and as a result globally increased oxygen extraction by the brain. It is measured by placing a catheter tip (equipped with a fiberoptic monitor) in the dominant jugular bulb and is reserved for patients with severe TBI. Current recommendations are to maintain jugular venous saturation between 55% and 75%, with this range intended to allow for a margin of error. Desaturations below 50 percent are associated with significant increases in patient mortality (81). Any reported desaturation must be confirmed by a jugular venous bulb blood sample being sent for analysis to confirm the reading. If a desaturation is confirmed, a workup is pursued to find its cause in an effort to reverse any potential secondary insults contributing to the desaturation, including overly aggressive hyperventilation (82).

While jugular venous oxygen saturation monitoring may be reflective of global oxygenation, regional oxygenation is better measured by brain tissue oxygen tension monitors (83). These monitors can be inserted in normal brain or preferably in the penumbra of an intracerebral lesion. Therapy then can be directed towards improvement of cerebral oxygenation (84). Brain tissue oxygen tension monitors can be placed safely and they reliably measure oxygen tissue tension adjacent to insertion sites. Because brain tissue hypoxia has been related to poor outcomes, efforts should be made to prevent this. The effects of tissue oxygen tension directed therapy need to be studied further before this modality is globally recommended (85).

Various centers routinely use a host of methods to measure cerebral blood flow, which are considered experimental techniques in the management of severe TBI. These include intermittent measurement techniques such as xenon techniques (including inhalational, intravenous and xenon/CT scanning), nitrous oxide saturation techniques, single-photon emission tomography (SPECT) and positron emission tomography (PET) scanning, gradient-echo echo planar imaging (EPI) using magnetic resonance imaging (MRI) technology and transcranial doppler (TCD) monitoring. Other techniques measure continuous regional cerebral blood flow such as laser-doppler flowmetry and thermal diffusion flowmetry. Cerebral blood flow measurement represents a method of assessing brain function in an objective manner. In non-pathologic conditions, cerebral blood flow and brain metabolism tend to be coupled. Thus increased cerebral metabolism tends to increase cerebral blood flow and vice versa. In patients sustaining TBI, however, this coupling is retained only in 45 percent of cases (86). Reduced cerebral blood flow has been associated with worse neurologic outcomes (87, 88). Further, global cerebral blood flow may be different than regional blood flow (89),

misleading a clinician to think that perfusion is adequate when critical structures are being under perfused. These technologies may actually allow a clinician to make management decisions resulting in a different maneuver than routine ICP directed therapies alone (which could potentially worsen regional blood flow related secondary insults)(90). The routine use of global and regional cerebral blood flow measuring technologies has yet to be widely accepted.

Another potentially useful monitoring modality in the management of severe TBI patients in the ICU is continuous electroencephalography (EEG) monitoring. EEG can detect both convulsive and nonconvulsive status epilepticus, which often is an unsuspected cause for altered consciousness in patients with severe TBI. In one series nonconvulsive status epilepticus was demonstrated in 11% of patients (91). It may be associated with poor outcomes (92). Continuous EEG monitoring is also mandatory in the monitoring of barbiturate therapy.

## OUTCOMES FROM TRAUMATIC BRAIN INJURY

Mild traumatic brain injury is noted for very often having an association with the troubling postconcussive syndrome. This can be described as having three categories of symptoms. These include cognitive complaints (e.g. decreased attention, poor concentration), somatic symptoms (e.g. headache, tinnitus, light sensitivity, etc.) and affective complaints, such as depression or irritability. These symptoms occur in 80 to 100% of individuals post mild TBI. These are paralleled by deficits in cognitive testing, with impaired speed and information processing and decreased performance on tests of memory and attention. At three months post injury, symptoms have resolved in two thirds of patients (20). Complicating the matter, many physicians are skeptical about the post concussive syndrome's existence, where often litigation is considered as a motive for continued symptoms. While secondary gain should always be considered in this group of patients, the majority of patients with post concussive symptoms have symptoms independent of litigation. Regardless of litigation, patient's with post concussive syndrome tend to have their symptoms improve with time (93). Despite the tendency for improvement with time, some people experience long term disability related to mild TBI including depression, sleep disturbances, post traumatic stress disorder and anxiety (20). A clinical evaluation by a neuropsychiatrist specializing in TBI can be very useful here where a combined educational and, if necessary, pharmacologic approach may prove beneficial.

Most patients with moderate TBI tend to improve neurologically. In one series following 79 patients, 67% of patients improved to GCS 15 by time of discharge.

At an average follow up of 27 months, Glasgow outcome scores (see below) were rated as good or moderate disability in the majority of survivors of moderate TBI, but only 74% of these patients who were employed prior to their TBI returned to work. The majority had significant cognitive and functional deficits, including memory problems, concentration difficulties and headaches, among others (94). Other reports have confirmed good recoveries in terms of general outcomes at 3 months but few patients are actually symptom free. When compared to patients who sustain mild TBI, those with moderate TBI recover less completely and more slowly. Patients tend to have difficulty with memory function and as many as 50 percent have some emotional or behavioral difficulty at 1-year post injury (95).

The mortality from severe TBI has fallen from the 50% range in the 1970's to the 30% range at present date. This is likely due to the implementation of prevention measures, safety legislation, public education initiatives, further improvements in and wider availability of emergency medical systems and regional trauma centers. Improvements in neurocritical care and the implementation of evidence-based treatment guidelines for severe head injury patients may also be responsible for improved survival rates(96). Advances in prehospital care may be contributing substantially to lower TBI mortalities. In San Diego county, California, from the years 1980 to 1982 there was a decline the head injury death rate by 24%. Similarly, the number of patients listed as dead on arrival at hospital emergency facilities decreased by 68%. This is believed to be due to a concurrent marked improvement in the county's ground and air emergency medical system(97). Becker et al. demonstrated a mortality in the 30% range in severe TBI patients managed with modern neurocritical care principals, including ICP monitoring, when compared with same era management at other institutions resulting in a mortality in the 50% range (47). Other series report similar mortalities from severe TBI in patients undergoing aggressive neurocritical care management(98, 99). Further, in patients with severe blunt TBI surviving beyond the emergency room, the mortality rate across the state of Pennsylvania for the years 1995–2000 was 34% for those undergoing ICP monitoring, while those managed without monitors had an overall mortality rate of 43% (100).

Numerous factors have been established as predictors of mortality in severe TBI. These include hypotension, hypoxia, decreasing GCS score, decreased GCS motor score, increased age, increased injury severity score, bilateral unreactive pupils, and abbreviated injury severity score of head among others. Head injury characteristics on CT have also been used as prognosticators regarding mortality in severe TBI. These include compression of the basilar cisterns, presence of traumatic

subarachnoid hemorrhage, presence of midline shift and the presence of other intracranial lesions on CT (31).

Though numerous studies have focused on predicting mortality in patients' with severe TBI, as survival improves, the focus of outcome assessments must be directed towards quality of survival and any residual disability. In this direction the term 'functional outcome' is gaining acceptance.

The World Health Organization (WHO) model of disease impact provides guidance as to the direction of outcome measures (101). This model identifies four areas in which an injury can be assessed: pathology, impairment, disability and handicap. Pathology is the most well known area to the acute care physician. It is determined by the lesion characteristics. These include location, hemorrhage, diffuse axonal injury, and elevated intracranial pressure among others. Impairment in the TBI patient refers primarily to the neurological deficits, but associated problems may have an impact on the level of impairment. For example, a patient with significant orthopedic injuries may have weight bearing limitations that contribute to the level of impairment. Disability and handicap outcomes are more familiar to rehabilitation specialists. These domains make up some of the major long-term limitations for the TBI patient (102). Disability is usually described in terms of activities of daily living (ADL). A number of measurement tools have been developed to assess this area. These include the Glasgow Outcome Scale (GOS), the Disability Rating Scale (DRS) the Functional Independence Measure (FIM), the Functional Status Examination (FSE), socioeconomic measures, quality of life measures and caregiver burden measures.

The GOS is frequently used in the neurosurgical literature. It was created in an effort to provide a global assessment of disability post severe TBI. The GOS has 5 categories: good recovery, moderate disability, severe disability, vegetative state, and death (Table 18-2) (103). Good recovery and moderate disability are generally grouped together as favorable outcomes, with the other 3 categories making up the poor outcomes. It is a fairly reliable measure but lacks sensitivity due to its broad categories. Nevertheless, at 6 months post injury the GOS has been shown to correlate well with neuropsychological, psychosocial, and vocational functioning (104).

The DRS was developed as a quantitative instrument for assessing outcomes in severe head trauma. It was designed to be easily learned, be quickly completed, be valid and have high inter-rater reliability. It consists of 8 items divided into 4 categories: 1. Arousal and awareness; 2. Cognitive ability to handle self-care functions; 3. Physical dependence upon others; 4. Psychosocial adaptability for work, housework, or school. Scores range from 0, which signifies no disability to 30, which indicates death (105). The DRS is widely used as an outcome assessment. It has shown good reliability, better precision

**TABLE 18-2**  
*Glasgow Outcome Scale (from Jennet and Bond (103))*

5	<b>Good Recovery:</b> resumption of normal life even though there may be some persistent neurologic and psychological deficits
4	<b>Moderate Disability:</b> disabled but independent. Though these patients may have considerable neurologic deficit (e.g. hemiparesis) they can travel independently and work in sheltered environments
3	<b>Severe Disability:</b> conscious but disabled. These patients are dependent for daily support due to physical or psychological limitations
2	<b>Persistent Vegetative State:</b> Unresponsive and speechless individuals who have sleep wake cycles
1	<b>Death</b>

than the Glasgow Outcome Scale, and greater reliability than other measures (106).

The FIM is an 18 item, 7 level scale that rates the ability of person to perform independently in self care, sphincter control, transfers, locomotion, communication and social interaction. The scores range from 18 (minimally dependent) to 126 (maximally dependent). The score can further be divided by two subscales, motor (the sum of 15 components of the scale) and cognitive (the sum of 8 components of the scale)(10). While showing good reliability for spinal cord injury as an overall assessment of self-care and mobility, it is also useful for assessment of functional outcomes post TBI (106).

The FSE was developed to evaluate functional changes as a result of TBI. It covers physical, social, and psychological domains. The FSE consists of data gathered through a structured interview and is scored from 0–28, where 0 signifies no change from preinjury, 27 maximum dependence on others and 28 death. The FSE is significantly related to important constructs such as family burden, significant other depression, and sacrifices the family makes, as well as overall indices of recovery and satisfaction with level of functioning. The FSE correlates with overall recovery and patient level of satisfaction significantly better than the GOS (107).

Functional outcomes in patients sustaining severe TBI vary by report but overall ~ 30% are reported as having good outcome on the GOS at 1 year. In 1977, Becker et al. reported patients surviving severe TBI. At 3 months or more post injury, 36% made a good recovery, 24% were moderately disabled, 8% were severely disabled, 2% were vegetative and 30% were dead (47). Jiang et al. (108) studied 846 patients with severe TBI and at 1-year reported good recovery in 31.56%, moderate disability in 14.07%, severe disability in 24.35%, vegetative

status in 0.59%, and a 1-year mortality of 29.43%. Rudehill et al. (109) reported data from the Karolinska institute regarding severe TBI in terms of GOS “when no further improvement could be anticipated. This final condition usually occurred 3–12 months after injury.” Forty one percent of patients with GCS scores 3–4 post resuscitation had GOS scores of 4–5, 21% had GOS scores of 2–3 and 38% had a score of 1 (death). Of patients with a GCS 5–8 post resuscitation, 70% had a GOS score of 4–5, 17% had a score of 2–3 and 13% had a score of 1. Data from the Trauma Coma Databank revealed GOS scores in patients sustaining severe TBI of 4–5 in 43%, 2–3 in 21%, and 1 in 36% (110). The European Brain Injury Consortium survey revealed GOS score in patients with severe TBI at 6 months post injury of 4–5 in 45% 2–3 in 19% and 1 in 36% (111). Thus, in modern series, the majority of severe TBI patients have favorable outcomes, with few patients surviving with severe disability or in vegetative states.

Nevertheless, few patients sustaining severe TBI return to their premorbid functioning and the majority have significant cognitive and emotional sequelae (112). Tate et al. (113) found that 75% of patients surviving severe TBI have major disability in terms of reintegration with regards to employment, interpersonal relationships, functional independence, social contacts and leisure interests. Even among those with GOS scores of good recovery and moderate disability, only 50% had good psychosocial reintegration. Another series found a 70% unemployment rate at 1 year and a 24% rate of depression following severe TBI. Of these patients, impatience was the most frequently described behavioral problem. Thirty percent of these patients had returned to live with their parents, and relationship breakdown occurred for 38% (114). In another series looking at patients at 3 years follow up, though only 5% of the patients had a GOS of 2 or 3, half of surviving patients were noted to have social handicaps and 78% were noted to have neuropsychological impairment. Half of these patients suffered from headaches (115). Severe TBI patients continue to experience significant cognitive difficulties at 1-year post injury. Kersel et al. (116) followed 65 patients with severe TBI and assessed their GOS and neuropsychological outcomes at 6 months and then at 1 year. They assessed pre-morbid intellectual level, current level of general intellectual functioning, simple and complex attention, verbal memory, executive functioning and perceptual functioning: despite 51% of patients having a good recovery and 20% having moderate disability on the GOS, at best 31% and up to 63 percent had difficulty in neurocognitive tests administered 1 year post injury. Impairment was most frequently seen in verbal memory tests, complex attention tests and executive functioning. General intelligence and perception were among the areas least affected 1 year post-injury.

Depression, decreased social contact and loneliness remain persistent long-term problems for the majority of individuals with severe TBI (117). Hoofien et al. (118) assessed 67 patients at 10 to 20 years post TBI and noted serious psychiatric symptoms in this group. About half the patients had problems with hostility including temper outbursts and poor self control. Depression and anxiety were also very common. The psychological and emotional consequences of severe TBI present an enormous caregiver burden. Despite a high incidence of physical disability and cognitive impairment in severe TBI patients at 1 year, the presence of emotional difficulties may cause the most stress for care givers. Anger, dependency and apathy were all found in one series to be the most difficult emotional problems (in severe TBI patients) for caregivers to deal with; over one third of caregivers were found to have clinically significant anxiety and depression and over one quarter reported impairment in their own social adjustment such as problems in their marriages or continuing employment (119). Psychosocial problems and difficulties with re-entry into the community thus represent a major challenge in the rehabilitation of patients sustaining severe TBI (117).

### THE ROLE OF THE REHABILITATION SPECIALIST IN PATIENTS SUSTAINING TBI

The rehabilitation specialist plays a pivotal role in the treatment of those sustaining TBI. While emergency medical service personnel/paramedics, emergency physicians, trauma surgeons, neurosurgeons and critical care specialists may be involved in the initial encounter and acute inpatient management of patients sustaining TBI, the rehabilitation specialist is essential in directing appropriate rehabilitative services to the patient sustaining brain injury. For mild TBI, a single early intervention may be appropriate or more intensive services involving neuropsychiatric intervention may be needed in some cases (20, 120).

For more severe TBI, extensive rehabilitation is often needed. This may be better started off early rather than later, with resultant improved mobility and decreased length of acute rehabilitation stay (121, 122). Intensive rehabilitation may also improve early functional outcome of TBI patients (123).

Acute rehabilitation for patients with severe TBI starts in the comatose and early arousal states, with the goals of preventing orthopedic and visceral complications. Subsequent inpatient rehabilitation is designed to help impairments recover and to teach patients to compensate for their disabilities. This includes both psychological and physical therapy. A third phase, and perhaps most difficult, is therapy "for achieving physical, domestic and social independence, reduction of handicaps and

re-entry into the community (124)." One controversial area is sensory stimulation which is intended to accelerate recovery or arousal in patients who are comatose or vegetative. There is little evidence to support or to challenge this practice (125).

Rehabilitation specialists need to be aware of the possible causes of readmission to acute care for patients sustaining TBI, including the possibility of patients requiring further neurologic workup. During the first year post TBI, the most common reasons for rehospitalization include orthopedic or reconstructive surgery, followed by infectious disorders and general health maintenance. After the first year, seizures and psychiatric problems represent a considerable portion of admissions (126). In the case of new onset post traumatic seizures, a detailed workup with neurologic consultation should be pursued. Posttraumatic hydrocephalus may be another problem seen late after TBI. Symptoms include arrest in clinical progress, dementia, gait disturbance and incontinence (127). The threshold to obtain a repeat CT scan should be low in the TBI patient with any neurologic deterioration. It should be kept in mind that even after one year post injury, patients sustaining severe TBI may significantly benefit from inpatient rehabilitation (128).

### Conclusions

TBI remains an enormous problem despite advances in its management in the last 30 years. It represents a tremendous social and economic cost. The patient experiencing head injury should be evaluated in a systematic manner with attention being paid to the possibility of the presence of a mass lesion. This may mean the need for a mechanical airway, decompressive surgery and the possibility of ICP monitoring. Hypotension and hypoxia, in addition to elevated ICP, are critical secondary insults that must be avoided if possible. Outcomes from TBI continue to improve but are still hampered by significant psychological, cognitive and economic disability in survivors. The rehabilitation specialist plays a key role in the care of patients post severe TBI by being involved in acute care, inpatient rehabilitation, outpatient treatment, and, ultimately, societal reintegration.

## Assessment, Early Rehabilitation Intervention, and Tertiary Prevention

*W. Jerry Mysiw  
Lisa P. Fugate  
Daniel M. Clinchot*

**A**n estimated 5.3 million Americans live with a combination of chronic physical, cognitive and neurobehavioral impairments secondary to traumatic brain injury (TBI) that adversely affects daily function, social participation and/or quality of life (1). The annual economic impact for the direct care of TBI survivors, excluding inpatient care, has been estimated at \$25 billion.<sup>1</sup> Also, the annual incidence of TBI is estimated at 180–220 per 100,000 population. As the subsequent fatality rate is estimated at 10%, that suggests that approximately 550,000 persons are hospitalized annually in the United States with brain injury. The vast majority of survivors with a mild TBI are expected to have a good recovery, but as many as two thirds of survivors with a moderate TBI and approaching 100% of severe TBI survivors are left with permanent impairments and disabilities (1–2). It is apparent that the societal impact of TBI will continue to grow when one considers these statistics together with the observation that TBI primarily occurs in young adults.

Some of the impairments and disabilities after TBI can be attenuated by tertiary preventative measures such as early and adequate treatment directed at arresting the ongoing injury process, preventing complications and by the early use of comprehensive rehabilitative interventions. The role of early and comprehensive rehabilitation in achieving these goals is increasingly supported in the neuroscience

and neurorehabilitation literature that studies aspects of brain plasticity in both animal models and clinical paradigms. These areas of research have documented the importance of enriched environments and physical activity to neurogenesis and cell survival (3). Animal and clinical studies have also documented the negative impact on outcome secondary to chemical and physical restraints relative to participation in rehabilitation (3–5).

The initial psychiatric evaluation of a traumatic brain injury survivor should, therefore, ideally occur within the first twenty-four hours of the event. That is, rehabilitation should no longer be considered the final stage of the recovery process but rather rehabilitative assessment and intervention should be implemented during the acute recovery period and continue through the subacute and chronic stages for a comprehensive rehabilitation program that maximizes functional outcome. Indeed, a small yet compelling body of evidence continues to evolve supporting the concept that early application of rehabilitation strategies shortens the length of hospitalization and enhances the quality of outcome (3,6,7).

The issues that a psychiatrist needs to consider during the initial evaluation of a patient with a moderate to severe traumatic brain injury include: 1) an assessment of residual impairments, 2) an estimation of prognosis, 3) initiation of early rehabilitation intervention emphasizing preparation for ongoing rehabilitation needs and prevention of complications, and 4) formulation of a long-term

treatment plan that will address the rehabilitation and reintegration needs of the survivor. This chapter will review those issues that are most germane to the physiatrist during the acute care phase of intervention after a traumatic brain injury.

## ASSESSMENT

### Residual Impairments

The impairments incurred secondary to a severe traumatic brain injury can be broadly categorized as physical, cognitive and neurobehavioral. Potential impairments are numerous and have been comprehensively reviewed elsewhere. (8) A thorough documentation of all impairments and deficits during the initial physiatric evaluation is often neither practical nor possible in a coma emerging patient where arousal, awareness or communication may be compromised. However, attention should certainly be directed to those impairments that have prognostic implications and those that have an impact upon the immediate rehabilitation strategies. Because the majority of traumatic brain injuries result from motor vehicle accidents, (9) associated injuries that can have a significant impact on survival and functional outcomes are found in 60% of patients (10–12). Hence, it is incumbent upon the rehabilitation team to be cognizant of medical issues such as fractures, that may have been undetected during the acute stabilization (10).

The physical consequences of neurotrauma most critical for assessment and early intervention are those that effect swallowing, communication, mobility and locomotion. Preliminary swallowing evaluation and treatment recommendations can be done at bedside while the patient is still in the intensive care unit and completed as the patient becomes more alert. The establishment of a consistent communication system is a prerequisite for determining the extent of cognitive deficits and thus appropriate rehabilitation interventions. Disorders affecting mobility and locomotion are often the primary focus of the family and render the survivor at risk for secondary complications.

Cognitive deficits have a greater impact on functional outcome than the residual physical deficits in longitudinal studies (13). However, the specific cognitive deficits that most profoundly effect long-term outcome remain to be determined through further research. Thus, the cognitive skills most appropriate for screening during the initial assessment are those that effect communication and the ability to learn basic functional skills.

Neurobehavioral sequelae of severe traumatic brain injury can have similar global effects in all functional spheres and may have the greatest impact in long-term outcome (8). Agitation, the most dramatic behavioral disorder

observed in the coma emerging brain trauma survivor, has significant impact on the initial type of rehabilitation services. Both the presence and presentation of agitation have long-term prognostic implications (14,15).

### Prognosis

Predicting outcome after TBI serves several practical purposes. Estimating prognosis permits the development of a more meaningful individualized rehabilitation plan. The family and subsequently the patient benefit from the prognostic information as part of their adjustment to the catastrophic event. Finally, the ability to accurately predict outcome is important for program evaluation purposes and in designing studies targeted to influence functional outcome. To date, the studies designed to identify significant prognostic variables have resulted in two general observations. First, no single variable is adequate to predict an outcome from an injury as complex and heterogeneous as TBI. Second, the importance of prediction variables is predicated on the outcome of interest. For example, injury severity variables predict rehabilitation readiness and, to some extent, rehabilitation outcome, but these variables are less robust at predicting vocational outcome (2,6,16–19). Similarly, vocational outcome prediction involves knowledge of premorbid, social and disability variables that are not immediately critical to the early assessment of the TBI survivor (17–19).

At the initial physiatric evaluation, a number of prognostic variables are available that include premorbid, injury severity, impairments and functional characteristics (Table 19-1) (2, 20–22).

Age at the time of injury appears to be the most powerful premorbid prognostic indicator of both mortality and functional outcome. Studies stratifying severe TBI patients at 50, 60, 65 and 70 years of age have consistently shown that mortality dramatically increases with increasing age. This prognostic indicator remains significant even when the severity of the injury is controlled for by using the Glasgow Coma Scale (GCS), the Injury Severity Scale, or other measures of trauma severity (23). Mortality as high as

**TABLE 19-1**  
*Early Predictors of Outcome*

Age
Primary brain injury
Secondary brain injury
Glasgow Coma Scale
Pupillary response
CT scan
Sitting balance
Functional Independence Measure
Post-traumatic amnesia

79% has been described in patients greater than 60 years old, and 33% has been described in those under 40 years of age (6). This same study compared outcome at 6 months and found that a good outcome in the greater than 60 years old group was limited to 2%. In the under 40 years old group, 38% had a good outcome. Finally, age remained a significant prognostic indicator even after controlling for past medical history (24).

The type of central nervous system lesion incurred at the time of trauma has been correlated with both survival and functional outcome. For example, the presence of a mass lesion implies a higher mortality and a poorer functional outcome (2,25). Most studies agree that the injury with the highest mortality rate and the poorest functional outcome is the subdural hematoma (25,26). Other acute computed tomography (CT) scan changes that carry prognostic implications include the presence of third ventricle and/or basal cistern abnormalities, implying raised intracranial pressure in excess of 20 millimeters; the functional outcome of survivors with this acute CT scan finding remains poor at 6 months post-injury (27). Temporal lobe lesions, with a resulting midline shift of more than 4 millimeters, carry negative prognostic implications for both survival and functional outcome (28). Finally, basal ganglion hemorrhages are rare CT abnormalities after a severe traumatic brain injury. As a primary lesion, basal ganglion hemorrhages carry a fairly good prognosis with the majority of patients achieving a moderate or good functional outcome (29).

The most comprehensive assessment of the predictive value of early CT scan findings and functional outcome at one year looked at 849 patients who were admitted to inpatient rehabilitation and followed for 1 year (20). This observational study found that a midline shift of greater than 5 mm or a subcortical contusion resulted in greater assistance requirements for activities of daily living (ADL), ambulation and supervision, whereas, bilateral cortical contusions were associated with significant global supervision needs but not ADL or ambulation assistance needs (20).

Both coma duration and coma depth are important markers of injury severity with prognostic implications, but coma duration may be a better predictor of motor and cognitive recovery than coma depth (30–33). Coma duration and outcome, assessed by the Glasgow Outcome Scale, have been found to be correlated in that functional outcome is proportionately worse at 1-year post injury with increasing length of coma and patients who remain comatose for greater than 2 weeks rarely achieve a good recovery (34). At the other end of the spectrum, coma durations as little as 1 hour have also been found to effect outcomes such as subsequent employment (34). This relationship between coma duration and outcome is more prominent with diffuse axonal injury and appears somewhat linear in that there is no clear cut-off that predicts outcomes assessed by the Glasgow Outcome Scale (30).

Coma depth, as measured by the Glasgow Coma Scale (GCS), has been an important prognostic indicator of mortality and to a lesser extent, outcome. Glasgow Coma Scale scores during the first 24 hours post-injury appear to be better predictors of survival than scores after the first 24 hours, but GCS scores 2–3 days post-injury are better predictors of functional outcome. A review of the prognostic importance of the Glasgow Coma Scale by the Brain Trauma Foundation concluded that there is an increasing probability of poor outcome with decreasing GCS scores in a continuous stepwise manner (2). However, most of these studies collapse the Glasgow Outcome Scale into two or three outcome categories; the predictive value of the initial GCS score is poor when trying to be more precise in using all five Glasgow Outcome Scale variables (2). Early GCS scores have limited prognostic value for acute inpatient rehabilitation outcome. The initial and lowest 24-hour GCS score has limited value as a predictor of rehabilitation admission and discharge Rancho Los Amigos Levels of Cognitive Functioning Scale, Functional Independence Measure and Disability Rating Scale scores (35). Another study found that the GCS score did not predict the degree of improvement in the Functional Independence Measure score during inpatient rehabilitation (36). A more recent analysis of GCS scores found that the admission GCS score during a period between 1997 and 2001 was not as predictive of the Glasgow Outcome Scale score at six months post-injury as had been observed between 1992 and 1997 (37). These data appear to reflect a change in the early management of TBI patients with more aggressive resuscitation. For prognostic purposes, GCS scores should be obtained after the patient has been resuscitated and after pharmacologic sedating and paralytic agents are metabolized (2).

The duration of post-traumatic amnesia (PTA) is thought to have an even stronger relationship with outcome than depth or duration of coma. Periods of post-traumatic amnesia ranging from 1 hour to several days have resulted in impairment of divided attention as determined by the Paced Auditory Serial Addition Task (PASAT) that persist for 15 and 40 days post-injury, respectively (30). The duration of post-traumatic amnesia has also been found to be predictive of functional outcome as measured by the rehabilitation admission and discharge Functional Independence Measure and Disability Rating Scale scores (22). Data from the International Data Coma Bank have demonstrated that less than 2 weeks of PTA resulted in 80% of patients achieving a good recovery and 0% remaining in the severe disability functional outcome category; after 4 weeks of PTA, functional outcome diminished to 27% achieving a good recovery and 30% remaining severely disabled (34). Others have demonstrated that greater than 4 weeks of PTA results in virtually no patients achieving a good recovery. After 12 weeks of PTA, severe cognitive deficits

and a very poor prognosis for functional independence at 1 year are observed (30). As a caveat, the importance of PTA duration on functional prognosis is most translatable to injuries involving primarily diffuse axonal injury. The relationship between PTA duration and outcome in patients with predominantly focal pathology is less clear (34).

Two forms of secondary brain injury have been correlated with outcome, raised intracranial pressure and hypotension. Raised intracranial pressure has been shown to be a strong predictor of outcome per the Glasgow Outcome Scale (2,34,38). The effect of raised intracranial pressure on neuropsychological function is less clear. Both initial and maximum intracranial pressure have prognostic significance, however, maximum intracranial pressure better predicts outcome (39). The impact of intracranial pressure on outcome is unrelated to the age of the survivor, the GCS scores or the type of CNS lesion. Hypotension is perhaps the secondary brain injury most detrimental to survival and functional outcome. Hypotension, along with age, intracranial lesion, pupillary reactivity and post-resuscitation GCS score, is considered as one of the five most powerful predictors of outcome during the injury through resuscitation period (2). The presence of hypotension with systolic pressures of less than 90 mmHg or a cerebral perfusion pressure less than 70 mmHg at the time of resuscitation increases the mortality and significantly decreases functional outcome (40–43). In contrast hypoxia, although more prevalent than hypotension at resuscitation, results in only a slight increase in mortality and may have little impact on long term outcome (40).

Increasingly, studies have explored the relationship between impairments and extent of disability at the time of presentation to rehabilitation with functional outcome. One study looked at CT scan abnormalities present at the time of admission to acute rehabilitation; an association was noted with functional outcome and disposition at discharge from rehabilitation (44). Normal CT scans implied an 83% chance of achieving independent living skills, independent mobility and returning to home. On the other hand, large ventricles implied a very poor prognosis for independence in self-care skills and mobility. Only half of the latter patients were able to return to home (44). In addition, FIM scores at the time of initiating rehabilitation have been found to be useful predictors of discharge FIM score and rehabilitation length of stay (6). Similarly, FIM scores have been highly predictive of minutes of required assistance and the extent of supervision needs (45). The impairments that have a significant impact on FIM gain and efficiency are varied but include cognition, balance and medical comorbidities (15,16,21,46).

In summary, traumatic brain injury outcome is too complicated to be predicted accurately with one or several variables. Also, this literature is limited in that the overwhelming preponderance of studies exploring the

impact of premorbid, acute injury and post-injury indicators on functional outcome have utilized the Glasgow Outcome Scale as the primary outcome measure; the Glasgow Outcome Scale, however, provides limited information concerning functional skills and limited insight into the comprehensive cognitive, behavioral, and physical deficits common after a traumatic brain injury. Increasingly, studies are examining the prognostic information available at the time of presentation to rehabilitation. At this time, the strength of these predictors remains inadequate to dictate the rehabilitation programming needs of an individual. Hence, the increasing availability of good prognostic information assist the physiatrist in developing an appropriate comprehensive rehabilitation plan, but the data to date remain inadequate to supersede clinical judgment.

### **Early Rehabilitation Intervention**

The significance of early and more aggressive rehabilitation on improving functional outcome has been supported through the observations that prolonged acute care length of stay and a subsequent delay in the onset of multidisciplinary rehabilitation is associated with a longer rehabilitation hospitalization and lower functional outcome (7,47,48). However, functional outcome between the early admission and the late admission groups appears comparable at 2 years (47). These observations, however, cannot exclude the impact of other TBI comorbidities on observed outcomes. Another study examined early intervention on a neurotrauma service while the patient was still on a ventilator (49). Early intervention resulted in shorter rehabilitation stays, higher Rancho levels at discharge from rehabilitation, improvement in the percentage of subsequent patients requiring institutional placement after acute rehabilitation and perhaps most remarkably, shorter durations of coma. Similarly, studies have found that earlier psychiatric involvement after TBI is associated with better functional outcome presumably due to the subsequent earlier initiation of multidisciplinary rehabilitation interventions (50). Studies such as these are of enormous significance because the role of rehabilitation in decreasing impairments, disability and handicap while also decreasing long-term health care expenditures has never been directly proven. These studies, however, are part of a growing body of evidence that support the important role of early rehabilitation intervention.

### **Management of the Minimally Responsive Patient**

Definable stages of recovery have been reported for patients emerging from traumatic coma. These stages have been most lucidly outlined by Hagen, Malkmus and

**TABLE 19-2**  
**Rancho Los Amigos Levels of Cognitive Functioning**

I. No response
II. Generalized response
III. Localized response
IV. Confused – agitated
V. Confused – inappropriate
VI. Confused – appropriate
VII. Automatic – appropriate
VIII. Purposeful – appropriate

Durham who developed the Rancho Los Amigos Scale of Cognitive Functioning (Table 19-2) (51).

This scale uses behavioral observation to categorize a patient's level of cognitive functioning; it works well as a simple means by which clinicians can communicate an individual's level of cognitive functioning and develop appropriate rehabilitation strategies.

The initial three Rancho stages represent the low level, or minimally responsive, brain injury survivor. A patient emerging into Level III begins to demonstrate localized responses such as tracking, pulling tubes, restlessness and the beginning of command following. Responses initially are inconsistent, and become more reliable as the patient progresses through stage IV. Recovery through Rancho Levels I, II and III may be protracted in one of eight severe TBI survivors (52). Therefore, objective means to document progress, monitor cognitive status and determine the therapeutic efficacy of intervention becomes an important adjunct in the clinical management of vegetative or low level, coma emerging populations. Examples of two scales utilized for the monitoring of vegetative or low functioning, coma emerging survivors are the Western Neurosensory Stimulation Profile and the Coma/Near Coma Scale.

The Coma/Near Coma Scale consists of eight parameters each with a specified number of stimuli and trials (53). Based on the numerical scoring system, patients are stratified into 1 of 5 categories: no coma, near coma, moderate coma, marked coma and extreme coma. The Coma/Near Coma Scale can be administered quickly. The Western Neuro Sensory Stimulation Profile is a more extensive instrument that consists of 32 items that assess arousal, attention, response to stimuli and expressive communication (54). This instrument, however, requires 20–40 minutes to complete. Both instruments have good interrater reliability and documented construct validity. However, the literature describing the utility of these or other instruments for monitoring the clinical course of vegetative or coma emerging patients remains limited.

Coma rehabilitation, or multisensory stimulation programs are rehabilitation programs designed for patients

that are in coma, coma emerging or a vegetative state that have as a primary purpose the prevention of complications associated with prolonged immobilization and the creation of an environment in which the patient has the maximum chance to emerge. This is accomplished by means of a multidisciplinary program involving medical and nursing interventions, sensory stimulation, regular exercise and family education (55,56). It is believed that in this environment, central nervous system pathways will begin to be able to process information with increasing complexity. Advocates of these programs profess that their intervention potentiates the maximum chance of recovery, allows close monitoring of cortical function and facilitates the development of the best overall care plan for the patient. However, a recent review of sensory stimulation literature for brain injured patients could find no adequate clinical trials or evidence to support, or for that matter, rule out the effectiveness of multisensory programs for patients in coma or vegetative states (56).

Multisensory stimulation programs typically stimulate the five senses directly and the patient responses are assessed with the intent of advancing the stimulations as the complexity of response increases (55). However, the optimal nature and frequency of stimulation remains to be defined and varies considerably through the literature. Programs range in intensity between two sessions of 10 minutes each per day to 36 repetitions of the sensory stimulation procedure per day, 7 days per week (55–58). In addition to the lack of consensus as to the nature of the intervention program, interpretation of the available literature suffers from a lack of consistency in definitions of coma or the vegetative state (56). Frequently, the outcome measures were either not objective or lacked clinical significance. These methodologic issues lead one to conclude that there is no compelling evidence to support or refute the possibility that the multisensory stimulation interventions are more effective than standard multidisciplinary rehabilitation at arousing the patient from coma or reducing the time to recover from coma (56). However, in view of the medical, psychological, economic and social implications associated with the treatment of this population, well designed investigation of multisensory stimulation after brain injury is warranted to determine if this strategy should be incorporated as a standard of care.

### Post-Traumatic Amnesia

Post-traumatic amnesia (PTA) represents a form of delirium that is both unique to traumatic brain injury survivors and universal in that all survivors of moderate and severe TBI experience post-traumatic amnesia. The period of post-traumatic amnesia has considerable clinical significance. Prognostic information can be discerned from this stage of recovery and both the cognitive and behavioral characteristics of post-traumatic amnesia have

an immediate impact on rehabilitation intervention strategies.

The definition of post-traumatic amnesia has evolved over time. Initially it was described by Russell as indicating a period of impaired consciousness after head injury (59). Later post-traumatic amnesia was defined as “taken to end at the time from which the patient can give a clear and consecutive account of what was happening around him” (60). Others have described post-traumatic amnesia as an absence of continuous memory or an inability to retain new information. Today, post-traumatic amnesia suggests the broader syndrome of disorientation to time, place and person, confusion, diminished memory and reduced capabilities for attending and responding to environmental cues (61).

Symonds in 1928 was the first to identify length of coma as an estimate of prognosis after brain injury (62). In 1882, Ribot proposed a classification of amnesia that included both anterograde and retrograde amnesias (63). The concept and clinical significance of post-traumatic amnesia, however, was first suggested in 1932 by Russell (59). Retrograde amnesia implies an inability to retrieve information that was acquired prior to the onset of a specific pathologic event (64). Typically retrograde amnesia involves a gradient; events closer to the injury are less likely to be recalled than earlier memories occurring before the injury. As the patient improves and confusion clears, the duration of retrograde amnesia usually shrinks from perhaps years to approximately 30 minutes or so preceding the pathologic event. After the survivor clears post-traumatic amnesia, the retrieval of remote memory remains impaired but there is no longer a temporal gradient; that is, there is not selective sparing of the oldest memories (64,65). Retrograde amnesia is rarely an isolated event and typically, post-traumatic amnesia is significantly longer than the duration of retrograde amnesia (66).

Post-traumatic amnesia is rarely if ever complete (67). Levin, et al found that during post-traumatic amnesia, initial learning and accelerated forgetting are both problematic but forgetting is particularly accelerated whereas acquisition of new information is less impaired (68). Also, patients during post-traumatic amnesia can demonstrate long-term learning, especially involving tasks that require limited attention. For example, a patient may demonstrate learning during post-traumatic amnesia in situations where the probability of response is increased with repetition (69). A patient may also learn during post-traumatic amnesia through stimulus response training such as acquisition of motor skills (60). The concept of learning during post-traumatic amnesia is salient to the rehabilitation professional in that issues of self-care, mobility and locomotion can be successfully addressed during this amnesic stage. Similarly, problem behaviors can be addressed during this amnesic state with behavioral interventions that are consistent and repetitious.

The duration of post-traumatic amnesia is a marker of injury severity and carries significant prognostic implications. By 1961, the duration of post-traumatic amnesia was thought to represent “the best yardstick we have” of blunt head injury severity (70). Over the decades, it has been demonstrated that the length of post-traumatic amnesia is predictive of functional outcome, return to work, occurrence of post-traumatic epilepsy and cognitive recovery (19,22,71–79).

Predicting resolution of post-traumatic amnesia also carries significant therapeutic implications in that the resolution of post-traumatic amnesia is often associated with a marked improvement in behavior, a reduction in agitation, an improvement in attention, a readiness to tolerate the demands of a more comprehensive neuropsychological assessment, and an increase in capacity to more fully participate in a comprehensive rehabilitation program (80). Therefore, predicting whether and when a patient will clear post-traumatic amnesia is useful in establishing a survivor’s programming needs. It has been speculated that the duration of post-traumatic amnesia is approximately four times the duration of coma, but other studies have failed to support the length of coma as a reliable predictor of clearing post-traumatic amnesia (80,81). A younger age implies a greater likelihood of clearing post-traumatic amnesia but age does not accurately predict when the survivor will clear this stage. Finally, several attempts to predict post-traumatic amnesia duration early in the post-acute period utilizing validated instruments that prospectively measure post-traumatic amnesia duration have yielded mixed results. Specifically, time after trauma and the first weekly aggregate score assessed by the Orientation Group Monitoring System accounted for only 15.9% of the variance (80). However, a model utilizing the Modified Oxford PTA Scale found that a three variable regression model, consisting of day after trauma when testing was started, rate of change of post-traumatic amnesic scores over the first 5 days of testing and the score on the first day of testing accounts for 89% of the variance in observed length of post-traumatic amnesia (82).

Traditionally the duration of post-traumatic amnesia has been estimated retrospectively. This is potentially problematic in that islands of intact memory may develop when the patient otherwise is unable to sustain continuous memory (83,84). Therefore, retrospectively inquiring as to the time of the first intact memory post-injury could result in an underestimation of post-traumatic amnesia duration. Similarly, retrospectively inquiring as to the interval when orientation normalized can lead to a misleading estimate of post-traumatic duration; 10% to 20% of survivors may be oriented without having cleared post-traumatic amnesia (83,85).

The first instrument developed to prospectively assess the duration of post-traumatic was the Galveston Orientation and Amnesia Test (GOAT) (84). This instrument is

**TABLE 19-3**  
*Prospective Measures of Post-Traumatic Amnesia Duration*

Galveston Orientation and Amnesia Test (68)

Orientation Group Monitoring System
Westmead PTA Scale (91)
Julia Farr Services PTA Scale (92)
Modified Oxford PTA Scale (24)

reliable (Kendall Correlation Co-efficient of 0.99). The core application for this instrument is the assessment of temporal orientation. This instrument can be administered daily at bedside during the course of a brief interview. Construct validity for the GOAT has been demonstrated through correlation with Glasgow Outcome Scale level, the severity of computed tomography findings, and functional outcome. Finally, the GOAT's brevity renders it more applicable to monitor recovery through PTA in the acute care setting than the other more extensive assessments of PTA such as the Orientation Group Monitoring System (86–89). Other instruments have subsequently been developed to prospectively measure the duration of post-traumatic amnesia (Table 19-3) (90–92).

Each instrument emphasizes different constructs of post-traumatic amnesia, and with the exception of the Orientation Group Monitoring System, are generally brief, lending themselves to bedside utilization. The Orientation Group Monitoring System is based on behavioral observations during a scheduled therapeutic orientation group and, therefore, is appropriate for an inpatient rehabilitation setting where its utility in the early detection of evolving medical complications that present as a decline in cognitive function can be utilized (89). The Galveston Orientation and Amnesia Test is the most widely utilized prospective assessment of post-traumatic amnesia with well established, sound psychometric properties (93).

Thus, the period of post-traumatic amnesia has important clinical significance. The duration of PTA carries prognostic implications concerning long-term outcome. During PTA, acquisition and storage of memory are impaired but under proper circumstances, new functional skills can be acquired. Finally, the behavioral and cognitive abnormalities characteristic of PTA carry significant therapeutic implications regarding supervision needs and formalized programming needs.

### **Agitation**

Perhaps the most compelling behavioral change during post-traumatic amnesia is post-traumatic agitation. Denny-Brown (1945) first described restlessness as a

natural sequela of traumatic brain injury (94). The classic example of agitation is the patient at Level IV of the Rancho Los Amigos Level of Functioning who is “confused-agitated” and functioning in a heightened state of activity and diminished capability for processing new information or responding to events in the environment. Various estimates of agitation incidence have ranged between 11%, 33% to over 50% (95,96). In part, this disparity was related to the absence of a consistent definition. In 1996, Sandel and Mysiw defined post-traumatic agitation as a subtype of delirium unique to TBI patients who are still in post-traumatic amnesia and who demonstrate excesses of behavior that include akathisia, aggression and emotional lability (97). This definition is consistent with the constructs defined in both the Agitated Behavior Scale, a reliable and valid instrument, designed to measure the severity and nature of post-traumatic agitation (98), and a survey of expert TBI rehabilitation psychiatrists (99).

The initial approach to the agitated patient includes a comprehensive examination emphasizing other medical or neurologic etiologies for the observed behavior prior to initiating treatment strategies. Fractures, peripheral nerve injuries, skin lesions, J/G-tube sites and tracheotomy sites, for example, are potential sources of noxious stimuli that left untreated with appropriate analgesia may present as agitated behavior in the coma emerging, confused patient. In addition, all medical conditions that have the potential to result in a decline in mental status or cognitive function should be considered as studies have shown that cognition improves before agitation and a decline in cognition often results in an increase in agitation (15,100). Also, all pharmacologic interventions should be reviewed for evidence of toxicity or adverse reactions.

Management strategies utilized in treating agitated behavior include one-to-one monitoring, behavioral modification, physical restraints, environmental modification and pharmacologic intervention (101). As rehabilitation stays shorten, the prompt resolution of agitation becomes increasingly important so as to not interfere with other treatment goals (101). Therefore, pharmacologic intervention has also become increasingly important as an adjunct in the treatment of the agitated traumatic brain injury survivor.

There have been six randomized clinical trials published exploring pharmacologic treatment options for agitated aggressive behavior after brain injury (102–107). Four of these studies looked at the role of beta blockers, one studied methylphenidate and the sixth study utilized amantadine. The beta blockers did appear to be most effective, but the population studied was not limited to traumatic brain injury survivors. The methylphenidate study looked at an aspect of agitation, namely aggression, in a group of TBI survivors who cleared post-traumatic amnesia. The amantadine study utilized a behavioral outcome not ideally suited to the assessment of post-traumatic agitation.

The balance of the studies exploring the efficacy of pharmacologic interventions for post-traumatic agitation are primarily case reports or series that utilized an AB rather than ABA design and lacked a reliable outcome measure. Also, these studies fail to consider the impact of the pharmacologic intervention on outcome. As previously noted in the post-stroke population, evidence has begun to emerge that suggests that certain categories of pharmacologic agents utilized in the acute care setting, namely neuroleptics, do have a negative impact on cognitive recovery during the rehabilitation setting (108).

Several classes of medications are most commonly utilized in the management of post-traumatic agitation (Table 19-4).

A survey of the American Academy of Physical Medicine and Rehabilitation Brain Injury Special Interest Group in 1997 revealed that the five most frequently prescribed drugs to diminish the severity of post-traumatic agitation were carbamazepine, tricyclic antidepressants, trazodone, amantadine and beta-blockers (99). During episodes of extreme agitation, the literature appears to support abortive agents such as short-acting benzodiazepines or atypical antipsychotics (109).

Data suggest that as patients emerge from coma, improvement in cognition precedes resolution of agitation (15,87). This supports the clinical observation that agitation management strategies that diminish cognition may, in fact, prolong and exacerbate agitation. Therefore, the ideal pharmacologic management of post-traumatic agitation would include the simultaneous objective monitoring of both the agitation severity and cognitive function. The Agitated Behavior Scale has been validated to provide an assessment of agitation severity, duration and the relative contribution of aggression, disinhibition or lability to the observed behavior (98). Two instruments that lend themselves to monitoring cognitive recovery during pharmacologic intervention of agitation include the previously mentioned Galveston Orientation and Amnesia Test and the Orientation Group Monitoring System (84,86). In the rehabilitation setting, the Orientation Group Monitoring System does offer a distinct advantage over the GOAT

through its increased sensitivity in detecting medical complications such as adverse drug effects, infections and hydrocephalus (88). The GOAT's brevity renders it the more useful instrument in the acute care setting.

In summary, multiple pharmacologic treatments have been proposed for the management of post-traumatic agitation; the efficacy and indications remain largely unproven. The optimal medication would: 1) control behavior without sedation; 2) augment or at least not delay or interfere with recovery of cognition; and 3) maintain a low side-effects profile. Given the heterogeneity of primary and secondary brain injury mechanisms, injury severity, presence of pre-existing conditions and the variable clinical presentation of post-traumatic agitation, it is unlikely that one pharmacologic agent will evolve as effective in the management of agitation in all or even a majority of survivors.

### Cardiovascular Autonomic Disorders

Cardiovascular disorders associated with TBI may include rhythm disturbances, ischemic changes, cardiac contusion, hypotension and hypertension. Of these, hypertension is the most common and immediate cardiovascular disorder associated with severe head injury (110). In fact, autonomic dysfunction has been reported in 15–33% of acute brain injury survivors (111,112). The condition is most commonly found after brainstem or diffuse axonal injury. Although tachycardia, fever and hypertension represent the most frequent presenting signs, the physical findings could include any combination of autonomic disturbances. (Table 19-5).

This diagnosis of autonomic dysfunction is a diagnosis of exclusion (Table 19-6) (111,112).

In the event that the clinical picture primarily involves hypertension, then other etiologies can be considered such as increased intracranial pressure (113), hydrocephalus (114), or medications such as steroids or nonsteroidal anti-inflammatory drugs.

The presence of autonomic dysfunction is associated with morbidity, due to possible secondary myocardial infarction, intracerebral hemorrhage, rhabdomyolysis. The hypertension and associated medical instability may

- Malignant hyperthermia
- Pheochromocytoma
- Thyroid storm
- Delirium tremens
- Lethal catatonia
- Serotonin syndrome

preclude initiation of most direct rehabilitative interventions. As such, patients who experience autonomic dysfunction are likely to require longer periods of inpatient rehabilitation and tend to have a longer period of post-traumatic amnesia, poorer Glasgow Outcome Scale score and lower Function Independence Measure score.

Again, although autonomic dysfunction is seen in 15–28% of TBI survivors acutely in the rehabilitation setting, the incidence is estimated to be between 10 and 15% and the prevalence diminishes rapidly to less than 3% after discharge (110,115). In Labi and Horn's retrospective study of 74 patients with no premorbid history of hypertension who were discharged from a rehabilitation hospital after their first TBI, only 11 (15%) developed hypertension during admission (115). Five (7%) were discharged on anti-hypertension medication, of whom 3 were able to discontinue or reduce medication at 1 month after discharge and 2 were lost to follow-up. In the interim, the treatment involves controlling the blood pressure with beta blockers or alpha blockers (116). In the more advanced forms of autonomic dysfunction, spasmolytics such as dantrolene, and analgesics such as opiates and either dopamine agonists or antagonists may prove effective at ameliorating some of these symptoms (117).

Hypotension in the rehabilitation setting is frequently associated with prolonged bed rest or medication adverse effects, volume depletion or neuroendocrine abnormalities. The most common medications causing orthostatic hypotension are anti-hypertensive, in particular diuretics, alpha blockers and vasodilators.

Electrocardiographic abnormalities commonly accompany early recovery from TBI. Incidence after severe head injury varies from greater than 80% during the acute medical admission (118) to approximately 20% during inpatient rehabilitation (110). ECG evidence suggesting myocardial ischemia, including prolonged QT interval, inverted T waves, and ST segment elevation has been well documented in the neurosurgical literature (113,118,119). Myocardial injury has been corroborated through

laboratory medicine and at autopsy. CK-MB activity may remain elevated at least 3 days after injury (113). Histologic evidence of myocardial necrosis at autopsy has confirmed the presence of myocardial injury following head injury (120). In the absence of direct cardiac trauma, myocardial damage may be secondary to massive release of catecholamine from autonomic dysfunction (121).

Dysrhythmias appear to occur less commonly, although the incidence has not been studied after TBI. Case reports include life-threatening torsades de pointes, concomitant pulsus alternans and U-wave alternans, transient heart block ranging from prolonged PR intervals to high-grade AV block with ventricular escape rhythm (121–124). Most commonly seen in the rehabilitation setting are nonspecific ST and T wave changes (110). Given the potential for underlying myocardial damage, baseline EKG at the time of rehabilitation admission is a valuable screening exam and an important adjunct to a thoughtful cardiopulmonary evaluation.

### Respiratory Disorders

Respiratory or pulmonary complications noted after traumatic brain injury include those directly related to trauma such as pneumothorax, hemothorax and flail chest. In addition, a number of pulmonary complications occur that are at least, in part, related to the subsequent neurologic dysfunction, including: respiratory failure, pneumonia, neurogenic pulmonary edema and tracheal/airway complications (125). Pulmonary complications are the most frequent complications occurring after the acute trauma through the rehabilitation hospital stay, with up to 60% of patients experiencing pneumonia, respiratory failure occurring in up to 43% and 39% requiring a tracheotomy (16,125–132).

In a British analysis of mortality after pediatric TBI, 93% of potentially preventable deaths prior to hospital admission were of respiratory etiology, predominantly aspiration (133). Following admission one quarter of all deaths were attributable to pulmonary abnormalities. Of those considered to be preventable deaths, nearly 60% were secondary to respiratory arrest or airway obstruction. More recent data has documented that the presence of respiratory failure, pneumonia and tracheotomies show a strong relationship to both acute and inpatient rehabilitation length of stay (16). In addition, those survivors without respiratory failure or who did not require a tracheotomy demonstrated a better one year outcome per the Disability Rating Scale and the Function Independence Measure (16).

Alcohol intoxication, frequently associated with TBI, is a significant risk factor for respiratory complications. In a study of 520 patients, nearly 40% were intoxicated at the time of admission (134). Although injury severity appeared similar to the non-intoxicated cohort, intoxicated patients were 30% more likely to require

intubation prior to admission and 80% more likely to have respiratory distress requiring artificial ventilation during the acute care admission. Potential factors contributing to a 40% greater risk of pneumonia included ethanol related immune suppression, a higher likelihood of aspiration and/or a higher prevalence of pneumonia preceding the TBI. Of note, where alcohol intoxication was documented on admission, length of hospital stay was not extended unless pulmonary complications developed, specifically respiratory distress or pneumonia. Given the frequency of these complications, alcohol intoxication complicating TBI has obvious economic and public health ramifications.

The majority of patients who undergo tracheotomy will recover sufficient neurologic integrity to consider decannulation. Decannulation is pursued when the individual no longer requires ventilation, effectively manages their secretions and is thought to be at low risk for aspiration (125). There is no standardized protocol for decannulation. Usually this is accomplished in a stepwise fashion with incrementally decreasing the cannula diameter followed by a trial of plugging the tube; if the patient is asymptomatic, has an effective cough and manages their secretions, then the tube is finally removed and an occlusive dressing is applied (125). Prospective studies of patients with long term tracheotomy, using direct laryngeal visualization prior to decannulation have demonstrated an incidence of serious abnormalities which exceeds 30%, in both the acute and subacute setting (129–131). Tracheal stenosis, subglottic stenosis, glottic stenosis, tracheomalacia, tracheal granuloma are seen most frequently with varying degrees of clinical symptoms. In view of these complications, direct laryngoscopy prior to decannulation has been suggested.

Where studies have stratified by cognitive level, as expected, morbidity and mortality are much higher for decannulation at Rancho Levels II and III (129). Central respiratory lability and poor pulmonary toilet with resultant pneumonia leading to sepsis contribute significantly to the increased mortality in the vegetative and coma emerging patient. Hence, the appropriateness or merit of decannulating patients who remain severely neurologically compromised remains uncertain. On the other hand, predictors of successful decannulation include: 1) traumatic mechanism of brain injury; 2) younger age; and 3) alert cognitive status (130). Also, of those in whom adequate cough and swallowing reflexes have been documented, complications are not observed to correlate with age, diagnosis, Rancho scale or duration of tracheotomy (131).

Several factors may predispose to increasing laryngotracheal mucosal reaction following traumatic brain injury (129). Emergent intubation frequently occurs under less than optimal circumstances. The peri-injury and acute stabilization period are frequently complicated by hypotension and resultant tissue hypoxia (129). Cervical

hyperextension associated with decerebrate or decorticate posturing can enable the posterior pharyngeal tissues to act a fulcrum for the rigid endotracheal tube (132). Head movement, potentially creating a see-sawing movement of the tube, may be marked with agitation (132).

Prolonged tracheal intubation is known to result in a number of complications. These complications can be diminished with proper choice of tube, meticulous attention to details of airway management to prevent excessive movement of the tube during turning, suctioning, and ventilator connection/disconnection, adequate sedation to prevent coughing, agitation and decerebrate or decorticate posturing, adequate humidification, use of soft nasogastric tubes, and prevention of tissue hypoxia, anemia and infection all of which further increase the risk of tissue injury.

### Fever

A common acute complication after a severe traumatic brain injury is fever. Although frank fever of unknown origin (temperature elevation of greater than 38.2° C on several occasions over at least a 3 week period of time and an inability to diagnose the underlying etiology after at least 1 week of intensive investigation) (134) is unusual, a similar systematic approach to diagnose the underlying etiology is often warranted. The differential diagnosis for fever of unknown origin is extensive and includes infectious, neoplastic, autoimmune, granulomatosis, metabolic, inherited, psychogenic, periodic and thermoregulatory disorders (134). The list of likely sources of fever after a severe traumatic brain injury is less extensive but this framework is often useful for accurate diagnosis (135).

Urinary tract infections affect approximately 40% of traumatic brain injury survivors during the rehabilitation phase of recovery (110). Ureteral obstruction is seen in approximately 1% of patients after a traumatic brain injury. Other potential genitourinary sources of fever include pyelonephritis, perinephric abscess and prostatic abscess.

Approximately 34% of traumatic brain injury survivors develop respiratory complications that predispose them to pulmonary infections (110). Poor ventilation with secondary atelectasis is thought to be the most common pulmonary complication of trauma and a potential forerunner of pneumonia. Tissue necrosis secondary to lung trauma with subsequent formation of a pulmonary cavity may also predispose the patient to secondary lung infections (136). The presence of endotracheal or tracheotomy tubes predispose patients to bacterial colonization and a greater risk of secondary lung infection. Finally, tubes utilized for enteral feeding increase the probability of aspiration pneumonia by as much as 25%.

The head and neck area includes several other potential sources of fever after a traumatic brain injury.

For example, perinasal sinusitis after nasotracheal intubation has been estimated to occur in approximately 26% of patients (139,140). Also nasogastric intubation has been reported to cause a similar rate of sinusitis and fever in trauma survivors. Finally, within the head and neck area, dental abscess is a potential etiology secondary to teeth rendered non-viable by trauma (141).

Cardiovascular etiologies for fever include subacute and acute endocarditis (142), dissecting aortic aneurysm (143), intravenous line sepsis (144) and thromboembolic disease (145). The incidence of thromboembolic disease after traumatic brain injury has been reported to occur at a rate as low as 4% during the rehabilitation course. However, this incidence is possibly low due to the nonspecific clinical presentation of thromboembolic disorders and the concomitant issue of impaired arousal and cognition.

Other sources for fever include musculoskeletal etiologies such as heterotopic ossification, (146) which can mimic deep venous thrombosis in its presentation, and osteomyelitis from either hematogenous or contiguous spread (110). Perisplenic, pericardial and retroperitoneal cryptic hematomas have been associated with a prolonged fever after trauma (110,147). Adverse reactions to medications includes drug fever; an important and potentially life threatening example of this would be the neuroleptic malignant syndrome (148,149). Finally, neurologic etiologies for fever after trauma would include bacterial meningitis, infected intraventricular shunts, hyperthermia reactions to acute hydrocephalus, neurogenic hyperthermia and the post-ictal period (150–154).

### **Bladder and Bowel Function**

Traumatic brain injury often results in injury to the frontal lobes resulting in loss of cortical control over urination and defecation (155). In addition, injury to the subcortical structures can result in the development of bladder dysnergia. In one large study of brain injury survivors, 38% of patients developed urinary tract infections. Although the majority of these patients had indwelling Foley catheters, 37% did not. Therefore, bladder dysfunction was seen in 8% of the cohort (110).

The incidence of urinary incontinence during the first 6 weeks after TBI has been found in approximately 62% of patients (156). Also, 9.5% of survivors are found to have evidence of urinary retention (156). Urodynamic studies primarily document an uninhibited over active bladder where the patient demonstrates loss of voluntary control over micturation, disturbed bladder perception and poor sphincter control to the extent that upon virtually the first sensation of filling, the patient develops almost immediate micturation (157).

The clinical significance of urinary incontinence and retention early in the coma emerging brain injured patient is that this increases the risk of urinary tract infection and

the development of skin ulcer (156,157). Also, the presence of urinary incontinence is associated with a poorer functional outcome at discharge from both acute care and inpatient rehabilitation and it increases the likelihood of requiring a long-term care disposition (156).

Treatment options for urinary incontinence after TBI includes behavioral strategies such as a timed voiding program (158). All predisposing factors to urinary tract infections such as Foley catheters, bladder retention, fecal incontinence, and inadequate hydration, are removed or addressed. A timed voiding program initially begins with toileting the patient frequently with gradual increases in interval length. For the patient who voids frequently in small amounts with low post-void residual volumes, anti-cholinergic agents can be considered as an adjunct (159). However, important possible adverse effects of anti-cholinergic agents include a slowing of cognitive recovery, worsening of delirium and the development of urinary retention.

Bowel dysfunction after traumatic brain injury often results from a loss of cortical control over the defecation reflex causing the patient to be incontinent. In addition, constipation is a frequent occurrence in the acute care setting due to lack of mobility, use of potentially constipating medication and alteration in normal diet. Stool softeners, osmotic laxatives, stimulant suppositories and adequate hydration are often helpful initially to maintain bowel regularity. As the patient recovers, the bowel program should be tailored to additionally utilize the gastrocolic reflex, approximately 30 minutes after eating, as well as gravity by having them sit in an upright position to defecate. As noted with urinary incontinence, the presence of bowel incontinence is associated with a more severe injury and poorer functional status at both acute care and other inpatient rehabilitation (160).

Diarrhea is a common occurrence in low level brain injury patients on enteral feedings. This can lead to loss of skin integrity, infect pressure sores and other wounds, and result in severe dehydration. Use of formulas high in fiber, and using isosmotic formulas are often helpful. Supplementing the enteral feeding with fiber compounds such as psyllium mucilloid can also be helpful in forming stool. The use of anti-diarrheal medications are not necessary and in the case of loperamide can be potentially sedating. Patients after severe traumatic brain injury often require antibiotic treatment for various infections, are debilitated, and in the hospital; thus they are at significant risk for the development of bowel infections. In the patient who has persistent diarrhea, infectious etiology should be considered (139).

### **Swallowing and Nutrition**

Two primary nutritional issues confront the TBI survivor, the timing of initiating nutritional support and the optimal

route of administration. After moderate or severe TBI, the patients demonstrate and increase in caloric requirements (161) due to hyper metabolism, increased energy expenditure and increased protein loss (162–164). This state can persist for up to 4 weeks (121). Studies have shown that early nutritional support prevents the loss of immune competence, decreases morbidity and mortality, shortens the length of hospital stay and may decrease subsequent disability (165–168).

The merits of enteral (gastrostomy versus jejunostomy) versus parenteral routes of nutritional support are not resolved. As arousal improves, swallowing evaluations involving a combination of bedside swallowing assessments or video fluoroscopy, are performed by a speech-language pathologist or occupational therapist, are warranted as swallowing disorders are estimated to occur in 25–30% of brain injury survivors (169,170). The video fluoroscopic evaluation is often an essential adjunct in the evaluation of these patients because physical findings alone are not sufficiently sensitive to predict the ability to safely swallow. In a study by Winstein, (170) 12% of patients with swallowing disorders had normal gag reflexes and 77% has a good voluntary cough reflex. Thus, the information provided by a comprehensive assessment helps the clinician to make important judgments about the patient's ability to begin oral feeding and which swallowing strategies would most facilitate safe swallowing.

At first, oral feeding is often restricted to therapeutic purposes and requires the direct supervision and intervention by a speech-language pathologist or occupational therapist. Safe therapeutic feeding is additionally predicated on the survivor's behavioral sequelae; behaviors such as agitation, impulsivity, lack of initiation, and hyperphagia should be monitored for and, when present, treated using appropriate behavioral management interventions. After oral feeding has begun, it is sometimes difficult for the patient to maintain adequate caloric intake necessitating a combination of oral and enteral feeding and close monitoring of nutritional status. Attempts to advance oral feeding are intermittently slowed by the loss of appetite. In these instances, a specific etiology should be sought such as an evaluation of taste and smell due to cranial nerve or cortical dysfunction, as well as local trauma, leading to anosmia and/or gustatory dysfunction. Depression, neuroendocrine perturbations and pharmacologic interventions should also be considered as etiologies for decreased appetite.

### **Spasticity, Dystonia and Other Muscle Overactivity**

After a traumatic brain injury, spasticity, dystonia and other forms of muscle overactivity are not limited to the limbs but can also present in the torsal, facial, and oral pharyngeal musculature. Interventions are clearly

warranted when the muscle tone significantly interferes with achievement of rehabilitation goals. Otherwise, it is a commonly held tenet that spasticity should not be treated unless it interferes with function. However, the veracity of this approach in a coma emerging patient, where plasticity may be affected by the consequence of abnormal tone has not been adequately studied.

The first stage of treatment for spasticity involves physical modalities, range of motion, and exercise.

Cryotherapy has been found to be helpful in temporarily reducing spasticity for 1 to 3 hours after application (171). This is often sufficient time to allow for therapeutic interventions including serial casting, ambulation or range of motion exercises. Application of casts to preserve or increase range of motion has been shown to have a secondary beneficial affect on reducing spasticity (172). Thus, through the use of serial casting early in the care of brain injury patients, improvements in tone and maintenance of joint range of motion can be fostered.

If spasticity continues despite these interventions, pharmacologic therapy is indicated (173,174). Unfortunately, the use of anti-spasticity medications can have negative effects on cognition (88). In the traumatic brain injury population, dantrolene sodium becomes an attractive pharmacologic agent, primarily because of low potential for cognitive side-effects; however, routine blood monitoring is required because of potential toxic effects on the liver. Other anti-spasticity medications primarily include tizanidine, baclofen and the benzodiazepines; a wide variety of other off-label agents exist with some value in tone reduction (173,174). Although these medications can all help with tone reduction, they require close monitoring because of the significant potential for impairing cognition.

If pharmacotherapeutic interventions are ineffective in reducing spasticity, motor point blocks, nerve blocks and botulinum toxin are effective in reducing tone in a specific group of muscles such as lower limb adductors or plantar flexors. Neurectomies and intrathecal infusion of baclofen have been shown to help with persistent hypertonicity (177,178). However, during the early rehabilitation assessment and intervention after TBI, these more invasive interventions are rarely indicated.

## **TERTIARY PREVENTION**

### **Venous Thromboembolism**

Deep venous thrombosis (DVT) represents a significant source of morbidity and potential mortality for patients with head trauma. Pulmonary embolism from DVT is apparently increasing in importance as a cause of death of inpatients with traumatic brain injury (179). The NIH Consensus Conference estimated the incidence of DVT after severe traumatic brain injury to be approximately

40% and the incidence of fatal pulmonary embolus is approximately 1% (180). The incidence of DVT in TBI patients upon admission to inpatient rehabilitation has been estimated as high as 20% (181,182). Despite these data, there is no standard of care for DVT prophylaxis, screening or treatment after TBI. In part, this is secondary to the safety concerns associated with the use of anticoagulation after trauma and a traumatic brain injury. However, there is increasing evidence to support the safety of initiating either heparin or low molecular weight heparin (LMWH) within 24–72 hours of severe head injury or intracranial bleed (183,184). Similarly, the value of screening for DVT at presentation to inpatient rehabilitation has been supported (185). The incidence of DVT can be significantly reduced using a specialized approach of prophylactic intervention in conjunction with routine monitoring in high risk patients. High risk categories include: 1) advanced age; 2) severe injury; 3) prolonged immobilization; 4) number of transfusions; 5) presence of clotting disorder (179,186–190).

In the event that prophylaxis against DVT is initiated, The Eastern Association for the Surgery of Trauma Practice Guidelines for the Prevention of Venous Thromboembolism in Trauma Patients in 2002 suggested that pneumatic compression devices may be of some benefit, LMWH is superior to heparin for prophylaxis in moderate to high risk trauma patients and duplex ultrasound is appropriate to diagnose symptomatic DVT and may be appropriate for screening of high risk asymptomatic patients (191). In those patients who are unable to receive these forms of prophylaxis, prophylactic Greenfield filter placement deserves strong consideration.

### **Contractures**

Contractures of the limbs, as well as the axial skeleton can potentially have devastating implications on self-care, mobility and even vocalization. Persons who are at greatest risk for contractures are those with: 1) a long period of coma and immobilization; 2) severe brain injury; and 3) altered muscle tone. The best treatment of joint contractures is prevention of contractures by an ongoing program of range of motion exercises and maintenance of postural adaptation (i.e., sitting, lying prone or supine and standing). Serial casting has been shown to be useful in the prevention and treatment of contractures (172,192,193). The therapeutic benefit of continual casting versus casting/bi-valve splinting has been debated with the current literature suggesting that continuous casting has a slightly better therapeutic advantage (193). However, others question the therapeutic value of orthotics and actively discourage their utilization due to a concern that motor relearning may be affected (194).

Once contractures develop, treatment depends on the severity of the contractures. Treatment options

include an aggressive stretching program in association with physical modalities, serial casting, and dynamic bracing. Pharmacologic interventions are initiated to address abnormal muscle tone. Other more focal interventions such as botulinum toxin, motor point blocks or neural blocks may be adequate and, thereby, minimize the potential adverse cognitive effects of antispasticity medications. In extreme cases, surgical release of the contracted tissue may be warranted to increase function. Surgical release of contracted tissue can improve skin care and hygiene, prevent the development and foster the healing of pressure sores, reduce pain and improve transfers and ambulation (186). However, such aggressive intervention for contractures is limited to the more chronic survivor who has failed conservative measures and are rarely if ever considered in the early course of the coma-emerging patient.

### **Fractures**

The incidence of concurrent fractures in patients with traumatic brain injury is approximately 30% (195); approximately 11% of these fractures are initially undetected (196). In brain injury survivors with fractures, there is an associated high risk of developing heterotopic ossification (197). This occurs especially in patients with forearm (198) and hip fractures (195). In a cohort of patients with hip fractures after traumatic brain injury, 100% developed heterotopic ossification (187). Conventional treatment of fractures including splints and casting often results in less than desirable results. Uncontrolled limb motion is common in the brain injury survivor especially early in the recovery as the patient emerges from coma (195). Early definitive fixation of upper and lower limb fractures allows for a shorter period of immobilization, early range of motion activity and less overall nursing care (198). Early mobilization and range of motion activities reduces the likelihood of developing severe spasticity, contractures, and ankylosing heterotopic ossification. In addition, early definitive fixation diminishes the need for casting of limbs, which often interferes with rehabilitation intervention.

### **Peripheral Nerve Injuries**

It has been estimated that 34% of patients admitted to a rehabilitation unit were diagnosed with previously undetected peripheral nerve injuries (199). Ulnar nerve entrapment in the cubital tunnel was found most frequently with brachial plexus injury and common peroneal compression neuropathies of slightly less frequency (199). Median nerve compression at the wrist has been reported in brain injury patients with wrist and finger flexor spasticity (200). Factors that are felt to contribute to compression neuropathies in the brain injury population include: 1) extrinsic pressure

from a hematoma or heterotopic ossification; 2) prolonged coma; 3) severe spasticity; 4) improper positioning; 5) fractures; and 6) improperly applied casts (199–201).

It has been estimated that 50% of these neuropathies are preventable (199). Thus, in the acute care setting, preventive measures are incorporated to the rehabilitation intervention such as proper positioning, monitoring of cast application, and the early treatment of spasticity and heterotopic ossification.

### Heterotopic Ossification

The risk of developing heterotopic ossification in the traumatic brain injury survivor is 20% and the risk increases as the severity of injury, length of immobilization and duration of coma increases (202). Also, the presence of spasticity and fractures increase the risk, especially if the fracture involves an open reduction, internal fixation or if there is a joint dislocation. Heterotopic ossification usually involves the large joints of the body (hips, elbows, shoulder and knees). Excess bone formation can result in significant disability by severely limiting the range of motion of a joint. Progressive loss of joint mobility and markers of increased osteoblastic activity such as an elevated fractionated alkaline phosphatase level warrants a comprehensive musculoskeletal examination, three phased bone scan and x-rays to confirm the presence, distribution and extent of heterotopic ossification (203). However, plain radiographs may not demonstrate the presence of heterotopic ossification for one to two months after the initial onset. Osteocalcin, another marker of osteoblastic activity, does not appear to be useful in the early detection of heterotopic ossification or in assessing its maturity (203). Heterotopic ossification often presents as a soft tissue swelling and loss of range of motion. The differential diagnosis includes thrombophlebitis, cellulites, septic joint, fracture, hematoma or soft tissue trauma.

The treatment of heterotopic ossification initially involves preventive strategies; once heterotopic ossification formation has begun additional preventive and therapeutic interventions are initiated. Diphosphonates and indomethacin have been shown to prevent heterotopic bone formation (199,204). Diphosphonates may also minimize the extent of heterotopic ossification formation after its onset, but the role of diphosphonates in this setting remains controversial. The treatment of heterotopic ossification also includes physical modalities such as aggressive range of motion exercises in an attempt to reduce the likelihood of bony ankylosis (204,205). Other investigators discourage aggressive range of motion out of concern that the micro trauma or local hemorrhage may predispose the development of heterotopic ossification. In the relatively rare event that heterotopic ossification causes sufficient joint ankylosis to impede function, surgery is usually performed in combination with the radiation of

the involved area in the hope of regaining range of motion and arresting further bone development. However, surgery is often discouraged until one to two years after the onset of heterotopic ossification due to increased risk of recurrence during the active growth phase of the ectopic bone.

### INDIVIDUALIZED REHABILITATION PLAN

After documenting the extent of impairments and estimating functional outcome, the physiatrist is charged with determining the most appropriate rehabilitation interventions for the survivor. Early rehabilitation is initiated while the survivor remains on the trauma or neurosurgical service. Rehabilitation options following this early stage are predicated on the nature of residual impairments (170). In the unlikely event that a survivor of a severe traumatic brain injury recovers sufficiently during acute care to permit rehabilitation management on an outpatient basis, individual outpatient services or a day-treatment program may be recommended. Typically day treatment rehabilitation offers survivors integrated programs of physical therapy, occupational therapy, speech pathology, cognitive remediation, vocational and psychological services up to 8 hours per day, 5 days per week.

If, at the time of discharge from acute care, the residual impairments are of such severity that the patient remains dependent, then options include either an acute or subacute rehabilitation program. The typical admission to a traumatic brain injury acute rehabilitation unit is an individual who is able to consistently follow a 1 step command, is commonly confused and disoriented, restless if not overtly agitated, and many have a combination of physical limitations or medical complications. Ideally, it is the goal of this phase of rehabilitation to assist the patient from the late stages of unconsciousness through clearing post-traumatic amnesia, resolution of agitation, and at least minimal independence in activities of daily living. For the individual and their family, the most salient goal of the acute rehabilitation phase is to regain optimal independence in activities of daily living. To remain in this rehabilitation environment, the patient must be able to tolerate and benefit from a minimum of 3 hours of therapy, 5 days per week.

Subacute rehabilitation programs are largely nursing home based. These programs do not require that a patient tolerate 3 hours of therapy per day. Consequently, subacute rehabilitation programs are most appropriate for survivors who remain in the “coma stages”, responds to simple commands inconsistently or the rate of progress is slow. The typical length of stay is considerably longer than the present national average of approximately 21 days in acute rehabilitation. Largely because of staffing and overhead, subacute rehabilitation offers health care

providers a less expensive form of specialized intervention. Although data exist supporting the importance of early rehabilitation interventions on outcome (43,44), virtually no data exist comparing acute versus subacute intervention outcome.

After inpatient rehabilitation, a number of post-acute management strategies are available. Again, if the patient can be managed at home, then rehabilitation options would include individual in home or outpatient therapy, or comprehensive day-treatment services. If a patient in an acute rehabilitation setting fails to achieve basic functional independence in a timely fashion, then a transfer to a subacute rehabilitation program may be warranted. In the event that behavioral problems such as agitation preclude discharge to the home, more specialized inpatient behavioral treatment programs are indicated.

Another level in the continuum of rehabilitation includes transitional living programs. These are typically residential, community based treatment alternatives for individuals with primarily cognitive and neurobehavioral deficits that preclude independent living. The length of stay in a transitional living program may last as long as 12 months with the ultimate goal being independent living.

The final stage in the rehabilitation continuum includes vocational rehabilitation. This stage in the recovery process is initiated a number of months post-acute injury. Hence, vocational rehabilitation, transitional living and even specialized behavioral programs are rarely relevant or pressing program options to consider during the initial psychiatric evaluation.

## TBI: A Pediatric Perspective

*Andrew I. Sumich  
Maureen R. Nelson  
James T. McDeavitt*

**S**erious illness in any child is a highly stressful event for all concerned: the child, parents, and family. Traumatic brain injury (TBI) can be particularly devastating. The injury commonly causes a variety of physical, emotional, cognitive and behavioral impairments. These impairments appear at a time of particular developmental vulnerability, and can significantly impact the child's ability to what children ordinarily do: grow, play, develop, learn, make friendships and gradually evolve into independent young adults. In an instant, parents' expectations for their child may be dramatically altered, and there is often no one in the health care system that can provide them with reliable information on recovery and prognosis.

Although many of the problems faced after brain injury in children occur in adults as well (e.g. seizures), children face a number of unique challenges in recovery. The following chapter will attempt to focus on those aspects of TBI which are unique to children.

### EPIDEMIOLOGY

Traumatic brain injury is the most common cause of acquired disability in childhood, with an incidence of approximately 200/100,000 per year in the United States. Incidence has been further broken down to 185/100,000

children for ages 0 to 14 and 295/100,000 adolescents and young adults (ages 15 to 24) (1). The leading cause of TBI varies with age. Pedestrian injuries and falls affect younger children while adolescents and young adults are more commonly injured in motor vehicle collisions and assaults. This rise in incidence at age 15 correlates with increased motor vehicle operation and assault (1, 2). The prevalence of TBI is twice as high in boys as it is in girls. Other factors associated with a higher risk of TBI are poverty, living in congested residential areas and parental instability (3).

### OUTCOMES

Of all children who sustain TBI, 95% survive (4); that number drops to 65% for those suffering severe TBI (5). Other studies have shown a biphasic association of age and survival after TBI. Highest mortality is in children less than 2 years of age with a gradual decline in mortality through age 12 and then a second peak in mortality at age 15 (6). With continued advancements in medical care, more and more children are surviving TBI. Survivor outcomes in pediatric TBI range from full recovery to severe physical and/or mental disabilities. It has been suggested that kids suffering TBI have better results in neurological and cognitive recovery compared with older groups. Using the Glasgow Outcome Scale (GOS), a study of 33 survivors

showed good recovery for 27%, moderate disability for 55% and severe disability for 18% (7). Generally children and adolescents do better than those older than 21, however it is important to note that children under seven do worse than older children (8, 9). A study looking at longer-term outcome (an average of 23 year follow up) reported 32.7% of survivors with physical complaints and 17.6% with psychological or psychiatric complaints (10).

Communication and cognitive dysfunction seems to contribute most to dependency. A study of 42 children and young adults found 37% of respondents were independent while 49% were dependent in some area of living. Of communication and cognitive deficits, memory problems contributed the most to dependence. Younger age groups and shorter duration of coma are associated with better functional outcomes. It theorized that improved functional outcomes for younger patients are secondary to greater plasticity in the younger brain. Also of note, chronic seizure or epilepsy can lead to greater dependence while presence of early seizures is not predictive of functional outcome (11).

## COGNITION AND PHARMACOLOGY

Cognitive deficits are a major contributor to disability following TBI, and this certainly holds true for the pediatric population. Cognitive impairments are manifest on many levels, including behavior, attention and memory (12). These changes probably are related to underlying alterations in cerebral neurochemistry. Brain injury results in a chain of neurochemical events beginning at the time of injury. Neurochemical changes have also been documented in chronic TBI.

Injury to a child's brain is particularly concerning because a child's brain is still developing. There are both immediate and long-term ramifications that result from pediatric brain injury. A child unable to learn new functional skills (physical and mental) as a result of a traumatic injury to the brain is severely disadvantaged as they progress to adulthood. Further complicating the issue is hidden deficits that may not be apparent immediately after injury. For example, one would not expect a three year old, healthy or impaired, to display higher level thinking; therefore a deficit might not be recognized until years later (13).

Arousal and attention are commonly impaired after injury, which often interferes with the patients' ability to process new information and consequently interferes with the rehabilitation process (14). Pharmacological interventions often target increasing arousal and attention. Tricyclic antidepressants, dopamine, norepinephrine and serotonin up regulators are often used (15, 16, 17). Conversely, pharmacological agents can sometimes interfere with arousal and attention, particularly antiseizure and

spasticity medications such as benzodiazepines and phenytoin.

Studies have shown a positive short-term effect of psychostimulants on behavior and cognitive functioning of adults with brain injury (18). While double blinded, placebo controlled, randomized studies of psychostimulants in the pediatric population are limited, there is some data involving methylphenidate. Methylphenidate presents perhaps the most intriguing possibility in the pediatric population because of its established use in attention deficit hyperactivity disorder. Williams et al. showed no significant difference between methylphenidate and placebo in terms of behavior, attention, memory and processing speed (19). However, the authors note some possible faults in study design including dosing, timing of intervention and length of intervention.

Many other drugs have also been used in the pediatric brain injured population, including tricyclic antidepressants, amantadine, atomoxetine and bromocriptine. Formal recommendations for pharmacotherapy in pediatric TBI are difficult to make because of the lack of solid evidence. White et al. point out that this is likely due to the lack of controlled studies, confounding effects of spontaneous recovery and imperfect outcome measures (20). While many drugs are used and often seem to have a clinical effect, further well designed clinical trials are needed.

## POST-TRAUMATIC SEIZURES

Post-traumatic seizures are typically divided into three types depending on their timing in comparison to the trauma. Seizures occurring within minutes of trauma are referred to as immediate seizures. Early seizures, by definition occur within one week of trauma, while late seizures occur beyond the first week on injury. A person who suffers two or more late seizures can be diagnosed with post-traumatic epilepsy. It has been established in adults that post-traumatic seizures and epilepsy adversely affect recovery from TBI. An overall decrease in quality of life is seen in these patients as a result from inability to work, social isolation and less return to leisure activities (21).

Studies have shown that children suffering TBI have a 3% to 9% incidence of early post-traumatic seizures, which is higher than expected for adults. This being said, the risk for late seizures is lower in children compared to adults (24–27). Severity of brain injury correlates directly with the incidence of epilepsy. Further illustrating this point is the fact that the greatest predictor of post-traumatic epilepsy is severity of injury (21). Appleton found that the only specific risk factor that was clearly correlated with the development of post-traumatic epilepsy (PTE) was early seizure occurrence within the first week after injury. The drugs they chose to use for treatment of PTE were carbamazepine or lamotrigine (22).

The morbidity and mortality associated with post-traumatic seizures and epilepsy has resulted in an effort to find medications to reduce the risk of both. Phenytoin has commonly been used as anti-seizure therapy in all groups with TBI. Early seizures have been shown to be decreased with phenytoin therapy, however phenytoin has shown no reduction of post-traumatic epilepsy (23). In addition, anticonvulsants may actually impede recovery. Therefore, if no seizures are documented in the first week, antiseizure medications should be discontinued. In cases when early seizures are present one is faced with a clinical dilemma, both the seizures themselves and the treatment may actually negatively affect recovery (21).

### **Deep Venous Thrombosis/Pulmonary Embolus (DVT/PE)**

Deep venous thrombosis and PE are seldom reported in pediatric literature and as a result there is limited information regarding thromboembolism and pediatric TBI. An incidence of < 5% has been reported in a general disabled pediatric population (28), further analysis showed one out of 185 children with closed head injury had a documented DVT (29). There are no current recommendations for screening for DVT in the pediatric population because of the low incidence. While DVT in children may present the classic with clinical signs and symptoms of leg swelling and pain, this is not always the case. A child may complain of only vague abdominal or inguinal pain. As a result, clinicians must maintain a high index of suspicion. General DVT/PE prophylactic anticoagulation is not currently recommended for prepubertal children (29).

### **PRECOCIOUS PUBERTY**

Precocious puberty is defined as the onset of secondary characteristics before age 9 in boys and age 8 in girls (30). Onset of precocious puberty in healthy children can take a severe emotional toll on both the child and family. Social difficulties also arise. The occurrence of precocious puberty in the child with a brain injury only magnifies these difficulties.

One study of 33 children with TBI found 7 to develop precocious puberty (31). Severity of brain injury does correlate with incidence of precocious puberty. Girls seem to be more at risk to develop this problem than boys. Of note, however is the fact that precocious puberty is seen more often in girls in the general population. While the exact cause behind precocious puberty following TBI is unknown it does not diminish the importance of the issue. Shortened adult stature can result as a result of early closing epiphysis. Clinicians should consider luteinizing releasing hormone (LH-RH) agonist therapy for a temporary and reversible treatment if precocious puberty is suspected (32).

### **HETEROTOPIC OSSIFICATION**

Heterotopic ossification (HO) is defined as ectopic bone formation that is seen in several medical conditions including central nervous system trauma, total hip replacement and burns. Incidence of HO in all TBI patients has been reported between 3% and 76% (33–35). In children and adolescents with TBI, incidence has previously been reported between 3%–20% (36, 37), depending on the methods used. An incidence of 22.5% was found using triple phase bone scan to screen all pediatric TBI patients, not just symptomatic children (38).

While there are no formal screening recommendations for HO, one must maintain a high index of suspicion. HO should be high on the differential when physical exam shows decreased range of motion, increased swelling or the patient complains of increased pain with joint movement. Further work up for HO should include triple phase bone scan and/or plain films.

The hips are the most common location for HO in children, followed by elbows, knees and shoulders (39). Several factors have been established as risk factors for HO. These include age older than 11 and coma lasting greater than 7 days. Multiple fractures have also been associated with increased incidence of HO. Perhaps the most concerning result of HO is that it has been shown to result in poorer functional outcomes (38).

Clinical findings often associated with HO include decreased range of motion (ROM), pain and swelling. DVT, infection and fracture can have similar presentations. In fact, there have been case reports of HO and DVT found simultaneously in pediatric patients (40). As in adults, the primary treatment of HO in children is ROM, both active-assisted and passive, as the mainstay. Etidronate has been shown to reduce the occurrence of HO in adults with severe head injury (41). A rachitic syndrome has been reported in a twelve year old boy with a brain injury and HO who was treated with etidronate. As a result, alternative treatment should be used in children (42). Nonsteroidal anti-inflammatory medications remain an option for treatment of HO in children. Indomethacin is often the NSAID of choice in treating HO. Pediatric dosing is recommended at 1–2 mg/kg/day divided in 2–4 doses, not to exceed 150–200 mg/day. Surgical removal of HO is rarely required and typically reserved for more severe cases, specifically when it interferes with positioning and personal care, which can lead to skin breakdown.

### **COGNITIVE/EDUCATION**

Neuropsychological testing is done to understand patterns of cognitive problems and to obtain information on the general level of a child's impairment. Testing can

estimate the child's pre-injury level of cognitive abilities by using some subtests that are less apt to decline with injury. Intellectual deficits are a relative factor depending on the child's pre-injury level of abilities. The pattern of cognitive assets and deficits that is found on this testing provides information for treatment approach in rehabilitation, as well as for school. It examines features such as whether someone is stronger at using verbal or visual learning and where memory strengths and weaknesses are, in order to formulate an effective treatment plan. Neuropsychological testing can also be performed to monitor a child's recovery pattern (43). The pattern of neuropsychological deficits depends on the developmental level at the time of injury as well as the hemisphere and site of lesion (44). Skills that are undeveloped at the time of injury may initially appear to be uninvolved, however as the brain becomes more mature, the impairment emerges (45). Children after TBI have been shown to have decrease in IQ, adaptive problem solving, memory and academic performance, along with psychomotor problem solving, compared to children without injury. The impairment on the testing is more severe in more severely injured children (46). IQ scores are minimally affected but testing shows decrease in speed and efficiency, more significantly with more involved children. Most of the children tested had few deficits from the TBI (46).

Bowen evaluated 22 children post-TBI and found no reliable association between neuroimaging data and cognitive measures, but found that children with more diffuse injury on scan did more poorly on the testing (47). Levin looked at 76 children with TBI and did find that the size of lesion on MRI was related to abnormalities in cognitive performance. He also found that cognitive impairment was more dramatically shown in children up to 10 years old than in teens (48).

Multiple studies have shown increased need for educational support and special education after TBI (49–53). One study of children with severe versus mild to moderate TBI showed significant effect in reading recognition, spelling and arithmetic scores in those with severe level, along with lower relative scores for teens than children in all levels of severity. This study also showed significant improvement from baseline to six months of injury but no change from six months to two years. They also found average achievement test scores at two years after TBI but 79% of the severely injured group were receiving special education or had failed a grade (54).

The effect of TBI on a child's language development has also been studied. In children there is more of an impact affecting linguistic abilities, where older children and teens have more of a disruption in higher order communication functions common due to the developmental level (55). More severely affected children have been shown to have more deficits in language skills (56).

One study examined pre-injury behavioral and learning characteristics of children, based on teacher assessment. There was a somewhat higher instance of pre-morbid behavioral problems in children with TBI. The TBI group also tended to include children of lower socioeconomic status (57). In those with behavioral difficulties after TBI, it is difficult to predict their prognosis. Behavioral evaluation can include many sources from throughout the environment. There is likely an interplay between cognitive deficits and behavioral difficulties (43).

Complex problem solving and abstract reasoning are high levels of cognitive processing. Difficulties with this affect new learning abilities and the ability to benefit from feedback and to solve problems. Being efficient in organizing activities in logical sequence can be impacted, as well as initiating and modifying behavior. This can lead to difficulties socially and in school (43).

Difficulty with executive function, in particular, reduced initiation and persistence, poor planning, poor organization and difficulty correcting errors are frequently seen post-TBI. This frequently leads to dissociation between a child's ability to verbally describe an activity versus an inability to actually perform the task. This may be related to deficits in speed of processing information. This may give the false appearance that a child is non-compliant with school requests (43).

## FAMILY

A child incurring a TBI can have a significant impact on the whole family. The entire spectrum of family life can be impacted from emotional to financial. Parents have reported difficulty with maintaining work schedules, as well as financial difficulties, secondary to injury and care for the child post-injury. Children who are hospitalized for longer or who had multiple types of injuries had families who were most impacted (58). Approximately one third of families in one study reported that there was a deterioration in their family financial status since the child's injury and just under 30% reported that an adult lost a job, either through firing or quitting due to their child's care needs (59). The family medical leave act (FMLA) should decrease the number of firings due to a child's severe injury but will not eliminate them. Changes in housing, also, are sometimes required and can also have a financial impact (59). Siblings can also suffer adverse consequences. One study demonstrated that over 50% of families had siblings with behavior problems, withdrawal from their injured sibling, and increased fearfulness (59). Conversely, fifty percent of families described that siblings became more involved in their family after injury. They also described decrease in school performance and difficulty with peer interactions (59). McMahon found no statistically significant difference in depression, self-concept

or behavior between siblings of children who had TBI and classmate controls. However, she did find that siblings of children with the most severe injuries did have a significantly lower self-perception, as well as, more symptoms of depression (60).

The importance of family needs and the percentage of needs that were unmet was a cause of significant amount of variability in family stress (61). Comparison of families with children with TBI versus other reasons for hospitalization has shown that parents of children with TBI are more likely to have unmet needs, including medical information, professional and community support, and a feeling of involvement in the child's care (62). One means of attempting to minimize the stress has been approaching the need for information by giving pamphlets about TBI (63). Snowdon described improving parental satisfaction by approaching the family's need for information, as well as, their need for social support (64). It has been described that the primary protection from a high level stress on the family and depression in family members of someone with TBI is a large amount of social support for the family (65). The number of medical problems was also found to be related to parental stress, with approximately one third of parents of children with TBI showing decreased psychological health (66). Social support was felt to be the biggest protector against psychological distress of families. If there was not adequate social support, caregiver distress was worsened with further time out from injury, cognitive dysfunction of the child, and unawareness of deficits by the child; but, if the social support was strong, these were not distressing factors (67).

The family also was found to have an impact on behavior and recovery of the children with TBI. Parental support and parental acute emotional reaction to the injury were predictive of the child's behavioral outcome in the first two years of TBI. This was believed to indicate the importance of the parents' coping on the child's development of behaviors (43). Psychosocial outcome in children post TBI has been described as more closely linked to pre-injury family function and behavior than to injury severity (68).

Coping strategies of the family have an impact on the stress of TBI in a child over the long-term period. Sixty percent of all families experience a change in their structure after TBI, showing changes in coping style, including cohesion and family roles (69).

It has been described that parents who are undergoing economic or personal stress more frequently respond punitively to their children. This may lead to the children then reacting with worse behavior in response (70). The stress of a TBI may adversely affect the parent-child interaction, which may then further exacerbate the child's behavior. Therefore, criticism by and conflict with the parents are seen more frequently with children with adjustment difficulty (71). High levels of parent-teen

conflict have been shown to be related to higher risk of delinquency (70). Increase caregiver stress contributes to more negative interactions with their children (70).

In a study comparing children with TBI versus orthopedic injury, the group with severe TBI has similar levels of criticism and coldness as well as personal engagement and levels of conflict as did the group with orthopedic injuries (72). They did find that higher levels of criticism, coldness and conflict were associated with worse outcomes for those with a TBI (72). This study showed association between parenting conflict and criticism, with adjustment long-term in parent and patient. This suggests that decreasing conflict and criticism in the relationship may improve long term functioning on both sides (72).

## SOCIAL/BEHAVIORAL

Success in social interactions is a key to positive outcomes in most areas of life. Social skills include the ability to understand another's feelings and the ability to interpret social cues and to predict and evaluate social/behavioral consequences (73). Social success is a combination of social skills, behaviors, and other factors such as athleticism and attractiveness (74). Social competence is felt to be a fundamental basis to developing friendships and to having positive evaluations from others (75). Impairment of social skills is correlated with poor social outcome (76).

It has been reported that the interrelationship of language, executive function and self-managing behavior may be the basis of social impairments associated with communication disorders (77). Chapman has demonstrated that traditional language tests underestimate communication difficulties in children with traumatic brain injury due to their difficulty with sequencing, developing resolutions, and obtaining the moral of a story, particularly if the frontal lobe is involved (78). These problems can have significant effects on the child's ability to interact in an acceptable manner with family, other children, and school personnel (79). Teenagers are at a key time for developing cognitive communication skills, to interpret implied meanings, particularly including sarcasm, negotiation, and complicated pragmatic cues. These skills may be compromised with a TBI during these years, thus compromising social abilities (80).

Cavell has described that social competence is measured at the following three levels: social skills, social performance on specific tasks, and social adjustment (74). Most testing examines social performance but not social skills. The latter includes the ability to perceive and interpret situations, decision skills that require the ability to determine expected outcomes of behavior, and, therefore, make decisions based on these, and enactment skills, which demonstrate the ability to generate a response (74).

Social skills frequently reported as impaired in adolescents with TBI include attentive listening behavior, perception of non-verbal cues, detection of sarcasm, sharing equal conversation burden, humility, and speaking at the listener's level (79). Turkstra studied normally developing teens and teens with TBI, looking at conversational skills. They examined the conversation skills of both, studying the emotions of anger, irritation, happiness, sadness and disgust, with consideration of the teens' self-regulation of behavior as well as intelligence. They found no impact of gender, intelligence, or race on emotions or conversation ability. They did find that teens with TBI performed more poorly on identifying emotions, though their errors were similar to the control group of teens. On evaluating the accuracy of conversations, the teens with TBI had many more errors and with a pattern that was unlike the errors made by the control group of teens. They had the most difficulty with the ability to detect sarcasm and the response to sarcasm, and also had difficulty with identifying bragging and a response to bragging. They found no correlation between vocabulary and the ability to identify emotions or intent in conversation. The teens with TBI had significantly more difficulty overall with detecting and evaluating social behaviors. The fact that sarcasm and bragging were the most difficult areas of evaluation was interpreted to mean that there was greater difficulty in social inference, particularly with different explicit and implicit messages (76).

Social success depends on effective self-regulation of cognitive and social behavior (81). The surrounding environment and supportive behavior of others can exacerbate or improve self-regulatory impairment in those with a TBI. Interventions to address these deficits, therefore, need to be sensitive to the child's social context, and the child or teen's daily activities are key to address in attempting to improve the performance of executive function related abilities (81).

Social functioning is a critical predictor of quality of life (82). Children with TBI are more concerned about losing friends than about success in schoolwork, their health, their ability with sports, or getting in trouble at school (83). An intervention program for children with TBI, called "Building Friendships", was described with a team of child/parent peers and school staffs to meet periodically, set an action plan, and increase the number of social contacts for the students (84). Unfortunately, the program was not found to sustain itself once facilitators had stopped their involvement.

Social function is shown to improve during inpatient rehabilitation stay with children and teens with TBI, with those with the greatest deficits showing the greatest gains (85). Social function skills are shown to continue to improve after return from rehabilitation to home (86).

In a multicenter study of 65 children and teens, only 3% to 27% were reported as ready for age-expected

participation at discharge in home, school, and community life, with social/behavioral deficits responsible for the majority of limitations (87). The Come Back Programme is a program for teens and young adults after TBI and after their initial rehabilitation program that had continued psychosocial deficits. The deficits reported were in independent living, employability, relationships, and contact with friends. In a follow up study one year or more after the completion of the program, there was no improvement seen in contact with family or leisure activities, however there was improvement in employability and independent living, but not back to the level of pre-injury (88). Their recommendations were for a second rehabilitation program, such as this, for psychosocial deficits as well as follow-up support and structural control for continued success (88). A program in New York worked with 80 individuals with TBI who had severe behavioral deficits at least two years post injury. This program's approach was long-term practice of participation-enhancing and disability-reducing strategies to result in automatization and internalization of strategies to reduce the impairment (89). Critical components were described as intervention being in context with the person's life and teaching those directly involved with each life how to perform this intervention. They found with these customized supports that they had a cost-effective improvement in quality of life for the individual and their loved ones, and greater than 80% of those with significant behavioral disorders were returned to their home communities (89).

Behavioral changes and difficulties have been widely reported in children after a TBI. Stancin found that 89% of parents of children with TBI interviewed reported behavioral change post injury (90). A British study described two thirds of the children with TBI with significant maladaptive behaviors several years post injury (91). A French study showed a higher frequency of depressive tendencies in teens with TBI, as well as, behavioral problems and a lack of self-awareness of the behavioral problems (92). In a phone interview of parents of children and teens one year after TBI, 40% of the children were described as having behavioral problems (93).

Psychiatric disorders are sometimes described after TBI in children and teens. One study evaluating the first three months after TBI showed that in the short term, children with more severe injury, previous psychiatric disorder, family psychiatric history, dysfunctional family, or lower socioeconomic class had high risk of a new psychiatric disorder (94). In looking at psychiatric disorders one year post TBI in children and teens, attention deficit hyperactivity disorder and depressive disorders were the most common diagnoses described, both new onset and previous. For new diagnoses, which were reported in 48% of the children studied, 74% persisted. Internalized disorders are more likely to resolve than externalized disorders (95). Interestingly enough, this study attempted

to exclude children with pre-injury psychiatric disorders but found 16 children with 20 previously undiagnosed disorders, primarily ADHD and anxiety disorders (95). Emotional distress may actually increase over time. Depression is commonly seen later as increases in cognition and self-awareness lead to recognition of deficits and, with that, depression (43).

Early agitation post-TBI may be a combination of an inability to filter out excessive stimulation, poor memory and cognitive limitations. This may manifest as combinations of old familiar memories intruding in current events and may appear to be psychiatric disturbances, but are in fact neuropsychologically based misperceptions (43).

In a broad ranging, greater than 25 year follow-up of 39 individuals in Finland who had TBI during the preschool years, it was reported that 59% of the children attended typical school, 21% attended a school for the physically disabled, and 18% attended a school for the mentally retarded. Only twenty three percent of adults worked full time in regular work environment with 26% working at a sheltered work place. With finding a large discrepancy between 59% reportedly having normal intelligence and normal school performance and only 23% in a regular full time work environment, it was interpreted to indicate that school performance or intelligence evaluation is not a guarantee for a good long-term prognosis (96).

## CONCLUSION

The bromide that "children are not small adults" certainly holds true for pediatric brain injury. The unique emotional, social and developmental needs of children demand a holistic and comprehensive approach by a broad-based team. Families also require special care to help calm the inevitable turmoil created by a life-changing injury. This care is ideally provided by a team of specialists with experience in brain injury, and in the care of children.

## The Older Adult\*

**Jeffrey Englander**  
**David X. Cifu**  
**Trinh Tran**

### DEMOGRAPHICS OF AGING

The older adult or geriatric population includes all individuals aged 65 years and older. This chronological cut-off is arbitrary and more related to federal statutes (in the United States, Medicare and Social Security Administration Retirement) than scientific standards. Improvements in standards of living and health care have led to greater life expectancies, as well as increased survivability from injury and disease, resulting in a significant increase in the number of older adults. Currently, 12.4 percent (35 million people) of the U.S. population are aged 65 years and older. This percentage of older adults will rise to 21 percent (64 million people) of the population by the year 2050. In addition, those 85 years and older (the so-called *oldest old*) will increase from 1.4 percent (3.9 million people) to 5 percent (15 million) in that same time frame (1). For this chapter *older adults* are those aged 65 years and older, unless otherwise noted.

### DISABILITY IN THE OLDER ADULT

More than 1.5 million (4.5%) older adults reside permanently in a nursing home and require functional

assistance (1). According to the most recent data, more than ninety percent of all community dwelling (including assisted living) older adults have no reported deficits in everyday functional abilities (2). Interestingly however, 40% report having a “disability” on their 2000 census (3). The limitations reported by the 6 percent who do report deficits are walking (19%), bathing (10%), getting outside (10%), getting in and out of bed (8%), dressing (6%), toileting (4%), and self-feeding (2%). Unfortunately, only 10% of these individuals reporting limitations actually receive assistance with these functional activities. The need for functional assistance increases with increasing age, and nearly 40% of individuals 80 years and older require help (2, 4).

### ETIOLOGY OF INJURY AND INJURY PREVENTION

Next to teenagers and young adults, older individuals have the next highest rate of hospitalization for TBI, with an annual rate of 121 per 100,000. It is the only age group where females and males have similar rates of injury. In the United States, Caucasians had 1 1/3 the incidence of

---

\*This chapter is an updated version of the one that originally appeared in the book, *Rehabilitation of the Adult and Child with Traumatic Brain Injury, Third Edition*, edited by M. Rosenthal, E.R. Griffith, J.S. Kreutzer, and B. Pentland, published by F.A. Davis in 1999.

Asians, 1 1/2 that of African-Americans and over 2 times that of Native Americans (5).

Unlike their younger cohorts, older adults sustain the majority of TBI's in domestic falls. Adults over 85 years old are 16.4 times more likely to sustain a TBI from a fall than those less than 65; 75–84 year olds are 7.6 times and 65–74 year olds are 3.1 times as likely. Moreover, the home discharge rates are 30% for those greater than 85, 41% for those 75–84, and 54% for those 65–74 compared to 86% for those less than 65 (6).

Risk factors for falls have been stratified into the following groups: 1) chronic, such as neurologic disease, sensory impairment, or musculoskeletal disease, particularly affecting the lower extremities; 2) short-term, such as episodic postural hypotension, acute illness, alcohol use, or medication effects; 3) activity-related, such as tripping while walking, climbing ladders, descending stairs or riding a bicycle; and 4) environmental, such as ill-fitting shoes or trousers, non-secure throw rugs, or poor lighting (8) These risk factors for falls also predispose the elderly to motor vehicle, pedestrian, and recreational accidents, any of which may result in TBI. The decrease in reaction time and walking pace commonly seen in the older adult additionally predisposes them to motor vehicle and pedestrian-motor vehicle accidents, respectively. Management of these risk factors includes scheduled, consistent, and competent primary physician care to minimize medical morbidities, regulate medications, and provide ongoing education. Additionally, focused rehabilitation interventions can be utilized to maximize physical abilities (gait, balance, strength), procure adaptive and assistive devices (canes, walkers, handicap parking stickers), and provide education. Finally, efforts to reduce violence against older adults are necessary to prevent this increasing cause of TBI.

### MECHANISM AND PATHOLOGY OF INJURY

Severe trauma in individuals over age 70 is six times more likely to cause intracerebral lesions than severe chest, abdominal, or pelvic injury, a trend that begins at age 40 years (9). Falls tend to result in focal brain injuries, most commonly subdural hematomas (SDH) and/or focal cortical contusions, usually involving the frontal and temporal lobes. These contusions may occur in multiple foci that appear on computed tomography (CT) scan several days after injury (10). Individuals on anticoagulation therapy for cardioembolic risk prevention or with coagulopathy from other medical conditions will have a greater likelihood of intracranial hemorrhage after a fall. Immediate loss of consciousness implies some degree of diffuse axonal injury (DAI) that can also occur with falls and portends a worse prognosis.

Motor vehicle crashes that injure older adults are commonly low-speed collisions, unlike the high-speed

collisions more typical of young adults. However, even these collisions can result in DAI in these individuals (11). Focal contusions and SDH's are also common in motor vehicle crashes.

Pedestrian-motor vehicle collisions in older adults frequently occur at crosswalks and in parking lots. They can result in DAI, focal contusions, and/or extra-axial lesions, most commonly SDH's. Individuals with these injuries are the most likely to have skeletal trauma, especially visceral injuries and pelvic and lower extremity fractures.

While assaults are a much more common cause of TBI in the middle-aged group, there is evidence that violent acts against elders are increasing, particularly in urban areas. These injuries invariably result in focal cortical contusions, skull fractures with SDH's and epidural hematomas (EDH), and intracranial bone and bullet fragments.

The injury severity profile of older individuals who survive their acute injuries and transition directly to acute rehabilitation differs from younger cohorts. In the NIDRR TBI National Data System (1989–2002, n = 3279:  $\geq 65$  years old = 259 subjects,  $< 65$  years old = 3020 subjects; all subjects are admitted to a model system emergency department within 24 hours of injury, are at least 16 years old, have acute trauma care followed immediately by acute inpatient rehabilitation), 71% have initial GCS 13–15 age  $\geq 65$  (27%  $< 65$  years), 14% have GCS 9–12 (19%  $< 65$  years), 7% have GCS 6–8 (28%  $< 65$  years), and 8 % have GCS 3–5 (26%  $< 65$  years). Time from injury to ability to follow commands is one day or less in 68% of those  $\geq 65$  years (39%  $< 65$  years), 2–7 days in 17% (29%  $< 65$  years), 8–31 days 25% (12%  $< 65$  years) and greater than one month in only 2% (7%  $< 65$  years). Computed tomography scans demonstrate no differences in degree of lateral shift or brainstem compression with regard to age group. Subdural hematomas occurred in 55% those  $\geq 65$  years (38% those  $< 65$  years) and EDHs in only 7% (11%  $< 65$  years). Bone and or metal fragments from open head injuries occurred in 3.1% those  $\geq 65$  compared with 6.9% of those less than 65 years old. Subcortical contusions in basal ganglia, internal capsule, pons, brainstem or cerebellum occurred in 9.1% those  $\geq 65$  compared with 17.3% of those less than 65 years old. The number and frequency of cortical contusions, subarachnoid (SAH) and intraventricular hemorrhages was not more than 3% different between the older and younger age groups (12). These findings are reflective of the increased likelihood for older individuals to suffer falls and resultant focal cortical injury with less time in coma compared with the higher incidence of subcortical injury in younger individuals. They are also more likely to incur SDH due to relative brain atrophy and fragility of bridging veins than younger individuals.

## MORTALITY

From 1989 to 1998, TBI-related deaths decreased in all age groups except those greater than 75 years, where the rate increased from 50 to 60.5 per 100,000. For that age group, falls, firearms and motor vehicles were the external causes, in that order of frequency, whereas for the 65–74 decade, firearms were the most frequent cause. Starting at age 55, mortality from firearm-related TBI was more common in Caucasians than African-Americans with the rate increasing every decade (13). An earlier CDC survey from 1980 to 1992, indicated that suicide was the third leading cause of traumatic death in those over age 65 after unintentional falls and motor vehicle crashes. Divorced and widowed men were in the highest risk group (14).

The largest group of older individuals with TBI studied in a neurosurgical population is from Rambam Medical Center in Haifa, Israel, consisting of 263 individuals. Mortality rate was 18%; however, many patients were transferred from other centers and had thus survived their initial injuries. The highest mortality group were those with subdural haematomas (33%), followed by contusions (27%), diffuse axonal injury (11%) and chronic subdural haematomas (3%) (15).

Smaller sample size studies from the early 1990s have indicated 80 % mortality and greater, with the great majority during the first 2 weeks of hospitalization. Subdural hematomas (SDH) requiring evacuation were the most common contributing cause of death. Cardiac, pulmonary and multi-system failure were more common in the older than younger individuals, but never exceeded 33% as the main etiology of death (16, 17). One research group proposed that it was futile to treat those over 80 years old with a GCS < 10, given the high degree of mortality and severe disability (18).

In clinical practice it may be difficult to limit the number and degree of interventions performed unless there are clear advanced directives giving relatives and health care providers guidance.

## MORBIDITY

### Multiple Trauma and Hypotension

Severe multiple trauma as measured by the Abbreviated Injury Severity (AIS) score is less common in older than in younger age groups. Hypotension and multiple trauma are closely associated. Severe multiple trauma without hypotension or hypoxia has not been associated with worse outcome as measured by the Glasgow Outcome Scale (GOS) (16).

Cerebrovascular events can occur as a result of hypotension in the peritraumatic period; strokes caused by thromboembolism, thrombosis, or ischemia from

massive swelling are uncommon causes of peritraumatic stroke in older adults.

## Fractures

In the NIDRR National Data System skull fractures occurred in 23% of those  $\geq 65$  years old compared to 37% under 65 years; lower extremity or pelvic fractures in 15% and 25%, upper extremity fractures in 12% and 13%, spine column fractures in 15% and 17% respectively. Combinations of TBI and spinal cord injury are 2–3 times more common among younger individuals (12).

## Medical Complications

Respiratory failure requiring mechanical ventilation for more than 7 days occurs in 22% of those  $\geq 65$  years old compared to 40 % of those less than 65 years of age who go to acute rehabilitation. Gastrostomies or jejunostomies were prevalent in 23% and 35% respectively (12).

Acute anemia occurs in nearly all individuals who incur trauma. Older individuals have poor tolerance for blood loss. Anemia may effect energy level, tolerance for activity, appearance and overall sense of well being. Laboratory values may not reflect lowered hemoglobin levels until after rehydration occurs as a result of iatrogenic effects of diuretics, mannitol, and bedrest which can result in lowered intravascular volume and relative hemoconcentration. Coagulopathy requiring the use of fresh frozen plasma or platelets occurred in 7.4% of those over 65 and 7.3% less than 65 years old (12).

## FACTORS AFFECTING OUTCOME

### Age and acute injury recovery

Most of our knowledge about outcome of older adults with TBI comes from studies involving all age groups. These investigations report the positive associations between increasing age and mortality (19–24). Several studies have examined the functional outcomes of older adults who survive brain injury (11, 19, 25, 26, 28). The majority of these investigations demonstrate poorer prognosis for the older than the younger adult, with a correlation noted as young as 40 years of age.

Looking at acute hospital discharge data, the CDC reported increasing length of stay for each advancing age decade. Only 55% of older individuals were discharged home compared to over 78% for all other age groups. Thirty-five percent were discharged to another facility compared to less than 13% for all other age groups. Acute hospital discharge outcome as measured by Glasgow Outcome Scores indicated that only 57% of older individuals had “good recovery”, 16% had moderate disability

and 11% had severe disability; in all categories, older individuals had worse outcome (5).

An injury severity matched analysis of data from the NIDRR TBI Model Systems from 1989 to 1995 revealed that individuals aged 55 years and older had twice the rehabilitation lengths of stay and costs, half the rate of functional recovery, greater cognitive impairment at discharge, and twice the nursing home placement rate of individuals who were aged 50 years and younger. At discharge the level of physical impairment was comparable for the two groups (29). From 1995 to 2002, rehabilitation LOS averaged only 5 days longer in those individuals older than 55 years compared to those 15–55 years old, Disability Rating Scale (DRS) and Functional Independence Measure (FIM) indicated more disability, and discharge to a private residence was 80.8% compared to 94.3% (30).

Further analysis of this data set through 2002 without injury severity matching demonstrated that those  $\geq 65$  years old had mean acute care and rehabilitation length of stays of 20 and 30 days, respectively. This corresponded to mean acute care costs of \$93,758 and inpatient rehabilitation costs of \$43,306. Length of stay and costs did not differ appreciably in older versus younger age groups. The discharge rate to a private residence was 67% for those  $\geq 65$  years compared to 87% in those  $< 65$ . At one-year post TBI, 80% of those  $\geq 65$  years lived in private residences versus 92% of those  $< 65$ . Disability Rating Scale (DRS) scores were one point worse for the older adult group at rehabilitation discharge and at 1-year post TBI (12).

At acute rehabilitation discharge, the median DRS level of functioning subscale score was 3.0 for those  $\geq 65$ , indicating requiring another person in the home, compared to 2.5 for those less than 65, indicating between needing a non-resident helper and a resident helper. Fourteen percent required placement in a skilled nursing facility (12).

Using two separate measures of independent functioning, the Disability Rating Scale (DRS) and Supervision Rating Scales (SRS), individuals  $\geq 65$  required and received higher degrees of supervision for their day to day care at one-year post TBI. On the DRS level of functioning scale, the median score for those  $\geq 65$  was 1.5, indicating between “independent in a special environment and requiring a non-resident helper,” while the median score for those less than 65 is 0.5, between “completely independent and independent in a special environment.” On the SRS, the median score for those  $\geq 65$  was 4, indicating overnight and part-time daily supervision, compared to 2.0 for those less than 65, indicating unsupervised overnight but living with another person who is not always present (12).

This association between age and outcome is of course quite complex and appears to be associated with the severity of injury as measured by initial GCS, duration of coma,

and duration of post-traumatic amnesia (PTA). The relationship between injury severity, particularly the GCS motor component, duration of coma or PTA and outcome that has been established in younger individuals probably applies to older individuals as well (6, 11, 17, 23, 31, 34, 35). Analyses from the Traumatic Coma Data Bank noted an association between those  $> 40$  years old and both mortality and poorer functional outcome as measured by the GOS. The relationship was further strengthened when initial GCS motor score and evidence of midline shift or cisternal compression was noted on initial CT scans (36). No other published TBI datasets have focused on the potential impact of mechanism of injury, neuropathology, associated injuries, or premorbid conditions on outcome in older adults. Other factors that appear to have some impact on the association between age and outcome include: a history of acute or chronic alcohol intake, post-injury depression and/or agitation, and a variety of formal and informal social support factors (6, 11, 17, 23, 31, 32, 37, 39). In contrast, other studies have demonstrated that favorable outcomes are achievable in the older adult with similar costs (33).

### Age and health after TBI

Individuals  $\geq 55$  years old living in the community who have experienced TBI within 4 years have more perceived health problems than age-matched controls. In a group of 49 individuals with TBI, prevalence of headache, thyroid problems, body temperature changes, skin and hair changes, headaches, speaking and understanding others, sensory changes, difficulty with movement and spasticity, sleeping problems, neck and back pain, were all greater than 30 age-matched controls (41).

## REHABILITATION

### Assessment

*Medical* The rehabilitation approach to an older adult after TBI is similar to the general geriatric rehabilitation approach with some specific modifications. Clearly, an understanding of pre-injury activity levels, cognitive limitations, behavioral issues, and chronic medical conditions is vital. This information will assist in the assessment of the potential physiologic reserve present prior to acute injury, which can assist in the immediate determination of an individual's readiness and appropriateness for specific rehabilitation interventions (i.e., specificity, intensity, and goal setting for therapies). Direct communication with the individual's primary care physician (PCP) or geriatrician can help to better understand the level of pre-morbid abilities and limitations and facilitate their specific management strategies into the rehabilitation program. This step is of additional importance for patients in managed care

networks, in which the PCP is often the gatekeeper for both current and future medical resource management.

An assessment of the acute medical and neurological status of the older adult with TBI must include a thorough evaluation of their medical systems, taking into account pre-morbid deficits. Screening of special senses (hearing, vision, touch) can provide useful information to the therapy treatment team on ways to optimally interact with the patient. While cerebrovascular, cardiovascular, metabolic and pulmonary diseases are common in this population, an appreciation of the clinical manifestations of these conditions will allow one to best structure the rehabilitation interventions. Joint and muscular abnormalities, especially pain, should be determined to help guide necessary management strategies and precautions. A thorough review of the patient's pre-injury and current medication routine is seminal in order to optimize treatments (e.g., pre-morbid medications may not have been restarted, numerous medications that are especially cognitive-impairing may no longer be necessary), define therapy parameters (e.g., anticoagulant use, antihypertensives), and prevent secondary conditions (e.g., antithrombotics are often underutilized in the frail older adult patient).

While serial brain-imaging studies are commonplace for patients with recent TBI, special attention should be paid to the presence of late or delayed bleeding and hydrocephalus. A follow-up imaging study, usually a CT scan, performed between 2 and 4 weeks post-injury can rule out these abnormalities, particularly if there has not been clinical improvement as expected. Indications for a MRI or dynamic imaging studies in the acute period after TBI would include unexplained clinical findings, such as brainstem pathology or a concomitant ischemic event. The patient's cognitive and behavioral status, diurnal variations in alertness, and ability to tolerate both physical and mental activities should be determined by examination and evaluation in the acute care and rehabilitation settings. Formal neuropsychological evaluations have little role in this acute period, but may prove to be invaluable in the post-acute phase or rehabilitation.

*Social* Of equal importance is a comprehensive review of the social support network, which involves an understanding of both the formal and informal support systems available (37). Formal support systems include federal (Medicare, Social Security), state (Medicaid, Department of Rehabilitation Services, welfare, area agencies on aging), and local (adult day health programs, transportation, Meals on Wheels) resources. Informal supports include family, friends, and religious affiliations. Early involvement of family and friends in planning and implementing the rehabilitation program is vital. Older adults tend to have significant others who are either older, disabled, or deceased, thus they are more likely to have increased involvement of extended families in their systems of

support. Daughters and female caregivers are more likely to play a major support role, particularly a physical or hands-on one, than sons are. It is essential to clearly understand the older adult's pre-morbid and/or present role in the social structure to which they expect to return. Additionally, one must consider advanced directives, congruence of patient and caregiver's goals, and religious and cultural factors.

*Funding* A working knowledge of the most common funding mechanisms available for post-TBI care of the older adults is extremely important. In the United States, for example, 98% of the older adults are primarily funded by a single source, Medicare. Similarly, in Canada, Australia, New Zealand, and most European countries, the government funds the overwhelming majority of rehabilitation care for the elderly. With Medicare, while physician (inpatient, outpatient, nursing home) fees and home-health and outpatient therapy are currently paid at 80% of "reasonable charges," inpatient and nursing home rehabilitation services have recently received a significant modification in reimbursement transitioning from the TEFRA to PPS (Prospective Payment System) model. The PPS reimbursement rate is adjusted if the patient is discharged to a skilled nursing facility. Secondary or co-payment insurance varies as greatly in coverage as standard commercial insurers, but rarely pays for extended rehabilitation services. Long term care or catastrophic insurance is increasingly available and provides reimbursement for subacute rehabilitation and custodial care within skilled nursing facilities (SNF).

Medicare is a federally sponsored program, so its coverage is uniform throughout the United States. Within *managed care Medicare health plans*, benefits vary depending on the plan chosen. Any individual who has paid into the federal tax system for 40 quarters (or was ever married to someone who has) and meets any of the following three criteria is eligible for Medicare part A at no cost: 1) age 65 years or older, 2) disabled and on Social Security Disability Insurance (SSDI) for more than 2 years, or 3) has end stage renal disease. Medicare part A reimburses for durable medical equipment, inpatient, and SNF rehabilitation services. Medicare part B, which is available to individuals on Medicare part A for a monthly fee, reimburses for physician services, home health and outpatient therapies.

Medicaid (e.g., Medi-Cal in California) is a state-sponsored and, therefore state-specific program to fund health insurance for the medically indigent, pregnant women, and children. Medicaid inpatient, outpatient, home health, nursing home, durable medical equipment, and physician benefits vary from state to state. Recently, numerous *managed care Medicaid* programs have become available that have further increased the diversity of covered services, in this case even within a state. At present, Medicaid pays for more than 85% of all custodial nursing

home care in the United States. Older adults who continue to work or who have been disabled veterans, federal or railroad employees typically have different commercial or managed care insurance as their primary funding source.

### Settings

Older adults with acute TBI should have access to rehabilitative services in the appropriate environment for their capabilities. Although most patients can benefit from some type and intensity of services, individuals who are most appropriate for 15 or more hours per week of interdisciplinary inpatient or day rehabilitation therapy programming are those who demonstrate the following characteristics: 1) an acute or new disability that is significantly below pre-morbid baseline; 2) a support system that will allow for return to a community residential setting; 3) the ability to tolerate, participate in, and improve with therapies, and 4) have appropriate funding to pay for services and after-care needs. See Table 21-1.

A return to the most familiar, pre-injury living environment is the first choice for discharge, but when not feasible an alternative reschedule (another family member's home, adult group home or assisted living) is a second option. Individuals who do not need or cannot tolerate inpatient or day rehabilitation services and can be managed in the community will often benefit from home health or outpatient therapy services. Skilled nursing facility-based subacute rehabilitation services are appropriate for older adults who are unable to tolerate the intensity of acute rehabilitation or cannot be otherwise managed at home. Common rehabilitation options are outlined in Table 21-1 (38–40, 42). In summary, the chosen rehabilitation pathway(s) will depend on medical and nursing acuity needs, endurance for therapeutic activities, formal and informal support systems, patient and family goals, and funding options.

## MANAGEMENT OF THE OLDER INDIVIDUAL WITH TBI

### Medical Issues

An assessment of rehabilitation issues should be initiated in the ICU. Early controlled mobilization in and out of bed minimizes the effects of prolonged bedrest, especially pressure sores, muscle contractures, spasticity, venous thromboembolism, cardiac deconditioning, atelectasis, aspiration pneumonia, constipation, urinary retention and infection, and sensory deprivation (43). Rest periods and up-down schedules may be required to gradually increase tolerance to activity. Improved participation and motivation can be facilitated by involving the individuals

with TBI and family in goal-setting and focusing on functional tasks that are similar to home routines.

Day-to-day medical management of the elderly individual recovering from acute trauma must be diligent and thorough. When a consistent team of rehabilitation professionals is working with an individual every day, changes in medical status and performance are more likely to be discovered earlier than by a smaller team of a physician, nurse, and family member. Newly identified problems must be evaluated efficiently and appropriate treatment instituted so that these problems interfere minimally with progress toward rehabilitation goals. If the identified problem is unlikely to resolve quickly, then the entire team must be informed so that the goals can be reformulated or the patient transferred to a different level of care.

### Medication Management

More than 90% of the entire population over age 65 takes at least one prescription medication daily; most take two or more. In addition, over-the-counter remedies are used ubiquitously (44). During the acute traumatic period, previously prescribed medications may be inappropriate, not feasible to administer, or unknown to the acute management team. Invariably, medications are used to treat or prevent conditions associated with acute trauma. Common medications include proton pump inhibitors or histamine-2 blocking agents to prevent stress ulceration, anticonvulsants to prevent seizures, sedatives and/or hypnotics for agitation, antiarrhythmics for transient or chronic cardiac conduction events, narcotics and analgesics for pain control, aerosolized inhalers for respiratory problems, and antibiotics for diagnosed or presumed infection. Insulin is more likely to be used than oral hypoglycemic agents for blood sugar abnormalities in acute care settings.

Medication review with the acute treatment team is crucial as the individual is transitioned from emergent and acute care to rehabilitation settings. Families should be encouraged to bring in all medications that they find in the patient's home as well; they are likely to have been prescribed by multiple physicians. Nonessential medications should be tapered or discontinued as soon as feasible. Medications that must be continued should be prescribed in the simplest form—that is, the lowest frequency with the fewest pills, during typical waking hours and corresponding to routine activities for that person. Principles of drug absorption, distribution, metabolism, tissue sensitivity, excretion, interaction, and compliance should guide the physician's choice of medications for any given condition (43).

### Pain

Acute pain from trauma is either nociceptive from visceral, bone and soft tissue damage or neuropathic from

**TABLE 21-1**  
*Levels of Care and Types of Rehabilitation Service Options for the Older Adult with Brain Injury*

LEVEL OF CARE	THERAPY INTENSITY/FREQUENCY	THERAPY SERVICES	REIMBURSEMENT	TYPE OF SETTING	DURATION OF PROGRAM	COMMENTS
Acute care services	5–6 days/wk; 0.5–2 hrs/day	Multidisciplinary (MD, N, PT, OT, SLP, RT, SW)	Medicare, Medicaid private insurance	Acute care hospital	3–21 days	After injury to prevent bedrest complications, allow comprehensive rehabilitation assessment
Acute inpatient Rehabilitation	6–7 days/week; 3–5 hrs/day	Interdisciplinary (MD, N, PT, OT, SW, TR, PSY, SLP, RT)	Medicare, Medicaid some private	Acute rehabilitation facility free-standing or attached to acute Hospital	7–35 days	After acute care or subacute care; specialization in rehabilitation medicine and therapy
Subacute care	3–5 days/ week; 0–2 Hrs/ day	Multidisciplinary (MD, N, RT, PT, OT, SW, SLP)	Medicare, some private	Free-standing or attached to acute hospital	7–100 days	Specialize in respiratory care
Skilled Nursing Facility (SNF)	0–5 days/ week; 0–2 hrs/ day	Multidisciplinary	Medicare, Medicaid, some private	Free-standing	7–lifetime	If discharge to community setting not possible
Home health services	3 days/wk; 0.5–2 hr/day	Multidisciplinary (N, PT, OT, SLP, HHA, SW with MD order)	Medicare, Medicaid private	Patient's home	2–12 wk	Homebound for physical or cognitive reasons after acute/ subacute care, inpatient rehabilitation
Outpatient services	2–3 days/wk; 0.5–3 hr/day	Multidisciplinary (PT, OT, SLP, PSY, SW)	Medicare, Medicaid, private	Clinic	2–8 wk	Living in community with focused needs (language, mobility, ADL)
Day rehabilitation services	3–5 days/wk; 3–5 hr/day	Interdisciplinary (PT, OT, SLP, SW, PSY, TR)	Private insurance	After acute care hospital, inpatient rehab or day rehabilitation	4–8 wk	Sufficient endurance to travel and good informal support systems; may allow shorter acute hospital or inpatient rehab length of stay
Day care services	5 days/wk; 4–10 hr/day	Health care attendants; Outpatient therapies available for brief periods as needed	Medicaid (Partial)	Custodial care of community dwelling older adults who need supervision for safety or who need minor assistance	Indefinite	Cognitively-impaired individuals who are physically mobile and able to perform self-care ADLs with supervision-assist

Abbreviations: MD = physician; N = nursing; PT = physical therapy; OT = occupational therapy; SLP = speech and language pathology; SW = social work; TR = therapeutic recreation, HHA = home health aid; PSY = psychology; RT = respiratory therapy.

peripheral or central nervous system injury. In addition, older individuals are likely to have one or more chronic conditions, such as arthritis, osteoporosis, or peripheral vascular disease, that may contribute to their experience of pain. Comprehensive pain assessment tools are available and often need modification when individuals have cognitive impairments. The goal of pain management is improved function, mood, and sleep (45).

For nociceptive pain, analgesic medications and physical modalities are often necessary to facilitate mobility. Comfortable positioning, physical activity, heat, ice, ultrasound, and massage are preferred first line non-medication interventions (46). If pain is occurring at predictable times of the day or with routine activities, then non-narcotic analgesic medications can be scheduled for these activities. Individuals may be incapable of asking for medications or knowing their schedules. Often just the anticipation of pain deters individuals from activities. The practice of scheduling pain medications allows for better overall pain control and facilitates the individual's performance of activities in the acute rehabilitation process. Acetaminophen requires no dosage adjustment in the elderly and has equal analgesic efficacy to non-steroidal anti-inflammatory medications (NSAIDs) (43, 47).

If there is concomitant inflammatory arthritis or heterotopic ossification, NSAIDs and disease modifying medications may be indicated, with appropriate monitoring for gastrointestinal, renal and cardiovascular toxicity (48, 49). Nociceptive pain that disturbs sleep may be addressed with bed positioning and non-narcotic analgesia at bedtime. Narcotic analgesics are more potent in older individuals and invariably cause constipation and lethargy; they should be reserved for pain refractory to the above approach.

Neuropathic pain caused by chronic pre-existing conditions, such as diabetes mellitus or alcoholism, will likely require long-term maintenance treatment. Pain from peripheral nerve, plexus injuries, or subcortical lesions may cause acute neuropathic pain. Tricyclic antidepressants and anticonvulsants are usually more effective than analgesic medications for both acute and chronic neuropathic pain syndromes. Cognitive and autonomic side effects, toxicity and drug interaction profiles will determine which of these medications will be most safe in the older individual.

### **Deep Venous Thrombosis and Pulmonary Embolism Risk**

No standard of care yet exists for prophylaxis of deep venous thrombosis (DVT) after traumatic brain injury for any age group. In the acute hospital setting, DVT incidence was reported as high as 54% in those with "major TBI" (50). On admission to acute rehabilitation units the reported incidence ranges from 1.6–20% in

various studies (50–53). Sequential compression devices (SCD's) with or without thigh-length antiembolism stockings are considered safe if they are initially applied within the first 2–3 days post-injury. Data support their use for DVT and pulmonary embolism (PE) prevention if they can be applied 23 hours per day (54, 55). This amount of SCD use is most feasible in acute care settings until the patient is mobilized out of bed for more than a few hours.

Low-dose unfractionated or low molecular weight subcutaneous heparin are often contraindicated with recent intracranial surgery or subdural hematoma. No consensus exists as to the exact time that post-injury prophylaxis is relatively less risky than recurrent intracranial hemorrhage or expansion of cerebral contusions. It is probably safe for individuals with DAI within a week post-injury (56–58). Although low molecular weight heparin may be superior to unfractionated heparin in high risk trauma cases, bleeding risk after severe TBI may preclude use of either agent. If DVT is suspected, duplex ultrasound is the least invasive but adequately sensitive test to detect symptomatic disease without confirmatory venography which carries more morbidity (58).

### **Seizure Risk**

During acute care and inpatient rehabilitation the seizure frequency is 11% in those  $\geq 65$  years old and 12% in those  $< 65$  (12). Englander and colleagues followed individuals admitted to 4 trauma centers with TBI and intracerebral lesions for up to 2 years post injury. Individuals over 65 years old had 22.7% incidence of seizures compared with 18.7% between 16 and 64 years old, which was not statistically significant (59). Most posttraumatic seizures (PTS) are focal or focal with generalization, rarely progressing to status epilepticus. If PTS occur within the first week post TBI or if an individual receives prophylactic medication during acute care, anticonvulsants can be stopped abruptly (phenytoin, fosphenytoin, carbamazepine, valproic acid, oxcarbazepine) or weaned (diazepam, lorazepam, barbiturates) to minimize risk of withdrawal symptoms without increasing the risk of subsequent seizures (60). For those with higher risk, such as those with penetrating injuries, intracerebral hematomas requiring surgery, or multiple contusions, the use of padded side rails or enclosure beds can protect the person from further injury, should seizures occur. The continued usage of anticonvulsant medication after 7 days post injury even in such higher-risk individuals is not recommended by the American Academy of Neurological Surgeons or the American Academy of Physical Medicine and Rehabilitation (60, 61).

If seizures occur in the absence of a correctable metabolic disturbance after the first week post TBI, then there is an 86% likelihood of recurrence (62). The choice

of antiepileptic medication in older individuals is predicated on the same principles of choosing any medication for long-term usage: side effects, the degree of protein binding, drug interactions, cost, and compliance. Some of the newer antiepileptic drugs have fewer interactions, greater therapeutic windows, and do not require serum monitoring, such as oxcarbazepine and levetiracetam (63, 64).

### **Nutrition and Swallowing**

Older individuals with TBI are just as likely as younger individuals to have neurogenic dysphagia and more likely to have some pre-injury gastrointestinal condition that affects eating or digestion, e.g., dental problems, gastroesophageal reflux. Dentures may no longer fit properly after they have been removed for even several days during acute care.

Reestablishment of adequate nutrition is important in facilitating health and optimal recovery. Determining an older individual's ideal body weight and eating habits is a start, although many older people have compromised nutritional baselines. Up to 20% of ambulatory older individuals have a measurable vitamin deficiency (43). Serum albumin levels less than 3 g/dl or cholesterol less than 160 mg/dl are indicators of inadequate nutrition. Low serum ferritin or iron levels are also common post-trauma; enteral formulas have variable amounts of iron, so supplemental iron is often necessary to replace iron stores even with normal hemoglobin levels. Full replacement of iron stores may take 3–6 months (65). Following weekly or biweekly weights can help monitor nutritional status; if this is not accurate or feasible, serial midarm circumference measurements are more accurate than skin fold thickness in older adults (66). Commonly used medications are associated with the side effect of decreased appetite, especially selective serotonin reuptake inhibitors (SSRI), NSAIDs, digoxin, L-dopa, and diuretics. Other medications and conditions can decrease psychomotor skills for self-feeding, such as antipsychotics, sedatives and the injury itself.

In order to avoid aspiration pneumonia, bedside evaluation of swallowing capabilities should be performed as soon as the patient is sufficiently alert. Further evaluation with videofluoroscopic studies is best decided jointly by the physician along with the therapist who evaluates swallowing and those helping with feeding. These studies are most helpful when silent aspiration is suspected or when there is uncertainty regarding the best compensatory swallowing technique (67). Frequent monitoring for symptomatic aspiration by lung auscultation, listening for laryngeal pooling of food or liquids with breathing or spontaneous speech and coughing with proximity of eating and drinking are effective bedside monitoring techniques.

Until oral feeding can occur, appropriate enteral formulas are necessary. The smallest-gauge feeding tube should be used for optimal patient comfort. A gastrostomy may be preferable if prolonged enteral feeding is projected. Using formulas with fiber and starting with half-strength solutions are less likely to cause diarrhea. Lactobacillus supplements are often helpful in counteracting the tendency for loose bowel movements associated with recent or concurrent antibiotic therapy. Bolus feeding routines that correspond with eventual oral meal times makes transition to an eating routine easier and facilitates gastrocolic reflexes that aid in regular basel elimination.

### **Substance Abuse**

After dementia and anxiety disorders, alcoholism is the third most common mental disorder among elderly men in the United States (68). In older adults alcoholism is closely associated with tobacco abuse, other drug dependence, hypertension, liver disease, and organic mental disorders such as delirium, dementia, and amnesic disorders (69). A substantial proportion of older individuals begin to have problem drinking after the age of 60; others have a life-long habit (70). Ascertaining the history of alcoholism and other substance abuse in TBI is a challenge in and of itself (71). The CAGE questionnaire is the one of the easiest and quickest clinical screening tools (72). Using the Center for Disease Control and Prevention (CDC) screening tool at one-year post injury, 19.7% of individuals  $\geq 65$  years old admitted to any alcohol use compared to 39.1% of younger individuals. Of those that drank, no one  $\geq 65$  admitted to drinking more than 5 drinks per day compared to 12.8% of younger individuals (12, 73).

Treatment of substance abuse in the older individual poses unique challenges. Most programs are designed for younger adults, and the group experience may be less relevant for the older individual. It is less likely for individuals of any age to live alone post-TBI, so caretakers or living partners must be educated on the consequences of ongoing substance use, such as increased risk for recurrent injury, lowered alcohol tolerance and seizure thresholds. It is advisable to make the discharge environment alcohol and substance-free. Co-dependency issues must be addressed and confronted directly. Hurt and colleagues recommend equally intense treatment of the older individual with alcoholism as the younger one. Follow-up of their cohort 2 to 11 years post-inpatient treatment showed that 25 percent were able to remain sober, 41 percent had returned to alcohol use, and 32 percent were dead, nearly one-half from alcohol-related causes (69).

### **Continence**

*Bladder* Normal aging affects bladder function in the following ways: 1) prostate hypertrophy in men with

relative bladder outlet obstruction and diminished capacity with symptoms of urinary frequency, hesitancy and/or diminished stream; 2) pelvic relaxation in women from uterine prolapse or cystocele resulting in intermittent stress incontinence; 3) decreased bladder capacity with urinary frequency; and 4) decreased capability to suppress bladder contractions at low volumes resulting in urgency (74). Individuals with TBI are typically incontinent with urinary frequency because of inability to sense bladder fullness and/or suppress the pontine micturition center (75). Increased frequency may be a symptom of urinary tract infection. Medications that commonly affect bladder emptying include those with anticholinergic side effects, calcium channel blockers, antihistamines and narcotics. Bowel impaction, prostatic hypertrophy, and peripheral neuropathy may cause relative obstruction or the tendency to retain urine, which may also lead to infection. Incontinence may also occur with normal bladder functioning if the individual has impaired mobility or self-care skills that prevent efficient use of a toilet or urinal. Assessment of pre-injury voiding patterns is helpful in discerning any underlying pathology, independent of the effects of the TBI.

The first step in re-assessing current bladder function is removal of the indwelling bladder catheter or diaper that invariably accompanies the individual with TBI from acute care or skilled nursing settings. Elimination of medications that interfere with bladder physiology as mentioned above permit adequate baseline performance. A timed voiding schedule using a bedside commode or toilet in sitting or standing position can then facilitate regular opportunities for bladder emptying. It is difficult for many able-bodied individuals to have adequate bladder emptying in bed. Measurement of the post void residual urine volume (PVR), either by portable bladder ultrasound or by one-time bladder catheterization, can quantify the degree of emptying. If the PVR is less than 50 cc, then further measurements are unnecessary; between 50–100 cc, it is advisable to perform several repeated measurements to insure that residual volumes do not put the individual at risk for infection. Larger PVRs greater than 30% of total bladder volume (spontaneous void plus PVR) may indicate mechanical outlet obstruction, poor detrusor contraction or incomplete sphincter relaxation. Common conditions associated with this pattern are prostatic hypertrophy, peripheral neuropathy, or cystocele. Alpha-receptor blockers such as alfuzocin, doxazosin, terazosin or tamsulosin may aid in allowing the individual to relax the internal and external sphincters.

Timed voiding schedules and medication use can be re-evaluated as the individual's self-awareness, mobility and safety with toileting techniques improve. These interventions are often necessary for several weeks, but their usage can avoid the morbidity associated with diaper, indwelling or even condom catheter use.

**Bowel** Patients' bowel routines are typically disrupted during hospitalization for trauma and are a low priority in acute care settings. In older individuals, such disruption can become a preoccupation unless it is properly addressed. Fecal incontinence is prevalent in 68% of individuals with TBI on acute rehabilitation admission, 12.4% at rehabilitation discharge and 5.2% at one-year follow-up. Among other variables age is associated with incontinence at discharge and one-year post TBI (76).

Ascertaining a person's pre-injury bowel routine is the first step in establishing goals. Dietary changes, immobility and narcotic use for pain management are the most common causes for constipation in this population (43). However, until safe swallowing, mobility and routine gastrointestinal motility are re-established, interim measures are usually necessary.

For suspected fecal impaction which can present as loose incontinent stool leaking around the impacted area, one-time laxative, bowel stimulant and /or suppository often relieves the problem. Stool softeners or fiber may be advisable for some time because of ongoing therapeutic measures for pain management or iron replacement.

Diarrhea or loose stool is common with antibiotic usage and some enteral formulas. Infectious causes of diarrhea, especially *Clostridium difficile* should be treated. Fiber-containing enteral formulas or lactobacillus supplements can improve stool consistency. Bolus feedings encourage the gastrocolic reflex and more regular bowel evacuation patterns. Once an acceptable pattern has been established, interventions can be weaned serially to determine which if any are still necessary (77).

## Sensory Health

**Vision** Normal aging is associated with changes in visual acuity and refractive power, decrements in extraocular motion, increases in intraocular pressure, decreased tear secretion, and decreased corneal and lens function (43). Most older individuals use corrective lenses for reading and many for distance vision as well. Corrective lenses are often lost or broken during the acute traumatic event and not used during acute hospitalization. Decreased visual function can add to perceptual deficits and confusional states. Easily correctable visual problems, especially the resumption of glaucoma medication or finding a useful pair of corrective lenses can aid the rehabilitation process.

**Hearing** Normal aging is associated with loss of sensitivity and signal distortion of higher frequencies, difficulty localizing signals needed for dual ear listening, and difficulty in understanding speech in unfavorable listening conditions. Life-long noise exposure, middle ear and vascular disease can also affect hearing. Presbycusis, affecting 60% of individuals over the age of 65, is a progressive sensorineural hearing loss separate from all of the

above (43). With trauma, middle ear ossicles or cranial nerve VIII can be selectively damaged, especially with basilar skull fractures. The use of pre-injury prescribed hearing aids is challenging because the injured individual is often the only one familiar with their adjustment. Yet accurate communication is critical in helping individuals progress through their acute confusional state and communicate with caretakers and helping professionals. Until hearing aid use can be reestablished, written communication, direct eye contact to facilitate lip reading, gestural communication, and an environment without extraneous noise are helpful alternatives.

*Smell* Anosmia is probably the most frequent cranial nerve and sensory loss specifically associated with TBI (78, 79). It may result in decreased appetite while in the hospital. In the home environment it may impair the individual's ability to detect burning objects promptly. Presence of smoke detectors in the discharge environment is therefore part of the evaluation that should accompany home safety assessment with caregivers.

*Taste* Normal aging is accompanied by loss of lingual papillae, decreased saliva volume, and a relative decrement of taste acuity (43). It is relatively easy to test the basic elements of salty, bitter, sweet and sour tastes. It is best to have visitors bring in the patient's favorite foods when it is deemed safe for swallowing to fully ascertain whether the changes in taste or smell are going to affect the patient's appetite.

*Touch, Vibration and Joint Position Sense* Vibratory sense diminishes with age. Conditions associated with peripheral neuropathy are also more frequent in older individuals, although acute peripheral nerve, brachial and lumbosacral plexopathies are less frequent concomitant injuries in older adults. Reversible etiologies of peripheral neuropathy such as vitamin deficiencies, thyroid abnormalities, and neurotoxic medications should be identified and treated. Less reversible causes such as diabetes mellitus, alcoholism, uremia, HIV and syphilis are still worth identifying so that progressive neuropathy may be managed with better glucose control, alcohol abstinence or definitive treatment of the underlying condition. Compensation techniques, assistive devices for mobility and self-care, and adequate lighting may help the individual adapt to these impairments.

### Behavior and Cognition

Dementia affects 3 to 11% of community-dwelling adults over age 65, 20 to 50% of those older than 85, and nearly 60% of centenarians. Traumatic brain injury is one of the multiple etiologies of dementia (80). Therefore, it is important to ascertain an individual's pre-injury motivation, behavior and mental capacity in order to have reasonable expectations for cognitive recovery from their TBI.

The typical recovery pattern for older adults with TBI is not appreciably different than younger individuals. It includes an initial period of diminished arousal, followed by hyperarousal and culminating in return to a new baseline level of arousal, that may differ from pre-injury function. Goldstein and Levin compared 22 individuals with TBI over age 50 living in the community with age, gender and education-matched controls and found that those with TBI had more difficulty with verbal and non-verbal learning, expressive language, executive functioning, and depression (81). The treatment team can influence a safe transition through the various levels of recovery by preventing secondary injury, treating concomitant symptoms and illnesses, targeting pharmacological interventions, and engineering the environment. Facilitating transition to the most familiar discharge setting and use of familiar calendars and memory aids can help with motivation and compensating for these deficits.

### Attention

Decreased arousal and attention are common after DAI, hypoxic ischemic injury and dorsal lateral or deep frontal lobe injury. Hypoarousal is characterized by difficulty staying awake despite adequate sleep and appropriate stimulation. Hypoattention is characterized by inability to attend to conversation or self-care tasks with adequate alertness. Either deficit can interfere with progress in recovery. Management techniques include normalizing sleep-wake cycles, establishing routine up-down schedules, minimizing medications with sedating side effects, and control of distractions in the environment. Attention deficits can be treated safely in the older adult without concomitant coronary artery disease with methylphenidate; the short-acting preparation will yield results within several days (82). Carbidopa/levodopa may be useful if inattention is accompanied by bradykinesia and rigidity, with results apparent within 1–2 weeks of initiating therapy. Amantadine, modafenil, and SSRI's are usually safe medications but have longer onset of action (83).

### Agitation

Restlessness and agitation occur in approximately one-third of individuals with moderate to severe TBI. They interfere with safety and participation in activities of daily living and especially rehabilitation programs (84, 85). The Agitated Behavior Scale and checklists that quantify specific behaviors are very useful for monitoring agitation over time (86, 87). Agitated individuals with TBI are more likely to have psychological adjustment difficulties, require supervision or institutional placement after discharge (88). Management strategies include behavioral plans, environmental modifications using cubicle or enclosure beds, structured therapy sessions with co-treatment, 1 to 1 attendant

care, appropriate pain control, and medications for specific targeted behaviors (89). Commonly used medications include non-sedating anticonvulsants, tricyclic or heterocyclic antidepressants, amantadine, beta-blockers, and atypical antipsychotics. Benzodiazepines are generally thought to be safe medications, but can cause paradoxical agitation or increase levels of confusion and amnesia particularly when the sedative effect wanes (90).

### Alteration in Mood and Sleep

Depression occurs in 20–70% of individuals during the first 2 years after TBI; studies do not stress that age is a risk factor for depression (91). In the general population, anxiety and major depression are less common in older than in younger individuals (92). Severity of injury and level of physical disability do not correlate with frequency or severity of depression (93).

Normalizing sleep-wake cycles is as important in managing mood disorders as it is in disorders of arousal and attention. Contributing factors to insomnia include interrupted sleep by hospital personnel or other patients, persistent effects of sedating medications, pain, and poor sleep hygiene. The latter can be addressed with a balanced activity schedule during the day, scheduled rest periods, minimizing nighttime disturbances, and having a daytime and evening routine (94). Low doses of eszopiclone, zolpidem or zaleplon can be useful for helping to initiate sleep for 3–4 weeks. If longer-term usage is anticipated, trazodone may be a better choice. Diphenhydramine and hydroxyzine are second-line agents, but should be used with caution because they may also cause urinary retention. Benzodiazepines frequently cause paradoxical reactions in the elderly, and tricyclic antidepressants are associated with postural hypotension and urinary retention that are poorly tolerated.

Psychological counseling is appropriate for the majority of individuals. Incorporating children and grandchildren into therapeutic and recreational activities can be most therapeutic. Early therapeutic outings to assess function in the home and community can enhance motivation. Methylphenidate is a short-acting agent that improves both arousal and attention and may assist in alleviating depressive symptoms. SSRI's are safe and common first-line antidepressant medications for older individuals because of their favorable side-effect profile. Onset of action is 3–6 weeks. Medication interactions and side-effect profiles are most important in this age group given concurrent morbidities (90).

### Safety Judgment

Pre-morbid or newly acquired deficits in cognition, strength, balance and sensation often challenge an individual's safety in the discharge environment. Awareness

and adjustment to these deficits determines the level of supervision needed at home (6). Prevention of future injury secondary to falls or wandering often requires added caretakers and resources in the discharge environment. See above section on Age and Outcome regarding supervision needs over time.

### Competence and Capacity

The acute and chronic cognitive, behavioral and communication deficits described above may affect capabilities for self-determination for health care and financial decisions in anyone with a TBI. *Competence* is legal term pertaining to an individual's right to self-determination; *capacity* is a medical term that pertains to the physical and cognitive abilities to convey and carry out one's wishes. An interdisciplinary evaluation by an appropriate and interested physician, psychologist, occupational therapist and / or speech and language pathologist is recommended to provide a comprehensive assessment that includes topographical and verbal orientation, money management, communication and reasoning skills (95). Older individuals are more likely to have a pre-existing durable power of attorney than younger individuals. If available, health care and even financial decisions can be facilitated. If not, each state or province has different guidelines regarding who can help the individual with TBI make such decisions. Court-appointed temporary and permanent conservators may be necessary to facilitate ongoing medical and financial decisions.

### Sexuality

As a consequence of common beliefs in our society, sexuality is often ignored in older adults. This tendency frequently persists in rehabilitation settings, particularly in the face of new disabilities. Sexuality encompasses a sense of self, the capacity to show affection, love and maintain relationships, and knowledge of the social context of sexual behavior and gender roles. In early stages of recovery from TBI, sexual comments may be less tolerated in older than younger individuals. Physiologic changes in vaginal mucosa, erectile and orgasmic performance often occur in normal aging. Changes in sexual desire in either direction can occur; there may be decreased interest and desire or an egocentric, impulsive, or disinhibited behavior pattern. Therefore, it is just as important to screen for sexual and relationship concerns in older individuals. Because of the multi-faceted nature of sexual relationships, techniques to enhance overall communication and interaction skills are most therapeutic (96). Sildenafil, tadalafil, and vardenafil, while effective for erectile dysfunction commonly encountered after TBI, is often contraindicated in older adults due to concomitant coronary artery disease and hypertension.

### Self-Care

Standard rehabilitation principles to recover self-care abilities are just as effective in the older adult with TBI. They may have comparable difficulty being motivated to learn “splinter skills” that are a small portion of a task, such as range of motion exercises alone. More whole task oriented therapy is better accepted. Learning an individual’s pre-injury habits and routines is vital to organizing relevant therapy. It is also important to secure some familiar clothing and grooming utensils, incorporating them into familiar daily routines in the hospital setting. Typical adaptive equipment recommendations include built-up or weighted utensils to accommodate upper body weakness, loss of dexterity and joint limitations; long-handled devices and reachers to accommodate difficulties with trunk balance and flexibility; bathroom safety aids (grab bars, tub or shower benches, hand-held shower heads, raised toilet seats or commode chairs) to compensate for decreased balance and strength. Home management skills, both physical performance as well as organization, are likely to require modification.

### Mobility

Challenges to safe ambulation in the older adult include learning how to accommodate for alterations in vision, peripheral or central sensation, balance, strength, and overall endurance. Chronic arthritis, joint and muscle stiffness are more common in the elderly. Household mobility may be facilitated with a home evaluation by members of the rehabilitation team to assess architectural barriers (doorways, stairs, floor coverings), furniture arrangement, adequacy of natural and artificial lighting as well as training for caregivers in safe mobility practices in the discharge environment.

Community mobility goals include the ability to get from place to place with route-finding and bodily transport and negotiating different terrains such as pavement, grass, curbs and stairs. Public transportation for individuals with disabilities is becoming increasingly available throughout the world, with various levels of governmental support. Focusing on familiar routes and routines, then gradually progressing to finding one’s way in new surroundings is a typical sequence for increasing community mobility skills.

### Driving

Safe driving after a TBI must take into account the older adult’s pre-injury capabilities and new impairments. Some jurisdictions require health care practitioners to report to public health authorities or the department of motor vehicles (DMV) physical or cognitive conditions that may alter one’s driving safety. The DMV’s response also varies

by location, even within the same state. Some states or provinces may revoke a driver’s license after being reported by a health care practitioner. Interviews and more rigorous testing procedures may be given to those with seizures, cognitive or motor deficits (97, 98). Comprehensive driving evaluations may be helpful, although third-party commercial or government insurance funding is rarely available, unless the disability is the result of a work or military service-related injury. Cognitive and physical testing may rule out an individual’s inability to drive if there are no obvious deficits in strength, sensation or vision. No test replaces an actual on-the-road evaluation in order to insure driving safety (99, 100).

### Recreation and Vocation

A thorough survey of an older adult’s pre-injury recreational pursuits is necessary in order to explore options post-TBI. Sedentary activities can usually be resumed with minor modifications, if any. Socialization opportunities may have been the primary leisure activity and is appropriate afterwards, perhaps minus any accompanying substance use. Resumption of group activities in the rehabilitation setting and community settings is important to minimize feelings of isolation.

Return to work rates are poor for older adults after TBI. Realistic goals need to be established with appropriate supports in the work place. Often early retirement or part-time volunteer work is necessary when an individual cannot return to their workplace (101).

### Case Example

AR is a 73-year-old married man who fell down a stairwell at a hotel party while on vacation, landing on his head. He lost consciousness at the scene, was initially unable to move his legs, and had significant scalp lacerations. In the ER, GCS was 12 and he began to move his legs. CT scan of his head revealed occipital and basilar skull fractures, multiple cerebral contusions, subdural and subarachnoid hemorrhages. None of these required surgical intervention. His associated injuries included right hemothorax and pulmonary contusions, grade 1 liver laceration, cervical 5–7 vertebral body fractures, thoracic, lumbar and sacral fractures, and bilateral pubic rami fractures. His past medical history included a cardiomyopathy, probably secondary to alcoholism, with 30 to 35% ejection fraction and an episode of ventricular tachycardia in the last year, gout, and colon cancer 10 years previously. He has an MBA, is retired as president of a construction company and has lived with his wife of 50 years in a 2-story home. His hobbies are playing tennis and traveling.

He was initially intubated for airway control and underwent tracheostomy, T3 – T12 laminectomies, rod- and bone graft; C3-7 posterior stabilization and

lumbosacral stabilization. He was extubated and started following commands consistently 3 weeks post-injury. He required no intracranial surgery.

Four weeks post-injury he was transported to a hospital in his community via air ambulance. Occupational, physical and speech therapies were initiated. Within 2 days he needed to be mechanically ventilated again due to exacerbation of congestive heart failure and was gradually weaned from the ventilator over 2 weeks while his cardiac medications were re-adjusted.

At 6 weeks post injury he was admitted to acute rehabilitation, dependent in all areas of mobility and self-care at Rancho level 5. His speech was fluent and he was oriented to person, city, and that he was in the hospital because of a fall. Upper extremity strength was symmetrical and grade 3/5 strength at the shoulders, 4/5 at the elbows, wrists and hands with wasting of his interossei but good dexterity. Lower extremities were symmetrical except at the ankles with grade 1/5 strength at the hips, 2/5 at the knees and left ankle, 1/5 at the right ankle. Sensory exam showed a stocking distribution of loss to all modalities below the ankles. His tracheostomy was being plugged for most of the day.

He emerged from posttraumatic amnesia 2 months post-injury while watching Wimbledon tennis matches on TV, which aided his orientation to time and date. A nerve conduction study showed moderate severe peripheral polyneuropathy with an additional right peroneal nerve injury. He had near syncopal episodes whenever he removed his elastic support hose with SBP as low as 70 mm Hg. After 4½ weeks of acute rehabilitation, he required extra time but was independent in eating, grooming, and using a urinal. He was supervised for donning a shirt and required less than 25% assistance for dressing and washing his lower body, transfers to unlevel surfaces using a sliding board. He could propel his wheelchair 100 feet before tiring and started walking using the parallel bars and a walker. He was discharged home with home health therapy for 3 weeks followed by outpatient therapy for 2 months. He progressed to using a front-wheeled walker or cane with a right ankle foot orthosis for household and short-distance ambulation. Within several months of discharge he was able to resume management of his financial affairs and even go on a cruise with his wife and friends. His most bothersome ongoing symptom is pain in his feet and legs from his polyneuropathy. One year later he still hopes to play tennis again.

AR had several poor prognostic signs, including previous symptomatic cardiomyopathy, multiple fractures requiring surgery and prolonged PTA. However, he received excellent medical and rehabilitative care, had good family support and the will to not just survive but make the most of his capabilities. His recovery illustrates how a coordinated system of care can produce favorable outcome despite many potential pitfalls.

### **TBI, Apolipoprotein E4 and Dementia**

Apolipoprotein E4 (APOE-4) is a lipid transporter in the brain and cerebrospinal fluid (102). and is believed to play a role in the inflammatory response and neuronal repair following trauma. It is the product of a single gene and has been related to age-related cognitive impairment, decreased synapse-neuron ratio, increased susceptibility to neurotoxins, and hippocampal atrophy (103). Individuals with a history of TBI and apolipoprotein E4 (APOE 4) allele had 10 times the risk of developing Alzheimer's disease compared with 2 times the risk with APOE 4 alone and no increased risk with TBI alone (104). Nicoll and colleagues examined the brains of 90 individuals who died of severe TBI. All individuals homozygous for APOE 4 had beta amyloid plaques (BAP); overall, 52% of those with BAP had at least one APOE 4 allele while only 16% of those with no BAP had APOE 4 (105). Teasdale and colleagues analyzed 89 individuals with TBI with and without apoE-4 allele. 57% of those with the allele versus 27% of those without had 6-month outcome of death, vegetative state or severe disability (106). The presence of APOE 4 alleles, especially in the homozygous condition appear to be associated with worse outcome after TBI. Individuals with APOE 4 allele also have associated poor outcome after spontaneous non-aneurysmal intracerebral hemorrhage, amyloid angiopathy, and subarachnoid hemorrhage(103). Nearly all the above studies have been performed on individuals of western European genetic backgrounds and environments, so it is difficult to generalize the association across races and environments (107, 108).

### **AGING WITH TBI**

Conflicting data exist in the literature regarding aging and TBI. Amongst the published studies, various issues were examined including: time of onset of Alzheimer's Disease (AD), long-term neuropsychological outcome, incidence and causes of mood disorders, re-hospitalization, morbidity, mortality, as well as psychosocial outcome and satisfaction with life.

### **Alzheimer's Disease**

In a population-based cohort who acquired their TBI between 1935–1984, Nemetz et al found no greater incidence in the number of individuals with Alzheimer's disease, but a earlier onset, 10 years versus 18 years, suggesting that TBI may reduce the time of onset of dementia in those already at risk for Alzheimer's disease (108).

### **Neuropsychological impairment**

Increasing age is associated with greater neuropsychological impairment (e.g. diminished memory, slower

processing speed), but it is unclear whether it is the case for aging with a brain injury.

Johnstone et al. studied 279 individuals with a TBI over a 4-year period. They used age-based normative data to determine the decline in cognition compared to pre-injury levels for different age groups. They found that neuropsychological impairments noted in older individuals with a TBI are typical of changes with normal aging (109). Millis and colleagues looked at neuropsychological recovery from 1 year to 5 years after injury. They studied 182 persons with mild to severe TBI. Digits forward and backward, logical memory I and II, token test, controlled oral word association test, symbol digit modalities test, trail making test, Rey auditory verbal learning test, visual form discrimination, block design, Wisconsin card sorting test, and grooved peg board were used as neuropsychological data. Improvement from 1 year after injury to 5 years was variable. On test measures, 22.2% improved, 15.2% declined and 62.2% were unchanged. Patients showing improvement were most likely to have changed on measures of cognitive speed, visual spatial construction, and verbal memory. Decline was most pronounced on measures requiring rapid performance and cognitive flexibility (110).

### Mood Disorders

Little is known about the long-term risk of depression after TBI. Holsinger and colleagues compared the prevalence of depression 50 years after injury in 520 World War II veterans with and 1198 veterans without TBI. Head-injured veterans were more likely to report major depression in subsequent years and were more often currently depressed.

Lifetime prevalence of major depression in the head injured group was 18.5% versus 13.4% with no TBI. Current depression was detected in 11.2% of the veterans with brain injury versus 8.5% of those without (111). Thomsen found 20% incidence of psychotic behavior with onset 3 months to 6 years post injury; symptomatic memory problems in 75%, personality and emotional changes in 65%, concentration and mental slowness in 53% and loss of social contact in 68% of 40 individuals between 10–15 years post severe TBI (112).

### Hospitalization

Regarding health issues after TBI, Marwitz and colleagues investigated the incidence and etiology of rehospitalization 1 and 5 years after injury in 799 individuals. The annual incidence and of rehospitalization ranged from 22.9% 1 year after injury to 17.0% 5 years after injury. At 5 years after injury, general health maintenance was the most common reason for admission (36%) followed by seizures (18.7%), psychiatric (16%) and orthopedic (13.3%) etiologies (113).

### Psychosocial Outcome

Corrigan JD and colleagues examined outcomes in the first 5 years after TBI. They studied 95 adults 6 months to 5 years after inpatient rehabilitation for a TBI. Their outcomes measures included the following: Functional Independence Measure (FIM), Sickness Impact Profile (SIP), Medical Outcome survey Short Form-36 (SF-36), Community Integration Questionnaire (CIQ) and Satisfaction with Life Scale (SWLS). Outcomes 5 years after discharge showed improvement with most change occurring within the first 2 years (114).

A study by Mazaux and colleagues followed 79 individuals with TBI by phone interview 9 years after injury to assess their late functional outcome and satisfaction with life. Sixty-five to 85% of individuals were independent in activities of daily living (ADL) whereas only 35–55% of persons with TBI were independent with social interaction. Most people were satisfied with their level of autonomy (67%), family life (66%) and financial status (41%). Dissatisfaction was expressed regarding leisure activities (36%), vocational adjustment (28%) and sexual function (32%) (115).

The TBI National Data Base has 178 subjects comprising a range of age 16 to 80 who have acute rehabilitation discharge, 1-year and 10-year follow-up data. Using a global functioning measure such as the DRS, there is evidence that individuals achieve overall improvement in capabilities and independence over time: scores improve from rehabilitation discharge (5.53, SD 2.87) to 1-year (2.93, SD 2.82) and 10-years (2.14, SD 2.65) post TBI. Competitive employment increases from 22.5 to 29.5% between 1 and 10-years post TBI, and there is also a trend towards retirement. Whether that is occurring for just age-related or medically-related reasons is not defined in the database. Return to school on at least a part-time basis is typical at 1-year post injury but not at 10 years. With this cohort there is also a bias with regards to their ability to be followed over time. Although there is no control group, the overall capabilities and employment demonstrated is less than the general population (12) (see Table 21-2). These and other data above indicate that improvement in social status and achievement can continue over time even as the basic neurological recovery has stabilized.

### Mortality

Shavelle RM and collaborators examined causes of death more than one year after TBI. Mortality rate was elevated for circulatory diseases, respiratory diseases, choking/suffocation, and seizures. Mortality was higher between 1 and 5 years post-injury than after 5 years and was strongly related to reduced mobility. The markedly elevated mortality in those with reduced mobility is not

**TABLE 21-2**  
*Productive Activity Before and After TBI (12)*

	PRE-INJURY	1 YEAR POST-INJURY	10 YEARS POST-INJURY
Competitive Employment	59.9%	22.5%	29.5%
Full-time student	9.0%	4.0%	0%
Part-time student	0.6%	5.8%	0.6%
Homemaker	1.1%	2.9%	2.9%
Retired (age)	4.5%	5.8%	29.5%
Unemployed	24.3%	53.8%	28.3%
Other	0.6%	5.2%	9.2%

surprising, as a sedentary lifestyle is known to be associated with increased mortality risk, especially because of diseases of the circulatory system (114).

## CONCLUSION

Traumatic brain injury in the older adult occurs primarily as a result of falls, pedestrian versus motor vehicle collisions, and low- to moderate-speed motor vehicle crashes. The aging of the population in industrialized countries has resulted in an increasing incidence and prevalence of TBI in this age group and particularly among older women. Cerebral pathology in these injuries tends to be more focal with SDH's and contusions. Injuries from motor vehicle crashes also result in DAI. Severe injuries are less commonly survived, but individuals who do survive can have favorable functional outcomes.

Caring for the older individual with TBI requires employing a combination of the principles of geriatric medicine and brain injury rehabilitation, with close attention to the timing, setting and intensity of therapeutic interventions. Models of care need to adapt to the unique needs of the older adult.

Older individuals with TBI usually require more time to recover cognitively and physically than younger individuals. Removal or simplification of medication regimens is usually more efficacious than adding new ones. Therapeutic interventions must be tailored to the individual's and family's needs in their specific post-discharge environment with early training of caregivers and environmental modifications for safety (41, 77). Aging with TBI may progress more rapidly than aging without such injuries, particularly in some individuals with genetic predisposition. Most individuals improve gradually over time with regards to their physical and cognitive functioning,

frequency of rehospitalization and employment. However, as a group individuals with TBI have more medical and psychosocial challenges than those who were never injured.

## Acknowledgements

Portions of this chapter were previously published by Jeffrey Englander and David X. Cifu, as "The Older Adult with Traumatic Brain Injury" in Rosenthal M, Griffith ER, Kreutzer JS and Pentland B (eds), *Rehabilitation of the Adult and Child with Traumatic Brain Injury*, 3rd edition. Philadelphia: FA Davis, 1999; 453-470, ISBN 0-8036-0391-6. Special thanks to Jerry Wright and Jenny Marwitz, MA for help with accessing the NIDRR TBI Model Systems Dataset and to Naomi McCarroll for manuscript preparation.

## Mild TBI

**Grant L. Iverson**  
**Rael T. Lange**  
**Michael Gaetz**  
**Nathan D. Zasler**

### INTRODUCTION

Mild traumatic brain injuries are common. Bazarian and colleagues (1) reported that 56/100,000 people are evaluated in the emergency department each year for an *isolated* mild traumatic brain injury (MTBI). Sosin et al. (2), based on the National Health Interview Survey in 1991, estimated that 1.5 million Americans suffer a traumatic brain injury each year (i.e., 618/100,000), with the vast majority being mild in severity. This, of course, is much higher than previous estimates based on hospital admissions because most people who sustain a mild traumatic brain injury are not evaluated in the emergency department or admitted to the hospital (2). For example, mild injuries, such as concussions in sport, are very common. In a recent study, 30 percent of high school football players reported at least one previous concussion; 15 percent reported that they had experienced a concussion during the current football season (3).

For most people, MTBIs are self-limiting and generally follow a predictable course. Permanent cognitive, psychological, or psychosocial problems due to the biological effects of this injury are relatively uncommon in trauma patients and rare in athletes (see Refs. 4–9 for recent comprehensive reviews). Slow or incomplete recovery from MTBI is poorly understood, despite decades of research.

The purpose of this chapter is to provide a comprehensive overview of MTBI. The discussion is divided into the following 11 sections: (a) terminology, (b) pathoanatomy and pathophysiology, (c) S-100B as a marker for injury and predictor of outcome, (d) neuropsychological outcome, (e) early intervention, (f) return to work, (g) depression, (h) post-traumatic stress disorder, (i) risk for Alzheimer's disease, (j) persistent post-concussion syndrome, and (k) conclusions. This chapter does not provide a detailed review of concussions in sports or the differential diagnosis of the persistent post-concussion syndrome. Two chapters in this book are devoted to those topics.

### TERMINOLOGY

There is no universally agreed-upon definition of MTBI. However, the most commonly used definitions are very similar. The maximum duration of unconsciousness, for example, has been 20, 30, or 60 min or less in various studies. The duration of post-traumatic amnesia has been 60 min or less in some studies, and less than 24 hr in others (see Ref. 10 for a review).

Some researchers have differentiated *complicated* from *uncomplicated* MTBI (11). A complicated MTBI is diagnosed if the person has a Glasgow Coma Scale (GCS)

score of 13–15 but shows some brain abnormality (e.g., edema, hematoma, or contusion) on a CT-scan. Skull fractures were also considered characteristic of complicated injuries in Williams et al., but fractures have been investigated separately by other researchers. Williams and colleagues noted that patients with complicated MTBIs are more likely to have persistent cognitive and psychological symptoms, and their 6-month recovery pattern is more similar to persons with moderate head injuries. Complicated MTBIs are discussed in detail in the pathoanatomy/pathophysiology and the neuropsychological outcome sections of this chapter.

The uncomplicated MTBI is characterized by having no intracranial abnormality or skull fracture, with all other severity criteria in the mild range. Notably, there are several subtypes of injuries; the severity of injury, types of symptoms, and course of recovery can vary in relation to these subtypes. For example, it is assumed (although not well studied) that the person who is “dazed” and may have lost consciousness for a few seconds is much more likely to experience a rapid and complete recovery than a person who is unconscious for 20 min and has post-traumatic amnesia for 12 hr.

An interdisciplinary subcommittee published a definition of MTBI that was designed to clarify classification and improve cross-study comparisons. The definition was developed by the Mild Traumatic Brain Injury Committee of the Head Injury Interdisciplinary Special Interest Group of the American Congress of Rehabilitation Medicine (12). This definition is provided in Table 22-1.

**TABLE 22-1**  
**ACRM (12) Definition of Mild Traumatic Brain Injury**

A traumatically induced physiological disruption of brain function, as manifested by at least one of the following:

1. any loss of consciousness;
2. any loss of memory for events immediately before or after the accident;
3. any alteration in mental state at the time of the accident (e.g., feeling dazed, disoriented, or confused); and
4. focal neurological deficit(s) that may or may not be transient; but where the severity of the injury does not exceed the following:
  - loss of consciousness of approximately 30 min or less;
  - after 30 minutes, an initial Glasgow Coma Scale (GCS) of 13–15; and
  - posttraumatic amnesia (PTA) not greater than 24 hr.

*Note:* A better conjunction after point #3 should have been “or” as opposed to “and”.

This article was intended to provide a standard definition, established by consensus of a committee, to facilitate communication regarding MTBI in research and in clinical practice. The focus of the article was on how to determine whether an MTBI has occurred, by establishing injury severity criteria. The committee definition is widely cited in clinical practice and research. A major limitation to this definition, however, is the inclusion of a broad range of injury severity. This definition ranges from a *trivial* injury involving seconds of confusion, to a complicated MTBI involving 20–30 min of unconsciousness, several hours of post-traumatic amnesia, and a focal contusion.

In a report to the U.S. Congress in 2003, a working group provided the conceptual definition of MTBI set out in Table 22-2 (13). This Centers for Disease Control (CDC) working group also proposed limited criteria for identifying MTBI-related impairment, functional limitations, disability, and persistent symptoms in population-based surveys. These criteria are set out in Table 22-3.

The CDC working group acknowledged that this definition does not define subtypes of MTBIs within the

**TABLE 22-2**  
**National Center for Injury Prevention and Control (13) Conceptual Definition of MTBI**

The conceptual definition of MTBI is an injury to the head as a result of blunt trauma or acceleration or deceleration forces that result in *one or more* of the conditions listed below.

Any period of observed or self-reported:

- Transient confusion, disorientation, or impaired consciousness;
- Dysfunction of memory around the time of injury;
- Loss of consciousness lasting less than 30 min.
- Observed signs of neurological or neuropsychological dysfunction, such as:
  - Seizures acutely following injury to the head;
  - Among infants and very young children: irritability, lethargy, or vomiting following head injury;
  - Symptoms among older children and adults such as headache, dizziness, irritability, fatigue or poor concentration, when identified soon after injury, can be used to support the diagnosis of mild TBI, but cannot be used to make the diagnosis in the absence of loss of consciousness or altered consciousness. Research may provide additional guidance in this area.

More severe brain injuries were excluded from the definition of MTBI and include *one or more* of the following conditions attributable to the injury:

- Loss of consciousness lasting longer than 30 minutes;
- Post-traumatic amnesia lasting longer than 24 hr;
- Penetrating craniocerebral injury.

spectrum of the injury, and that researchers might continue to establish the importance of subtypes. The working group noted that the presence of an intracranial abnormality was one injury characteristic that should routinely be reported when available.

**TABLE 22-3**

***CDC Working Group Limited Criteria for Identifying MTBI-Related Impairment, Functional Limitation, Disability, and Persistent Symptoms in Population-Based Surveys [National Center For Injury Prevention and Control (13)]***

Current symptoms reported consequent to MTBI not present before injury or those made worse in severity or frequency by the MTBI:

- Problems with memory
- Problems with concentration
- Problems with emotional control
- Headaches
- Fatigue
- Irritability
- Dizziness
- Blurred vision
- Seizures

Current limitations in functional status reported consequent to MTBI:

- Basic activities of daily living (e.g., personal care, ambulation, travel)
- Major activities (e.g., work, school, homemaking)
- Leisure and recreation
- Social integration
- Financial independence

The CDC working group cautioned that most of these symptoms and limitations in Table 22-3 are associated with many other conditions, not just MTBI. The working group expressed concern regarding the limitations associated with the lack of specificity of the symptoms and functional limitations, but thought that these problems could be partially mitigated by the careful selection of appropriate comparison groups, cautious interpretation of findings, and by evaluating pre- and post-injury symptom reporting.

Under the auspices of the European Federation of Neurological Sciences, a task force published a classification system for MTBI that could be used to guide initial *management decisions* for emergency physicians (e.g., whether or not to undergo brain CT scanning). The EFNS subclassifications (14) for MTBI are presented in Table 22-4.

In 2004, a comprehensive review of the literature on MTBI was published in a series of articles in the *Journal of Rehabilitation Medicine* (e.g., 5, 15–18). The WHO Collaborating Centre Task Force on Mild Traumatic Brain Injury provided the following definition.

MTBI is an acute brain injury resulting from mechanical energy to the head from external physical forces. Operational criteria for clinical identification include: (i) one or more of the following: confusion or disorientation, loss of consciousness for 30 minutes or less, post-traumatic amnesia for less than 24 hours, and/or other transient neurological abnormalities such as focal signs, seizure, and intracranial lesion not requiring surgery; (ii) Glasgow Coma Scale score of 13–15 after 30 minutes post-injury or later upon presentation for healthcare. These manifestations of MTBI must not be due to drugs, alcohol, medications, caused by other injuries or treatment for other injuries (e.g. systemic

**TABLE 22-4**

***EFNS Classification Guidelines (14) for the Acute Management of MTBI***

<b>INJURY SEVERITY CLASSIFICATION</b>	<b>GLASGOW COMA SCALE</b>	<b>LOSS OF CONSCIOUSNESS</b>	<b>POST-TRAUMATIC AMNESIA</b>	<b>RISK FACTORS</b>
Category 0	15	None	None	None
Category 1	15	< 30 minutes	< 1 hour	None
Category 2	15	< 30 minutes	< 1 hour	Yes
Category 3	13–14	< 30 minutes	< 1 hour	Yes or No

Risk factors for intracranial complications following MTBI: (1) unclear or ambiguous accident history, (2) continued post-traumatic amnesia, (3) retrograde amnesia longer than 30 min, (4) trauma above the clavicles including clinical signs of skull fracture, (4) severe headache, (5) vomiting, (6) focal neurological deficit, (7) seizure, (8) age < 2 yr, (9) age > 60 yr, (10) coagulation disorders, (11) high-energy accident, (12) intoxication with alcohol/drugs.

*Note:* The subclassifications were proposed to facilitate initial management decisions. Category 0 was conceptualized as a head injury with no traumatic brain injury. “According to Advanced Trauma Life Support principles, a high-energy (vehicle) accident is defined as initial speed >64 km/h, major auto-deformity, intrusion into passenger compartment >30 cm, extrication time from vehicle >20 min, falls >6 m, roll over, auto-pedestrian accidents, or motorcycle crash >32 km/h or with separation of rider and bike (406, 407)” (p. 210).

injuries, facial injuries, or intubation), caused by other problems (e.g. psychological trauma, language barrier, or coexisting medical conditions) or caused by penetrating craniocerebral injury” (page 115; 10)

Without question, MTBIs can be characterized by damage to the structure and certainly the function of the brain. A minority of patients with MTBIs have visible abnormalities on CT or MRI conducted on the day-of-injury or within the first two weeks post injury. The mainstream definitions of MTBI include patients with these visible structural abnormalities. For the most part, however, the pathophysiology of MTBI is neurometabolic. The pathoanatomy and pathophysiology of MTBI are discussed in the next section.

### **PATHOANATOMY AND PATHOPHYSIOLOGY**

MTBIs can be characterized by damage to the structure of the brain. Clinicians and researchers often emphasize that most patients with MTBIs have normal structural neuroimaging studies; this is certainly true. However, a substantial minority of patients have day-of-injury abnormalities visible on CT. Approximately 7 to 20 percent of consecutive patients presenting to the emergency room<sup>1</sup> with an MTBI have bleeding, bruising, or swelling on day-of-injury computed tomography (17, 19–24). Borg and colleagues conducted a comprehensive review of this literature and concluded that the estimated prevalence of CT abnormalities of patients seen in the hospital was 5 percent for those with GCS scores of 15 and 30 percent or more for those with GCS scores of 13 (17). Not surprisingly, patients with macroscopic abnormalities on their day-of-injury CT have microscopic damage or dysfunction as well, as reported in both the animal and human literature. For example, in animal (25) and human studies (26–28) there appear to be observable changes in the vicinity of brain contusions that are related to neuronal metabolic pathophysiology (most notably with *N*-acetylaspartate, creatine and phosphocreatine, glutamate, and lactate) and glial reactivity (e.g., choline and inositol).

<sup>1</sup> Victims of serious assault, people who fall or are struck hard enough to fracture their skull, or people in high-velocity accidents are at increased risk for intracranial abnormalities (14), and these individuals are more likely to be seen in the emergency room. Note that at least 25 percent of people with MTBIs seek no medical attention and 14 percent are seen at their doctor’s office or in clinics (2). Moreover, there is a low risk for observable intracranial abnormalities in athletic concussions, most athletes are not taken to the hospital, and a significant percentage of athletes with minor concussions don’t even report the injury to their coaches or trainers (3). Therefore, the true incidence of structural lesions in *all people* with MTBIs is likely far less than these estimates.

Researchers have reported that some patients with normal CT scans show abnormalities on MRI (29–32) or single photon emission computed tomography (SPECT; 33–35). In some patients with mild or moderate TBIs, brain atrophy can be quantified on serial quantitative MRI over a interval of several months (36, 37). A careful MRI examination of Virchow–Robin spaces (i.e., extensions of the subpial space surrounding perforating arteries and emerging veins serving cerebral cortex—when enlarged, these have been linked to white matter injury) in non-complicated (i.e., 23/24 with GCS of 15 and 20/24 with unremarkable MRI) MTBI might reveal trauma-related findings (38). Abnormalities on positron emission tomography (35, 39) and SPECT (40, 41) have been observed in some patients with persistent postconcussion syndromes. Of course, many patients with chronic complaints do not have abnormalities on functional imaging, such as fMRI (42). Notably, abnormal functional neuroimaging studies do not *diagnose* the presence of an MTBI; there is a large literature on functional imaging abnormalities in patients with diverse neurological or psychiatric problems.

In most people, MTBIs are not associated with macroscopic abnormalities on neuroimaging. Moreover, in animal studies the microscopic damage associated with the milder injuries is very sparse. The physiological changes following MTBI at the cellular level have been examined extensively over the past 20 years, through animal and in vitro modeling. Based on the animal literature, it is assumed that most of the pathophysiology of concussion renders neurons and neural systems *dysfunctional* but *not destroyed*.

Contrary to popular belief, mild (as well as moderate) traumatic brain injury does not result in “shearing” of axons. Axons stretch and twist without being sheared or torn (43–46), even after repeated stretch injuries (47). What was originally conceptualized as “shearing”<sup>2</sup> (48–50) is actually a gradual process where stretched and badly damaged axons swell and eventually separate (43). This process (in MTBI) occurs in a very small number of axons; the vast majority of axons that are initially affected recover over time. The cellular pathophysiology associated with traumatic brain injuries, of all severities, is described in the next section.

### **Pathophysiology**

Advancements in neuroscience have changed our basic understanding of the pathophysiology of neuronal injury. It was once considered that excessive acceleration/deceleration forces caused shear strains on the brain that resulted in tearing or stretching of neurons at the time of

<sup>2</sup>The original neuropathology studies were based on patients with severe TBIs who were rendered in a persistent vegetative state or with severe dementia.

injury (48, 51, 52). Further, it was considered that the brainstem was the focus of injury (53, 54). Taken together, these studies have led numerous clinicians and researchers to conclude that acceleration/deceleration injuries result in shear strains within the cranial vault, and these in turn lead to shearing of neurons and blood vessels occurring principally in the brainstem. Although no one doubts the existence of shearing strains as the primary pathophysiologic mechanism responsible for damage to axons, the pathophysiologic sequence that leads to traumatic injury to neurons is “a process, not an event” (Ref. 55, p. 163).

The Ommaya and Gennarelli (56) model of TBI suggested that acceleration/deceleration forces can cause mechanical strains that occur in a “centripetal sequence.” Injuries of this nature occur when the head is propelled through space and is abruptly stopped by a solid object, such as the ground, or when the head is set into motion, such as when a car is struck from behind by another car. With mild forces, the sequence begins at the surface of the brain and then progressively affects deeper structures as forces become more severe.

Based on their original classification system, the authors postulated three critical predictions. First, when the degree of trauma is sufficient to produce LOC, cortex and subcortical white matter will be primarily affected, with damage to cortex and its associated white matter being more severe than that found in the rostral brainstem. Second, damage to the rostral brainstem will not occur without more severe damage occurring in the cortex and subcortical structures, because the mesencephalon is the last area to be affected by such centripetal forces. Third, cognitive symptoms such as confusion and disturbance of memory can occur without LOC; however, the reverse cannot occur (i.e., LOC cannot occur without accompanying cognitive symptoms) (56). In addition to these critical predictions, the theory reinforced three important aspects of how TBI can occur and the potential effects that different acceleration/deceleration forces have on the brain. First, it reinforced the principle that the *direction* of force can determine severity of injury. Second, a continuum of injury exists whereby mild, moderate, and severe brain injuries caused by acceleration/deceleration forces are not discrete entities but occur on a continuum. This continuum occurs from the surface of the brain inward with increasing amounts of damage occurring at each level of depth as forces increase (49, 57). Third, acceleration/deceleration forces alone are sufficient to cause severe TBI, as supported by research in human trauma cases (58–61). Understanding the importance of acceleration/deceleration forces and their role in the pathophysiology of MTBI can be seen in the number of methods that are being developed to measure these forces in motor vehicles (62) and in athletes (63–66).

It is important to link the presence of acceleration/deceleration forces with the primary mechanism of

injury in the neuron-axonal (and potentially dendritic) stretching. Recent studies have shown that axons of cultured human neurons have a remarkable capacity for stretch with no primary axotomy observed with strains below 65 percent of the length of the axon. In addition, axons exhibit the behavior of “delayed elasticity.” In other words, stretch causes a temporary deformation of an axon that gradually returns to the original orientation and morphology even though internal damage was sustained (67). Once stretched, a pathophysiologic process begins that can lead to further structural change and metabolic dysfunction. First, strain on the axonal membrane causes an abnormal influx of  $\text{Na}^+$  through mechanosensitive sodium channels, a reversal of the  $\text{Na}^+$ - $\text{Ca}^{2+}$  exchangers, and activation of voltage-gated  $\text{Ca}^{2+}$  channels (68). This in turn causes selective proteolysis or a breakdown of  $\text{Na}^+$  channels and progressively increasing levels of intra-axonal  $\text{Ca}^{2+}$  (69). The massive influx of  $\text{Ca}^{2+}$  leads to damage to the axonal cytoskeleton and initiates the pathophysiological process that follows.

Stretching of axons has functional and structural implications. In an animal model, stretch below four millimetres (mm) did not cause any morphological change in axons, a stretch of five mm produced changes in visual evoked potentials that were significantly different from controls, with a six mm stretch causing morphological change including retraction balls and axonal swellings (70). Therefore, a single acceleration/deceleration event might result in (a) no apparent change in structure or function, (b) functional or metabolic change, or (c) eventual structural change in the axon. These outcomes are dependent on the force applied to the brain.

Metabolic dysfunction that occurs in neurons following their exposure to acceleration/deceleration forces and blunt trauma has been recently reviewed (7, 71). Both reviews focus on compromised metabolic pathways that affect cellular energy production systems. Following axonal stretch, small ion species enter the axons at or near the nodes of Ranvier. This initiates metabolic dysfunction and when acceleration/deceleration forces are sufficiently high, will cause damage to the cytoskeleton and microtubules (this process will be described next) (43–46, 72–74). Immediately following this event, there is an indiscriminate release of neurotransmitters and uncontrolled ionic fluxes. The first of these are potassium ( $\text{K}^+$ ) efflux and sustained calcium ( $\text{Ca}^{2+}$ ) influx that activate pumps to restore cellular homeostasis. This will of course affect glucose utilization leading to dramatic increases in the local cerebral metabolic rates. Where this becomes problematic is when “hypermetabolism” occurs in the presence of decreased cerebral blood flow that can impact the functioning of ion pumps. In addition to increased glucose utilization, there may be impaired oxidative metabolism and diminished mitochondrial function. This can lead to the over-reliance on less efficient anaerobic

metabolic pathways. The net effect can be elevated lactate and reduced intracellular magnesium levels (magnesium is a very important component for generation of adenosine-triphosphate [ATP-energy production], the initiation of protein synthesis, and the maintenance of the cellular membrane potential). Mitochondrial accumulations of  $\text{Ca}^{2+}$  can lead to metabolic dysfunction and eventually energy failure (7, 71).

Recently, animal experimentation has provided evidence that depressed mitochondrial functioning might be improved by treatment with hyperbaric oxygenation (75). (See Chapter 57 by McElligott and colleagues in this book for a discussion of this topic.) In humans, magnetic resonance spectroscopy has been useful in detecting additional metabolic changes that can occur following MTBI. N-acetylaspartate (NAA), a marker of neuronal axonal viability, total choline (Cho), a marker of membrane metabolism, total creatine (Cr), which reflects energy status, and lactate (Lac), an indicator of ischemia, were measured at 2–30 days following injury in 14 subjects with an average GCS score of 14.4 (range 13–15) and 10 of 14 with positive CT or MRI indicators of neurotrauma. Significant differences were found for the NAA/Cr ratio in parietal white matter, Cho/Cr ratio in occipital grey matter, and the NAA/Cho in four occipital lobe regions. All three ratios were different in temporal lobe compared to control. The ratios were consistent with decreased NAA and increased Cho found in severe TBI (26).

The sustained influx of  $\text{Ca}^{2+}$  has another important effect; the initiation of a pathophysiologic process of axonal injury. Axons contain numerous microscopic elements including microtubules and neurofilaments. Microtubules are thick cytoskeletal fibers and consist of long polar polymers constructed of protofilaments packed in a long tubular array. They are oriented longitudinally in relation to the axon and are associated with fast axonal transport (76). Neurofilaments are essentially the “bones” or cytoskeleton of the axon and are the most abundant intracellular structural element in axons (76). When acceleration/deceleration forces are sufficient, a massive influx of  $\text{Ca}^{2+}$  leads to damage to the axonal cytoskeleton and initiates the formation of axonal swellings. This process has been reviewed in detail by Gaetz (77) and will be summarized here.

The pathophysiologic events that lead to secondary axotomy associated with animal models of traumatic axonal injury (TAI)<sup>3</sup> occur within minutes of injury. Five minutes after a moderate injury, neurofilament networks appear dense or more tightly packed, and local mitochondrial abnormalities have been observed without any

<sup>3</sup>The term traumatic axonal injury has replaced diffuse axonal injury because the damage is to axons that tend to group in various areas of the brain and are therefore not considered truly “diffuse”.

overt disruption of the overlying axolemma (74, 78). Within 30 minutes of a traumatic injury, scattered axons showed slight swelling, multiple swellings, and/or infolding of the axolemma. When this occurs, there can be focal neurofilament disarray and misalignment of the axon with local axolemmal infolding (74).

In the hours following injury, a gradual progression of axonal pathology occurs in the absence of local hemorrhage or damage in the surrounding tissue. Axonal swelling continues and focal aggregations of organelles occur (including mitochondria and neurotubules) with no physical tearing or shearing of the axon cylinder (43). Over a period of hours, this process leads to some axons having focal swellings with others in early stages of disconnection due to a disruption of axoplasmic transport (45). At three hr post-injury a further axonal change is observed including disconnection of the axon with continued expansion to form a mature reactive swelling. Some reactive axons display a proximal stump undergoing continued swelling due to increased accumulation of organelles capping an expanding neurofilamentous core (74). At four to six hr following brain injury, proximal and distal swellings are further enlarged, more complex, and are often separated by a thin strand of protein linking the two segments (43).<sup>4</sup> At 12–24 hr post-injury, Povlishock et al. (43) reported that swellings had progressed to resemble enlarged ball-like expansions with no continuity that could be identified between their proximal and distal axonal segments, suggesting an abrupt separation of the axon cylinder.

From 24 to 72 hr in animals, a further enlargement of cleanly separated axons was observed, with some showing what was assumed to be a regenerative attempt in the form of growth cones that protruded from reactive axonal swellings (45). At 24 hr in humans, the reactive swellings exhibit further change in their appearance and the process of axonal separation begins. From 30 hr to one week, grossly swollen axonal segments disconnected from one another are observable in humans (46, 73). At three to four days following injury, Povlishock and Becker (44) noted that the injury profiles differed from axon to axon. By 88 hr in humans, further progression of the reactive swellings had occurred with heterogeneity observed among the population of reactive axons (46).

At 5–7 days, various forms of reactive change were identified (44). This pattern continues until 9–14 days

<sup>4</sup>This pathophysiologic process has been observed in humans following fatal motor vehicle accidents and *severe* brain injury (46, 73), although it appears to occur more slowly in humans. The degree to which this pathophysiological process occurs following MTBI, and the numbers and locations of cells involved, is unknown. Nonetheless, it very likely occurs in patients with MTBIs of the more serious nature, such as complicated MTBIs or MTBIs resulting from high speed motor vehicle accidents.

two conditions are predominant (44). In one group of cells, the degenerative response continued, displaying several retrogressive changes such as lobulation, increased electron density, and axolemmal/axoplasmic disruption, all of which were accompanied by focal macrophage accumulation. In another group of cells, a regenerative response was observed (44). At 17–30 days, regenerative or degenerative axonal changes predominated. Macrophages observed in the presence of degenerating axons actively phagocytosed the damaged swellings. Some of these pathophysiologic changes were observed by Oppenheimer (79) decades ago. Recently, Bigler (80) reported single case autopsy data showing “scattered macrophages in the white matter” in the frontal and temporal lobes in a patient with an MTBI who died from other causes several months post injury. This patient was in a high speed MVA, his vehicle was “demolished,” he suffered cervical fractures due to projectiles, he had an initial GCS of 14, LOC of unknown duration, no significant post-traumatic amnesia, and a head CT that did not appear to show a trauma-related abnormality.

The changes observed in animal models and humans are consistent with a progressive series of neurophysiologic events initiated by acceleration/deceleration forces on the axon, and ending in some cases with a frank separation of proximal and distal axon segments. As Povlishock and Becker (44) stated, it had been long assumed that axonal shear or tensile force caused a physical disruption of the axon into a proximal and distal segment. These studies provide evidence contrary to the shearing hypothesis, and instead, suggest that even relatively low-intensity mechanical brain injury produces axonal change that is more subtle than that suggested previously (i.e., direct tearing of the axon).

Neuroscience has not only provided a new vantage point to consider the pathophysiology of injury, it has given us a better understanding about which neurons are vulnerable to injury. Early studies suggested that the brainstem was the primary site of injury (e.g., Refs 81, 82). However, recent studies point to cellular injury that does not specifically involve the brainstem, especially with injuries produced by mild to moderate forces. Various characteristics of neurons themselves appear to make them more susceptible to injury: when axons change direction, enter target nuclei, or when they decussate, they can be more easily damaged (45, 73, 79, 83, 84). Large caliber neurons are injured more often than smaller neurons that surround them (45). Of particular importance, injured axons are observed more often where a change in tissue density occurs, such as at the grey/white matter interface near cerebral cortex (49, 73, 84, 85), a finding supported by functional neurophysiology (86) and MRI. Because the cerebral cortex plays a substantial role in maintaining a distributed consciousness (87), trauma involving cortex and sub-cortical white matter will affect

consciousness because brainstem reticular cells will be suppressed due to a lack of input.

The features of cellular injury, dysfunction, and death have been described in detail in this section. It is important to appreciate that cell death is closely related to injury severity. Mild traumatic brain injuries, especially injuries on the milder end of the spectrum, are typically characterized by cellular dysfunction that is reversible. There is a continuum of injury, at the cellular level, ranging from completely and rapidly reversible cellular dysfunction, to slow but complete recovery, to slow and incomplete recovery, to cell death. Very mild concussions likely produce virtually no permanent damage to cells resulting in long-term symptoms or problems whereas severe traumatic brain injuries, especially those involving considerable forces, often produce widespread cellular death and dysfunction with clear functional consequences; complicated MTBIs and moderate TBIs likely fall in between.

### **S-100B AS A MARKER OF INJURY AND A PREDICTOR OF OUTCOME**

Over the past decade, there has been an increased interest in the role of various biochemical markers for use as diagnostic and prognostic measures of brain damage in the first few days post-TBI (88, 89). Biochemical markers are of great interest because they may provide a more cost effective and efficient measurement of brain damage than can be assessed in the acute treatment phase. Clinicians typically rely on static imaging techniques such as CT and MRI to determine the extent of brain damage. However, CT scanning tends to have a low sensitivity to diffuse brain damage and the availability of MRI is limited in many settings due to high costs (89). There is a growing body of research literature suggesting that the neuroprotein S-100B may be a reliable marker for brain damage (e.g., 88–95). S-100B is a calcium binding protein which is found in high concentrations in astroglial and Schwann cells, predominantly in the central nervous system. When these cells are structurally or ischemically damaged, it is believed that S-100B is rapidly released into the cerebrospinal fluid (CSF) and secondarily across the blood-CSF barrier into circulation (91). Measurements of S-100B are acquired from serum obtained from a standard blood sample (90). If the neuroprotein S-100B could be established as a reliable marker of brain damage, S-100B has the potential to serve as a cost-effective measure to (a) initially screen patients in the first hr post injury to detect brain damage, (b) monitor the occurrence of secondary complications during recovery, and (c) be used to predict future outcome (96).

Researchers have reported that the concentration level of S-100B is significantly higher in patients with MTBIs than in controls (91, 94, 97, 98). Unlike Glasgow

Coma Scale (GCS) scores, the presence of alcohol at the time of injury does not influence the serum concentrations of S-100B in patients with MTBIs or healthy controls (92, 98), even in injured patients with blood alcohol levels of 2.5 to 5 times (i.e., 250–500 mg/dl) the legal level of intoxication (91).

Researchers have reported that S-100B levels are associated with (a) the presence of brain abnormalities detected by CT scans (91, 95, 98, 99), (b) prediction of severe outcome 1 month post-injury as measured by the Extended Glasgow Outcome Scale (100), (c) the rate of failure to return to work 1 week post-injury in patients with very mild brain injuries (101), (d) injury severity as measured by the GCS and the Coma Remission scale (95, 97, 99, 102, 103), and (e) the presence of neuropsychological deficits 2 weeks and 6 months post-injury (95). However, not all studies have been as favorable. Some researchers have reported that S-100B levels taken directly after injury are *not* associated neuropsychological test results at 7 to 21 days post injury in an uncomplicated mild TBI sample (104) or with PCS symptom reporting 1-year following MTBI (105).

Although much of the research in this area does support a relationship between S-100B levels and outcome following MTBI, there are a number of limitations of using S-100B as a diagnostic marker for brain damage in this population. S-100B tends to be a sensitive marker for brain damage, but not a very specific marker. Various studies have examined the clinical value of S-100B levels to predict various outcomes from TBI such as abnormal CT scans (91, 97, 99, 103), abnormal MRI scans (106), severe disability as measured by the Extended Glasgow Outcome Scale scores (100), and return to work rates (101). A summary of the sensitivity, specificity, and predictive power values for S-100B to predict these outcomes is presented in Table 22-5. The results from these studies are remarkably consistent. Across all studies, sensitivity is high to very high (range = 80–100 percent) and specificity is moderate to high (range = 40.5–81 percent). However, positive predictive power (PPP) values are low to moderate (range = 21–40.5 percent). In contrast, negative predictive power (NPP) is very high (range = 95.1–100 percent).<sup>5</sup> Ideally, it is preferred for all four measures to be high. However, in these studies, only sensitivity and NPP have acceptable values. Nonetheless, these studies can provide some important information for prediction of outcome from MTBI using S-100B. These studies suggest that although S-100B *is not useful* for identifying individuals who are “at risk” of poor outcome from TBI (i.e., PPP), it *is useful* for identifying those individuals who are “*not* at risk” of poor outcome from TBI (i.e., NPP; individuals who will have a good outcome

post-injury). As a diagnostic tool, the practical implication of this finding is that S-100B measures will misidentify a significant portion of individuals “not at risk” (i.e., good outcome) as being “at risk” (i.e., poor outcome). That is, the test will be positive and they will falsely be labelled as being at risk for poor outcome. Theoretically, this could lead to unnecessary treatment or unnecessary worry for the patient. To our knowledge, there is no research that has compared the diagnostic accuracy of S-100B to current clinical decision rules.

Another limitation is the extracranial release of S-100B (105). Elevated S-100B levels have been found in trauma patients who *have not* sustained a head injury (107) and in healthy subjects involved in various sports (108–110). Anderson and colleagues found that S-100B levels measured immediately after admission to the emergency department were most elevated in trauma control subjects who had incurred bone fractures. However, patients with soft-tissue injuries and burns also had elevated S-100B levels that were 40 times greater than healthy controls<sup>6</sup> (107). Researchers examining athletes have found that the release of S-100B increases after various sporting activities compared to pre-activity levels (108–110). However, participation in certain sports results in the release of S-100B levels differently. Otto and colleagues found that competitive boxing resulted in the highest increase of S-100B, followed by jogging, running, 25km race, and sparring (108). Stalnacke and colleagues also found similar increases in S-100B levels in elite basketball, ice hockey, and soccer players (109, 110). Otto and colleagues hypothesised that the increase in S-100B after running activities may be the result from “brain tissue, axial vibration of the brain at each step” during the jogging and running action (108). This hypothesis, however, is purely speculative at this time. Although these studies do show that participation in various sports increases S-100B levels, the increase is lower than in patients who have sustained an MTBI (108, 111).

Methodological differences between studies make drawing any conclusions regarding the efficacy of S-100B as a useful marker for brain injury difficult. One major methodological difference relates to the time post-injury S-100B is measured. Measurement of S-100B greatly varies across studies ranging from as quickly as 44 minutes post-injury (93) to as long as 27 hr post-injury (95, 102). The majority of studies have measured S-100B within either 2 hr (97, 98, 100), 4 hr (99, 101, 103, 105), or 6 hr post-injury (94, 104, 112). This is an important issue because it is thought that S-100B levels rapidly increase in the circulation system within the first few minutes of injury, reaching a concentration peak within 20 min (91). S-100B is then eliminated quickly by renal

<sup>5</sup> See the table note in Table 22-5 for an explanation of these statistics.

<sup>6</sup>This study highlights the importance of comparing trauma controls to TBI in research studies.

**TABLE 22-5**  
*Summary of Sensitivity, Specificity and Predictive Power Values of S-100B Levels to Predict Outcome*

FIRST AUTHOR	N	COUNTRY	SETTING	SAMPLE TYPE	TIME OF BLOOD SAMPLE	S-100B CRITERIA	OUTCOME	SEN.	SPEC.	PPP	NPP
Stranjalis 2004	93	Greece	Hospital ED	MTBI (GCS = 15)	3 hr	0.15 µg/L	Failure to return to work 1 week post-injury (Yes/No)	80	74.4	37.5	95.1
Mussack 2002	20	Germany	Level 1 Trauma	Severe TBI (GCS 3–8)	M = 43.8 min (range 22.6–72.4 min)	0.76 ng/mL	“Unfavorable outcome” defined by GOS = 1–3	100	50	24.1	100
Biberthaler 2001	52	Germany	Level 1 Trauma	MTBI (GCS 13–15)	116 mins (SD = 18.8 mins)	0.1 ng/mL	Abnormal CT scan	100	40.5	40.5	100
Townend 2002	148	England	Hospital ED x 4	Mild-Severe TBI (88 percent GCS = 15)	M = 130 mins	0.32 µg/L	Severe disability at 1 month post-injury: GOSE < 5	93	72	33	99
Ingebrigtsen 2000	182	Norway Sweden Denmark	Hospital ED	MTBI (GCS = 13–15)	Within 3 hr	0.2 µg/L	Abnormal CT scan	90	65	13	99
Ingebrigtsen 1999	48	Norway Sweden Denmark	Hospital ED	MTBI	Within 6 hr	0.2 µg/L	Abnormal MRI scan	80	81	33	97
Romner 2000	278	Norway Sweden Denmark	Hospital ED	Mild-Severe TBI (91 percent MTBI)	M = 3.8 hr (range = 0.5 to 24 hr)	0.2 µg/L	Abnormal CT scan	92	66	21	99

*Note:* GOSE = Extended Glasgow Outcome Scale; GOS = Glasgow Outcome Scale; Sen = Sensitivity; Spec = Specificity; PPP = Positive predictive power; NPP = Negative predictive power.

For these studies, sensitivity, specificity, and predictive power statistics evaluate the ability of S-100B levels to predict, for example, abnormal CT and MRI scans, severe disability as measured by the GOSE, and return to work rates. Sensitivity is the true positive rate for a test/measure. It answers the question: knowing that the individual has a positive CT scan (for example), what percentage of these individuals will actually be correctly identified as having a positive CT scan using S-100B. Specificity is the true negative rate for a test/measure. It answers the question: knowing that that individual has a negative CT scan, what percentage of these individuals will actually be correctly identified as having a negative CT scan using S-100B. However, positive predictive power (PPP) and negative predictive power (NPP) are the statistics most suited as a diagnostic tool in a clinical setting (n = 1). These statistics provide us with information relating to how confident we can be, in terms of a percentage, that a given score on a test/measure actually predicts what the test is designed to predict. PPP statistics answer the question: knowing that the person has been classified as likely to have a positive CT scans based on S-100B, what is the probability that the person will actually have a positive CT scan. On the other hand, NPP statistics answers the question: knowing that the person has been identified as likely to have a negative CT scan using S-100B, what is the probability that the person will actually have a negative CT when scanned.

metabolism and urinary excretion (113), with a number of studies demonstrating a significant decline in S-100B within the first few hours after injury (e.g., 95, 99, 102, 105). S-100B is estimated to have a biological half-life ranging from 30 to 113 min (91, 113, 114). To date, there is no consensus in the literature on the dynamics of S-100B after TBI (104) or when is the right time to measure it (105). There is a lack of knowledge regarding how quickly S-100B is released following injury and how quickly it is eliminated by the body (104). While current research shows promise for S-100B as a marker for brain damage, much more research will be required before this biochemical marker will be accepted as a reliable measure of brain injury. Future research must strive to understand the dynamics (i.e., time of release and elimination) of S-100B after TBI and employ trauma control subjects to determine whether S-100B levels are unique to TBI.

### NEUROPSYCHOLOGICAL OUTCOME

Historically, some researchers and clinicians believed that loss of consciousness (LOC) was necessary for the *diagnosis* of MTBI. In the 1920s, Symonds (115) discussed the importance of traumatic LOC as an essential feature of concussion. He said that in

the initial stage the patient is completely unconscious and in a state of flaccid paralysis. In a severe case the respiratory and cardiac functions may hardly continue. In a few minutes recovery begins; the visceral reflexes are the first to return, and vomiting is common at this stage. The other cerebral functions recover more gradually, and there may be a phase of some hr during which consciousness is clouded. Following this again there may be complaint of headache and giddiness, but at the end of twenty-four hr in an uncomplicated case of concussion recovery should be complete.” (p. 829)

Of course, it has been recognized for many years that concussions can occur without LOC (e.g., 116). In fact, the vast majority of injuries in sports (117–119) and many injuries in medical trauma settings (e.g., 120–122) are not associated with LOC. The presence or duration of LOC is not always used as a criterion for MTBI in research studies (see Ref. 10 for a review).

The more interesting question is whether brief loss of consciousness is associated with worse outcome. Gennarelli and colleagues conducted an extraordinary series of primate studies (e.g., 123) illustrating that both the presence of diffuse axonal injury (i.e., traumatic axonal injury) and functional outcome are associated with duration of unconsciousness (i.e., coma). It is certainly well known that an *extended* period of unconsciousness/coma in humans is associated with poor long-term outcome. Repeated demonstrations in the literature of worse outcome

associated with more severe brain injuries—as defined by duration of coma—can understandably influence scientific beliefs regarding the importance of traumatic LOC in *very mild* injuries, such as those sustained in sports. There is no doubt, as a general rule, that patients with comas lasting 1–2 weeks have worse outcome than patients with comas lasting less than 24 hr (e.g., 124). However, this logic should not be assumed to hold true for MTBI. Researchers studying trauma patients have reported that there is no association between *brief* loss of consciousness and short-term neuropsychological outcome (e.g., 121, 125, 126) or vocational outcome (120). Some researchers examining *athletes* with concussions have reported an association between LOC and immediate or short-term outcome (e.g., 127–129), while others have not (e.g., 130, 131). However, athletes with concussions, as a rule, recover relatively quickly and fully (see the chapter by Collins, Iverson, Gaetz, and Lovell in this book for a review). Therefore, based on the literature to date, it would be a mistake to assume that brief LOC is a reliable predictor of worse short-, medium-, or long-term outcome in trauma patients.

### Post-Traumatic Confusion and Amnesia

Post-traumatic amnesia (PTA) has been related to outcome in many (e.g., 132–136) but not all (e.g., 137) studies involving patients with moderate to severe traumatic brain injuries. By inference, mainly, it is often presumed that PTA is also a predictor of outcome following mild traumatic brain injury. However, the duration of PTA in mild cases is difficult to determine because, by definition, it is a relatively short period of time and it is rarely assessed prospectively. The accuracy of retrospective reports of PTA is questionable.

Post-traumatic amnesia lasting more than 30 min in patients with MTBIs has been associated with cerebral hypoperfusion on day-of-injury SPECT scans (33). The presence and duration of post-traumatic confusion/amnesia has been associated with worse immediate outcome and slower recovery in athletes (128–130, 138, 139). Again, the literature regarding athletes is less relevant because they tend to recover quickly.<sup>7</sup> For trauma patients, there appears to be a relation between post-traumatic confusion/amnesia and short-term neuropsychological outcome (see the original data presented in Tables 22-7 and 22-8), but by three months post-injury this association may disappear (140). Some researchers have reported that duration of post-traumatic amnesia is related to one-year return to work rates, but this effect

<sup>7</sup>Athletes tend to be young, very healthy, highly motivated, and they usually don't have co-morbid conditions that might slow down recovery from MTBI or mimic the postconcussion syndrome in the post-acute period.

**TABLE 22-6**  
*Demographic and Injury Severity Variables by Post-Injury Confusion Groups*

VARIABLE	GOAT > 89 (N = 527)	GOAT < 90 (N = 227)
Age	26.0 (6.9)	26.1 (6.4)
Education	12.1 (1.8)	11.8 (2.0)
Gender	Male = 69.3 percent	Male = 72.7 percent
Race	Caucasian = 94.7 percent African-American = 3.3 percent Hispanic = 1.9 percent	Caucasian = 93.4 percent African-American = 5.5 percent Hispanic = 1.1 percent
Skull Fracture	18.0 percent	18.5 percent
Abnormal CT	12.5 percent	16.9 percent
GCS = 15	89.9 percent	73.6 percent
GCS = 14	10.1 percent	26.4 percent
Positive LOC	60.4 percent	65.7 percent
Negative or Equivocal LOC	39.6 percent	34.3 percent

GOAT = Galveston Orientation and Amnesia Test; GCS = Glasgow Coma Scale

was mostly due to the inclusion of patients with moderate TBIs and PTA greater than 24 hr (141).

### Complicated MTBIs

Commonsense would suggest that patients with complicated MTBIs (i.e., bleeding, bruising, or swelling on their

day-of-injury CT) would have worse short-, medium-, and long-term outcome than patients without obvious structural damage. Surprisingly, the literature is somewhat mixed on this issue. In most studies, patients with complicated MTBIs perform more poorly on neuropsychological tests in the initial days and weeks post injury (142–144), and they appear to have worse 6–12 month

**TABLE 22-8**  
**Neuropsychological Test Results for Patients with Abnormal CT-Scans**

(11, 30, 145) and 3–5 year (146) outcomes than patients with uncomplicated MTBIs. In contrast, some researchers have reported no differences (120) or equivocal differences associated with early structural abnormalities (36, 147). In a well-controlled prospective study, McCauley and colleagues reported that CT abnormalities were not associated with increased risk for postconcussion syndrome at 3 months post injury (148).

### Original Research: Relation Between Post-Traumatic Confusion and Neuropsychological Outcome

There has been very little research that has examined the relation between post-traumatic amnesia and short-term neuropsychological outcome in trauma patients. We present here original data in a carefully defined sample of young adult trauma patients with mild traumatic brain injuries who completed neuropsychological testing within the first week post injury. Participants were selected from a large database ( $N = 1,695$ ) of patients seen on the Trauma Service of Allegheny General Hospital in Pittsburgh, Pennsylvania between May of 1991 and June of 1994. The basic clinical pathway for any person with known or suspected brain injury, irrespective of severity, involved a GCS rating, skull x-ray, CT scan of the brain, and an assessment of post-traumatic amnesia with the Galveston Orientation and Amnesia Test (GOAT; 149).

To be included in this study, patients must have (a) had a GCS score of 14 or 15, (b) been under 40 years of age, and (c) been tested within *seven days post injury*. The total sample consisted of 484 patients who met these criteria. The average age of the total sample was 26.0 (SD = 6.7) years and their average education was 11.9 (SD = 1.9) years. Seventy-one percent were male and 29 percent were female. The mechanisms of injury for the patients were as follows: (i) motor vehicle accident without seatbelt = 47.5 percent, (ii) motor vehicle accident with seatbelt = 15.1 percent, (iii) falls = 10.1 percent, (iv) motorcycle with helmet = 7.6 percent, (v) struck by object = 6.2 percent, (vi) pedestrian = 4.3 percent, (vii) other = 4.1 percent, (viii) missing = 3.5 percent, and (ix) motorcycle with no helmet = 1.5 percent. Eighteen percent had GCS scores of 14 and 82 percent had scores of 15. The breakdown regarding loss of consciousness for the sample was 55.6 percent positive, 17.8 percent negative, 15.1 percent equivocal, and 11.6 percent missing. Skull fractures were present in 16.1 percent, absent in 72.3 percent, and missing in 11.6 percent of cases. The prevalence of intracranial abnormalities on day-of-injury CT was 11.8 percent. The remaining subjects had negative (68.6 percent) or missing (19.6 percent) results. Because 19.6 percent of the sample either did not undergo CT-scanning or their results were not coded into the database, it can be assumed that the actual prevalence of intracranial abnormalities was higher than 11.8 percent.

The patients underwent 35–45 minutes of neuropsychological testing. The tests administered are listed in Tables 22-7 and 22-8. Trails A and B are from the Halstead-Reitan Neuropsychological Battery (150). As tests of information processing speed, they require visual-motor tracking and sequencing. The Trails B test is more difficult because it requires set shifting (i.e., alternating between numbers and letters) during the sequencing task. Digit Span, Logical Memory, and Visual Reproduction were administered from the Wechsler Memory Scale-Revised (151). The ability to repeat a series of digits forward and backward is a measure of attention-concentration and mental control. The Logical Memory (LM) subtest is a memory test for stories. Two stories are read, one at a time, and the subject is asked to recall everything he or she can remember from the story. There is an immediate recall trial (Logical Memory I) and a 30-minute delayed recall trial (Logical Memory II). The LM percent retention score reflects the percentage of information retained after the delay interval (i.e., LMII/LMI). The Visual Reproduction subtest is a memory test for geometric designs. Each design is presented to the subject for 10 seconds, removed, and then the subject is instructed to draw it from memory. After 30 minutes the subject is asked to reproduce all of the previously presented designs (Visual Reproduction II; VRII). The Visual Reproduction retention score is derived by dividing VRII by VRI. The Controlled Oral Word Association Test (152) is a measure of lexical verbal fluency. Patients are given a letter of the alphabet (e.g., C, F, or L) and asked to orally-generate as many words that they can that begin with that letter.

The Wisconsin Card Sorting Test-64 (WCST-64; 153–154) is an abbreviated version on the WCST (155). The WCST contains two decks of 64 cards that the patient must sort on the basis of certain characteristics. This is a nonverbal problem-solving test. The WCST-64 employs only the first of the two decks (156). The Hopkins Verbal Learning Test (HVLT; 157) is a 12-item, three trial word list learning test. The original test has been modified to contain a delayed recall and recognition trial, and normative data are available (158).

The patients were sorted into two groups on the basis of their GOAT scores. Those with GOAT scores of 90 or more were viewed as having no obvious, sustained post-injury confusion. Those patients with scores below 90 were considered to have possible to probable post-injury confusion or amnesia. A score of 90 was the closest value to a median split, with 53 percent of the total sample in the higher group and 47 percent in the lower group. Demographic and injury severity characteristics of the two groups are presented in Table 22-6. The patients with lower GOAT scores had a greater proportion of subjects with GCS scores of 14 ( $X^2(1) = 22.0, p < .001$ ). The groups did not differ in their proportions of patients

with skull fractures ( $p < .90$ ), CT abnormalities ( $p < .22$ ), or loss of consciousness ( $p < .27$ ).

Descriptive statistics, mean comparisons, and effect sizes for the neuropsychological tests in the patients with *normal* CT-scans by group are presented in Table 22-7. The groups did not differ in age ( $t(482) = -.16, p < .88$ ) or education ( $t(461) = 1.6, p < .12$ ). The groups did not differ in gender ( $p < .41$ ) or in race ( $p < .49$ ), based on chi square analyses. The patients with high versus low GOAT scores were compared using parametric or non-parametric pairwise tests. Levene's test for equality of variances was used to determine whether the t-test was appropriate, or whether a nonparametric test should be used. The Kolmogorov-Smirnov procedure was used to determine whether the variables had non-normal distributions. Although the t-test is rather robust in regards to violations of general linear model assumptions (e.g., normally distributed variables and homogeneity of variance), nonparametric analyses (i.e., Mann-Whitney U tests) were conducted on most variables because heterogeneity of variance or non-normal distributions were present. The probability of Type 1 error increases when multiple statistical comparisons are conducted, so the reader should have the most confidence in findings that are below  $p = .01$ . Using this criterion, the patients with lower GOAT scores also scored significantly worse on Trails B, HVLT total and delayed recall scores, Logical Memory II and savings scores, Visual Reproduction II, and Digit Span Forward and Backward.

Descriptive statistics, mean comparisons, and effect sizes for the neuropsychological tests in the patients with *abnormal* CT-scans are presented in Table 22-8. The groups did not differ in age ( $t(55) = -.8, p < .43$ ) or education ( $t(52) = .5, p < .61$ ). The patients with high versus low GOAT scores were compared with parametric (i.e., independent *t*-tests) and nonparametric (i.e., Mann-Whitney U) tests using the same procedures as reported for the patients with normal CT-scans. Although there were fewer significant findings, there was still a clear pattern of worse neuropsychological test performance in persons with lower GOAT scores. It should be noted that the significance values in Table 22-8, as compared to Table 22-7, are reduced as a function of sample size. By examining estimated effect sizes, it can be seen that variables with medium to large effect sizes, if stable, would be "more significant" if the sample sizes were increased.

In the present investigation, patients were sorted on the basis of their GOAT scores into high and low groups through an approximate median split. This is not a conventional method for examining GOAT scores. Rather, it is an attempt to estimate more subtle aspects of post-injury confusion as opposed to simply identifying frank PTA (i.e., GOAT scores below 75, which infrequently occur in people with MTBIs). The groups did not differ

in age, education, gender, race, frequency of skull fracture, frequency of abnormal CT scans, or frequency of positive LOC. Not surprisingly, at admission, those with lower GOAT scores had lower GCS scores (i.e., a greater proportion had scores of 14). On the neuropsychological tests, significant differences emerged on several variables measuring aspects of concentration, processing speed, learning, verbal memory, and visual memory. This same methodology, when applied to similar groups but with loss of consciousness (LOC) as the independent variable, failed to reveal any significant differences on the neuropsychological tests (121, 125, 159). Therefore, when trauma patients are evaluated shortly after an MTBI, there is good evidence that post-traumatic confusion is related to worse short-term neuropsychological outcome and good evidence that brief traumatic LOC (e.g., less than 5 min) is *not* related to short-term neuropsychological outcome. Of course, these findings relate to short-term outcome (first few weeks post injury). To best understand long-term outcome, one should consider the results from several recent meta-analytic reviews of the literature.

### Results From Meta-Analyses

A large number of prospective studies and several recent meta-analyses have greatly enhanced our understanding of the natural history of MTBI. Trauma patients and athletes often report extensive symptoms, and they perform more poorly on neuropsychological tests, in the initial days (118, 119, 128, 147, 160, 161) and up to the first month following the injury (e.g., 118, 140, 162, 163, 164). Due to natural recovery, neuropsychological decrements typically are not seen in athletes after 2–21 days (3, 118, 119, 160, 161, 165), and in trauma patients after 1–3 months (e.g., 140, 166, 167) or certainly a year (e.g., 124, 168–171) in prospective group studies. Several meta-analyses (4, 6, 8, 172) and recent reviews (5, 7, 173) of this literature are available and, as a rule, report very good neuropsychological outcome from MTBI.

Clinicians and researchers should carefully, deliberately, and critically read the literature relating to MTBI in trauma. Historically, the majority of studies over the decades have not been carefully controlled or prospective. It is essential to study the selection criteria and methods to appreciate the characteristics of the sample and the population to which that sample might generalize. Over the decades, there have been varying degrees of prevailing beliefs and themes that MTBIs (a) are minor injuries with no long-term consequences, (b) are serious injuries that frequently result in significant long-term consequences, or (c) are significant injuries that result in short-term consequences for most people and medium-term consequences for some. A person holding any particular belief or bias regarding MTBI can easily support that

view using select studies within the existing literature. It is getting increasingly difficult, however, to find good scientific evidence that MTBIs are associated with demonstrable cognitive deficits or symptoms that are due to the biological effects of the injury in more than a small minority<sup>8</sup> of patients who are more than 3 months post-injury.

Neuropsychological meta-analyses allow us to quantify the effects of certain injuries, conditions, or diseases on cognitive functioning. These aggregated estimates of effect size are important because they consider the literature as a whole and typically are based on hundreds, if not thousands, of subjects. The fact that clinical groups overlap substantially with the normal population, and with each other, is poorly understood amongst clinicians and researchers. Researchers, reporting the results from individual studies, emphasize the differences between groups that are statistically significant, and then write that group A could be “differentiated” from group B on the basis of these statistically significant findings. Small differences between groups can be statistically significant, but what is typically not reported is that the two groups are far more similar than they are dissimilar. Clearly, small statistically significant differences between groups might not have any practical, clinical, or real-world significance.

The distributions of neuropsychological test performance across diagnoses, circumstances, or conditions, based on meta-analytic reviews of the literature, are illustrated in Figure 22-1. The shaded line in the middle represents the average score for healthy normal adults (i.e., a z-score of zero). The upper and lower shaded lines represent the expected scores for 50 percent of healthy adults. Similarly, 80 percent of healthy adults are expected to score between the solid lines. As seen in the second column, 90 percent of normal adults are expected to score between the upper and lower “90.” The ranges of scores for all of the clinical groups are based on the theoretical normal distribution. Deviations from normal (i.e., neuropsychological deficits) are based on the effect sizes reported in the meta-analyses, and for each clinical group one can see the spread of scores expected for 80 percent and 90 percent of that particular group.

In the third column, notice that athletes tested within the first 24 hr post-injury have a marked deviation from normal (effect size of  $-1.0$ ), similar to the deviation seen in patients with moderate to severe traumatic brain injuries who are tested within the first six months post injury (effect size of  $-1.0$ ). This illustrates the major adverse effect of concussion on neuropsychological functioning immediately after injury. However, after seven

<sup>8</sup>This “small minority” cannot be determined at this time but it is likely less than the 15-20 percent estimates in the past literature.

days (column 5), concussed athletes' neuropsychological functioning has essentially returned to normal<sup>9</sup> (as reported in this meta-analysis of the literature). Notice that there are relatively small deviations from normal in patients with MTBIs, and by 1–3 months post injury they cannot be distinguished from the general population. The effects of MTBI on neuropsychological functioning, after the acute recovery period, are considerably less than the effects of litigation, depression, or ADHD. A striking feature of Figure 22-1 is the substantial overlap in expected scores across the clinical groups. In other words, the overall neuropsychological test performances of people in these groups are much more similar than they are dissimilar.

Clearly, our ability to accurately detect cognitive and neurobehavioral decrements associated with an MTBI, through interview, rating scales, or neuropsychological testing, diminishes in tandem with the passage of time. This, of course, is due to recovery. Nonetheless, in clinical practice, we frequently see patients who do not return to their pre-injury level of functioning and who are highly symptomatic. These patients frequently are conceptualized as having poor outcome following an MTBI, and the MTBI is believed to be the direct and/or indirect cause of the poor outcome. These people are typically diagnosed with the controversial persistent postconcussion syndrome.

Differential diagnosis is very important in these cases. The clinician should try to identify and treat the underlying cause, or causes, of these symptoms and problems (which can be diverse, and include cranial and/or cranial adnexal injury, cervical injury, psychological problems and disorders, or pain disorders). Ideally, clinicians should try to *prevent* poor outcome in people who have suffered a MTBI. There is reasonably good evidence that early intervention, as simple as education and reassurance of a likely good outcome, can be effective for reducing symptoms and problems in most patients.

## EARLY INTERVENTION

A number of intervention protocols designed to minimize persisting problems following MTBI have been described in the literature for some time (e.g., 174–176). In the early studies, researchers reported that simple intervention programs applied within the first 3 weeks post-injury can reduce the number and frequency of post-concussion symptoms (177) and increase return to work rates (178).

The content of early intervention programs varies, ranging from, at minimum, the provision of an educational

brochure containing information regarding the effects of MTBI (e.g., Ref. 179) to a more comprehensive intervention program that couples educational material with various forms of treatment (e.g., access to a multi-disciplinary outpatient brain injury program; e.g., Ref. 180) and/or assessment (e.g., neuropsychological; e.g., 181)<sup>10</sup>. Providing educational information is a standard component in the majority of studies. Although the content of the educational sessions varies, these sessions typically aim to provide information regarding common symptoms, likely time course of recovery, reassurance of recovery, and suggested coping strategies following MTBI (e.g., Refs. 185–188). The mode of information dissemination ranges from the distribution of written information alone (e.g., 187) to providing written educational material and a discussion of its contents with a neuropsychologist (e.g., 180).

Research focusing on intervention following MTBI can be classified into three types of studies: (a) studies that treat MTBI patients with persistent symptoms many months post-injury, (b) studies that compare MTBI patients assigned to an intervention program versus a control group, and (c) studies that compare the efficacy of different types of intervention programs.<sup>11</sup> Two studies have evaluated the effectiveness of intervention programs for MTBI patients experiencing persistent problems. Ho and Bennet (189) reported that patients participating in a comprehensive brain injury treatment program had improved activities of daily living, neuropsychological test scores, and ratings on behavioral scales. Cicerone et al. (190) reported that 50 percent of patients who participated in a comprehensive brain injury program could be classified as having a good outcome (defined as resumption of pre-injury activities or other similar productive activity), improved scores on neuropsychological measures, and a reduced frequency of self-reported post-concussion symptoms following treatment. However, these two studies have been criticized by Paniak and colleagues for two reasons. First, they lack the inclusion of a control group that prevents ruling out explanations for improvement other than treatment. Second, they include patients who are first seen many months post-injury (and in some cases years), reducing the likelihood that patients are being treated for symptoms resulting from MTBI versus pre-existing disorders or co-morbid conditions (see 180 for a further discussion).

The majority of intervention studies compare patients assigned to a control group versus an intervention program within the first 1 to 3 weeks post-injury. In general,

<sup>10</sup>There are a few exceptions, with a handful of studies that have evaluated various interventions such as bed rest (182), hospital admission (183), and homeopathy (184).

<sup>11</sup>The first two types were conceptualized by Paniak et al. (180).

<sup>9</sup>Please see the chapter by Collins, Iverson, Gaetz, and Lovell in this book for a comprehensive review of outcome from sport concussion.

**FIGURE 22-1**

Comparing the neuropsychological effects of MTBI to the normal population and other clinical groups: Distributions derived from meta-analyses.

*Note:* This figure illustrates, based on meta-analytic studies, the distributions of neuropsychological test performance across diagnoses, circumstances, or conditions. The shaded line in the middle represents the average score for healthy normal adults. 50 percent of healthy adults are expected to perform between the upper and lower shaded lines, and 80 percent of healthy adults are expected to perform between the solid lines. All groups are based on the theoretical normal distribution. The far left column represents z-scores (mean = 0, SD = 1). A z-score of  $-.67$  falls at the 25<sup>th</sup> percentile and  $.67$  falls at the 75<sup>th</sup> percentile. A z-score of  $-1.28$  falls at the 10<sup>th</sup> percentile and  $1.28$  falls at the 80<sup>th</sup> percentile. A z-score of  $-1.64$  falls at the 5<sup>th</sup> percentile and  $1.64$  falls at the 95<sup>th</sup> percentile. Deviations from the normal distribution are based on the effect sizes reported in the meta-analyses. For example, for MTBIs that are 1–3 months post injury, the effect size reported in the literature was  $.12$ . Therefore, the “Average” score for that group was dropped one position from the mean of zero, and the spread of scores was then centered around that average score. Effect sizes typically are expressed in pooled, weighted standard deviation units. However, across studies, there are some minor variations in the methods of calculation. By convention, effect sizes of  $.2$  are considered small,  $.5$  medium, and  $.8$  large. This is from a statistical, not necessarily clinical, perspective. For this figure, the overall effect on cognitive or neuropsychological functioning is reported. Sport concussion < 24 hr, 1–7 days, and >7 days, all in Belanger & Vanderploeg (4); MTBI 0–6 days, 7–29 days, 30–89 days, moderate-severe TBI 0–6 months, >24 months, all in Schretlen & Shapiro (8), Cannabis (411); Depression (412); Litigation/financial incentives (339); ADHD (413), based on Full Scale IQ, 123 studies; Exaggeration/Malingering (414).

researchers have reported favorable outcomes. Patients participating in intervention programs consisting of educational materials plus various additional treatments and/or assessments (e.g., neuropsychological testing, meeting with a therapist, reassurance, access to a multidisciplinary team) report fewer post-concussion symptoms at 3 months post injury (181, 187) and at 6 months post injury (177, 185, 188) compared to patients who received standard hospital treatment. However, not all research has been as favorable. Some researchers have reported that early intervention programs using educational material alone and educational material plus access to a specialist outpatient brain injury team, did not result in reduced self-reported post-concussive symptoms in children 3 months post injury (179) and adults 6 months post injury (191).

Although the majority of the research in this area points towards the usefulness of early intervention programs, our understanding of the *type* of intervention required is limited. The intervention programs evaluated in the literature to date vary considerably, ranging from economical programs (e.g., distribution of written educational materials) to much more expensive programs (e.g., multidisciplinary brain injury programs). Few studies have attempted to evaluate different intervention programs. In one of the first studies of this kind, Alves, Macciocchi, and Barth (192) compared the outcome of patients provided with standard hospital treatment to two different intervention programs provided within the first week post-injury: (a) education only, and (b) education and reassurance. Alves and colleagues concluded that intervention assignment was not associated with the number or duration of self-reported post-concussive symptoms at 3, 6, or 12 months post-injury.

In a more recent study, Paniak and colleagues compared patients assigned to two different treatment modes: (a) single session (i.e., a brief, educational and reassurance oriented session) and (b) treatment as needed (i.e., including education, reassurance, psychological, personality, and neuropsychological testing and feedback, consultation with physical therapist, and access to multidisciplinary brain injury treatment program as needed). Paniak and colleagues concluded that the brief educational and reassurance oriented intervention was as effective as the more comprehensive and expensive treatment model. There was no difference between the two interventions in self-reported post-concussive symptoms at 3 months and 12 months post-injury (180, 186).

The research focusing on early intervention is promising. However, this research is certainly not without its methodological problems. Some of the more serious problems include (a) the differences in definition of MTBI used across studies, and (b) the high attrition rate of patients belonging to the “intervention” group. Nonetheless, the literature suggests that early intervention

can be useful in this population by reducing the number of individuals who experience long term symptoms post-injury. In addition, and perhaps more importantly, research by Paniak and colleagues suggests that early intervention programs need not consist of complex multidisciplinary brain injury treatment programs, but may consist of a simple education session provided soon after injury. This is a conclusion echoed by Borg et al. (16) in their review of interventions for people with MTBIs. The effective use of simple education-oriented programs is supported in the literature (e.g., 181, 187). Future researchers are encouraged to (a) evaluate different treatment models in an effort to replicate the findings by Paniak and colleagues, (b) develop methods to minimize attrition rates, and (c) use “gold standard” definitions for selecting patients with MTBIs.

## RETURN TO WORK

Vocational outcome following traumatic brain injury is important for individual patients and society as a whole (193–197). For many individuals, the inability to return to work can result in a number of economic, social, family, and interpersonal problems (198–200). In addition, the economic burden placed on society is of concern (e.g., long-term sickness benefits, unemployment benefits), particularly because many individuals who sustain a TBI tend to be young and have their whole working lives ahead of them (196).

Some researchers have reported that injury severity, as measured by post-traumatic amnesia, loss of consciousness, and/or Glasgow Coma Scale scores, is associated with the time in which individuals return to pre-injury employment following TBI (e.g., 194, 197, 201, 202). However, other studies have failed to support the relation between injury severity and post-injury employment status (e.g., 203–207).

Despite these inconsistencies, individuals who have sustained an MTBI have consistently higher return to work rates when compared to individuals who have sustained a moderate or severe TBI (e.g., 197, 198, 208–211). However, not all individuals who have sustained an MTBI return to work at the same rate. Within the spectrum of MTBI, those individuals with lesser injuries (e.g., GCS = 15; no LOC) tend to have a higher return to work rate compared to those with more significant injuries (e.g., GCS = 13–14; with LOC; e.g., 101, 212, 213).

Return to work rates following MTBI vary substantially in the research literature. Post-injury employment rates have ranged from (a) 25 percent to 100 percent within the first month post-injury (e.g., 101, 198, 200, 214), (b) 38 percent to 83 percent six to nine months post-injury (147, 198, 199, 212, 215, 216), (c) 47 percent to

83 percent one to two years post-injury (141, 198, 209, 211), and (d) 62 percent to 88 percent three or more years post-injury (193, 197, 208, 209, 213). The literature regarding return to work following MTBI is summarized in Table 22-9.

The variability in return to work rates is likely due to the many methodological differences between studies. The most problematic of these include (a) differences in definitions of return to work (e.g., return to pre-injury employment vs. return to meaningful activity), (b) variations in the definition of MTBI (e.g., inclusion of GCS = 15 only versus GCS = 13–15), (c) variations in the inclusion and exclusion of individuals who were unemployed or performing domestic duties pre-injury in the sample, and (d) the failure of some studies to take into account pre-injury employment status (e.g., return to full time vs. part time vs. unemployed). For a comprehensive discussion regarding return to work following TBI, the interested reader is referred to the chapter by West and colleagues in this book.

Under most circumstances, we should anticipate good recovery and return to work following an MTBI. Patients should be reassured, and health care providers can work with injured adults to address the difficulties they face with particular symptoms while they resume their normal daily activities (e.g., work or school). Unfortunately, some trauma patients transition from acute postconcussion symptoms and problems into a mild depression (or major depressive episode). In people who transition, it might not be possible to determine if their primary diagnosis is depression or postconcussion syndrome. Basic and clinical research is needed in this area. Although the neuropathophysiology might be difficult to describe, the condition might be amenable to pharmacological and psychological intervention.

## DEPRESSION

Depression is common following traumatic brain injury of *all severities* (see 217 for a review). Prevalence estimates vary widely (e.g., from 11 percent to 77 percent; e.g., 218, 219, 220). In epidemiological studies, 11 percent to 21 percent of people with a history of TBI also have depression (e.g., 218, 221). In studies based on admissions to trauma centers or rehabilitation hospitals (222–227) or large samples of outpatients (228, 229) the rates of depression typically range from 14 percent to 42 percent. Recent well-controlled studies have concluded that depression occurs frequently in the first year post injury (224, 225), with rates decreasing over time (224, 230). Researchers have often reported that people who suffer traumatic brain injuries have higher rates of pre-injury psychiatric disorders (219, 231–233), such as depression and substance abuse.

Hibbard and colleagues (233) assessed 188 community-dwelling adults with *moderate to severe* traumatic brain injuries in a longitudinal cohort study. On average, the patients were evaluated 2.5 years post injury and then approximately 12 months later. The authors reported that 48 percent did not meet criteria for a major mood disorder at time one or time two, 29 percent were diagnosed with major depression at time one which resolved by time 2, 10 percent had late-onset depression (diagnosed at time 2 but not at time 1), and 14 percent had chronic depression (diagnosed at both time periods).

Depression is a heterogeneous condition. It can be a secondary or tertiary condition associated with traumatic brain injury, or it can be unrelated to the original brain injury. Researchers have speculated that depression can arise directly or indirectly from the biological consequences of the traumatic brain injury, it can be a psychological reaction to deficits and problems associated with having a brain injury, or both. A constant theme in the professional and scientific literature is that there are many methodological differences and scientific limitations across studies that make it very difficult to understand the prevalence, etiology, and natural history of depression in people with traumatic brain injuries. Moreover, most of the literature (as described in the previous paragraphs) relates to depression following *moderate or severe* traumatic brain injury. A review of prevalence studies relating to depression in people with MTBIs is presented in Table 22-10.

When patients report symptoms and problems many months after an injury, differential treatment often flows from differential diagnosis. Given the clear overlap between the symptoms of depression and postconcussion syndrome, some researchers have recommended treatment with antidepressants (e.g., 148, 234–236) or cognitive behavior therapy (e.g., 185, 237). Medications and psychotherapy would be an obvious choice, of course, if depression is simply mimicking the postconcussion syndrome. Those recommending cognitive behavior therapy have set forth a treatment protocol that is based on CBT principles but is tailored toward the postconcussion syndrome and belief systems relating to symptoms and brain damage.

Certainly, depression is relatively common in patients with traumatic brain injuries, although it is not necessarily more common in these patients than in patients with general trauma (227). The presence of depression in a person with a history of traumatic brain injury presents an obvious challenge if one attempts to diagnose a persistent postconcussion syndrome given the overlap in symptoms. Iverson (238) reported very high rates of possible *misdiagnosis* of persistent postconcussion syndrome in patients with depression. Participants were 64 physician-diagnosed inpatients or outpatients with depression who had independently-confirmed diagnoses on the Structured

TABLE 22-9 (continued)

FIRST AUTHOR	SETTING	N	COUNTRY	TIME POST-INJURY	PERCENT RTW	MTBI DEFINITION	RTW DEFINITION	PRE-INJURY WORK STATUS: INCLUSION/EXCLUSION CRITERIA	TYPE OF STUDY AND REFERRALS
Asikainen (1996)	HOC	118	Finland	12 yr	61.9 percent	GCS = 13–15	Return to independent work only	No apparent exclusions based on work status	Retrospective Selected sample (patients with brain injury and post-injury problems in education and employment)
Asikainen (1996)	HOC	118	Finland	12 yr	72.9 percent	GCS = 13–15	Return to independent work or subsidized employment or education continuing	No apparent exclusions based on work status	Retrospective Selected sample (patients with brain injury and post-injury problems in education and employment)

Notes: <sup>1</sup>HTC = Hospital trauma center; RC = Rehabilitation clinic; LITC = Level 1 trauma center; NMC = U.S. Navel medical center; TTC = Tertiary trauma center; USVV = U.S. Vietnam veterans; HOC = Hospital outpatient clinic

<sup>2</sup>Consecutive = Consecutive referrals; Retrospective/Prospective = retrospective/prospective study design.

<sup>3</sup>A follow-up interview was obtained in 63 of the 66 patients 90 days post-injury regarding their condition on returning to work. Of these patients, 60 percent reported experiencing symptoms when they first returned to work and 46 percent reported that they were unable to do their work as well as usual.

<sup>4</sup>Workers were defined as individuals who defined themselves as “workers” regardless of whether they were employed or unemployed at the time of injury.

<sup>5</sup>Limited duty is a duty status within the military for individuals with ongoing medical problems; it has fewer responsibilities, some limitations, and decreased performance standards. Individuals are placed on limited duty for periods of six months, with the expectation of recovery and eventual return to full duty status” (p. 1106).

<sup>6</sup>It is not entirely clear whether this percentage includes individuals who were employed pre-injury, or also includes individuals who were retired, students, and unemployed.

<sup>7</sup>Of these patients, 12 percent returned to premorbid level of work and 30 percent returned to modified employment.

<sup>8</sup>Modified conditions was defined as “working shorter hr, performing lighter work, performing part of the job at home, or trading difficult tasks with other workers” (p. 393)

**TABLE 22-10**  
*Summary of Depression Prevalence Rates in MTBI*

FIRST AUTHOR	N	COUNTRY	POST-INJURY INTERVAL	SETTING	RATE OF DEPRESSION	MTBI DEFINITION	DEPRESSION DEFINITION	TYPE OF STUDY/ REFERRALS
Goldstein (2001)	18	USA	2 months	Acute care neurosurgery services affiliated with University hospitals	33 percent	GCS 13 to 15 LOC < 20 min Normal CT or MRI	GDS > 10	Prospective Consecutive
Mooney (2001)	80	USA	Median = 25.5 weeks	Rehabilitation Program, University hospital	44 percent	ACRM criteria	DSM-IV criteria	Prospective Selected Sample (individuals who failed to recover as expected 3 months post injury)
Levin (2005)	129	USA	3 months	Level I trauma center	11.6 percent	GCS 13 to 15	SCID: DSM-IV	Prospective Consecutive
McCauley (2001)	95	USA	3 months	Level I trauma center	21.4 percent	GCS 13 to 15 LOC < 20 mins Normal CT	DSM-IV Major Depressive Disorder criteria	Prospective Consecutive
Levin (2001)	60	USA	3 months	Level I trauma center	18.3 percent	GCS 13 to 15 LOC < 20 mins Normal CT	DSM-IV Major Depressive Disorder criteria	Prospective Consecutive
Horner (2005)	524	USA	12 months	State hospital	21.3 percent	<sup>1</sup> Injury to the head ICD/AIS = 2	“Since your injury, has a doctor told you that you had depression?”	Retrospective Random Selection of TBI
Parker (1996)	33	USA	M = 20 months	Private Practice/ Compensation	36 percent	Dx of “Whiplash” from medical records or on self description- excluded if LOC > 5 minutes or presence of cerebral abnormalities.	DSM-III-R	Prospective Selected Sample

Note: GDS = Geriatric Depression Scale; ACRM = American Congress of Rehabilitation Medicine (LOC < 30 mins, initial GCS = 13–15, PTA < 24 hr).

<sup>1</sup>TBI was defined as an injury to the head associated with decreased consciousness, amnesia, neurological abnormalities, skull fracture, or intracranial lesion, in accordance with the Centre for Disease Control and Prevention” (p. 323). TBI severity was determined by translating ICD-9-CM codes to ICD/AIS scores using ICDMAP-90 software” (p.324) Sources: Goldstein, Levin, Goldman, Clark, & Altonen (169); Horner, Ferguson, Selassie, Labbate, Kniele, & Corrigan (221); Levin, McCauley, Josic, Boake, Brown, Goodman, & Merritt (408); Mooney & Speed (409); McCauley, Boake, Levin, Contant, & Song (148); Parker & Rosenblum (410).

Clinical Interview for DSM-IV. These patients completed the British Columbia Postconcussion Symptom Inventory-Short Form (239, 240), a 16-item measure designed to assess the frequency and severity of symptoms based on ICD-10 criteria for postconcussion syndrome. Specific endorsement rates of postconcussion-like symptoms ranged from 31 percent to 86 percent for symptoms rated mild or greater, and from 11 percent to 58 percent for symptoms rated moderate-to-severe. Approximately 9 out of 10 patients with depression met liberal self-report criteria for a postconcussion syndrome and more than 5 out of 10 met conservative criteria for the diagnosis (in the absence of a previous MTBI). Depression is also common in persons with chronic pain (241, 242), and it is associated with increased disability in these patients (243, 244). Chronic pain is a frequent co-morbidity with depression (245–247). Therefore, patients seen long after a mild traumatic brain injury who have chronic pain, depression, or both are very likely to meet diagnostic criteria for a persistent postconcussion syndrome, even if the problems associated with the mild traumatic brain injury have long-since resolved.

### Post-Traumatic Stress Disorder

Post-traumatic stress disorder (PTSD; 248) occurs in some people who experience *intense fear, helplessness, or horror* during or immediately after experiencing or witnessing a traumatic event (except when “delayed”). Symptom onset typically occurs in the first few days (in fact the first 24 hr) in most people. The traumatic event is *persistently re-experienced* through (a) intrusive and distressing recollections of the event including visual images, thoughts, or perceptions; (b) distressing dreams (nightmares), (c) acting or feeling as if the traumatic event was happening again (e.g., dissociative flashbacks); (d) intense psychological distress when exposed to things (e.g., thoughts or external visual reminders) that symbolize or resemble an aspect of the event; or (e) physiological reactivity when exposed to things that symbolize or resemble an aspect of the traumatic event. In addition to the persistent re-experiencing, there is *persistent avoidance* of things associated with the traumatic event and a numbing of general responsiveness. Examples of avoidance and numbing of responsiveness include: (a) avoiding thoughts, feelings, or conversations associated with the event; (b) avoiding activities, places, or people that stimulate thoughts or memories of the event; (c) feeling detached or estranged from others; or (d) having a sense of a foreshortened future (e.g., not expecting to have a career, marriage, children, or a normal life span). In addition, the person has persistent symptoms of *increased arousal* such as (a) difficulty falling or staying asleep; (b) irritability or outbursts of anger; (c) difficulty concentrating; (d) hypervigilance; and (e) an exaggerated startle response. If a person meets criteria after one-month post event, PTSD is diagnosed.

Developing PTSD following a car accident is uncommon. Some estimates of the rate of this disorder in accident victims have been 9 percent (249), 12 percent (250), and 6.3 percent and 8.8 percent for men and women respectively (251). Essentially, 90 percent of people in car accidents do not develop PTSD. For comparison, less than 5 percent of individuals develop PTSD after a natural disaster (251). In a sample of survivors of the September 11, 2001 terrorist attack on the Pentagon, 14 percent had PTSD 7 months after the event (252). Sexual assault is associated with the highest incidence of PTSD, with estimates ranging from 46 percent to 80 percent (250, 251).

Patients with PTSD often report the same symptoms as patients who have sustained MTBIs. For example, in a sample of 128 patients with PTSD, 89 percent reported irritability, 56 percent reported memory problems, 92 percent reported concentration problems, and 90 percent reported difficulty sleeping (253). A controversial and confusing issue is whether a person who sustains a traumatic brain injury can develop PTSD. There are data to support the position that MTBI and PTSD typically are mutually exclusive (254–256), although researchers have put forward a compelling rationale for how, under certain circumstances, PTSD could emerge in a patient with a brain injury (257, 258). The conceptual question at the heart of the debate is whether a person with no memory for a traumatic event can develop PTSD. In other words, how can you be traumatized by an event you can't remember? How can you re-experience, through flashbacks, images, or dreams, an event you cannot remember? Some mechanisms might include islands of memory of traumatic events occurring outside of the amnesic gap (such as gaining awareness in the hospital with a tracheotomy in and on a ventilator), or so-called elaborative cognitions.

A recent, well-controlled study provides additional information to better understand this issue. Gil and colleagues prospectively studied 120 accident victims who sustained a mild traumatic brain injury and who were hospitalized for observation immediately after their trauma. They were assessed within the first 24 hr and at one week, three months, and six months. At 6 months post-injury, 14 percent met diagnostic criteria for PTSD. Predictors of PTSD at 6 months were (a) PTSD symptoms, depressive symptoms, and anxiety symptoms at one week post-injury, (b) history of psychiatric disorder, and (c) memory for the event. Of the patients with memory for the event, 13/55 (23 percent) had PTSD at 6 months post-injury, compared to only 4/65 (6 percent) who did not have memory for the event (259). Therefore, the literature to date suggests quite clearly that having no memory for the event likely protects the individual from developing PTSD.

Clinicians should be very cautious in diagnosing PTSD in a person who has sustained an MTBI if that

person does not exhibit prominent symptoms in the initial days post injury. The onset of symptoms in PTSD generally is rapid. For example, the onset of PTSD symptoms in the survivors of the Oklahoma City bombing was swift, with 76 percent reporting symptoms on the day of the event (260). Delayed symptom onset is very uncommon. For example, there were no cases of delayed onset PTSD associated with the Oklahoma City bombing (261, 262) or a mass shooting incident (263, 264). Delayed onset PTSD, in the vast majority of studies, has been considered rare (e.g., 265–267). Therefore, if delayed onset phenomena appear, they might be a joint product of (a) insensitive diagnostic criteria and methods, (b) individual differences in avoidance behavior that masks other PTSD symptoms, (c) post-trauma stressors that exacerbate psychological distress, and/or (d) delayed compensation motivation (265, 268). As illustrated in the study by Gil and colleagues, patients with MTBIs are likely at increased risk for developing PTSD if (a) they have a psychiatric history, (b) they have memory for the event, and (c) they develop major symptoms within the first 24 hr or first week post injury (259).

### RISK FOR ALZHEIMER'S DISEASE

There has been considerable research interest regarding whether mild, repetitive mild, moderate, or severe traumatic brain injuries increase a person's risk for developing Alzheimer's disease (AD). Before discussing this literature, it is important to consider the broader literature on risk for AD. Without question, the biggest risk factor for AD is age. Living longer greatly increases one's chance of developing the disease. Several meta-analytic studies have consistently found that the prevalence of AD around the world increases with age (e.g., 269–272). In an early meta-analysis of 22 studies, Jorm and colleagues (270) reported that the prevalence of AD doubled every 4.5 years; they reported the following prevalence rates stratified by age group: 65–69 years (1.4 percent), 70–74 years (2.8 percent), 75–79 years (5.6 percent), 80–84 years (11.1 percent), and 85 years or more (23.6 percent). Using the United States census data, Hebert and colleagues estimated that in 2000 4.5 million persons in the United States had AD, and by the year 2050 this figure will triple to 13.2 million due to the ageing population (273).

An overview of the recent literature reveals considerable scientific interest in many other potential risk factors, such as genetics (274), particularly the apolipoprotein E (ApoE) gene (275, 276); genetics and a high fat diet (277); oxidative stress, disturbed protein metabolism, and their interaction (278, 279); zinc metabolism (280); cerebrovascular disease and vascular risk factors (281, 282); cardiovascular disease, particularly in the subgroup with peripheral arterial disease (283); high cholesterol (284),

elevated plasma total homocysteine concentrations and low serum folate concentrations (285); midlife obesity (286); loss of microglial cell function (287); decreased melatonin (288); heavy metal exposure (289); and lack of exercise (290). The risk of AD appears to increase with the number of vascular risk factors (diabetes + hypertension + heart disease + current smoking), with diabetes and current smoking being the strongest risk factors in isolation or in clusters in a recent study (291). Mental health problems, such as a history of depression in adulthood (292), particularly for men (293), have been associated with an increased risk for AD. Even a man's height has been associated with risk for AD! Short men are at increased risk (presumably due to its association with childhood nutrition and other risk factors for dementia) (294). Watching too much television in middle-adulthood has been associated with an increased risk for AD, presumably as a marker for reduced participation in intellectually stimulating activities (295).

For the past 20 years there has been considerable interest in the relation between traumatic brain injury and the future development of AD. It has been suggested that traumatic brain injuries reduce "cognitive reserve," resulting in increased vulnerability to developing the disease (296). The animal literature has revealed evidence that some of the pathological features of AD arise shortly after traumatic brain injury (see 297 and 298 for reviews), and human autopsy studies also have supported these findings (299, 300). A number of studies have reported a relation between a history of traumatic brain injury and a current diagnosis of AD (e.g., 301–314), although several studies have failed to find this association (e.g., 315–323). Mortimer and colleagues conducted an important meta-analytic review of the literature published prior to 1991 (324). They reported that traumatic brain injuries were associated with a 1.82 relative risk (RR) (95 percent confidence interval = 1.26 to 2.67) for developing AD. The relative risk was significant for men (RR = 2.67, 95 percent CI = 1.64 to 4.41) but not women (RR = 0.85, 95 percent CI = 0.43 to 1.70). Fleminger and colleagues conducted a second meta-analytic review of the literature, published in 2003, and reported that the literature published since 1991 did *not* reveal a statistically significant increased risk for AD (325). However, the literature as a whole (i.e., the studies published before and after the Mortimer meta-analysis) did reveal an increased risk for AD associated with a history of TBI (Odds Ratio (OR) = 1.58, 95 percent CI = 1.21 to 2.06). Again, the increased risk was significant for men (OR = 2.26, 95 percent CI = 1.13 to 4.53) but not women (OR = 0.92, 95 percent CI = 0.53 to 1.59). Starkstein and Jorge (326) suggested that this increased risk in men and not women might simply reflect men getting more severe traumatic brain injuries. Jellinger, in his review of the literature, emphasized that

epidemiological and autopsy studies have provided evidence of an association between *severe* traumatic brain injury and AD, but the relationship between AD and brain injury and apolipoprotein E status is still ambiguous (298). Overall, there are many conflicting results in this large literature spanning more than 20 years. Nonetheless, it is reasonable to conclude that patients who sustain *severe* TBIs are at a small increased risk for developing AD, as concluded by Starkstein and Jorge (326) and Jellinger (298).

In conclusion, most prospective studies showed a significant, albeit weak, association between dementia and history of TBI. Some studies showed that a history of TBI may result in a relatively early onset of dementia, but this was not replicated by others. The association with the APOE-e4 allele status is conflicting as well, from one study showing a tenfold increase in the risk for dementia for individuals with both a history of TBI and APOE-e4, to another study showing an increased risk for dementia among those *without* an APOE-e4 allele. (p. 599; Ref. 326)

Given that (a) many studies have failed to find an association between history of TBI (of any severity) and AD, (b) the meta-analyses have only identified this association for men, (c) several studies have found a severity effect (i.e., risk is greater in patients with more severe brain injuries), and (d) the pathophysiology of MTBI, especially on the milder end of the spectrum of this injury, is temporary and reversible, it would be a mistake to assume, at this point in time, that patients with *MTBIs*, as a group, are at increased risk for AD. Several specific studies suggest that there is not a relationship between MTBI and risk for AD (e.g., 306, 310, 321).

## PERSISTENT POST-CONCUSSION SYNDROME

There is a so-called “miserable minority” (327) of patients who appear to have poor long-term outcome following a mild traumatic brain injury (MTBI). The etiology of the so-called *persistent* postconcussion syndrome has never been agreed upon (see 7, 328–330 for reviews). For decades, researchers have questioned the validity of this diagnosis as a true syndrome or disease entity (e.g., 331–336). Others have noted that the syndrome is rare in prospective studies (e.g., 192, 333), and concerns regarding the role of financial compensation on symptom reporting have been expressed for many years (331, 337–340). Most researchers simply suggest that the etiology is due to the biological effects of the injury, psychological factors, psychosocial factors (broadly defined), chronic pain, or a combination of factors (171, 341–348). Ruff and colleagues (327, 330, 349) have stressed a multidimensional cumulative stressor conceptualization of

the persistent post-concussion syndrome. Essentially, setbacks in several aspects of a person’s life (physical, emotional, cognitive, psychosocial, vocational, financial, and recreational) serve as cumulative stressors that interact with personality and premorbid physical and mental health factors, resulting in the syndrome. This model stresses the complexity of the etiology and maintenance of the syndrome.

Experienced clinicians and researchers know that it is extraordinarily difficult to disentangle the many factors that can be related to self-reported symptoms in persons who have sustained remote MTBIs (328). This is a challenging and potentially contentious diagnosis, of course, because post-concussion-like symptoms are common in healthy subjects (240, 350–355), in patients with no history of brain injury, such as outpatients seen for psychological treatment (356), outpatients seen for minor medical problems (357), personal injury claimants (357, 358), patients with post-traumatic stress disorder (253), patients with orthopedic injuries (332), individuals with chronic pain (359–362) and patients with whiplash (363). Thus, the differential diagnosis of the persistent post-concussion syndrome is very challenging.

## CONCLUSIONS

Mild traumatic brain injury, and the potential for incomplete recovery and poor psychosocial outcome, has been recognized as a public health problem (364–366). The pathophysiology of MTBI is predominately neurometabolic and reversible. However, this injury can be characterized by structural damage that is visible with static neuroimaging (e.g., CT or MRI; 17, 19–24) and cellular damage that is not visible through neuroimaging (80) in some people.

Despite decades of research, slow or incomplete recovery from MTBI is poorly understood. For a substantial majority of people, MTBIs are self-limiting and generally follow a predictable course. Permanent cognitive, psychological, or psychosocial problems due to the biological effects of this injury are relatively uncommon in trauma patients and rare in athletes (4, 6–9).

However, some people do not appear to recover completely following this injury; these individuals have been referred to as the “miserable minority” (173, 327, 328). Some have estimated that 10–20 percent of people with MTBIs will have incomplete recovery (e.g., 173, 367), although this figure is likely an over-estimate (7). When a person does not recover quickly, health care providers are very concerned about the possibility of a persistent postconcussion syndrome (328, 329, 341, 342, 345, 346), the development of depression (see 217 for a review), and/or a failure to return to work (101, 141, 147, 193, 197–200, 208, 209, 211–216). The underlying cause

for poor outcome in a minority of patients is likely multifactorial, and could involve combinations of factors such as pre-existing personality characteristics, life stress, psychiatric conditions, or substance abuse problems (140, 330, 368); co-morbid conditions, such as chronic pain, depression, PTSD, life stress, or substance abuse (148, 359, 361, 362, 369–371); structural damage (macroscopic and microscopic) to the brain (11, 146); litigation (338, 340, 372); exaggeration or malingering (373–377); and symptom expectations, misattribution, and response bias (352, 370, 378–383).

Health care providers should try to prevent or reduce the severity of symptoms and problems that extend beyond a few weeks or months post injury. Early identification and intervention, with education and reassurance of the likelihood of a good outcome, to ameliorate anxiety and facilitate adjustment to transient impairment, is a recommended treatment for persons with MTBIs. Most researchers (177, 180, 181, 185–188) but not all (179, 191) have reported very favorable outcomes in studies on early intervention following MTBI.

Health care providers should be cautious when diagnosing someone with a persistent postconcussion syndrome, because this implies directly or indirectly that the person has “permanent brain damage.” This can be a relief to some patients as an explanation for their perceived problems or it can have serious iatrogenic implications for other patients, a so-called “nocebo effect.” This might promote a preoccupation with symptoms, fear of permanent brain damage, with hypochondriacal concern and adoption of a sick role (as per the ICD-10 diagnostic criteria for the postconcussion syndrome). For those with persistent problems, differential treatment often flows from differential diagnosis. Given the clear overlap between the symptoms of depression (and PTSD) and post-concussion syndrome, some researchers have recommended treatment with antidepressants (e.g., 148, 234–236) or cognitive behavior therapy (e.g., 185, 237). Those recommending cognitive behavior therapy have provided a treatment protocol that is based on CBT principles but is tailored toward the post-concussion syndrome and belief systems relating to symptoms and brain damage.

It will not be possible to significantly advance our understanding of poor outcome in people with MTBIs without multidisciplinary and multimodal research. This includes psychosocial and psychological research (e.g., symptom expectations and attributions), functional imaging studies, as well as differential diagnoses and specificity studies (e.g., direct comparisons with patients who have problems with depression, anxiety, substance abuse, or ADHD). Much more research is needed regarding the sensitivity and specificity of structural and functional neuroimaging techniques for trauma patients who have poor outcome from MTBI. Researchers should consider the broader neuroimaging literature in biological psychiatry.

This is because depression, chronic pain, PTSD, alcoholism, and ADHD are associated with abnormalities on SPECT (384, 385), PET (386–389), fMRI (387, 389–391), MR spectroscopy (392–396), and quantitative structural imaging (397–405). Therefore, trying to isolate imaging findings that are *specific* to the long-term effects of an MTBI should occur in the greater context of studying similar abnormalities associated with possible co-morbid conditions (e.g., depression, chronic pain, or substance abuse) or other mitigating factors.

The ability for patients with MTBIs to be properly diagnosed and treated will be greatly enhanced by three major and likely developments in the field of brain injury medicine. First, we need to develop and implement a system of standardized international terminology and classification for the condition. Second, we need to advance neurodiagnostic technology that facilitates the diagnosis of persistent cerebral functional impairment due to MTBI with high levels of sensitivity and specificity. Finally, we need to enhance our understanding of how pre-injury, injury, and post-injury vulnerability factors can affect functional outcome and can be accommodated for in the context of treatment planning. Although there is still much that we have to learn about the condition of MTBI, we have made significant progress and further progress will clearly lead to both better diagnostic accuracy and better neurological as well as functional outcomes.

## Post-Concussive Disorder

**Grant L. Iverson**  
**Nathan D. Zasler**  
**Rael T. Lange**

### INTRODUCTION

A concussion, by definition, is a mild traumatic brain injury (MTBI). MTBIs are expected to be self-limiting and to follow a predictable course. Permanent cognitive, psychological, or psychosocial problems due to the biological effects of this injury are relatively uncommon in trauma patients and rare in athletes (1–6 and see chapters by Collins et al. and Iverson et al. in this book). However, some people do not appear to recover well following MTBI; these individuals have been referred to as the “miserable minority” (7, 8). When a person does not recover quickly, health care providers may be very concerned about the possibility of a persistent post-concussive disorder (9–14), the development of depression (see 15 for a review), and/or a failure to return to work (16–28), among other potential complications.

The post-concussive disorder is one of the most controversial syndromes/disorders in medicine and psychology. In medicine, we consider a syndrome a group of signs and symptoms that collectively indicate or characterize a disease, psychological disorder, or abnormal condition. The signs and symptoms of a syndrome are believed to have a common cause. It is widely believed that 10–20% of people who sustain an MTBI will develop a more persistent form of the syndrome (i.e., lasting one or more years). A 15% prevalence of poor outcome has been cited

frequently over the past 25 years based on the results from a prospective study in the mid 1970s by Rutherford and colleagues. These researchers followed consecutive admissions to the hospital for MTBIs and reported that 14.5% of patients had *at least one* symptom at one-year post-injury. However, fewer than 5% had multiple (four or more) symptoms. This figure is never cited. Moreover, the authors’ concerns about the validity of the syndrome have been lost over the years, and only the “15%” figure has been retained.

It is probably the multiplicity and the diversity of complaints which has given the term ‘post-concussion syndrome’ such widespread acceptance. However, of the 19 patients who complained, 6 had only 1 symptom and a further 7 had 2. The remaining 6 had between 4 and 9 symptoms. In a syndrome one expects groupings of inter-related symptoms. We found no such groupings either at 6 weeks or at 1 year (Ref. 29; p. 228).

The widely-cited estimate of 10–20% of patients suffering a long-term post-concussive disorder is both confusing and incorrect. It is confusing because there is often an assumption that if a person reports symptoms long after an MTBI, that the symptoms are causally-related to the biological effects of the injury (by logical inference, the symptoms are related to damage to the

structure or function of the brain). It is incorrect because the constellation of symptoms comprising the post-concussive disorder likely occurs in far less than 10–20% of patients with remote MTBIs. Moreover, there are numerous potential underlying causes for these symptoms that are unrelated to traumatic brain damage.

If we consider *all* MTBIs, the percentage of people with poor long-term (e.g. greater than one year) outcome is likely very small (i.e., clearly less than 5%). This is because the definition of concussion, as it is generally defined, is so broad that a person simply needs to feel momentarily dazed, and unwell for a brief period of time, to meet criteria. A mild injury to the brain is common in daily life and in sports. Those injuries on the milder end of the “mild” spectrum, as a rule, do not result in biologically-based symptoms and problems that last beyond a few minutes, days, or weeks. For example, a substantial minority of amateur and professional athletes who sustain a concussion have no residual symptoms or problems after a few hours or a single day; and 90% of concussed university football players appeared recovered in 7 days (30). In a recent, large-scale prospective study with high school football players, approximately 90% were recovered within the first month post-injury (31). Although it is possible for an athlete to have a persistent post-concussive disorder, and we occasionally see these athletes in clinical practice, the incidence of this syndrome/disorder in athletes is extremely low (of course, far less than a 15% estimate of poor outcome at one-year post-injury).

The estimates that 10–20% of patients have poor outcome, and thus possibly a “persistent” post-concussive disorder, come from studies of trauma patients seen in the hospital, not athletes with MTBIs or civilians seen by their family doctors or in clinics. According to a US Census Bureau survey, more than 600 people per 100,000 sustain a brain injury with loss of consciousness each year (32). Of these people, 35% are seen in the emergency room, 25% are hospitalized, 14% are seen in doctors’ offices or clinics, and 25% seek no medical care. Historical prospective studies reporting poor outcome have been based on either the 25% of cases that are hospitalized or the 35% seen in emergency departments. In the past, these patient groups were broadly defined, in terms of injury severity, and likely included a subset of patients with complicated MTBIs or moderate TBIs. Researchers have reported that patients who agree to participate in prospective research on outcome from MTBI have more severe injuries than those who refuse participation (e.g., rate of CT abnormalities was 33% in participants and 6% in refusals; 33). Thus, the historical studies often began with a non-representative sample and then, due to attrition (severe in some studies), the final sample was highly non-representative. Moreover, in some studies patients were considered to have persistent problems if they endorsed

a single symptom (e.g., headaches or concentration problems) at one-year post-injury! In a large scale prospective study, Alves and colleagues (34) reported that at one year post-injury single symptoms were commonly experienced but multiple symptoms were “extremely rare” (2–6% of subjects).

There are other data suggesting that the disorder, or at least some persistent symptoms, might occur in *more* than 10–20% of people at one-year post-injury (e.g., 35–37). In general, studies involving the “persistent post-concussive disorder” should be reviewed carefully from a methodological perspective to determine (a) the representativeness of the sample, and (b) the criteria used to “diagnose” the disorder. Is the sample comprised of patients and litigants long after an injury who are referred to a specialty clinic? What are the criteria for assuming continuing symptoms arising from the original injury? Does the person need to report one, two, three, or more symptoms? That is, can the condition be considered syndromal in the absence of a threshold number of symptoms and/or signs? If there are a specific number of symptoms and/or signs that need to be present to reach a threshold for diagnosing the disorder, which ones should they be? That is, are there symptoms/signs that should be more heavily weighted than others based on them being more likely to be a biological consequence of the MTBI rather than arising from other etiologic factors? For example, in a prospective study conducted in Lithuania, if the disorder was defined as endorsing three or more symptoms at one-year post-injury, 78% of patients with mild traumatic brain injuries met criteria. However, in the same study, 47% of trauma control subjects, with no history of head or brain injury, met criteria for the persistent post-concussive disorder using the three or more symptoms criteria (38). These authors reported that if a constellation of six core symptoms were necessary to meet criteria for the diagnosis, then after 3 months, only 1% of patients with MTBIs and 1.4% of trauma controls would meet criteria for diagnosis. At one-year post-injury, only 0.5% of patients with MTBIs and 0.005% of trauma controls had this symptom combination. Therefore, a researcher or clinician can draw radically different conclusions from different data presented in the same study.

Despite decades of research, the incidence, prevalence, and etiology of the post-concussive disorder have never been established in a manner that would meet evidence-based medicine criteria. We believe that the post-concussive disorder can arise following a mild traumatic brain injury as a direct or indirect consequence of this injury. The “true” disorder is very much influenced by psychological factors (e.g., see 39), with varying degrees of underlying neurological or neurophysiological problems. The disorder can also be misdiagnosed because the symptoms are non-specific. There are numerous diverse factors that can influence how people perceive and report

their symptoms and functional problems long after a mild traumatic brain injury. The purpose of this chapter is to examine some of the more likely factors that may contribute to persistent and sometimes even permanent symptoms and problems following traumatic injuries that may (or may not) involve mild traumatic brain injury. The thesis of this chapter is that the post-concussive disorder is a non-specific cluster of symptoms that can be mimicked by a number of pre-existing or co-morbid conditions. The disorder, theoretically, also can occur in tandem with these conditions. Therefore, it is important to consider carefully the differential diagnosis of the disorder, in the hopes that differential diagnosis leads to differential treatment and rehabilitation, reduced patient suffering, and better functional outcomes. This chapter is divided into the following five sections: (a) diagnostic criteria, (b) differential diagnoses & co-morbidities, (c) iatrogenesis, (d) factors relating to the perception and reporting of symptoms, and (e) conclusions.

## DIAGNOSTIC CRITERIA

There are two current sets of research criteria for the post-concussive disorder: the International Classification of Diseases, 10th edition (ICD-10), and the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV). According to the ICD-10 (40), a person must have a history of “head trauma with a loss of consciousness” preceding the onset of symptoms by a period of up to 4 weeks and have at least three of six symptom categories. These include: (a) headaches, dizziness, general malaise, excessive fatigue, or noise intolerance, (b) irritability, emotional lability, depression, or anxiety, (c) subjective complaints of concentration or memory difficulty, (d) insomnia, (e) reduced tolerance to alcohol, and (f) pre-occupation with these symptoms and fear of permanent brain damage.

The syndrome occurs following head trauma (usually sufficiently severe to result in loss of consciousness) and includes a number of disparate symptoms such as headache, dizziness (usually lacking the features of true vertigo), fatigue, irritability, difficulty in concentrating and performing mental tasks, impairment of memory, insomnia, and reduced tolerance to stress, emotional excitement, or alcohol. These symptoms may be accompanied by feelings of depression or anxiety, resulting from some loss of self-esteem and fear of permanent brain damage. Such feelings enhance the original symptoms and a vicious circle results. Some patients become hypochondriacal, embark on a search for diagnosis and cure, and may adopt a permanent sick role. The etiology of these symptoms is not always clear, and both organic and psychological factors have been proposed to account them. The nosological status of this condition is thus somewhat uncertain. There

is little doubt, however, that this syndrome is common and distressing to the patient. Diagnostic Guidelines: At least three of the features described above should be present for a definite diagnosis. Careful evaluation with laboratory techniques (electroencephalography, brain stem evoked potentials, brain imaging, oculonystagmography) may yield objective evidence to substantiate the symptoms but results are often negative. The complaints are not necessarily associated with compensation motives (Ref. 40; section F07.2).

The specific research criteria for the Post-concussional Syndrome are set out in Table 23-1. Notice that the ICD-10 criteria do not require “objective” evidence of cognitive problems (in contrast to the DSM-IV criteria described later). The emphasis is on subjective cognitive complaints that are not, in fact, easy to document through neuropsychological testing. This, presumably, is to distinguish the diagnosis from the more serious injuries, conditions, and diseases affecting the brain that have more pronounced associated neurocognitive impairments. Also note that a person with “emotional changes, insomnia, and a pre-occupation with having brain damage” would meet diagnostic criteria for the syndrome. This definition incorrectly and implicitly “assumes” that numerous physical symptoms commonly considered secondary to MTBI are only associated with MTBI and do not have other etiologies, thereby implying a lack of need for adequate differential diagnosis of the cause of the various symptoms reported after traumatic injury.

The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV; 41) included research criteria for the Post-concussional Disorder (see 42, for an interesting discussion of the development and limitations of these criteria). According to these criteria, the individual must show objective evidence on neuropsychological testing of declines in some of his or her cognitive abilities, such as attention, concentration, learning, or memory. The person must also report three or more subjective symptoms from Category C, and these symptoms must be present for at least 3 months. The Category C symptoms are: (a) becoming fatigued easily, (b) disordered sleep, (c) headache, (d) vertigo or dizziness, (e) irritability or aggression on little or no provocation, (f) anxiety, depression, or affective lability, (g) changes in personality (e.g., social or sexual inappropriateness), and (h) apathy or lack of spontaneity. The DSM-IV includes the additional criteria: “The disturbance causes significant impairment in social or occupational functioning and represents a significant decline from a previous level of functioning.”

The essential feature is an acquired impairment in cognitive functioning, accompanied by specific neurobehavioral symptoms, that occurs as a consequence of closed head injury of sufficient severity to produce

**TABLE 23-1**  
**FO7.2 Post-Concussional Syndrome (Research criteria from the ICD-10)**

Note: The nosological status of this syndrome is uncertain, and criterion A of the introduction to this rubric is not always ascertainable. However, for those undertaking research into this condition, the following criteria are recommended:

- A. The general criteria of F07 must be met.  
(The general criteria for F07, Personality and Behavioral Disorders Due to Brain Disease, Damage and Dysfunction, are as follows: G1. Objective evidence (from physical and neurological examination and laboratory tests) and/or history, of cerebral disease, damage, or dysfunction. G2. Absence of clouding of consciousness and of significant memory deficit. G3. Absence of sufficient or suggestive evidence for an alternative causation of the personality or behavior disorder that would justify its placement in section F6 (Other Mental Disorders Due to Brain Damage and Dysfunction and to Physical Disease).
- B. History of head trauma with loss of consciousness, preceding the onset of symptoms by a period of up to four weeks (objective EEG, brain imaging, or oculonystagmographic evidence for brain damage may be lacking).
- C. At least three of the following:
- (1) Complaints of unpleasant sensations and pains, such as headache, dizziness (usually lacking the features of true vertigo), general malaise and excessive fatigue, or noise intolerance.
  - (2) Emotional changes, such as irritability, emotional lability, both easily provoked or exacerbated by emotional excitement or stress, or some degree of depression and/or anxiety.
  - (3) Subjective complaints of difficulty in concentration and in performing mental tasks, and of memory complaints, without clear objective evidence (e.g. psychological tests) of marked impairment.
  - (4) Insomnia.
  - (5) Reduced tolerance to alcohol.
  - (6) Preoccupation with the above symptoms and fear of permanent brain damage, to the extent of hypochondriacal over-valued ideas and adoption of a sick role.

a significant cerebral concussion. The manifestations of concussion include loss of consciousness, post-traumatic amnesia, and less commonly, post-traumatic onset of seizures. Specific approaches for defining this criterion need to be refined by further research. Although there is insufficient evidence to establish a definite threshold for the severity of the closed head injury, specific criteria have been suggested, for example, two of the following: 1) a period of unconsciousness lasting more than 5 minutes, 2) a period of post-traumatic amnesia that lasts more than 12 hours after the closed head injury, or 3) a new onset of seizures (or marked worsening of a pre-existing seizure disorder) that occurs within the first 6 months after the closed head injury (p. 760, DSM-IV-TR, Ref. 43).

Notice that the DSM-IV criteria require objective evidence of cognitive problems. The DSM-IV emphasizes that the “closed head injury” is sufficient to produce “a significant cerebral concussion.” As is often the case in the literature, there is an intermingling of terminology that lacks precision in this definition. In some places “closed head injury” seems to imply cranial trauma and in other places it is used analogously with MTBI. The injury severity markers provided as examples included loss of consciousness (LOC) greater than five minutes, post-traumatic amnesia (PTA) greater than 12 hours, or the new onset of seizures. Clearly, it was the intent of the authors to differentiate the MTBI believed to underlie this

disorder from very mild concussions often experienced in day-to-day life. This definition implies that the disorder should be considered uncommon in people who do not have these more significant injury severity markers, although some researchers have reported that these markers are not reliable predictors of the disorder (e.g., 44, 45). Ruff and Jurica (44) reported that subjective complaints and neuropsychological test performance did not differ in a sample of post-acute patients with mild traumatic brain injuries, of different severities within the mild spectrum, as might be expected if the DSM-IV criteria were predictive of outcome.

When the ICD-10 and DSM-IV criteria are compared in the same set of patients, large diagnostic differences emerge (46, 47). This is because the DSM-IV criteria requires (a) neurocognitive impairment, and (b) impairment in important role functioning. The ICD-10 does not have these “impairment” criteria. Researchers have reported that consecutive patients with mild traumatic brain injuries, seen at a Level I trauma center and followed prospectively, have relatively low rates of diagnosis at three months post-injury using the DSM-IV criteria (i.e., 11% to 17%) compared to the ICD-10 criteria (54% to 64%) (46, 47).

Ruff (7) proposed four modifiers for the Post-concussional Disorder. These modifiers are as follows: (a) PCD with objective neuropathological features, (b) PCD with neurocognitive features, (c) PCD with psychopathological features, and (d) PCD with neurocognitive and

psychopathological features. The PCD with objective neuropathological features classification identifies those patients with a combination of neuropsychological deficits and abnormalities identified on neuroimaging (i.e., those with “complicated” MTBIs). PCD with neurocognitive features is used if (a) a cluster of cognitive deficits consistent with MTBI are reliably documented on neuropsychological testing, (b) there is an absence of significant emotional overlay, and (c) there is an absence of positive neuroimaging. PCD with psychopathological features is used when (a) persistent emotional sequelae dominate the clinical picture (e.g., acute stress reaction, depression, panic attacks), (b) neuropsychological deficits are disproportionate with the duration of loss of consciousness or post-traumatic amnesia, and absence of neuroimaging findings, and (c) symptoms tend to persist or even worsen over time. PCD with neurocognitive and psychopathological features is used when there is a mixture of documented neurocognitive deficits and acquired emotional problems that demonstrate some improvements over time, and there is an absence of positive neuroimaging.

The most serious and obvious problem with the ICD-10 and the DSM-IV criteria for the post-concussive disorder is causally linking the subjective, self-reported symptoms to the original MTBI. In fact, the etiology of the so-called *persistent* post-concussive disorder has never been agreed upon (see 4, 12, and, 48 for reviews). For decades, researchers have questioned the validity of this diagnosis as a true syndrome or disease entity (e.g., 29, 38, 49–52). Others have noted that the syndrome is rare in prospective studies (e.g., 29, 34), and concerns regarding the role of financial compensation on symptom reporting have been expressed for many years (49, 53–56). Most researchers suggest that the etiology is due to the biological effects of the injury, psychological factors, psychosocial factors (broadly defined), chronic pain, or a combination of factors (9–11, 14, 39, 57–60). Ruff and colleagues (8, 48, 61) have stressed a multidimensional cumulative stressor conceptualization of the persistent post-concussive disorder. Essentially, setbacks in several aspects of a person’s life (physical, emotional, cognitive, psychosocial, vocational, financial, and recreational) serve as cumulative stressors that interact with personality and premorbid physical and mental health factors, resulting in the disorder. This model stresses the complexity of the etiology and factors that might maintain the symptoms chronically. The model, as written, does not require “brain damage” as a pre-requisite for diagnosis. In addition to cumulative stressors, Wood (13) has described numerous factors that can mimic, reinforce, or perpetuate post-concussion or post-concussion-like symptom reporting.

The ICD-10 criteria explicitly recognize that the cause of the person’s symptoms is not always clear. It has been documented repeatedly by researchers that the

symptoms that comprise the diagnostic criteria are non-specific and they occur frequently in healthy adults and in a variety of patient groups who have not suffered an MTBI (38, 62–77). Examples of the prevalence of these diagnostic criteria in healthy adults, patients with depression, and patients with fibromyalgia are provided in the next section.

### **Nonspecificity of ICD-10 & DSM-IV Diagnostic Criteria**

In this section we provide information regarding the prevalence of the ICD-10 and DSM-IV diagnostic criteria in healthy adults and in patients with depression or fibromyalgia. These data illustrate (a) the nonspecificity of these criteria, and (b) how easy it is to misdiagnose a person with a post-concussive disorder. A post-concussion questionnaire, patterned after the ICD-10 criteria, was developed in the late 1990s and has been used in several studies (73, 78, 79).

The British Columbia Post-concussion Symptom Inventory (BC-PSI; see Appendix A & B) is a 16-item measure designed to assess the presence and severity of post-concussion symptoms (73, 78, 79). The test was based on ICD-10 (40) criteria for Post-concussional Syndrome, and requires the test taker to rate the frequency and intensity of 13 symptoms (i.e., headaches, dizziness or light-headedness, nausea or feeling sick, fatigue, sensitivity to noises, irritability, sadness, nervousness or tension, temper problems, poor concentration, memory problems, reading difficulty, and sleep disturbance), and the effect of three life problems on daily living (i.e., greater present versus past effects of alcohol consumption, worrying and dwelling on symptoms, and self-perception of brain damage).

Normative data for the BC-PSI are available for 158 healthy, community-dwelling, adults from the greater Vancouver metropolitan area. All subjects were working or going to school, and none had a current mental health problem. All were screened for depression and scored below 17 on the Beck Depression Inventory-Second Edition. As seen in Tables 23-2 and 23-3, most healthy adults endorse some symptoms. Approximately 32% of this sample obtained a total score of zero. However, 15% obtained a score of 10 or higher. Scores from 10–14 are considered unusually high and score above 15 are considered extremely high for healthy adults.

The BC-PSI has also been given to large samples of patients with depression or fibromyalgia. The patients with depression were referred by their psychiatrist or family physician (N = 64). All subjects were administered the Structured Clinical Interview for DSM-IV (SCID-I). The SCID-I is a semi-structured clinical interview used to establish DSM-IV Axis I diagnoses. The version of the SCID-I used in this study was the nonpatient research

N = 158.

version 2.0, August 1998 revision (80). All patients had a SCID diagnosis of major depressive disorder (92%), dysthymic disorder (5%), or depressive disorder NOS (3%). The patients with fibromyalgia (N = 54) were recruited from two rheumatology practices and one outpatient hospital program. All patients were examined by a rheumatologist and were included in the study only if they met the American College of Rheumatology criteria for the syndrome (81). On average, the participants had 13.8 trigger points (SD = 2.1, Range = 11–18), and less than one control point (Range = 0–3).

As seen in Table 23-4, mild levels of symptom endorsement occur in a minority of healthy adults and a

**TABLE 23-3**  
**Interpreting Total Scores in Healthy Adults: British Columbia Post-Concussion Symptom Inventory**

TOTAL RAW SCORE	PERCENTILE RANKS	CLASSIFICATION
0	0 – 32%	Low
1 – 9	33 – 85%	Normal
10 – 14	86 – 95%	Unusually high
15+	96 – 100%	Extremely high

The community volunteers were from the Greater Vancouver area (N = 158). All were working or going to school, and none had current mental health problems. The sample was 41% male and 59% female. Their average age was 35.7 years (SD = 16.3). Their average education was 14.8 years (SD = 2.5). They should be considered a high functioning, well-educated sample of healthy adults. The internal consistency reliability (Cronbach's Alpha) for the items comprising the total score is  $r = .82$ .

majority of patients with depression or fibromyalgia. Headaches were reported by nearly 20% of healthy adults, 59% of patients with depression, and 72% of patients with fibromyalgia. Noise sensitivity was reported by 11% of healthy adults, 50% of patients with depression, and approximately 69% of patients with fibromyalgia. The ICD-10 diagnostic criteria also identify reduced tolerance to alcohol, fear of brain damage, and a pre-occupation with symptoms and problems as characterizing the post-concussive disorder. The percentages of patients that endorsed these problems were as follows: (a) reduced tolerance for alcohol (depression = 39% and FM = 35%), (b) concern about having brain damage (depression = 28% and FM = 33%), and (c) worrying about or dwelling on their symptoms and problems (depression = 75%, FM = 85%).

Symptom endorsement for each group can be compared to the DSM-IV and ICD-10 diagnostic criteria. Six of the eight DSM-IV Category C symptoms are represented on the BC-PSI. For the depressed patients, the majority of subjects (85.9%) endorsed three or more DSM-IV Category C symptoms. Over half of the sample (53.1%) endorsed three or more of these symptoms at a clinically significant level (moderate-to-severe). Depressed patients' symptom endorsement also was compared to diagnostic criteria from the ICD-10. All diagnostic criteria from the ICD-10 are represented on the scale. These criteria are grouped into six categories. The specific rates of endorsement for the six mildly endorsed and moderately-severely endorsed symptom categories for the ICD-10 were as follows: (1) headaches, dizziness, general malaise and excessive fatigue, or noise intolerance = 92.2% and 65.6%; (2) irritability, emotional liability, depression, or anxiety = 87.5% and 68.8%; (3) subjective complaints of concentration or memory difficulty = 78.1% and 54.7%; (4) insomnia = 78.1% and 53.1%; (5) reduced

Healthy adults (N = 158), patients with depression (N = 64), and patients with fibromyalgia (N = 54). Patients with depression were diagnosed by their family physician or psychiatrist, and their diagnosis was confirmed using the SCID-I. Their average age was 41.1 years (SD = 12.5), and their average education was 14.6 years (SD = 3.2). Approximately 71% of the sample was female. The patients with fibromyalgia were mostly women (94%). Their average age was 51.4 years (SD = 12.8, Range = 17 – 75). Their average education was 13.5 years (SD = 2.4, Range = 7 – 20)

tolerance to alcohol = 35.9% and 12.5%; and (6) pre-occupation with these symptoms and fear of permanent brain damage = 76.6% and 26.6%. The majority of the sample (89.1%) endorsed three or more ICD-10 Category C symptoms, with 57.8% endorsing these symptom categories at a clinically significant level.

The patients with fibromyalgia had similar results. The majority of subjects (81.5%) endorsed three or more DSM-IV Category C symptoms. Half of the sample (50.0%) endorsed three or more of these symptoms at a clinically significant level (moderate-to-severe). Their specific rates of endorsement for the six mildly endorsed and moderately-severely endorsed symptom categories for the ICD-10 were as follows: (1) headaches, dizziness, general malaise and excessive fatigue, or noise intolerance = 96.3% and 83.3%; (2) irritability, emotional lability, depression, or anxiety = 81.5% and 50.0%; (3) subjective complaints of concentration or memory difficulty = 77.8% and 53.7%; (4) insomnia = 87.0% and 59.3%; (5) reduced tolerance to alcohol = 35.8% and 33.3%; and (6) preoccupation with these symptoms and fear of permanent brain damage = 87.0% and 63.0%. The majority of the sample (94.3%) endorsed three or more ICD-10 Category C symptoms, with 66% endorsing these symptom categories at a clinically significant level.

What is clear from the data presented in this section is that (a) the diagnostic criteria for the post-concussive disorder are non-specific, and (b) patients with fibromyalgia who report problems with depression, chronic pain, or both are very likely to be diagnosed (or misdiagnosed) with the disorder. In fact, 9 out of 10 patients with depression or fibromyalgia report a symptom constellation that can meet criteria for a post-concussive disorder (in the absence of a traumatic injury to their head or brain). The rates at which the patients with depression and the patients with fibromyalgia met diagnostic criteria for the two classification systems were very similar because only the symptom criteria were applied. The additional DSM-IV criteria for measured neurocognitive impairment and impairment in real-world functioning were not applied. What is interesting, of course, is that when patients are followed prospectively out of the hospital and assessed at three months post-injury, a minority meet DSM-IV criteria (11–17%) and over half meet ICD-10 criteria (54–64%) (46, 47). However, as illustrated with this section of the chapter, if a person has depression (and no head or brain injury), he or she is 90% likely to meet ICD-10 criteria (if the head injury criterion is waived). The remainder of the chapter addresses the complexities of differential diagnoses.

## DIFFERENTIAL DIAGNOSES AND CO-MORBIDITIES

There are many possible differential diagnoses, comorbidities, and social-psychological factors that may *cause or maintain* the myriad of symptoms and problems reported by patients long after experiencing a mild injury to their head, brain, or both. These differential diagnoses or co-morbidities might be largely unrelated to the original MTBI. In practice, it is oftentimes difficult to disentangle the many factors that can be responsible for the symptoms following a remote MTBI or a craniocervical trauma with an MTBI. This is because the more chronic symptoms that are believed to be associated directly or indirectly to the remote injury are common in healthy subjects (62, 72–77), in patients with no history of brain injury, such as outpatients seen for psychological treatment (63) or minor medical problems (64), personal injury claimants (64, 65), patients with post-traumatic stress disorder (66), patients with orthopedic injuries (38), individuals with chronic pain (67–70), and patients with whiplash (71). Thus, the differential diagnosis of the persistent post-concussive disorder is very challenging. The most commonly encountered clinical conditions that might lead to a diagnosis of “post-concussive disorder” are traumatic cervical injuries due to whiplash-associated disorders; post-traumatic chronic pain, particularly headache (cephalgia) and neck pain (cervicalgia); depression; and the anxiety spectrum disorders (including post-traumatic stress disorder). Each of these conditions might co-occur with an MTBI or they might occur independently from an MTBI. If they co-occur, the challenge is trying to determine if the person recovered from the MTBI and the ongoing symptoms and problems reported are more likely to relate to one of the co-morbid conditions. These conditions will be reviewed next.

### Cervical Injuries and Whiplash-Associated Disorders

Cervical spine injuries are common, particularly following rear-end motor vehicle accidents (82). Most patients recover from these injuries in a few weeks. However, there are others who have longer-term problems related to numerous potential secondary complications. The diagnostic and treatment challenges are mainly relevant to this chronically-symptomatic group.

It is generally agreed that whiplash injury typically involves a flexion-extension movement, but torsional-rotational movement may also play a role. The presumed cause of the acute injury is mechanical strain with or without contusion of ligaments and muscles supporting the cervical spine. Safety belts appear to actually increase the risk for cervical injury and, to a lesser extent, thoracic vertebral fractures (83). Because most cervical acceleration/

deceleration injuries are not exclusively in the sagittal plane, the pathomechanics can be complicated and this has important implications for what part of the neck might be damaged as a result of rotational injury. Structures that become more susceptible to injury when there is cervical rotation include the facet (zygapophyseal) joint capsules, alar ligament complex, and intervertebral discs (84). The forces involved in cervical injury include extension, flexion, lateral flexion, and shear. Shear forces typically are horizontal in nature. Cervical symptoms may be caused and maintained as a result of injury to multiple structures within the neck including intervertebral discs, muscles, ligaments, the atlantoaxial complex, cervical vertebra, zygapophyseal (facet) joints, and neurovascular structures (85). Imaging methods, particularly conventional radiography, do not visualize many of these types of lesions very well.

The most common acute symptoms following whiplash are neck pain, headache, and limitation in neck range of motion (82, 86, 87). Many other symptoms have been associated with this type of injury, including visual disturbances, dizziness, auditory disturbances, balance disorders, and cognitive dysfunction (85, 88).

Visual disturbances have been associated with whiplash and might be subjectively reported as “blurriness”. Most commonly, this subjective impairment is associated with findings of decreased accommodative and convergence function (89, 90). Other problems, such as disturbances in saccadic eye movement, have also been reported (91).

Cervicogenic vertigo or dizziness is a complaint that often accompanies cervical whiplash injury and may be related to (a) problems with the afferent input from positional proprioceptors in the cervical and lumbar regions (92, 93), (b) over-excitation of the cervical sympathetic nerves (94), (c) compromise of vertebral artery blood flow (95, 96), and/or (d) cervical/lumbar hypertonicity (94). Non-cervicogenic causes of vertigo or dizziness include perilymphatic fistulas<sup>1</sup>, post-traumatic endolymphatic hydrops<sup>2</sup> (e.g., Meniere’s disease), and benign paroxysmal positional vertigo<sup>3</sup> (97–99). Some patients report general feelings of whooziness, giddiness, and/or imbalance. Stapley and colleagues hypothesized that this phenomena occurs as a result of neck muscle fatigue and associated increases in postural body sway (100). Balance disorders

<sup>1</sup> An abnormal communication between the fluid-filled perilymphatic space of the inner ear and the air-filled middle ear cavity.

<sup>2</sup> Increased hydraulic pressure within the inner ear’s endolymphatic system that can cause hearing loss, episodic vertigo, tinnitus, and pressure sensation.

<sup>3</sup> Benign paroxysmal positional vertigo can occur following head trauma and might relate to a collection of debris in the inner ear. Symptoms include dizziness or vertigo, light-headedness, imbalance, and nausea.

following whiplash are believed to be associated with (a) altered vestibular and/or proprioceptive input (101), (b) neck muscle fatigue (102), (c) joint position error (103), and/or (d) abnormal cervical afferent input (104).

Auditory symptoms, such as tinnitus, hyperacusis<sup>4</sup>, and hearing loss (105, 106), may also occur following whiplash. There is controversy regarding the etiology of neuro-otological impairments of these types following cervical whiplash, but they clearly can occur in the absence of acquired brain injury. The cause of tinnitus has not been determined definitively, but it is possible that following whiplash cranio-cervical somatic dysfunction may modulate dorsal cochlear nucleus activity (107), and/or aberrant nociceptive input to the brainstem from upper cervical (e.g., atlas) and associated cervical myofascial dysfunction (108) may be the underlying cause(s). Temporomandibular joint dysfunction also might underlie tinnitus in some patients (109).

Neurocognitive complaints also are common following whiplash (110), and a substantial minority of patients remain symptomatic at one year post-injury (111, 112). These problems should be conceptualized as either perceived, self-reported symptoms or measured problems on neuropsychological tests. In a meta-analytic review of the literature, Kessels and colleagues (113) concluded that cognitive functioning, as measured by neuropsychological tests, can be adversely affected following whiplash. Not all studies, of course, report neuropsychological changes associated with whiplash injury (e.g., 114). The cause of cognitive complaints or measured cognitive decrements in a subset of patients with whiplash is unknown; researchers suggest they might be related to damage to the brain (110), somatization (114), distraction due to pain (115), or a combination of factors.

There are multiple potential causes of chronic pain following whiplash. Possible etiologies, singly or in combination, include myofascial dysfunction of the paracervical (anterior and posterior) and upper shoulder girdle musculature, C2-C3 facet joint pain, neuralgia of the greater and/or lesser occipital nerve, internal derangement of the temporo-mandibular joint, basilar artery migraine, and/or cervico-thoracic somatic dysfunction (116). Facial, neck, and shoulder dysesthesias (e.g., burning, pins and needles, itching sensation) can arise from the upper cranial nerves and their superficial branches (greater auricular nerve, superficial cervical nerve, and supraclavicular nerve), and the descending tract of the trigeminal nerve and/or its associated fibers (i.e., fibers 5, 7, 9, and 10). Knibestol and colleagues reported that some patients with whiplash have facial sensory changes in vibratory and temperature perception that might be related to damage to the central trigeminal system in the upper spinal cord segments and pontomedullary levels of the brainstem (117). Herren-Gerber

and colleagues reported that there is modulation of central hypersensitivity by nociceptive input following whiplash injury and that different mechanisms likely underlie hypersensitivity to pain (hyperalgesia) localized to areas around the pain site versus distant body areas (118). Chronic cervical facet joint pain can occur following whiplash. Dwyer and colleagues “mapped” characteristic patterns of cervical zygapophyseal joint pain in normal volunteers; this mapping may be useful for constructing pain charts (119).

The best initial treatment for cervicogenic pain is exercise and manual therapy. In more intractable cases, where facet involvement is suspected, interventional pain management through the use of local blocks and/or neuromodulation procedures is recommended (120, 121).

### Cranial Trauma

Head injury can, of course, result in damage to the skull or its adjoining parts (i.e., the cranium or cranial adnexal structures). This damage might underlie some of the symptoms and problems reported by patients acutely and post-acutely without necessarily having concomitant brain injury (98).

Skull fractures are relatively uncommon in patients who sustain mild traumatic brain injuries. When they occur, they may be closed or compound and depressed or non-depressed. Basilar skull fractures, as opposed to linear skull fractures of the cranial vault, often have important clinical implications. If the dura mater is torn, the chance of a cerebrospinal fluid fistula is increased. A dural tear or basilar skull fracture will increase the patient's risk of meningitis. Cerebrospinal fluid leaks may occur through the nose (rhinorrhea) or ears (otorrhea) and may be missed in the acute setting. Approximately 4% of mild head injury patients may have an unsuspected temporal skull fracture (122).

Hearing loss can arise from damage to cranial adnexal structures. Longitudinal fractures are more commonly associated with conductive hearing loss due to either ossicular chain disruption or traumatic tympanic membrane tear and blood in the middle ear. Transverse temporal skull fractures often will be associated with either mixed or profound sensorineural hearing loss, hemotympanum, dizziness, and/or facial nerve injuries (123, 124). The conductive hearing loss associated with hemotympanum is typically temporary and resolves as the blood is re-absorbed. Progressive hearing loss following trauma should prompt further assessment for either perilymphatic fistula or endolymphatic hydrops (125). The most common type of ossicular dislocation associated with temporal skull fractures is the separation of the incudostapedial joint, with or without dislocation of the body of the incus from the articulation with the malleus head. Surgical correction can restore hearing.

<sup>4</sup> Hypersensitivity to sound.

Complaints of “dizziness” following head trauma and/or mild traumatic brain injury are extremely common. If these problems persist beyond the acute stage of recovery, thorough clinical evaluation is important. Neurodiagnostic evaluation of the dizzy patient might include: audiologic testing, a platform fistula test, electronystagmography, and/or posturography (99, 126). Labyrinthine concussion can result in transient auditory and vestibular symptoms without associated skull fracture. Sudden deafness following a blow to the cranium may be partially or completely reversible. Benign paroxysmal positional vertigo is the most common neuro-otologic problem following head trauma. Most patients demonstrate a paroxysmal positional nystagmus with rapid changes in position (127). Although, benign paroxysmal positional vertigo may have periodic exacerbations even after the symptoms have subsided, this is the exception rather than the rule. Vestibular suppressant medications may be used, but generally these agents should only be considered if symptoms are severe enough to dramatically compromise functional activities such as frequent falls or significant nausea and/or vomiting. Vestibular exercises may also be prescribed to hasten neurologic and functional recovery via several proposed physiologic mechanisms including central sensory substitution, rebalancing tonic activity, and physiologic habituation (128–132). Clinical researchers suggest that a three-pronged approach should be utilized as part of an organized vestibular rehabilitation program: (a) habituation exercises, (b) postural control exercises, and (c) general conditioning activities (133). Surgery may be considered as a last resort for intractable benign paroxysmal positional vertigo; it has been reported to be successful in more than 90% of cases (134).

The clinician should always consider the possibility of a post-traumatic endolymphatic hydrops (Meniere’s syndrome) after cranial trauma when there is ipsilateral low-frequency hearing loss, tinnitus, and a sensation of fullness in the ear. Treatment of post-traumatic Meniere’s disease may include vestibular suppressants if patients are symptomatic to the point that daily function is significantly adversely affected. Head movements and rapid changes in head position should be avoided. In the remission phase, Meniere’s disease may be treated with medications including vestibular suppressants and/or diuretics as well as steroids, low pressure pulse generators (Meniett device), and surgical procedures (both destructive and non-destructive; 135, 136–138).

Post-traumatic perilymphatic fistula can occur following trauma as a result of rupture of the oval and less commonly the round window with subsequent communication between the inner ear and middle ear resulting in inappropriate stimulation of labyrinthine receptors (139). Unfortunately, there is no pathognomonic or characteristic electronystagmographic sign for the condition. Symptoms can include vertigo, fluctuating hearing loss

(usually a late complication), tinnitus, chronic low grade nausea, endolymphatic hydrops, abnormal cervical muscle tone (myodystonia), and persistent or exertional headache (140). Patients quite frequently complain of aural fullness (141). Patients will often complain of non-specific imbalance problems worsened by sudden turning, as well as disequilibrium with perceptually-complex external stimuli such as patterns and wide-field motion evidenced with escalator rides, revolving doors, and crowds (141, 142). The sensation while ambulating has been described as “walking on pillows” (135). The aforementioned experiences sometimes promote a mild agoraphobia. Although there is no definitive bedside clinical test for post-traumatic perilymphatic fistula, application of pressure to the tympanic membrane with a pneumatic otoscope (Hennebert’s fistula test) or application of pressure over the tragus might produce worsening of vertigo or nystagmus. Both the aforementioned tests are suggestive but not diagnostic for a perilymphatic fistula. Some investigators believe that caloric hypoexcitability or unexcitability associated with even partial conservation of cochlear function is a very good indicator of the condition (143). Black, Lilly, and Nashner (144) described the platform fistula test utilizing posturography as a means of objectively diagnosing this clinical condition. The ability of posturographic testing to delineate perilymphatic fistulas has been questioned by one of the authors (NDZ) as well as others (145). However, further research is definitely indicated to clarify the role of this diagnostic modality. Early treatment measures include bedrest, head elevation, and avoidance of straining (135). The duration of bedrest is somewhat controversial although many clinicians advocate 5 to 10 days given the functional and physiologic implications of prolonged immobilization. Perilymphatic fistulas usually heal spontaneously. Exploratory tympanotomy is necessary to definitively establish the diagnosis, but is generally *not* recommended unless symptoms last longer than a month or if there is a progressive hearing loss. Chronic perilymphatic fistulas can be addressed surgically by “patching” the leaking oval/round window utilizing temporal aponeurosis or stapledectomy with interposition (146). Recent work has shown that the presence of beta-2 transferrin may serve as a marker for perilymphatic fistula-related leaks (147, 148). Surgical treatment generally aids in control of vertigo much more so than the restoration of hearing (141, 143).

Tinnitus can occur following head trauma. It is important to note that tinnitus is a symptom not a disease entity, the etiology of which must be defined before it can be effectively treated. Audiologic battery testing is indicated in all post-head injury patients with complaints of tinnitus. Hearing aids, cochlear implants, tinnitus maskers, and hearing instruments have been used to decrease the subjective symptoms associated with this disorder. The protocol that is clearly the most well

accepted is the Jastreboff tinnitus retraining program<sup>5</sup> (149). No drug has been FDA approved for treating tinnitus and current choices are at best controversial and poorly studied (150). Antidepressant medications, biofeedback, hypnosis, avoidance of stimulants including caffeine, and proper sleep hygiene have also been recommended because tinnitus can be exacerbated by stress and anxiety (151).

Olfactory and gustatory problems also can occur following injury to the cranium and/or brain. There are several million olfactory neurons located in the olfactory epithelium on the wall of the nasal cavity. Each of these neurons extends an axon to the olfactory bulb (on the surface of the brain, along the orbital-medial surface of the frontal lobe). The bulb neurons extend axons, via the olfactory tracts, to make contact with neurons located in the olfactory cortex. The primary olfactory cortex is located near the anteromedial part of the uncus on each side. Because the olfactory tract is attached to the outer aspect of the hemisphere, the impact of the skull's jagged interior<sup>6</sup> upon the uncus could damage the primary olfactory cortex or the terminal portion of the olfactory nerve or both. Costanzo and Zasler (153) listed the known and presumed mechanisms underlying olfactory impairment following head trauma or TBI as follows: (1) traumatic damage to the nasal epithelium; (2) shearing of the olfactory fila, arising from the nasal epithelium, prior to entering the olfactory bulbs, as a presumed consequence of movement of the brain relative to, and/or fracture of, the cribriform plate; and (3) contusions or edema effecting the olfactory bulb or the lateral or medial olfactory tracts. All of these mechanisms could cause impairment in the ability to detect odors. Isolated gustatory dysfunction is uncommon. Typically, peripheral injury involves the facial nerve (CN VII) because it is more prone to injury than the glossopharyngeal (CN IX) and vagus (CN X) nerves which are also involved in mediation of taste (153). Timely neuromedical and rehabilitative interventions (154) including comprehensive objective quantification of deficits through established "Chemosensory Clinics" can be helpful.

Visual problems can occur at a peripheral level and be unrelated to a brain injury. These deficits can be due

<sup>5</sup> The authors know specialists in neuro-otology that strongly prefer to not take patients into a tinnitus retraining program while they are involved in litigation, given limited resources and less "subjective improvement" in patients involved in stressful, adversarial, protracted litigation.

<sup>6</sup> The upper border of the sphenoid bone is sharply angulated, like the edge of a shelf. In the center of the skull base, the sphenoid wings or ridges terminate in two bony projections called the anterior clinoid processes. They are adjacent and immediately anterior to the uncus on both sides and point posteriorly towards the foramen magnum. Therefore, with a violent forward movement of the brain relative to the skull, the anterior clinoid processes could produce contusions in the region of the uncus (152).

to disorders of the vitreous, both prefoveal and foveal, commonly associated with traction on the retina with resultant subjective symptoms of floating spots (so-called "floaters"; 155, 156). Retinal injury, including detachment, tear, and hemorrhage (157, 158), also causes visual symptoms. Approximately 20% of patients evaluated with mid-facial trauma were noted in one study to have accommodative and/or convergence insufficiency (159). A cursory assessment of the optic disc by the physician will obviously miss the types of subtle lesions responsible for many post-traumatic visual symptoms. It is therefore important to refer patients with visual complaints for appropriate diagnostic assessment as well as functionally oriented treatment. Professionals that may assist in these aforementioned areas include ophthalmology, neuro-ophthalmology, and neuro-optometry (See chapter in this text by Padula and colleagues).

Headache and neck pain are the most common physical complaints following concussion (mild brain injury) (See chapters in this text by Zasler, Martelli, et al. and Martelli, Zasler, et al. on Pain Management). Headaches, of course, are common in the general population as well (160, 161). Pre-existing headaches, post-traumatic headaches, or both might largely underlie a diverse set of symptoms and problems in people who have sustained an MTBI (as well as patients with whiplash-related problems or cranial-trauma related problems). Patients with problematic headaches, such as migraine or tension, often have comorbid depression (162–165). Elevated levels of psychological distress (i.e., symptoms of anxiety, depression, or both), that may or may not break threshold for diagnosing a psychiatric condition, have been reported in numerous studies involving patients with headache conditions (166–171).

When a patient presents with headaches long after an MTBI, it is difficult to determine whether (a) the original injury is the underlying cause of the headaches, and (b) to what extent other factors have caused, or are maintaining, the headaches. It is estimated that 4–5% of adults experience chronic daily headaches (172, 173). Medication overuse (i.e., drug rebound headache) is the most treatable cause of refractory headaches (174–179). Medication overuse might result from patients' attempt to treat their headaches or other bodily pain. Febrile or viral illnesses, general surgery, or a stressful life event appear to be the most common events that precede new daily persistent headaches (180).

When a person is involved in litigation, headaches typically are attributed to the tort (i.e., injury being litigated). Of course, headaches are common in daily life and people who are not involved in litigation attribute a variety of factors to the underlying cause of their headaches. Boardman and colleagues (181) conducted a large-scale survey study of adults in Great Britain. In this sample of 1, 871 adults who suffered from headaches in the past

3 months, factors *perceived* (i.e., self-reported) to be related to their headaches were as follows: stress (71%), tiredness (65%), menstrual cycle (55%), having too much work to do (41%), drinking alcohol (33%), sleeping too long (21%), and not eating regularly (20%). The respondents also completed several psychological tests (e.g., measuring depression and anxiety) and questionnaires (measuring pain, disability, sleep problems, and alcohol and caffeine consumption). Headache occurrence was most strongly associated with anxiety and sleep problems.

### Chronic Pain

Patients with chronic pain often complain of physical, cognitive, and psychological symptoms that closely resemble post-concussion-like symptoms (e.g., 68, 70, 114, 182–189). If chronic pain does not co-occur in patients who are slow to recover following an MTBI, then the similarity between chronic pain symptoms and post-concussion symptoms is not problematic. However, patients who sustain MTBIs in falls or motor vehicle accidents frequently have a comorbid chronic pain problem. Uomoto and Esselman (190) reported that 95% of patients with MTBI's reported the presence of at least one chronic pain symptom 24 months post-injury (e.g., headaches, neck/shoulder pain, or back pain). Thus, because chronic pain often accompanies MTBI, attributing post-concussion symptoms to brain injury in patients with comorbid pain is problematic.

McCracken and Iverson (185) reported that 54% of chronic pain patients from a university pain management center endorsed at least one subjective cognitive complaint (e.g., forgetfulness, minor accidents, difficulty finishing tasks, difficulty with attention). Roth et al. (187) found that 62% of chronic pain patients from a university hospital pain management program reported experiencing at least one subjective cognitive complaint as being a moderate to severe problem, and 28% of the patients endorsed 5 of 5 cognitive complaints as being a moderate to severe problem (i.e., trouble remembering, having to recheck things, difficulty making decisions, mind going blank, and trouble concentrating). Jamison, Sbrocco, and Parris (184) found that 54.5% of chronic pain patients from a university medical pain control center reported having moderate to extreme problems with both memory and concentration.

In a study comparing post-concussion-like symptoms to DSM-IV criteria for Post-concussional Disorder, Iverson and McCracken (68) examined 170 non-litigating, chronic pain patients with no history of head injury. On self-report inventories, 42% of these patients reported at least one cognitive complaint that had an impact on their health (i.e., attention, concentration, or memory). A large percentage (80.6%) of these patients endorsed three or

more of the symptoms from Category C of the Post-concussional Disorder criteria in the DSM-IV (41). The percentage of these patients who would meet self report criteria for a Post-concussional Disorder was calculated by determining the number of patients who reported cognitive problems and three or more symptoms from Category C. Based on self report alone, 39% of the chronic pain patients met criteria for a Post-concussional Disorder (except, of course, they had no history of head injury).

Gasquoin (67) compared post-concussion-like symptom reporting in a small sample of 10 patients with MTBIs and 18 patients with chronic back pain. No differences between the MTBI group and chronic back pain group were found on any PCS symptoms, even on symptoms that were typically "head injury related" (e.g., headache, dizziness, recent memory, concentration). Smith-Seemiller and colleagues compared symptom reporting on the Rivermead Post-concussion Questionnaire in 32 patients with chronic complaints following an MTBI and 63 chronic pain patients. More than 80% of both groups met DSM-IV self-report symptom criteria for a Post-concussional Disorder. No differences between groups were found on the total post-concussion symptoms. However, on the subscales of the Rivermead Post-concussion Questionnaire, the MTBI patients endorsed more cognitive symptoms and fewer emotional symptoms compared to the chronic pain patients. There were no differences between groups on the somatic symptoms of the Rivermead. These authors cautioned, however, that there was a high base rate of patients undergoing litigation in the chronic pain sample that may have biased symptom reporting in this group (70).

Some researchers have suggested that the reporting of cognitive complaints in chronic pain patients may be associated with depression, anxiety, and fatigue (e.g., 185–187). Similarly, these complaints may be influenced by factors including the pain experience itself, comorbid psychiatric disorders, medication side effects, iatrogenic factors, and possible malingering. However, the influence of these factors is poorly understood. Given that (a) chronic pain conditions frequently accompany MTBI many months post-injury (190), (b) patients with chronic pain report identical symptoms as those attributed to a post-concussive disorder (e.g., 68, 70), (c) depression frequently co-occurs with chronic pain (191–195), and (d) patients with depression report very similar symptoms as those attributed to a post-concussive disorder (cf. the DSM-IV diagnostic criteria and associated features and Iverson (79)), it is not surprising that a person with chronic pain can be easily misdiagnosed as having a persistent post-concussive disorder, or chronic pain might be the predominant underlying cause of the disorder (See chapters in this text by Zasler, Martelli, et al. and Martelli, Zasler, et al. on Pain Management).

### Depression, Anxiety, Stress, and Somatic Preoccupation

Depression is common following traumatic brain injuries of all severities (196, 197). Depression is also common in patients with chronic pain (191, 194), and it is associated with increased disability in these patients (193, 198). Depression is also common in trauma patients (199), and patients with chronic headaches (165, 200–202), post-traumatic stress disorder (66, 203–205), or substance abuse problems (206–210). Of course, depression is one of the most common mental health problems in the world, and people who suffer a single episode of major depression are at greatly increased risk for a future episode, with estimates of recurrence ranging from 50% to 80% (211–215). People who have had two or more episodes of depression are at extremely high risk for a future episode (43, page 372, 213, 216–218). Therefore, the underlying cause of depression, in any given person at any given time, can be very difficult, if not impossible, to determine. Depression represents the most challenging differential diagnosis for the post-concussive disorder (of course, depression might be the predominant etiology of the disorder for some patients). Many of the specific symptoms of depression, and other problems associated with this condition, are similar to the post-concussive disorder. The diagnostic criteria for major depression include the following symptoms: (a) diminished ability to think or concentrate, (b) indecisiveness, (c) fatigue or loss of energy, and (d) sleep problems (DSM-IV; 41; p. 327). In addition, major depression often is associated with irritability, excessive worry over one's health, and headaches (41; p. 323). Common lifestyle and psychosocial problems include strained social relationships, marital and family distress, occupational problems, academic problems, and substance abuse (41; p. 323). Therefore, it is extremely difficult to determine if a person's self-reported symptoms are due to depression, a persistent post-concussive disorder, or both because many of the symptoms are nearly identical in these conditions.

Patients with depression are expected to have cognitive complaints. Perceived cognitive impairment is a *cardinal feature* of depression (43). However, the relation between depression and cognitive difficulty goes much further. The co-occurrence of perceived cognitive problems and symptoms of depression has been demonstrated repeatedly in the literature in diverse groups of unselected community-dwelling adults (219–221) and specific clinical groups, such as patients with cancer (222), chronic fatigue syndrome (223), HIV (224, 225), major non-cardiac surgery (226), epilepsy (227, 228), chronic pain (185, 188), and sleep apnea (229). This is a consistent finding across different cultural and ethnic groups, including Chinese (230), French (231), Dutch (232), and African Americans (233). Therefore, broad and diverse research converges to illustrate clearly that the diagnosis

of depression, or a depressive experience that does not meet criteria for a diagnosis, is likely to be accompanied by perceived cognitive problems.

The perceived cognitive problems reported by patients with depression have been illustrated more objectively through neuropsychological studies (234–247). However, there has never been a study showing that the cognitive effects of depression can be reliably differentiated from the cognitive effects of an MTBI. The problem for clinicians and researchers is that a person with depression is virtually guaranteed to meet diagnostic criteria for a post-concussive disorder, regardless of whether that person (a) has ever injured his brain, or (b) the past injury to his brain is causally-related to his current symptoms.

Another challenging differential diagnoses for the post-concussive disorder is Post-Traumatic Stress Disorder (PTSD). Patients with PTSD often report the same symptoms as patients who have sustained MTBIs. For example, in a sample of 128 patients with PTSD, 89% reported irritability, 56% reported memory problems, 92% reported concentration problems, and 90% reported difficulty sleeping (66). Therefore, it is easy to misdiagnose PTSD as a post-concussive disorder, and vice versa.

A controversial and confusing issue is whether a person who sustains a traumatic brain injury involving amnesia for the event can develop PTSD. There are data to support the position that TBI and PTSD typically are mutually exclusive (248–250), although researchers have put forward a compelling rationale for how, under certain circumstances, PTSD could emerge in a patient with a brain injury in the presence of amnesia (251, 252). The conceptual question at the heart of the debate is whether a person with no memory for a traumatic event can develop PTSD as a result of that traumatic event.

Gil and colleagues prospectively studied 120 accident victims who sustained an MTBI and who were hospitalized for observation immediately after their trauma. They were assessed within the first 24 hours and at one week, three months, and six months. At six months post-injury, 14% met diagnostic criteria for PTSD (notice that this prevalence rate is very similar to the rate of people believed to have the post-concussive disorder at 6–12 months post-injury). The statistical predictors of PTSD at 6 months were (a) PTSD symptoms, depressive symptoms, and anxiety symptoms at one week post-injury, (b) history of psychiatric disorder, and (c) memory for the event. Of the patients with memory for the event, 13/55 (23%) had PTSD at 6 months post-injury, compared to only 4/65 (6%) who did not have memory for the event (253). Therefore, the literature to date suggests quite clearly that having no memory for the event likely protects the individual from developing PTSD.

Therefore, a person who sustains an MTBI who has upsetting and traumatic memories of the accident, assault, or injury, and who has nightmares and sleep disturbance,

might have PTSD, a post-concussive disorder, or both. It is extremely difficult to accurately diagnose both conditions in a patient, and the combination of the two is statistically uncommon. Therefore, it is more parsimonious to diagnose, and treat, the PTSD if it appears to be present and wait to see if the patient has ongoing residual problems that might relate to a brain injury following improvement or remission.

Symptoms of anxiety, stress, and somatic preoccupation also occur frequently in patients who are symptomatic beyond a few weeks post-injury. In a prospective study, Ponsford and colleagues reported that patients who were symptomatic at three months post-injury were likely to have high levels of stress and anxiety (254). As noted in the ICD-10 diagnostic criteria, symptoms following an MTBI “may be accompanied by feelings of depression or anxiety, resulting from some loss of self-esteem and fear of permanent brain damage. Such feelings enhance the original symptoms and a vicious circle results. Some patients become hypochondriacal, embark on a search for diagnosis and cure, and may adopt a permanent sick role” (40; section F07.2). Clinicians working with symptomatic patients are acutely aware that anxiety, and fear of permanent brain damage, can be prominent psychological features. Clinicians should take steps to reduce patients’ subjective distress and guard against behavior that can be iatrogenic.

### IATROGENESIS

An iatrogenic condition is a state of ill health or adverse effect caused by medical treatment, usually due to mistakes made in treatment (255). The word literally means “caused by a doctor” (*iatros* means physician in Greek), though such conditions can be the fault of therapists and/or pharmacists as well. This phenomenon is poorly researched in the field of rehabilitation, neurology, and neuropsychology, and there is no literature per se on the topic as related to MTBI. Nonetheless, it is a well-recognized issue in the field of brain injury rehabilitation.

Professionals involved in rehabilitation have a clinical responsibility to patients with MTBI. To the extent that symptoms are ever iatrogenic, we provide a disservice to patients. To the extent that symptoms are neurologically, emotionally, environmentally, or motivationally based, we have a responsibility to understand and address these issues clinically to the best of our ability (Ref. 256, p. 57).

The tendency for medical, medical-legal, and rehabilitation professionals to diagnose “brain damage” or “diffuse axonal injury” as an explanation for persistent problems following a mild uncomplicated concussion (i.e., a “mild MTBI”) can be iatrogenic. The authors have

seen, on numerous occasions, psychological harm resulting from telling people they have brain damage and they will need to cope and compensate for that damage, when in fact the probability of permanent brain damage was very low and the probability of a “treatable condition”, such as depression, anxiety, sleep disturbance, and cumulative life stress, was high. Remember, if a person has chronic bodily pain, depression, or both, they are virtually guaranteed to meet self-report criteria for a post-concussive disorder regardless of whether they ever sustained a concussion. When a person is misdiagnosed as having presumed permanent brain damage it sends a strong, negative, prognostic message. It also might lead to (a) the person seeking support from brain injury associations, (b) the person receiving rehabilitation services normally designated for patients with moderate to severe brain injuries, and (c) the failure to provide effective treatment for the person’s real underlying problems.

Roger Wood has noted that the early iatrogenic potential of general practitioners and hospital doctors may create insecurity and/or reinforce illness perceptions thereby instigating perceptions of disability and “illness behavior” due to both negative expectancies and the nocebo effect (see below) (13). Certainly, incorrect diagnosis may lead to treatment that is potentially both ineffective and possibly deleterious, physically and/or psychologically, to the patient. Oftentimes, misidentification and mislabeling of patients produces perpetuation of the actual impairment(s) and creates a more recalcitrant condition with a poorer prognosis (257). Parallel to experiences with pain patients, persons with MTBI may experience the negative ramifications of iatrogenesis in the context of over-investigation, particularly with unproven “neurodiagnostic” techniques, inappropriate information and advice, misdiagnosis, over-treatment, and inappropriate medication prescription (the latter which may produce further impairment and/or complications) (257). Iatrogenesis may not only have negative consequences on the patient but also on their family and/or significant other(s).

Physicians and other health care clinicians should be sensitized to the importance of avoiding iatrogenic complications. Some have considered iatrogenesis to be a “violation of moral norms, insufficient professionalism, negligence and indifference” (258). Others might argue that what sometimes appears to be iatrogenic illness may in fact be driven by unethical clinical practice, examiner bias, and/or examiner secondary gain. There are tremendous financial and professional pressures and incentives in the medical-legal setting, and it is widely believed that some experts adopt rather extreme, predictable, and polarized opinions that result in routine labeling of people as having long-term problems due to, presumably, permanent brain damage following a mild concussion. Better guidelines are clearly necessary to aide clinicians evaluating

and treating persons with MTBI to avoid iatrogenesis. Moreover, everyone involved with patients conceptualized as having a post-concussive disorder should be aware of the numerous psychological factors that can cause or maintain the condition. These psychological factors are not only important for understanding the disorder, they represent obvious, typically overlooked, areas for treatment.

### FACTORS RELATING TO THE PERCEPTION AND REPORTING OF SYMPTOMS

A diverse range of psychological factors can influence the perception and reporting of symptoms long after an MTBI. A person's psychological history, emotional response to injury, coping mechanisms, and psychosocial environment (e.g., work and family) are all factors that can influence the perception and reporting of symptoms and problems, as well as impact how the person functions in day-to-day life.

The experience of being ill can, in some ways, be rewarding for the patient. For example, the patient may get special privileges and extra attention from their spouse, family, coworkers, and friends. For many years, these issues have been studied in patients with chronic pain syndromes. Researchers have demonstrated that extra attention, changes in household responsibilities and routines, and the avoidance of undesirable activities all can *increase* patients' reporting of pain and disability. It is reasonable to think that some individuals with persistent symptoms and problems following an MTBI, similar to chronic pain patients, could derive reinforcement for disability behaviors. This is sometimes referred to as a *reinforced behavior pattern*.

The next section provides an overview of the role of personality characteristics and disorders in outcome from MTBI. The following sections relate to important social-psychological factors and influences on the etiology and maintenance of symptom experiencing and reporting in some patients.

#### Personality Characteristics and Disorders

Personality characteristics influence how people respond to illness, injury, or disease. Therefore, these characteristics are likely to be very important for understanding who is at risk for developing a persistent post-concussive disorder, and some of the psychological factors that maintain the disorder. At present, there is limited research available regarding the influence of personality styles as they might apply to the development, exacerbation, and maintenance of symptoms and problems following an MTBI.

As clinicians, it is very common to see a great deal of variation in individual response styles to life stressors

and/or traumatic events. Although most people tend to be remarkably resilient to traumatic life events or injuries, some individuals are emotionally fragile and have relatively catastrophic reactions to seemingly small events. To most of us, it makes perfect intuitive sense that premorbid personality factors would influence individual response styles to life stressors and/or traumatic events.

In psychiatry and psychology, there is considerable interest in the role of personality characteristics in the etiology of mental health problems. This large literature, by extension, is relevant to understanding the post-concussive disorder, and the differential diagnosis of this disorder. Researchers frequently have reported that certain personality characteristics appear to be risk factors for major depression. People with high levels of neuroticism or negative affectivity, low self-esteem, and poor life coping skills are at increased risk for developing depression (259–263). These same personality characteristics, in addition to anger/hostility and narcissism, have been reported in numerous studies as risk factors for PTSD (264–267).

Kay and colleagues provided an elegant discussion of the role of personality styles and characteristics as they relate to the experience of symptoms and the recovery from MTBI (268). They proposed three personality factors that may influence the development and maintenance of symptoms following MTBI: (a) individual response style to trauma, (b) emotional significance of a particular event for each person, and (c) vulnerable personality styles.

First, individuals tend to respond to the acute symptoms in different ways. Some individuals tend to over-emphasize cognitive and physical symptoms, whereas others tend to de-emphasize them. A certain symptom may be extremely debilitating for one person, yet another person may see this same symptom as simply slightly annoying. These response differences are not just determined by the differences in internal responses due to personality variables, but also by the environmental demands that challenge the person's ability to cope with that symptom. A laborer might be far less bothered by minor memory problems than a business-person, and an office worker might be only minimally concerned about mild balance problems compared to a roofer.

Second, there are differences in the emotional significance of a particular event for each person. Notwithstanding the emotional experience of the trauma itself, "for some persons the actual injury, the feelings evoked, and the response—or lack thereof—from others can trigger old, unresolved emotional issues. Often this takes the form of being vulnerable and unprotected, of not being responded to when hurt or sick, or of not being able to gain retribution when one has been wronged. Persons who grew up with significant holes in their emotional nurturing appear more at risk for responding in catastrophic ways to the emotional meaning of the injury" (p. 379–380) (268).

Third, based on their own clinical experience, Kay et al. proposed five different personality traits that they considered to be vulnerable to poor outcome following MTBI. These include: (a) overachievement, (b) dependency, (c) insecurity, (d) grandiosity, and (e) borderline personality characteristics (not disorder). Kay and colleagues explained the role of these traits as follows:

The *overachiever*, who is often obsessive-compulsive and derives his or her sense of self from driven accomplishment, is at risk for a catastrophic reaction when subtle cognitive slippage takes the edge off his or her performance. The *dependent person* is susceptible to being paralyzed by his or her symptoms. The experience of decreased efficacy dips him or her below the critical threshold of ability to cope independently and results in a behavioral freezing up that can become self-perpetuating. The *insecure person*, while sharing some of the same dynamics of the dependent person, also has the tendency to focus in on and therefore magnify his or her symptoms, thus adding another dimension to perpetuating dysfunction. *Grandiose persons* get into trouble by being so unable to acknowledge their decrease in ability that they deny it to themselves and others and continue to blunder into situations that evoke failure. The crash of self-esteem, when it comes, is usually catastrophic. The person with *borderline personality characteristics* (not disorder), an individual who is often high-achieving but unable to relate to others, is a prime candidate for significant personality disorganization at all levels after MTBI (Ref. 268, p. 379).

These vulnerable personality traits have received support in the literature by some researchers and clinicians who have provided case studies to highlight the importance of these premorbid personality traits (8). Ruff and colleagues present case discussions of four patients who sustained a MTBI, who they characterized as (a) grandiosity and narcissistic features, (b) borderline traits with recurrent depression, (c) over-achiever with perfectionist tendencies, and (d) unmet dependency needs. In line with Kay et al., Ruff and colleagues concluded that "For the individuals we presented, the resistance to recovery appears to have had its basis in unmet needs and trauma from early childhood. As adults these individuals developed psychological defenses which enabled them to have some of their previously frustrated needs met, which preserved them a sense of self-esteem. However, their prior needs and insecurities were reactivated by the MTBI" (p. 562).

Hibbard and colleagues (269) examined the frequency of personality disorders before and after sustaining a traumatic brain injury. Participants were 100 patients seen at least one year following a TBI ranging from mild to severe. Using a modified SCID-II interview to reflect pre-injury characteristics, 24% of the sample was diagnosed with pre-injury personality disorders. The most

common disorders were antisocial (15%) and obsessive-compulsive (6%) with incidence rates higher than community base rates reported in the literature. Higher rates of post-TBI personality disorders were found, with 66% of the sample meeting criteria for at least one personality disorder. The most common post-TBI disorders were borderline (26%), avoidant (26%), paranoid (17%), and obsessive-compulsive (24%). However, individuals with pre-TBI personality disorders were found to be at a greater risk of acquiring additional psychopathology post-TBI.
