TBI can cause both confabulations and delusions. These disorders lie at the interface of memory, self-awareness/self-monitoring, visual perceptual and executive function abilities after TBI and occur as direct effects of brain injury and as associated features of organic psychoses. Some patients show confabulations within the context of significant amnesia, attempting to fill in gaps of memory loss with overlearned knowledge about themselves and others. This kind of confabulation is thought to involve a combination of amnesia and disinhibited responding, usually associated with temporal and frontal dysfunction. Several delusional misidentification syndromes have been described, centering around altered ability to recognize people and the belief that people are disguising themselves in some way. These have been associated with combined damage to frontal (usually bilateral) and right posterior hemisphere regions. Examples include Capgras syndrome, defined as the impaired belief that someone well known to the patient has been replaced with a look-alike imposter (also described as reduplicative paramnesia) (73), and Fregoli syndrome in which the patient believes that a stranger (e.g., another patient or a staff member) is actually a familiar person (such as their mother) (74). Confabulations and delusions generally resolve over time, but are also known to persist chronically. Challenging patients' false beliefs is often not helpful in recovery and family members as well as providers often must accommodate these fixed beliefs. A single delusion can occur or there may be several co-occurring delusions, not necessarily inter-related. Misidentification and delusional syndromes can occur after TBI without other features of psychosis.

## SPATIAL COGNITION

Spatial cognition subserves a variety of adaptive behaviors, from navigation within diverse environments to spatial-related attention, memory and reasoning. Spatial cognition is obviously critical to daily activities such as driving, ambulation, dressing, self-care and keeping track of items maintained in home and work settings. TBI infrequently causes the striking hemispatial neglect syndrome often associated with right parietal lobe damage, but can lead to changes in attention to spatial cues, visuomotor scanning that underlies spatial search, constructional praxis, and learning/memory of places as well as various spatial patterns and complex scenes (66, 75, 76). Exploratory deficits and other motor-intentional spatial disorders commonly occur after TBI, associated with medial frontal cortical dysfunction and hypokinesia (77). Most often, spatial cognitive deficits associated with TBI have not been singled out per se, but rather discussed within the context of attention,

intelligence, memory and executive functions. Spatial representational and spatial-motor dysfunction after TBI have been less fully investigated.

### CHEMICAL SENSES

TBI can dramatically affect both olfaction and taste. Olfactory deficits have been associated with multiple types of trauma to the head as well as trauma to the nasal cavity, olfactory epithelium, and the olfactory nerve as it travels through the cribriform plate to the olfactory bulb. Brain pathophysiology from inflammation, white matter shearing, hemorrhage, contusion and other effects can cause particular damage to the main olfactory structures of the brain including the olfactory bulb, tract, and interconnected subcortical and piriform cortical regions in the basal and medial aspects of the frontal and temporal lobes (78). In a comprehensive study of 268 patients with TBI, studied at a specialty smell and taste center, Doty and colleagues (77) reported that 66.8% showed anosmia (complete loss of smell) and 20.5% demonstrated microsmia (partial loss of smell). The incidence of these deficits was higher than other reports probably because of specialty center referral patterns. Performance was based on scores from the University of Pennsylvania Smell Identification Test, a 40-odorant scratch and sniff, multiple choice recognition test. About one-half of the cases suffered head trauma from motor vehicle accident, with head trauma from falls the second most likely cause. Follow-up testing of 66 patients, varying from 1 month to 13 years later (mean follow-up period was 5.5 years, with mean age 41.25 years, and the sample 55% male), showed that 36% improved slightly while 45% experienced no change and 18% worsened in their olfactory deficit. Three patients actually regained normal olfaction although none had anosmia to begin with. The incidence of parosmia (olfactory distortions) decreased from 41% to 15.5% over an 8-year follow-up period. Parosmias varied from transient to intermittent to persistent in severity. There were no significant effects of age, sex or time since injury on olfactory deficits. Other changes in olfaction include decreased threshold, hallucination (usually associated with post-traumatic epilepsy), and decreased recognition memory.

Taste can be affected by TBI in a variety of ways, although usually not as severe as olfaction. Quantitative changes in gustation include altered threshold levels and decreased intensity of taste that are often described as ageusia or hypogeusia (80). Occasional increased sensitivity or hypergeusia can occur as well. Changes in taste are typically measured in relationship to detection and recognition of the four basic taste stimuli: salty, sweet, sour, and bitter. Qualitative changes in gustation are often described as onset of unpleasant tastes such as bitterness, metallic and even rancid, and as a loss of typical taste

preferences. Deems et al. (81) reported that 18% of all taste problems evaluated at a specialty smell and taste clinic were related to trauma. These disorders are generally not amenable to treatment once other modifiable causes have been ruled out (e.g., oral hygiene, sinus, oral secretions, toxic exposures, smoking). Subcortical-cortical gustatory regions and pathways are less vulnerable to damage from head trauma than olfaction. Complaints of decreased taste can be related in many cases to olfactory loss, leading to decreased flavor detection and perception rather than gustatory deficit per se.

### EXECUTIVE FUNCTIONS

Executive functions encompass cognitive and emotional processes that underlie many aspects of human adaptation, adjustment, and achievement. These processes have often been defined in terms of complex cognitive activities such as planning, judgment, decision-making and anticipation that require the coordination of multiple sub-processes to organize behaviour and achieve particular goals. Associated cognitive operations include working memory, prospective memory, strategic planning, cognitive flexibility, abstract reasoning and self-monitoring. Executive functions have also been implicated in the goal-directed *regulation* of attentional resources, sensory-perception, and actions in order to manage transitions from one activity to another throughout the day and across diverse settings (8, 82–85).

The neural systems involved in executive functions include the prefrontal cortex most prominently, together with interconnected neural circuitry forming prefrontal-cortical and subcortical networks. Some of these networks have been described under the terms *dorsolateral*, *orbital* and *medial* (86, 87). The dorsolateral prefrontal circuit is thought to mediate many higher cognitive aspects of behaviour such as abstract reasoning, planning and working memory. The orbital prefrontal circuit has been implicated mainly in social and emotional aspects of behavior including certain kinds of decision-making, theory of mind, emotional-based learning and social judgment. The medial prefrontal circuit has been related to motivational and attentional processes including initiation, inhibition and maintenance of behavior. In studies of TBI-related pathology, orbital and medial regions of the prefrontal cortex have been found to be especially vulnerable to damage by mechanisms of shearing and stretching of fibers as well as direct injury from impact against the irregular base of the skull. The orbital-medial prefrontal region is especially affected by strong blunt impact as well as physical acceleration/deceleration forces. Applied force vectors and tissue compliance influence the intensity of the coup, countercoup, angular and rotational forces that stretch and lacerate brain tissue centrifugally,

from midline sagittal aspects (i.e., medial and orbital prefrontal cortex impacting against the lamina cribrosa and the roof of the orbit as well as against the wing of the sphenoid bone) toward the surface of the cortex (lateral prefrontal cortex) and the deep connections with the striatum, thalamus and other subcortical nuclei such as the amygdala.

TBI-related damage to prefrontal neural circuits has been linked to the variety of executive function deficits. Impairments on measures of working memory (e.g., Paced Auditory Serial Addition Test), divided attention and sequencing (e.g., Trail Making), verbal associative fluency, learning and memory as well as planning and set shifting have been reported, even in cases after mild TBI (88, 89). Some clinical disorders such as distractibility and impulsivity have been found to be related to measured attentional and executive function deficits (90, 91). Significant correlations between measures of executive functions and regional cerebral glucose metabolism have been found in the mesial and lateral prefrontal regions and the cingulate gyrus. Interestingly, the correlations were evident despite the absence of detectable structural lesions on brain MRI. These findings confirmed those reported previously by Goldenberg et al. (92) who also noted correlation of executive measures with reduced blood flow in the thalamic region. Hence, impairments of executive functions may be related not only to focal traumatic lesions of the prefrontal cortex but also to white matter disconnection (i.e., diffuse axonal injury) of prefrontal-related networks that link to the thalamus and other important cortical and subcortical regions.

Some behavioral disorders after TBI have not been linked to cognitive deficits per se and may be due to alterations in emotion-related processing. For example, Rolls et al. (93) reported that patients with ventral frontal damage after TBI had particular difficulty in reward-based contingency learning. That is, after successfully learning an initial stimulus-reward association, they were impaired in both reversal learning (when the stimulus signalling reward was reversed) and in extinction learning (when the stimulus no longer signalled reward). The impairments were correlated to surveyed behavioral deficits that included disinhibition, social difficulties, lack of initiative and perseveration. Interestingly, the behavioral deficits were not correlated with verbal IQ, paired associate learning or Tower of London performance. Emotion processing may also be an integral part of decision-making capacities when one must rely on judgment of chance and probability of consequences such as gambling. This has been operationalized into a standardized task (The Iowa Gambling Task) in which subjects must learn to choose cards from stacks that are rigged to have different levels of risk and pay-off, varying from high risk-high win to low risk-low win (94). Patients with ventral frontal damage performed poorly on this task, choosing high risk

options that led to huge losses. Furthermore, many did not generate the anticipatory skin conductance responses that might typically signal risk-taking effects. Another facet of emotion-related processing involves recognition of common forms of emotional expressions. Hornak et al. (95) showed that ventral frontal damage from head trauma (and other etiologies as well) was associated with deficient recognition of emotional facial expressions and correlated with subjective emotional change and social behavior of patients.

Both focal and diffuse frontal lesions disrupt activities of daily living (ADL) and executive impairment may represent a main component of ADL failure (96, 97). In particular, executive abilities of planning, self-monitoring and self-correction, decision-making and judgement are considered critical for independent, adaptive functioning within real world settings (98). Deficits of inattentiveness, mental slowing, impulsivity, and lack of prospective memory can all contribute to functional impairments after TBI. The impact of such impairments can be viewed as damaging a complex cognitive-emotional *macrostructure* or *managerial knowledge unit* (including strategic planning, procedural memory, working memory) that underlies most multi-step requirements of real life, such as meal preparation or a recreational activity (97, 99). Meal preparation or going to a movie may well be more difficult than many cognitive tasks presented during a formal cognitive testing session in the laboratory because of the need to impose structure and invest executive resources in planning, implementing and accomplishing the many aspects of the task (82, 83, 99, 100). In cognitive testing the patient typically is administered a single problem with instructions, learning trials may be short, initiation is prompted and feedback is often given at the end of the task. Certainly it is not the same in real world settings, where situational constraints, priorities and requirements are not always clear, and success depends on timely, internally-generated and self-monitored processing without the benefit of feedback. Most neuropsychological tests do not specifically explore strategic planning, competitive skills, or prospective memory. A notable exception to this is the experimental Strategic Management Simulation technology that has shown promise in detecting executive impairments in TBI patients with good medical recovery and few neuropsychological test deficits (101). An important priority in both assessment and linkage to cognitive remediation is the development of further paradigms that tap multiple problem solving variables in real time and with varying degrees of structure and feedback.

### Social Cognition and Behavior

Humans are naturally social creatures, born to live and thrive within social settings with many complex forms

of interaction that have emotional coloring and context. Hence, an important facet of human cognition and executive functioning extends beyond the strictly intellectual endeavors of planning, concept formation, and problem-solving to domains such as metacognitive thinking, social skills, moral beliefs, personality traits, and “theory of mind”, a special faculty of the human brain that mediates interpretation and appreciation of other people’s feelings and mental states (8, 102, 103). Fronto-temporal damage from TBI can lead to dramatic alterations of conduct, personality, and psychosocial integration, at times leaving most cognitive and sensory-motor functions relatively intact. From a clinical standpoint, there is often a spectrum of social-behavioral symptoms associated with TBI rather than definite syndromes. Some patients become puerile, profane, facetious, irresponsible, irascible, and aggressive as forms of social disinhibition. Others lose spontaneity, initiative, curiosity, and develop mental and behavioral inertia as forms of abulia and apathy (104). Still others develop lack of awareness and insight, loss of creativity and emotional vitality. Some of these deficits are expressed as loss of pragmatic aspects of communication, loss of empathy and inability to understand and appreciate sarcasm, jokes, irony, and other vital social communication tools (105, 106). Although many of these social-emotional deficits are difficult to objectively evaluate and measure, they are important and problematic sequelae of TBI that must be evaluated and managed. The combined use of clinical interview with patient and family members and behavioral inventories can uncover many of these deficits. Experimental measures of social judgment, theory of mind abilities, social knowledge and emotion-related processing are beginning to shed light on deficits underlying these real-life problems and are increasingly targeted in experimental intervention programs.

### SUMMARY

Cognitive impairments after TBI often present significant challenges for recovery and return to premorbid levels of occupational and social functioning. In early stages, patients’ lack of awareness of their deficits (anosognosia), impaired self-regulation, and post-traumatic amnesia constitute major limitations to participation in rehabilitation services and safety. Often there is a combination of attentional, memory, perceptual, processing speed, executive function and social-emotional deficits that require multimodal therapy services and a gradual return to independent daily activities. Cognitive and social-emotional deficits are frequently slower to recover than physical injuries and require outpatient therapy services with medical follow-up care. Education of caregivers is particularly important for monitoring and continued remediation of

such impairments within home and community settings. When cognitive deficits remain persistent, individualized therapy is usually required combining aspects of skill retraining, compensatory strategies, and environmental supports to optimize functional cognitive capacities.

## Neuropsychological Assessment and Treatment of TBI

*Laura A. Taylor*  
*Lee A. Livingston*  
*Jeffrey S. Kreutzer*

**C**linical neuropsychologists are professionals within the field of clinical psychology who have special expertise in the area of brain-behavior relationships. According to the National Academy of Neuropsychology (NAN) definition (1), clinical neuropsychologists use “psychological, neurological, cognitive, behavioral, and physiological principles, techniques, and tests to evaluate patients’ neurocognitive, behavioral, and emotional strengths and weaknesses and their relationship to normal and abnormal central nervous system functioning.” Results from comprehensive evaluations are utilized for identification and diagnosis of neurobehavioral disorders, prognostication, development of treatment plans, and rehabilitation of individuals with neurologic conditions, health problems, neurodevelopmental disorders, cognitive problems, learning disorders, and psychiatric conditions. Many neuropsychologists are also responsible for the development and implementation of individual, group, and family therapy and education programs. This chapter will review guiding principles for neuropsychologists, the process of neuropsychological assessment and report writing, the contribution of neuropsychological assessment to the development of treatment recommendations, and neuropsychologist’s role in rehabilitation and treatment. This chapter further strives to explore the role of neuropsychology in rehabilitation and a holistic approach to patient care.

### PRINCIPLES GUIDING THE PRACTICE OF CLINICAL NEUROPSYCHOLOGY

Neuropsychologists play a key role in the evaluation and treatment of individuals with traumatic brain injury (TBI). Some view neuropsychology as a purely technical field with practitioners focusing on cognitive testing and functional neuroanatomy. More recently, neuropsychologists have taken a holistic perspective on practice focusing on issues of emotional adjustment, family functioning, and treatments to help patients return to normal life.

A set of guiding principles has been developed to help neuropsychologists develop a more holistic practice. Consideration of the following principles can help clinicians more efficiently achieve positive outcomes and effect greater levels of client satisfaction:

- empower patients and their families to take an active role in the evaluation and treatment process
- believe that people with neurological disabilities are more like people without neurological disabilities
- convey honesty and caring in personal interactions to form an adequate foundation for a strong therapeutic relationship
- develop practical plans for rehabilitation and explain rehabilitation techniques in language that patients, families, and interdisciplinary professionals are likely to understand

- help patients and their families understand the common neurobehavioral sequelae of brain injury and the typical recovery course
- recognize that change is inevitable and help the patient and family develop plans to deal with changes as they arise over time
- remember that every patient is important and deserves to be treated with respect
- remember that patients and families often have different perspectives; consider their individuality when formulating treatment approaches
- be willing to refer to other professionals if a case extends beyond personal areas of expertise and clarifies roles of various treatment providers.

**TABLE 43-1**

*The Caring, Understanding, Respecting, and Trust-Building Checklist*

- Review the patient's chart before seeing them; try to remember important details, and bring the details into your conversations.
- Go beyond your job description, at least sometimes.
- Ask the patient if they have questions or want to mention something that has not come up in conversation; answer their questions in language they can understand.
- When you can't help, refer to others who can.
- Discuss your ideas about helping the patient and your plans to do so.
- When asked by the patient, communicate to significant others about the patient's needs and care.
- Listen carefully.
- Give the patient time to finish what they are saying.
- Paraphrase what the patient says to convey your understanding.
- Maintain eye contact and face the patient when talking to them.
- Be on time for appointments and apologized on the rare occasions when you are not.
- Address patients by their proper surname (Mr., Mrs., or Ms.) unless instructed by them to do otherwise.
- Frequently inquire about the patient's needs, priorities, and perceptions of progress.
- Ask the patient for ideas about how to make things better and try to use their ideas.
- Carefully explain and discuss the limits of your expertise.
- Do what you say you will when you say you will.
- Respect the patient's right to confidentiality.
- Acknowledge when circumstances prevent you from doing what you agreed to and discuss acceptable alternatives.

Adapted from *The Brain Injury Handbook: A Guide for Rehabilitation Providers for Improving Therapeutic Relationships* (Kreutzer, Kolakowsky-Hayner, & West, 1999) (2).

To facilitate a positive and effective practice, many rehabilitation professionals employ a variety of trust-building behaviors with their patients. Table 43-1 displays a checklist of behaviors, which neuropsychologists and other rehabilitation professionals are encouraged to incorporate into their standard practice.

## COMPREHENSIVE NEUROPSYCHOLOGICAL ASSESSMENT

Comprehensive neuropsychological evaluation typically involves clarification of the referral question, review of records, clinical interviews, behavioral observation, and administration of standardized measures. Standardized measures are used to assess cognitive, academic, neurobehavioral, and emotional functioning. In addition, the impact of the acquired brain injury on the family, pain, substance abuse, vocational potential, motivation, effort, judgment, and safety are also areas of emphasis in neuropsychological assessment. The following sections will describe these evaluation techniques in more detail.

### Referral Question

The first step in neuropsychological assessment is identifying issues of concern and clarifying referral questions. Doing so allows selection of relevant assessment methods. Directly answering the referral source's questions and addressing their concerns is a hallmark of a beneficial neuropsychological report.

Referral sources often request information in three areas: (1) information pertaining to diagnosis, prognosis, and neuropsychological, neurobehavioral, and emotional functioning; (2) information about functional abilities, including level of independence and academic and vocational functioning; and (3) information about treatment and rehabilitation needs. Tables 43-2, 43-3, and 43-4 depict common referral questions encountered by neuropsychologists in each of these three areas. The variety of referral questions highlight the variety of complex issues and questions which neuropsychologists are often asked to address in their assessments. Answering these questions appropriately necessitates comprehensive, holistic assessment. They also provide insight into potential recommendations and treatment needs.

### Records Review

Thorough review of the records is the foundation of the evaluation process, providing guidance for the interview, test selection, and treatment planning. In addition, familiarity with records allows the examiner to ask the patient relevant questions during the initial interview and communicates to the patient that the examiner is well-prepared

TABLE 43-2

*Referral Questions Regarding Cognitive, Emotional, and Neurobehavioral Functioning*

- Is there any evidence of preexisting cognitive, emotional, or neurobehavioral difficulties? Describe levels of functioning in each area relative to preinjury.
- How has the neurological injury impacted their cognitive, emotional, or neurobehavioral functioning?
- Are current symptoms consistent with preexisting difficulties, psychological disorder, brain injury, or a combination of factors?
- Is there evidence that emotional/psychological difficulties contribute to cognitive deficits?
- To what extent does pain or unresolved physical problems contribute to emotional or cognitive impairments?
- Is the patient at risk of harming him/herself or others?
- Is there evidence of posttraumatic stress disorder, depression, anxiety, or other psychological disorders?
- Within each area of cognitive, intellectual, and psychomotor functioning, compare the patient's performance to the normal population. Which areas would you consider to be relative strengths and which areas would you consider to be weaknesses?
- Compare the patient's level of functioning in each area to the patient's last evaluation. Which skills have improved, declined, and remained stable? Identify potential factors which may have contributed to improvements or limited change.
- What is the prognosis for future improvements or declines?
- When will it be helpful to evaluate the patient again? for what purposes?
- Is the patient eligible for special services, programs, or benefits?

and interested in the patient's well being. Review of medical, psychological, criminal, academic, and vocational records is strongly recommended. Review of medical and rehabilitation records provides information about pre- and post-injury history of health problems and treatment. Information pertaining to mechanism of injury, injury severity, injury-related cognitive and physical sequelae, and rehabilitation services may also be obtained. Pre- and post-injury mental health records provide an invaluable source of information about long-standing emotional issues and substance misuse and post-injury emotional, neurobehavioral, and personality changes. Mental health records also provide information about treatments and medications which have been effective. Criminal records may elucidate difficulties with authority, antisocial behavior, mental health issues, substance abuse problems, and litigation history.

In reviewing school records, the neuropsychologist gains information about history of learning difficulties, academic potential, and information about the patient's

TABLE 43-3

*Referral Questions Pertaining to Adaptive, Educational, and Vocational Functioning*

- Is the patient safe to drive? If not, what are the patient's needs with respect to driving evaluation, driver's training, and instruction in use of public transportation? Is the patient eligible for transportation services for persons with disabilities?
- Is the patient safe to live independently? If not, what supervision level or alternative living arrangements are recommended?
- Is the patient competent to manage their finances?
- Can the patient manage their medication independently?
- Please provide information about the patient's judgment and safety.
- How will the patient's neurobehavioral status impact parenting?
- What is the patient's potential for academic and vocational success?
- How has the injury impacted the patient's academic and vocational potential?
- Is the patient able to manage part-time or full-time work schedule?
- What kinds of training, accommodations, and interventions are most likely to increase their potential for academic or vocational success in the current school/work environment?
- Can the patient succeed in the present academic/work environment? Should an alternative academic placement or employment opportunity be considered?
- How will the patient's neurobehavioral status impact their ability to interact with coworkers, customers, family, friends, etc.?
- Identify which neuropsychological factors are primarily contributors to functional impairments.
- Is there evidence that emotional/psychological difficulties contribute to functional impairments?

strengths and weaknesses. Vocational records review includes examination of performance reviews, job descriptions, and information about wage history, attendance records, grievances, and disciplinary actions. Based upon review of vocational records, the neuropsychologist has the opportunity to ascertain pre- and post-injury work experience, habits, attitudes, and accomplishments. In addition, records review provides information about the patient's ability to function within structured environments, response to authority figures, and interpersonal skills. Academic and vocational history provides the basis for making recommendations about vocational and academic potential, optimal work/school settings, and appropriate accommodations. In addition, review of academic and vocational records provides an opportunity for estimating patients' premorbid or expected level of functioning.

**TABLE 43-4**  
**Referral Questions Pertaining to Treatment Issues**

- What types interventions have the potential to benefit the patient (e.g., medication, rehabilitation services, psychotherapy, support group, vocational rehabilitation, etc.)?
- Provide information about reasonable treatment goals, priorities for intervention, optimal frequency of services, potential service providers, and associated costs.
- Which factors will affect the patient's ability to benefit from rehabilitation interventions and treatment? Are there interventions that would minimize limiting factors (e.g., pharmacologic, compensatory)?
- Is the patient a good candidate for individual, group, marital, or family therapy?
- What is the patient's prognosis for improvement with and without intervention?
- Is the family a good support system? How are family members helping the patient or contributing to present difficulties?
- What are the family's expectations regarding recovery and the patient's ability to return to previous activities? What are the family's needs with respect to education about the recovery process?
- What support and education programs would benefit family members? Describe potential service providers, optimal frequency of services, and associated costs.

Establishing the premorbid level of functioning provides the basis for judging current levels of impairment.

### Behavioral Observations

Behavioral observation during the course of interview and testing affords the examiner with the opportunity to assess behaviors, which are not readily tapped by quantitative assessment devices. Table 43-5 depicts information that is typically gathered through behavioral observation. Observation across different settings, by different observers, and at different times is optimal. Interviewing patients in their home or current living situations is an excellent means of obtaining information about how patients react in their home environments. If home-based observation is not possible, family members and caregivers may be able to provide additional information about behavior observed in the home. Neuropsychologists also gather information about behaviors from members of the interdisciplinary team members who may have the opportunity to observe the patient in other settings.

### Clinical Interview

The clinical interview provides a valuable sample of behavior. The examiner has the opportunity to observe

how the patient interacts and responds to questions. In addition, the clinical interview affords an opportunity for clarifying information from the records, gathering historical information, and ascertaining primary presenting concerns. During the clinical interview, special care is taken to collect the following information: presenting complaints; family/caregiver concerns; injury information; postconcussive symptoms; academic and vocational history; family and social functioning; medical and psychological history; history of prior TBIs; and current daily living situation and functional capabilities. Every effort is made to interview the patient and one or more family members/caregivers. If in-person interview with family members is not possible, telephone interview may be a viable option. Interviewing employers, teachers, and treating providers is also valuable.

### Quantitative Assessment

Quantitative neuropsychological assessment findings provide a useful complement to data gathered through behavioral observation and clinical interview. Quantitative assessment provides the opportunity to gather data about neuropsychological functioning in a standardized way, allowing the examiner to make comparisons to normative data and to make comparisons over time with repeated testing (3). In determining which assessment instruments to use, neuropsychologists consider several factors. First, comprehensive assessment is multidimensional and multimethod, covering a range of functioning areas using a variety of measures to assess each area. Second, tests are selected with emphasis placed upon problem areas endorsed by the patient, his or her family, and the referral source. Third, measures are chosen based upon ease of completion and administration time whenever possible. Finally, in determining which tests to use, neuropsychologists consider the test reliability and validity, normative samples, and research findings specific to brain injury.

This section does not provide encyclopedic knowledge about the function and process of quantitative neuropsychological assessment. On the contrary, we purport to offer a broad overview of the topic emphasizing the importance of evaluating patients as multi-faceted beings with significant pre-injury histories, interpersonal relationships, emotional reactions to injury and so forth. Those interested in comprehensive reviews of this subject are encouraged to peruse Lezak's text, *Neuropsychological Assessment* (3) and the chapter entitled, "Neuropsychological Evaluation of the Patient with Traumatic Brain Injury" in *Rehabilitation of the Adult and Child with Traumatic Brain Injury* (4).

### Evaluation of Cognitive and Academic Functioning

Following TBI, individuals commonly experience cognitive difficulties. Comprehensive assessment of cognitive

FUNCTIONING AREA	TEST(S)
Visuomotor & Visuoconstruction	Digit Symbol, Block Design and Object Assembly (WAIS-R & WAIS-III); ROCF; SDMT; Trail Making Test A and B
<b>Language Skills</b>	
Vocabulary	Clinical Interview; Vocabulary (WAIS-R & WAIS-III)
Oral Fluency	Controlled Oral Word Association Test
Naming	Boston Naming Test
Expressive Language	Aphasia Screening Test (HRB); Boston Diagnostic Aphasia Examination; Clinical Interview; Oral Expression (WIAT-II)
Receptive Language	Behavioral observation of instruction following; Clinical Interview; Listening Comprehension (WIAT-II); Token Test
<b>Reasoning and Judgment</b>	
Verbal Reasoning	Comprehension and Similarities (WAIS-R & WAIS-III)
Nonverbal Reasoning	Category Test (HRB); Picture Arrangement (WAIS-R & WAIS-III); Ravens Progressive Matrices; Trail Making Test B (HRB); Wisconsin Card Sorting Test
Judgment of Safety	Comprehension (WAIS-R & WAIS-III); Independent Living Scales; Judgment and Safety Screening Inventory (JASSI) – Patient and Informant Versions
Self-Awareness	Clinical Interview; Judgment and Safety Screening Inventory (JASSI), comparison of patient and family responses; Neurobehavioral Functioning Inventory (NFI), comparison of patient and family responses

and academic functioning can help elucidate deficits. Areas which are typically assessed in comprehensive evaluation of cognitive and academic functioning include: academic skills, attention and concentration, motor abilities, sensation, learning and memory, visuoperception, visuoconstructional abilities, language, and reasoning. Table 43-6 depicts specific tests and the corresponding areas of functioning assessed. The reader is referred to Lezak's (3) seminal text on neuropsychological assessment for further information about tests which are commonly used to assess cognitive and academic functioning.

#### *Assessment of Emotional, Personality, and Neurobehavioral Functioning*

Neurobehavioral and personality changes are common following TBI. In addition, survivors typically have difficulty adjusting to injury-related changes, increasing the risk of emotional difficulties. As such, comprehensive neuropsychological evaluation involves assessment of neurobehavioral, emotional, and personality functioning. Table 43-7 describes several measures which are commonly administered to assess these areas of functioning.

Concern has been expressed that measures of emotional and personality functioning have limited utility for patients with TBI. First, many instruments were developed specifically for people with psychiatric difficulties, not for those with neurological disorders. Many individuals with TBI may be diagnosed with psychiatric disorders

secondary to the overlap between sequelae of TBI and psychiatric symptoms. Witol and colleagues (6) caution clinicians to consider the contributions of TBI when interpreting the results of measures of emotional and personality functioning. The Neurobehavioral Functioning Inventory (NFI; 10) and the Neurobehavioral Rating Scale (NBRS; 11) were developed for use with TBI populations, and may be good alternatives. Second, reliance on self-report is difficult following TBI secondary to difficulties with self-awareness. As such, clinicians seek out corroborating information from family members and records review. Finally, many measures are long and require at least a sixth grade reading level. Many individuals experience reading comprehension problems, visual disturbances, pain, and attention and concentration problems. Each of these injury-related sequelae can negatively impact patients' abilities to respond to the questionnaires. If concerns about a patient's ability to respond to the questionnaire emerge, clinicians may wish to consider clinician-rated measures such as the NBRS and the Hamilton Depression Rating Scale (HDRS; 8).

#### *Evaluation of Judgment and Safety*

Safety is a common area of concern for families and referral sources following TBI. Questions often arise surrounding safety in the following situations: driving, living alone, working, and managing finances and medications. In assessing safety issues, evaluating patient's

**TABLE 43-7**  
*Measures Used to Assess Emotional, Personality, and Neurobehavioral Functioning*

MEASURE	BRIEF DESCRIPTION
Beck Depression Inventory (BDI)	The BDI is a 21-item, self-report measure designed to detect the presence and severity of depression symptoms (5). The multiple-choice format requires a sixth grade reading level. Repeated administrations permit monitoring of treatment effects. Notably, the BDI emphasizes the vegetative symptoms of depression which may be consistent with TBI and medical illness (6).
Brief Symptom Inventory (BSI)	The BSI, a shortened version of the Symptom Checklist-90-R, is a 53-item self-report measure, which is designed to evaluate the severity of psychiatric symptoms (7). A sixth grade reading level is required. Few studies have been conducted with TBI populations. Witol and colleagues (6) expressed concern about the possibility neurobehavioral symptoms would be labeled as psychiatric.
Hamilton Depression Rating Scale (HDRS)	The HDRS is a 17-item screening instrument, which was designed to assess the cognitive, emotional, and physical symptoms of depression (8). The measure is completed by the clinician during the clinical interview with the patient and family and records review. As such, the measure is useful for screening depression in individuals who have limited reading abilities or vision problems which preclude reading. There is limited research examining the validity of using the HDRS with TBI populations. Witol and colleagues (6) expressed concern that many of the items are consistent with neurobehavioral sequelae of TBI.
Minnesota Multiphasic Personality Inventory – 2nd Edition (MMPI-2)	The MMPI-2 is a 567-item, self-report measure of personality and emotional functioning in adults (9). A 6th grade reading level is required, but audiotaped versions are available. Concern has been expressed about overpathologizing of individuals with TBI on the MMPI-2. Witol and colleagues (6) urge clinicians to consider the contributions of TBI when interpreting the results of the MMPI-2.
Neurobehavioral Functioning Inventory (NFI)	Developed for use with a TBI population, the NFI is an 83-item measure which was designed to examine the frequency of neurobehavioral difficulties post-injury (10). The measure can be administered in a self-report format or orally. Patient and family versions are available, allowing for comparison of responses. Normative data, based upon age and injury severity, is available. Information is gathered about functioning in six domains: depression, somatic symptoms, memory/attention, communication, aggression, and motor abilities.
Neurobehavioral Rating Scale (NBRS)	Adapted from the Brief Psychiatric Rating Scale, the NBRS was designed to assess behavioral and emotional symptoms, which are commonly exhibited post-TBI (11). The 27-item scale is completed by a clinician based upon observations during an interview. Items are rated on a scale from 1 (not present) to 7 (extremely severe). Witol and colleagues (6) assert that the NBRS is an extremely useful tool for assessing neurobehavioral functioning acutely.

judgment is critical. To assess judgment and safety, the examiner may ask patients and their family members about daily functioning. For example, with regard to driving, information may be gathered about recent accidents or traffic violations and about patient and family members' concerns. Medication issues include forgetting

medications and not taking medications as prescribed. With respect to financial management, the examiner may ask about bounced checks, late or missed bills, and utilities being turned off.

The Judgment and Safety Screening Inventory (12) was designed to assess judgment and safety concerns in

**TABLE 43-8**  
*Methods Used to Assess Substance Use*

MEASURE	BRIEF DESCRIPTION
Addiction Severity Index (ASI)	The ASI assesses recent and lifetime alcohol and illicit drug use difficulties and gathers information regarding legal issues, medical and vocational history, and family/social functioning (21). The ASI has been found to have good reliability and validity (22); however, research on the ASI and acquired brain injury populations is very limited.
Brief Michigan Alcoholism Screening Test (B-MAST)	The B-MAST, a shortened version of the MAST, contains 10 of the original 25 MAST items and is highly correlated with the MAST (23). The B-MAST has been found to be useful in the detection of alcohol abuse among individuals with TBI (20).
CAGE	The CAGE is a four-question screening tool, which is easily administered and scored. Each question follows a yes/no format. Two or more positive responses are suggestive of alcohol problems. The CAGE has been shown to be highly effective in detecting alcohol abuse in the general population (24) and in individuals with TBI (20).
Michigan Alcoholism Screening Test (MAST)	The MAST is a 25-item screening questionnaire that focuses on lifetime problems and consequences of drinking in the areas of social, vocational, and family functioning (25).
Quantity-Frequency-Variability Index (QFVI)	The QFVI is a self-report measure, with patient and informant versions. The QFVI classifies drinking behavior in one of five categories: abstinent, infrequent, light, moderate, or heavy (26, 27). The QFVI has been shown to be effective in assessing pre- and post-injury alcohol use among survivors of TBI (28). Concordance rates between family members' and patients' reports on the QFVI have been found to exceed 90% (29).
Substance Abuse Subtle Screening Inventory (SASSI)	The SASSI is a 78-item, self-report alcohol and drug abuse assessment instrument, which has been found to have high sensitivity and specificity when used with the general population. However, the SASSI appears to be less effective in detecting substance abuse problems among individuals with TBI (30).

the following areas: travel; financial management; interpersonal functioning; food and kitchen; use of appliances, tools, and utensils; household issues; medications and alcohol; fire safety; and firearm safety. Respondents are asked to identify their concern level (none, little, much, or very) about different aspects of each functioning area. Space is provided for open-ended responses from patients and other informants. Patient and informant versions allow for comparisons between respondents.

### *Substance Abuse Assessment*

Substance abuse is a significant problem for individuals with TBI and occurs more frequently among survivors of TBI than in the general population (13–16). In a comprehensive review study, Corrigan (17) indicated that approximately two thirds of individuals with TBI have a history of substance abuse pre-injury, and one third to one half of individuals hospitalized are intoxicated at the time of injury. In a study by Hall and colleagues (18), approximately 30% of participants with a brain injury were alcohol dependent whereas 20% were drug dependent at two years post-injury.

Given the significance of this problem among survivors of TBI, substance abuse screening is an important part of comprehensive neuropsychological evaluation. Substance abuse assessment involves administration of standardized assessment measures and thorough review of records. Measures designed to assess substance abuse in the general population are often used to assess pre- and post-injury substance use in persons with acquired brain injury. Research reveals that composite measures are helpful in diagnosing and treating substance abuse problems among persons with brain injury (19). Assessment measures frequently used include the Michigan Alcoholism Screening Test (MAST), Brief Michigan Alcoholism Screening Test (B-MAST), CAGE, Quantity-Frequency-Variability Index (QFVI), Addiction Severity Index (ASI), and Substance Abuse Subtle Screening Inventory (SASSI). Table 43-8 provides descriptions of each measure. Overall, research suggests that the CAGE or B-MAST are more effective screening instruments for TBI populations and less time-consuming than the SASSI and ASI (20).

Self-report measures are easily administered and relatively inexpensive, and as such, they are often the

cornerstones of substance abuse assessment. However, self-report measures are limited due to their reliance upon individuals' willingness and ability to disclose information accurately. Patients may be reluctant to admit the extent of alcohol or drug use. Patients with memory problems or limited self-awareness may also be unreliable historians (29). Family members' reports may also be inaccurate secondary to minimization or denial of problems, personal substance abuse history, perceptions about substance use, or lack of information regarding the patient's use (30). Given the aforementioned limitations, accurate assessment of substance use may be compromised if one relies predominantly on information provided by one source. To address these limitations, neuropsychologists solicit information from a variety of informants, including family members, caregivers, and employers. Records review also allows for corroboration of informant and patient reports.

### *Pain Assessment*

Pain, a common complaint of individuals who have sustained TBI, often contributes to cognitive deficits and negatively impacts quality of life secondary to activity restrictions. Individuals' response to pain varies significantly based upon the meaning of pain to the individual and the impact of pain on their life. Thorough pain assessment may include administration of standardized measures, such as the McGill Pain Inventory (31) and visual analog scales (32). Information is gathered about pain intensity, frequency, duration, quality, location, date of onset, history of pain problems, family history, and treatments and their effectiveness. In addition, behaviors which exacerbate and improve pain are important to assess. Patients are often asked to rate their pain on a 1 (no pain) to 10 (extreme pain) scale throughout the assessment in order to establish if poor performances are related to pain. During the evaluation, examiners are alert to pain behaviors (e.g., shifting in seat, rubbing areas of pain focus) and to medication side effects (e.g., fatigue). The reader is referred to the chapter in this book entitled, "Pain Assessment and Management," by Drs. Zasler, Nicholson, Martelli, and Bender for detailed information about the assessment and treatment of pain among individuals with TBI.

### *Assessment of Motivation and Effort*

Comprehensive neuropsychological assessment typically incorporates evaluation of patients' motivation and effort during the evaluation. As a general practice, patients are often encouraged to exert maximum effort during the testing process to reduce concerns about malingering (33). When there is a question of malingered neuropsychological impairment, practitioners have several techniques to discourage and identify such activity. Neuropsychologists look for consistency in performance across tests, consistency of

test performance and presenting complaints with those expected given injury severity, and consistency between observed behaviors and presenting complaints.

Neuropsychological and psychological tests may be used to assess legitimate versus malingered memory impairments or exaggerated symptoms. Mittenberg, Azrin, Millsaps, and Heilbronner (34) found a pattern of scores on the Wechsler Memory Scale-Revised (35) that differentiated individuals instructed to malingere head trauma symptoms from patients with head injury. Discrepancy between predicted and obtained scores on the Wechsler Adult Intelligence Scale-Revised (36) may be used to discriminate between patients with TBI and those producing insufficient effort (37).

Specialized tests developed specifically for detection of malingering are available for inclusion in neuropsychological test batteries, including the following: Portland Digit Recognition Test (38), Recognition Memory Test (39), Rey 15-Item Test (40), Test of Memory Malingering (41), and the Word Memory Test (42). Normative data on the F(p) Scale of the MMPI also aids in the identification of unusual response patterns suggestive of insufficient effort or symptoms exaggeration (43).

Secondary gain issues are important to consider, including revenge, attention seeking, escape from responsibility, and pending lawsuits, Worker's compensation hearings, or disability benefit hearings. History of litigation and benefit seeking should be ascertained during interview and records review. The reader is referred to the chapter in this book entitled, "Assessment of Response Bias," by Drs. Martelli, Zasler, and Bender for a thorough review of assessment techniques for evaluating motivation and effort.

### *Vocational Assessment*

Research suggests that a majority of persons with moderate or severe TBI are unable to sustain employment (44-47). Vocational issues are a primary concern for patients and their families, and referral sources frequently list return to work among their primary concerns for patients. Referral questions often focus on individuals' readiness to return to work, potential work capacity, and needed accommodations and rehabilitation services. Prognostication about vocational potential should be based upon thorough return to work assessment and comprehensive neuropsychological evaluation revealing strengths and limitations. Comprehensive assessment reveals potential obstacles to successful return to work, including cognitive deficits, emotional issues, interpersonal difficulties, transportation issues, anger management problems, and pain and other physical symptoms.

Areas which are commonly assessed in comprehensive assessment include the following: (1) job responsibilities, including special training required, equipment used,

and interpersonal interaction with co-workers and customers; (2) conditions set by employer regarding return to work; (3) the patient's perceptions about obstacles to working and about their ability to return to work on a part-time or full-time basis; (4) transportation requirements for the job; (5) work schedule issues (e.g., hours required, over time, swing shift work, possibility of working part-time, flexibility of position, openness to accommodations); (6) safety issues on the job, including history of prior injuries on the job; (7) work-place response to others with injuries and disabilities; (8) relationship with supervisor; (9) supervisor's knowledge of the injury and extent of injury-related sequelae; (10) pre-injury work history; (11) patient perceptions about job security; and (12) the patient's career goals, desire to return to work, and willingness to consider other job options. In addition, consideration of the nature of the job in question is valuable. Individuals tend to be most successful returning to work in family-owned or small businesses, which are supportive and allow for accommodations.

### *Family and Caregiver Assessment*

As the length of hospital and rehabilitation stays decrease (48, 49), family members have had to take on the principal caretaking role soon after injury. Caregiving places significant burden on the family. Research reveals that caregiving family members are at risk for emotional difficulties (50–58). Given the importance of the family's role in caring for the survivor, assessment of the impact of injury on the family is critical to ensure they have the support needed to continue performing their vital role. Family and caregiver assessment should center around gaining an understanding of the impact of injury on emotional functioning, relationship quality, financial situation, life plans, quality of life, and daily responsibilities (e.g., work, child care, household responsibilities). In addition, clinical neuropsychologists often explore existing supports and consider additional support needs. Written recommendations that include options for increasing family supports are extremely beneficial. Special care should be taken to help the caregiving family member(s) understand that they will be unable to support the survivor if they do not take care of themselves and seek assistance in managing their increasing responsibilities. The reader is referred to James Malec, Ph.D.'s chapter in this text entitled, "Family and Caregiver Issues and Interventions," for information about issues related to assessment and treatment of family members and caregivers.

### **Comparison to Premorbid Functioning**

Neuropsychologists are often asked to determine whether or not the injury resulted in cognitive, academic, neurobehavioral, or emotional impairments. Determining deficits requires comparison of current functioning to pre-morbid functioning. Three methods may be employed to

estimate premorbid functioning. First, several indicators are highly correlated with intelligence, and as such, provide an estimate of premorbid functioning. These indicators include grades, scores on standardized testing, and educational and vocational attainment. Review of records and clinical interview are avenues of gathering this information. Second, some measures of cognitive functioning (e.g., single-word reading) are highly correlated with intelligence and are typically not affected by TBI (59). Scores on these standardized measures will likely be comparable to premorbid levels of functioning. Finally, within the "best performance method," the highest test scores obtained during comprehensive neuropsychological evaluation are considered in the estimation of pre-injury abilities (3).

## **PROGNOSTICATION AND TREATMENT PLANNING**

### **Prognostication**

Questions about future prognosis are typically among the primary questions posed by referral sources. As such, clinical neuropsychologists are often called upon to provide information about long-term academic, vocational, and independent living potential. In addition, questions are often posed about an individual's likelihood of benefiting from rehabilitation services and potential treatment benefits. Thorough review of the research literature on outcomes following TBI provides the foundation for prognostic estimation. Several factors need to be considered when making predictions about an individual's outcome, including age, premorbid level of functioning, injury type and severity, additional injuries (e.g., orthopedic), pre-existing medical and psychological issues, extent and chronicity of deficits, daily functioning, and availability of support services and interventions (3).

### **Recommendations and Treatment Planning**

Comprehensive neuropsychological assessment culminates in the development of practical, feasible recommendations and the development of treatment plans. The goal is to develop recommendations and identify interventions, which will enhance patients' and families' well being and optimize functioning. Referral for medical follow-up, psychological services, psychiatric intervention, support, vocational/academic assistance, and other rehabilitation services in the community are commonly included. Compensatory strategies to address impairments are typically provided. Repeated neuropsychological testing is often suggested to monitor progress or deterioration. Based upon findings from re-evaluation, amendments may be made to the existing treatment plan. Table 43-9 depicts recommendations that may be provided to address problems in a variety of functional areas.

**TABLE 43-9**  
*Post-Injury Problem Areas and Aample Recommendations*

FUNCTIONAL AREA	RECOMMENDATIONS
<b>Academic skills</b>	
Arithmetic	<ul style="list-style-type: none"> <li>• use a calculator for all but the most basic mathematical operations; check work carefully; rely on family for assistance with financial management</li> </ul>
Reading comprehension	<ul style="list-style-type: none"> <li>• use chapter headings to outline material; take notes and highlight or underline key words while you are reading; use self-sticking notepaper to create indexes in the reading material to facilitate reviewing information; use the PQRST method (preview, question, read, study, test)</li> </ul>
Spelling	<ul style="list-style-type: none"> <li>• use an electronic spelling aid or word processing spell checker; purchase a portable electronic spell checker for home use; spell the word out loud, or mouth each letter as you spell the word to help focus your attention as you write; keep a small speller's dictionary near where you write; use index cards to make flash cards of words you find yourself missing often and test yourself; play Scrabble; work cross-word and other puzzles</li> </ul>
Writing	<ul style="list-style-type: none"> <li>• focus on quality versus quantity; allow ample time for task completion; dictation; remedial training</li> </ul>
<b>Attention and concentration</b>	
	<ul style="list-style-type: none"> <li>• reduce distractions (e.g., ear plugs, sit facing wall, clear desk before beginning work); avoid interruptions (e.g., use 'do not disturb' sign); use self-coaching to stay on task; schedule breaks throughout the day; avoid multi-tasking; before changing tasks, record information about stopping point</li> </ul>
<b>Motor/sensory functioning</b>	
Coordination and motor slowing	<ul style="list-style-type: none"> <li>• occupational and physical therapy; fitness training; sports and recreational activities; pace tasks; allow adequate time for task completion and transition between tasks; organize environment for efficiency (e.g., gather all needed materials prior to initiating project); set realistic timelines for task completion</li> </ul>
Vision	<ul style="list-style-type: none"> <li>• neuro-ophthalmologic evaluation; corrective lenses; vision therapy; use large print reading materials and thick pen when writing notes to be read by client; audiotape instructions/reading material; make sure there is appropriate light; avoid glare</li> </ul>
Hearing	<ul style="list-style-type: none"> <li>• audiology examination; ask others to speak loudly and enunciate clearly; hearing aids</li> </ul>
Smell	<ul style="list-style-type: none"> <li>• smoke detectors; label and date perishable foods</li> </ul>
<b>Learning and memory</b>	
	<ul style="list-style-type: none"> <li>• present information in many forms (e.g., auditory, visual, kinetic); use to-do lists, calendars, memory notebook, and other assistive devices; repeat information; use mnemonics and imagery; demonstrate tasks; record and replay information; break tasks down into small steps and introduce new steps as earlier steps are accomplished</li> </ul>
<b>Visually based skills</b>	
	<ul style="list-style-type: none"> <li>• use a blank piece of paper or fold the sheet to mask extraneous details on a page; use a straight edge, ruler, or finger to follow a line of text; always check work in the same order; describe a design or task in words rather than rely on a mental image; take part in activities which require hand-eye coordination</li> </ul>
<b>Language</b>	
Instruction following	<ul style="list-style-type: none"> <li>• improve instructional format (e.g., short, simple sentences); simplify or reduce variety of tasks; reduce distractions; provide instructions in multiple formats; shaping</li> </ul>
<b>Judgment and safety</b>	
Judgment and safety issues	<ul style="list-style-type: none"> <li>• consider supervised living situations; 24-hour supervision; respite for family; seek feedback from others before beginning a task</li> </ul>
Problem solving	<ul style="list-style-type: none"> <li>• teach structured problem solving; develop and maintain mentor relationship; ask client how they plan to approach task prior to beginning</li> </ul>

TABLE 43-9 (continued)

FUNCTIONAL AREA	RECOMMENDATIONS
Driving	<ul style="list-style-type: none"> <li>take precautions to maximize safety (e.g., avoid driving in inclement weather or traffic, drive with licensed driver, take breaks on long trips, drive familiar routes, drive only when well rested, reduce distractions); driving evaluation; driver's training; training in use of public transportation; exploration of other transportation options (family, friends, neighbors, and area resources);</li> </ul>
Financial management	<ul style="list-style-type: none"> <li>rely on family to assist with financial management; use an organizer with dated slots and place bills in slots one week before they are due; record due dates for bills in a calendar or planner; use a calculator; check work carefully; take care of challenging tasks only when well rested and distractions are minimized</li> </ul>
Medication management	<ul style="list-style-type: none"> <li>use a compartmentalized medication box, distributing medication in appropriate compartments at the beginning of the week; set an alarm to cue when to take medication</li> </ul>
<b>Fatigue/sleep problems</b>	<ul style="list-style-type: none"> <li>promote sleep hygiene (e.g., regular sleep schedule, limit caffeine/exercise before bed); medication consultation (stimulants and sleep medication); consider sleep study; adjust work schedule; schedule breaks; schedule most challenging tasks at times of peak energy level</li> </ul>
<b>Emotional issues</b>	
Depression	<ul style="list-style-type: none"> <li>supportive psychotherapy; medication management; enhance support network; increase activity level and participation in pleasant activities; encourage focus on progress; avoid comparisons to the past; monitor sources of stress</li> </ul>
Frustration, irritability, and anger problems	<ul style="list-style-type: none"> <li>stress management and relaxation training; anger management; assertiveness, conflict resolution, and social skills training; medication management</li> </ul>
Feeling misunderstood by others	<ul style="list-style-type: none"> <li>communication and social skills training; educate client about how to discuss injury with others; education of coworkers, employers, and family; supportive psychotherapy; support group; enhance social support</li> </ul>

## DIFFERENTIAL DIAGNOSIS

Patients with TBI present for assessment and treatment with myriad cognitive, behavioral, emotional, and somatic symptoms. Differential diagnosis is often the culmination of a comprehensive neuropsychological assessment. Differential diagnosis requires a breadth of knowledge about the spectrum of the *Diagnostic and Statistical Manual of Mental Disorders, 4th edition* (60) conditions and proficient interviewing skills. Information about the onset, nature, intensity, and duration of symptoms provides valuable insights into conditions, which should be considered as possible diagnoses. Oftentimes, the confirmation of a diagnosis follows long-term evaluation and treatment of the patient. Exacerbation or abatement of symptoms, as well as the emergence of additional problems, are monitored to facilitate differential diagnosis.

Neuropsychological evaluators and rehabilitation treatment providers incorporate a multitude of data collection strategies to glean pertinent information for differential diagnosis. Clinicians may enlist assistance from family members, friends, or significant others in order to procure thorough medical, social, and psychiatric patient

and family history. Unstructured, semi-structured, or structured interviews are often utilized to this end. The *Structured Clinical Interview for DSM-IV Axis I Disorders—Clinical Version* (61) is an assessment tool available to practitioners for determining pre and post-injury psychological difficulties. Glenn (62) advised conducting a structured search in order to best discover etiology and recommended the following information be ascertained: pre-injury diagnosis, neuropsychological disorders, sensorimotor disorder, medical disorders, adverse effects of medication, reactive mood and anxiety disorders, and sleep disorders.

There is often considerable overlap between symptoms of medical and psychological disorders. For example, cognitive impairments are typical consequences of most neurological conditions, including frontotemporal dementia and TBI (63). However, impairments in cognition are often evident in individuals with psychiatric disorders, including major depressive disorder and anxiety disorders. As such, differentiation between the etiologies of cognitive impairments may be challenging.

Differentiation between pre-existing conditions and post-injury complications is often critical to forming an

accurate diagnosis and to planning effective treatment. Premorbid psychological or personality disorders, learning disabilities, drug or alcohol problems, and medical conditions (e.g., cerebrovascular disease, hypertension, diabetes, epilepsy, prior TBI) are potential mediating variables that commonly influence the course of a TBI. In conducting a comprehensive evaluation, neuropsychologists attempt to tease out premorbid problems from current injury-related complications and sequelae. In order to assist clinicians in differentiating between premorbid problems and post-injury complications, Table 43-10 provides referral questions to consider during comprehensive neuropsychological assessment.

Identification of comorbid conditions is one of the principal aims of comprehensive neuropsychological assessment. Psychological comorbidities are quite common after a TBI. Hibbard and her colleagues (64) found two or more Axis I diagnoses post-TBI, representing 44% of their sample. Depression and anxiety disorders (e.g., PTSD, OCD, panic disorder, GAD) were the most frequently cited post-injury affective problems of this sample. Researchers have found that approximately 60% of individuals with a TBI meet criteria for major depression at some point after a brain injury (64). Research indicates the frequency of reported emotional difficulties is directly proportional to injury severity, except in the most severe cases of TBI (65). Table 43-11 depicts common comorbidities encountered in the clinical practice of patients with TBI.

Neuropsychological evaluators consider the impact of comorbidities such as mood disorders or psychosis on

patients' assessment findings. For example, conditions that alter mental status (e.g., delirium, vegetative states, or active hallucinations) may invalidate results of assessment. Screening with measures such as the Mini-Mental Status Examination (66) or the Minnesota Multiphasic Personality Inventory-II (67) is recommended. These instruments help to rule-out potentially confounding factors of diminished consortium or significant affective disturbance, respectively. Table 43-12 provides a list of test measures least and most susceptible to the affect slowed mental processing and/or psychomotor performance often observed with certain mood disorders.

Mild head injury offers unique challenges to evaluators in terms of differential diagnosis than moderate and severe neurological damage. Clear physiological

**TABLE 43-11**  
*Common Comorbidities*

- Adjustment Disorder with Anxiety or Depressed Mood
- Adjustment Disorder with Mixed Emotional Features and Disturbed Conduct
- Major Depressive Disorder
- Mood Disorder due to General Medical Condition
- Personality Change Secondary to General Medical Condition
- Polysubstance Abuse
- Post-traumatic Stress Disorder
- Substance Abuse or Dependence

**TABLE 43-10**  
*Questions to Facilitate Differentiation Between Premorbid Problems and Injury-Related Sequelae*

- Did patient have problems with substance misuse prior to the TBI?
- Did the individual have a pre-injury personality disorder?
- Was the patient receiving mental health treatment for a mood disorder or other psychological problem before the injury?
- Did the patient have pre-existing learning difficulties?
- Were pain or sleep problems apparent prior to the patient having a TBI?
- How was the patient's daily functioning prior to the injury? Explore areas such as relationships, occupational or educational pursuits, and recreational activities.
- Have others noticed a change in the patient's functioning since the injury?
- When did emotional difficulties or substance use issues arise?

**TABLE 43-12**  
*Tests Least and Most Susceptible to Affect of Mood Disorders*

LEAST SUSCEPTIBLE	MOST SUSCEPTIBLE
Category Test	Symbol Digit Modalities Test
WAIS Verbal Subtests Vocabulary Comprehension Similarities	WAIS Performance Subtests Block Design Digit Symbol-Coding

Wide Range-Achievement Test Reading Spelling	Grooved Pegboard Test
Token Test	Controlled Oral Word Association Test

consequences of serious brain injury are unquestionable, such as positive CT or MRI findings. For mild brain damage, however, hard neurological signs of injury may not be present. Comorbid problems with somatic functioning may complicate differential diagnosis after mild head injury. Practitioners are encouraged to be familiar with

difficulties associated with somatic problems. According to the DSM-IV (60), there are a number of distinct disorders with a physical presentation, including Pain Disorder, Hypochondriasis, Somatization Disorder, and Conversion Disorder. Table 43-13 depicts highlights of the DSM-IV criteria for each of these diagnoses.

**TABLE 43-13**  
*DSM-IV Diagnoses and Associated Criteria for Selected Disorders*

DSM-IV DIAGNOSIS	CRITERIA
Pain Disorder	<ul style="list-style-type: none"> <li>• pain reported at one or more anatomical sites</li> <li>• pain is sufficient in severity to warrant clinical attention</li> <li>• pain causes significant distress or impairment in functioning</li> <li>• psychological factors have an important role in onset, severity, exacerbation, or maintenance of pain</li> <li>• symptoms or deficits are not better accounted for by another mental condition (i.e., mood, anxiety, or psychotic disorder) and does not meet criteria for Dyspareunia</li> <li>• symptoms or deficits are not intentionally feigned</li> </ul>
Hypochondriasis	<ul style="list-style-type: none"> <li>• preoccupation with fears of having a serious disease</li> <li>• fear is often based on the person's misinterpretation of bodily symptoms</li> <li>• preoccupation persists despite appropriate medical evaluation and reassurance</li> <li>• belief is not of delusional intensity and is not restricted to a circumscribed concern about appearance</li> <li>• preoccupation causes clinically significant distress or impairment in functioning</li> <li>• duration of the disturbance is at least 6 months</li> <li>• preoccupation is not better accounted for by Generalized Anxiety Disorder, Obsessive-Compulsive Disorder, Panic Disorder, a Major Depressive Episode, Separation Anxiety, or another Somatoform Disorder</li> </ul>
Somatization Disorder	<ul style="list-style-type: none"> <li>• history of many physical complaints beginning before age 30 years</li> <li>• complaints must continue for several years and result in treatment being sought</li> <li>• after appropriate investigation, each of the physical symptoms cannot be fully explained by a known medical condition or the direct effects of a substance (e.g., a drug of abuse, a medication)</li> <li>• when there is a related general medical condition, the physical complaints or resulting impairment are in excess of what would be expected from the history, physical examination, or laboratory findings</li> <li>• patient reports or displays symptoms at any time during the course of the disturbance as described below: <ul style="list-style-type: none"> <li>○ four pain symptoms</li> <li>○ two gastrointestinal symptoms</li> <li>○ one sexual symptom</li> <li>○ one pseudoneurological symptom</li> </ul> </li> </ul>
Conversion Disorder	<ul style="list-style-type: none"> <li>• one or more symptoms or deficits affecting voluntary motor or sensory function</li> <li>• symptoms are suggestive of a neurological or other medical condition and may not be intentionally produced or feigned <ul style="list-style-type: none"> <li>○ symptom cannot, after appropriate investigation, be fully explained by a general medical condition, or by the direct effects of a substance, or as a culturally sanctioned behavior or experience</li> <li>○ symptom causes clinically significant distress or impairment in social, occupational, or other important areas of functioning or warrants medical evaluation</li> <li>○ symptom is not limited to pain or sexual dysfunction, does not occur exclusively during the course of Somatization Disorder, and is not better accounted for by another mental disorder</li> </ul> </li> </ul>

## NEUROPSYCHOLOGICAL REPORT WRITING

Communicating results from the neuropsychological assessment to referral sources, treating providers, patients, and their families is a critical task for neuropsychologists. If test results are not communicated effectively, the utility of the entire assessment process comes into question. When writing a helpful report, neuropsychologists consider the following:

1. Review records thoroughly to ensure that historical information, pre-existing conditions, and injury severity are understood and considered in formulating impressions and recommendations.
2. In formulating diagnostic impressions, consider the impact of pre-existing conditions, psychological and emotional issues, motivation, effort, self-awareness, and pain.
3. Write reports in a language that patients and lay people can understand, avoiding use of jargon.
4. Tailor reports to each specific patient rather than being generic.
5. Write and disseminate reports in a timely fashion. Review test results with the patient and discuss findings in a meaningful way. Encourage the patient and his or her family to ask questions.

6. Take special care to ensure reports address and answer the referral source's questions and concerns.
7. Consider the patient's and family's concerns and the meaning of the injury to the patient during report development.
8. Consider the patient's reactions to test findings and impressions, and take special care to ensure the presentation of the findings and conclusions will be palatable to the patient.
9. Highlight strengths as well as deficits.
10. Translate test results into recommendations which will make patients' lives better.

Although practitioners are encouraged to develop unique reports which are specific to each patient, structure is an important way to provide a familiar framework for referral sources. Placing information in similar sections with distinct headings allows readers to locate information quickly. Structured report formats also provide a way to organize large amounts of information and to increase efficiency. Table 43-14 depicts important sections that may be included in comprehensive neuropsychological reports and content which may be included in each section.

**TABLE 43-14**  
*Report Structure and Content*

REPORT SECTION	CONTENT OF SECTION
Confidentiality Statement	<ul style="list-style-type: none"> <li>• Include statement indicating that report contents are "strictly confidential" and should not be disseminated or reproduced without the patient's explicit permission</li> </ul>
Agency Contact Information	<ul style="list-style-type: none"> <li>• Include agency name, complete mailing address, telephone number, fax number</li> </ul>
Demographic Information and Referral Source	<ul style="list-style-type: none"> <li>• Include patient's name, address, race, marital status, handedness, date of birth, age, current medications, date of injury, and referral source</li> </ul>
Presenting Problem and Reason for Referral	<ul style="list-style-type: none"> <li>• Highlight presenting problems, including injury date, etiology, and injury specifics</li> <li>• Identify specific referral questions</li> </ul>
Basis of Evaluation	<ul style="list-style-type: none"> <li>• Provide sources of interview information</li> <li>• Identify records which were reviewed</li> <li>• Provide checklist of tests administered in the appendices</li> </ul>
Behavioral Observations	<ul style="list-style-type: none"> <li>• Describe behavioral observations during the testing process, including information presented in Table 43-4 (general behavioral observations included in "Behavioral Observations" section and specific test related behaviors included in "Test Results" section)</li> </ul>
Current Symptoms	<ul style="list-style-type: none"> <li>• Identify current problems reported by the patient and his or her family members</li> <li>• Include current neurobehavioral symptoms endorsed on the Neurobehavioral Functioning Inventory, listing specific items endorsed in a table</li> <li>• Highlight changes in functioning compared to pre-injury</li> </ul>

TABLE 43-14 (continued)

REPORT SECTION	CONTENT OF SECTION
Historical Information	<ul style="list-style-type: none"> <li>• Include information about the following: <ul style="list-style-type: none"> <li>• Academic/vocational history</li> <li>• Family/social history</li> <li>• Medical/mental health history; current treatment</li> <li>• Pre- and post-injury substance use</li> <li>• Criminal history</li> </ul> </li> </ul>
Summary of Medical Records	<ul style="list-style-type: none"> <li>• Provide summary of principal medical and mental health records reviewed</li> </ul>
Daily Living Abilities	<ul style="list-style-type: none"> <li>• Identify current living situation, daily activities, and ability to perform activities independently and safely (e.g., hygiene, driving, medication compliance, financial management)</li> <li>• Note any post-injury change in living situation, daily activities, and independence</li> <li>• Highlight judgment and safety issues, with table depicting responses on the Judgment and safety Screening Inventory</li> </ul>
Test Results	<ul style="list-style-type: none"> <li>• Provide behavioral observations pertaining to approach to testing and reaction to testing</li> <li>• Note level of motivation and effort</li> <li>• Estimate pre-injury abilities (Impaired to High Average)</li> <li>• Describe of test performance in each functional area</li> <li>• Provide table comparing test data to pre-injury estimates, prior tests, and normative data</li> <li>• Provide graphical depictions of selected test results in appendices (e.g., performance across trials on verbal learning tasks, figure depicting MMPI-2 results)</li> </ul>
Impressions	<ul style="list-style-type: none"> <li>• Integrate information from various report sections</li> <li>• Note and discuss consistencies between various information sources</li> <li>• Provide diagnostic formulation and support for each diagnosis</li> <li>• Provide table depicting DSM-IV and ICD diagnoses</li> <li>• Respond to referral questions clearly</li> <li>• Highlight interactions between cognitive, emotional, neurobehavioral, pain, and medical factors</li> <li>• Provide conclusions about prognosis for improvement and future academic and vocational functioning</li> </ul>
Recommendations	<ul style="list-style-type: none"> <li>• Provide practical, feasible recommendations that address cognitive, neurobehavioral, and emotional issues</li> <li>• Provide recommendations regarding judgment, safety, and daily living activities</li> <li>• Provide referrals for services which may improve functioning (e.g., medical follow-up, evaluation, therapy, support group) (see Table 43-9 for sample recommendations)</li> </ul>

## NEUROPSYCHOLOGICAL TREATMENT

Neuropsychologists specialize in the assessment and treatment of neurobehavioral disorders encountered across the lifespan. As treatment providers, neuropsychologists offer invaluable expertise in developing compensatory strategies and identifying resources to help patients cope with disruptions in their daily functioning. Neuropsychological treatments and interventions are ideally created with appreciation of individuals' unique characteristics and needs. Treatment plans aim to accentuate patients'

strengths, to help them overcome neurocognitive and behavioral challenges identified by assessment, and to maximize coping. Staples of neuropsychological rehabilitation include education and referral, individual and family psychotherapy, support groups, behavior management, cognitive remediation, and job advocacy and planning.

### Education and Referral

Research has found that family members of people with TBI most frequently cited health information as an important

need (68). Rehabilitation professionals strive to provide reliable and accurate information about TBI to patients, family members, friends, teachers, employers, and other treatment providers. Bibliotherapy is chosen by many professionals to facilitate communication of vital medical knowledge. Patients may be provided with written material for review and discussion. For example, *Getting Better and Better after Brain Injury: A Guide for Families, Friends, and Caregivers* by Kreuzer and Kolakowsky-Hayner (69) offers pertinent information about consequences of TBI and the recovery process. Rehabilitation specialists may also be called upon to provide referral sources with information about the common manifestations of TBI. Providers of adjunctive therapies are likely to profit from understanding an individual patient's neurobehavioral or cognitive post-injury difficulties.

Patients often demonstrate needs outside the realm of a neuropsychologist's expertise. Treatment providers are encouraged to be mindful of adjunctive treatments which may prove beneficial to patients. Appropriate and timely referrals to alternative treatment professionals are encouraged. The identification of services likely to be helpful to patients is the first step. Rehabilitation professionals may consider patients' abilities and willingness to fully participate and make use of additional treatments. Examples of adjunctive services include substance abuse treatment, psychotropic medication, vocational rehabilitation, clubhouse programs, support groups, or comprehensive driver's evaluation.

### Individual Psychotherapy

Psychotherapy is considered an essential component of holistic treatment for patients with TBI by many rehabilitation professionals (70–73). Qualified neuropsychologists play a vital role in providing psychotherapy for individuals with TBI (71). Individual therapy with patients and family members is a useful and commonly practiced mode of inpatient and outpatient rehabilitation. Patients may benefit from attending sessions without their family members present for private discussions of personal issues. Conversely, family members may be invited to sessions in order to obtain psychoeducation about the patient's injury or to provide input about the patient's functioning outside of session.

Psychotherapy further offers people with TBI the opportunity to learn skills to better deal with dramatic life changes encountered after a TBI. Practitioners and patients with TBI determine mutually acceptable therapy goals to address areas of deficiency. Improving emotional adjustment, communication skills, and symptom management are examples of typical therapy goals. Training in anger or stress management, social skills, and strategies to manage depression or anxiety are therapeutic strategies often employed with patients following a TBI.

### Family and Marital Intervention

Research supports the need for interventions following TBI for families. (68, 74–76). Researchers have found that nine out of 10 patients are discharged to home after inpatient rehabilitation (48). Family members of patients have an understandably difficult time coping with role changes, increased responsibilities, and stress associated with TBI (e.g., insurance issues, financial strain, and medical appointments). Despite the efforts of rehabilitation staff to prepare families for patients' discharge, many family members report feeling overwhelmed and ill-equipped to manage the long-term needs of survivors (18, 77).

Most families do not receive professional emotional support following the TBI of a family member (68). Research on caregiver burden revealed that over one-third of caregivers endorsed clinically significant levels of depression and anxiety (55). Emotional reactions of families following the brain injury of a loved one may also include intense feelings of anger, blame, and guilt. Reassuring family members that these reactions are normal responses to a tragic event can enhance long-term functioning.

Family interventions not only provide a valuable means for improving emotional support, but also may help with symptom reduction and coping skills enhancement. Some family members receive individual therapy as an adjunct to or as a substitution for family therapy. Neuropsychologists are often pro-active in recommending and implementing treatments tailored for the needs of a family or an individual family member.

Psychotherapy provides patients and their families the opportunity to share their feelings of grief, loss, and helplessness in a supportive and understanding environment. Treatment providers also impart information regarding the patients' neurological condition through patient-family education. Information commonly shared with family members includes the effects of brain injury, the process of recovery from TBI, and compensatory strategies. Dysfunction in sexuality may also be addressed as a component of therapy. Psychosocial treatment approaches are associated with helping survivors and their families cope with post-injury issues of such as impaired sexual performance or disinhibition (78). Readers interested in additional information about families of patients with TBI are referred to the chapter in this text by James Malec, Ph.D., "Family and Caregiver Issues and Interventions."

### Support Groups

Support groups for survivors of TBI and their family members or friends provide a number of benefits to participants. Community based support programs offer survivors of brain injury and their family members or friends help in managing a wide range of disability-related stressors. For example, support groups are a source of emotional support, education, and social networking. Participants in a

peer oriented group for survivors reported having increased knowledge about TBI, enhanced quality of life, improved general outlook, and better emotional coping (79). Patients and their families often benefit emotionally from the shared experiences of others. Support group members commonly disclose information regarding resources or coping strategies they have found useful in recovering from TBI. People are given the opportunity to extend their social connections within the community through their participation in support groups. An organization such as the Brain Injury Association of America, Inc. provides referral services and information about local support groups for interested parties. Common objectives of a group for persons with TBI may include discussing needs of survivors and families, sharing information, identifying local resources, and networking. Rehabilitation specialists are encouraged to be familiar with such organizations and groups in their area.

### **Behavior Management**

Behavior management is another tool available to treatment professionals for patients demonstrating disruptive or dangerous behavior. Behavior management may incorporate aspects of cognitive remediation in applying interventions. Behavioral approaches providing emotional support and maintaining sensitivity to the contextual environment of the patient are recommended (80). Yody and colleagues (81) advocate for behavior management training that reduces unwanted behaviors by reinforcing alternative behaviors serving similar functions or purpose. Families and other service providers (e.g., teachers, nursing staff, and employers) may benefit from learning behavior management techniques. Problems such as impulsivity and aggressiveness can greatly interrupt patients' social functioning at work, home, or in treatment facilities. For example, behavior modification techniques to enhance the inhibitory control of patients have demonstrated effectiveness (82).

## **COGNITIVE REMEDIATION**

Ben-Yishay and Diller (83) argued for an integrative, holistic approach to cognitive remediation that considered issues of awareness, self-concept, and self-efficacy. Mateer and colleagues (84) further recommended integrating cognitive and emotional interventions given the interaction between the two domains of functioning. The authors indicated that successful integration maximizes treatment potential.

Direct intervention to address cognitive deficits incurred as a result of a TBI may be obtained through cognitive retraining (85). Neurocognitive domains (e.g., attention/concentration, memory, learning, and planning) and

academic skills may be amenable to remediation efforts. The preponderance of evidence indicates there is some benefit of cognitive rehabilitation programs across a continuum of services (86). Cicerone and colleagues (87) reported that therapies for skill acquisition and domain-specific knowledge could be beneficial for individuals with moderate to severe memory impairments. Research suggests that enhancement of specific skills areas may account for the majority of noted benefits observed from cognitive retraining in such domains as attention (88).

Cognitive rehabilitation typically includes training patients in compensatory strategies to enhance functioning compromised by neurological damage. Patients' strengths and skills are often exploited in attempts to overcome areas of relative neurocognitive weakness. For example, rehabilitation specialists train patients in the effective use of memory logs, checklists, mnemonic devices, and self-monitoring to help them compensate for cognitive deficits. Keith Cicerone, Ph.D., addresses this topic more thoroughly in the chapter entitled "Cognitive Rehabilitation." Table 43-15 depicts programs and strategies developed to ameliorate cognitive dysfunction.

### **Job Advocacy and Planning**

As TBI frequently occurs to young people in arguably the most productive years of their working lives, employment is an especially important issue (111). A common goal for adults who have experienced a TBI is employment or return-to-work (112). Following comprehensive evaluation, neuropsychologists often advocate for services their patients need to successfully return to work. Specific cognitive skills (i.e., concept formation, cognitive flexibility, and problem solving) are cornerstones of functional recovery and successful rehabilitation that may be disrupted by a TBI and identified during the assessment process (111).

Persons recovering from brain injury often require additional programs and supports to supplement traditional models of vocational rehabilitation. Wehman, West, Kregel, Sherron, and Kreutzer (113) conducted a study about the efficacy of a supportive employment program for survivors of severe brain injury. Program participants were matched with a job opening based on preliminary assessments. Interventions such as work and social skills training, job modifications, and counseling were completed. Patients also received assistance with addressing common obstacles to employment (e.g., interpersonal conflicts, or lack of transportation or housing) by an employment specialist. Helping survivors find financially and socially rewarding jobs and appropriate vocational supports enhances the probability patients will experience a successful return to work after a TBI. Wehman and colleagues (114) investigated the long-term follow-up of persons with TBI after being involved in supported employment. Findings suggested that

supported employment was cost-effective for individuals with TBI.

The 2005 article by Wehman, Targett, West, and Kregel (115) reviews the research literature with respect to TBI and employment, and provides a series of recommendations for future research and public policy. The reader is referred to the chapter in this book entitled, "Vocational Rehabilitation Issues," by Dr. Paul Wehman for detailed information about employment services for individuals following a TBI.

### SUMMARY

Early on, neuropsychologists were primarily involved in quantifying cognitive abilities and endeavoring to localize brain dysfunction. Over the past several decades many neuropsychologists working in rehabilitation settings have expanded their practice to address the diverse and

long-term needs of persons with brain injury and their families. Neuropsychologists have had important roles on rehabilitation teams addressing issues relating to behavioral management, emotional adjustment, substance abuse, family functioning, and return to work. With larger numbers of people surviving traumatic brain injury, neuropsychologists have had an opportunity to play an increasingly important role in rehabilitation. Undoubtedly, many persons with brain injury face long-term difficulties adjusting and returning to productive lives. Neuropsychologists are often well qualified to help patients and their families, and many have chosen to expand their roles far beyond that of cognitive evaluator.

# Principles of Behavioral Analysis and Modification

*Robert L. Karol*

## INTRODUCTION

Psychological considerations are integral to the treatment of persons with brain injury. Most of the elements people use to define their self-worth, such as intelligence, physical prowess, financial status, etc., are vulnerable after brain injury. Moreover, coping skills may decline and behavioral dyscontrol may increase due to alterations in cognition. Treatment protocols that de-emphasize psychological status are less likely to be successful than therapy programs that incorporate psychological deliberations.

Often treatment programs focus on medical, physical, and cognitive factors: (1) walking, balance, transfers between a bed and a chair, or transferring into a car; receptive and expressive language deficits; upper extremity use and activities of daily living; and medical stability. It is natural to give weight to these functions. It is apparent to all professionals when persons with brain injury are unable to walk, talk, or care for themselves. Physicians are trained to intervene when there is medical instability. Moreover, persons with brain injury and their families are exquisitely aware of these problems and they want professionals to fix them. They assume that recovery of personality will accompany physical recovery (2).

Hence, persons with brain injury become a set of symptoms. The term “medicalization” describes this process (3). In part, the power of this process is based

upon our society’s expectation for health care. People in our society expect our health care professionals to act in a certain way – to use medications and high technology to focus on symptom cure – stemming from people’s familiarity with acute medical care, sometimes from media entertainment (4) or from media reporting of advances in research. Professionals accommodate people’s expectations. After all, expectations are an important element in care (5). However, fulfilling this expectation can leave persons with brain injury and their families dissatisfied. Psychological variables determine their comfort level with care, but frequently persons with brain injury and their families articulate poorly their psychological needs. The challenge is that psychological variables seem nebulous and indistinct. Yet, in the long term, factors associated with psychological variables and quality of life can have a greater impact on persons with brain injury and their families than other variables, (6) and cognitive and behavioral concerns tend to be most burdensome (7). To be more helpful, rehabilitation ought to address higher needs related to satisfaction with life (8).

Unfortunately, third party reimbursement sources compound the potential inattention to psychological considerations. Insurance system changes are leading to shorter hospital stays, and there is more pressure on families to provide care at home (9). Nevertheless, insurance often fails to cover community support services (10).

When persons with brain injury are able to walk, talk, perform activities of daily living, and are medically stable, insurers press for program discharge, regardless of whether persons with brain injury or their families are psychologically ready for return to the natural environment, or even for transfer to another program or care setting. Furthermore, there is little attention paid to the willingness to perform skills that professionals have taught persons with brain injury and their families.

It is a mistake when professionals, persons with brain injury, families, and insurers downplay psychological variables. Psychosocial sequelae may be a better predictor of outcome than physical symptoms (11). Also, outcome itself can be a function of psychological care. The intensity of psychological care correlates with cognitive gains (12). Hopefully, this is familiar knowledge among rehabilitation professionals. Behavioral or emotional dysfunction can be hard to treat and untreated can disrupt the care of cognitive and physical functioning (13). The satisfaction persons with brain injury and their families express regarding their rehabilitation is likely to be influenced by their perceptions of their treatment. Awareness of the importance of psychological variables is important. Sadly, families report being inadequately informed about brain injury and rate professionals as unhelpful (14).

Hence, this chapter will address behavioral and psychological care. The intent of the chapter is to provide an overview of assessment and intervention methods and issues, identify important behavioral and psychological process variables in rehabilitation, and highlight selected applications.

## PRINCIPLES OF ASSESSMENT AND INTERVENTION

### Assessment

*Introduction to Assessment* Professionals ought to predicate treatment on thorough assessment. Psychological assessment dovetails with evaluations by all other disciplines because psychological variables affect the outcome of all disciplines' evaluations and their treatment efforts. For example, low effort due to depression can contaminate the findings of physical therapists. Hopelessness can interfere with the educational efforts of nurses leading to poor reliability in the self-administration of medications. The beliefs of persons with brain injury influence compliance with physicians' recommendations. Therefore, psychological assessment is essential for the provision of services to persons with brain injury, not just for psychological care, but also for success by all disciplines.

Psychological assessment primarily covers three domains: emotional, behavioral, and cognitive functioning. Emotional status includes factors such as depression,

anger, anxiety, etc. The examples in the preceding paragraph derive from emotional variables that have behavioral implications. Behavioral considerations range from noncompliance to aggression. Cognitive functioning includes executive processes, memory and learning, intellectual abilities, etc. and are evaluated using clinical observation and neuropsychological testing.

*Assessment of Emotional Status* Emotional disturbance is a significant component of brain injury. The National Institute of Health Consensus Statement (15) states, "Mood disorders, personality changes, altered emotional control, depression, and anxiety are also prevalent after TBI" (p. 12). Because the brain regulates emotional functioning, (16–18) organic damage can cause direct emotional changes. In addition, the recognition and expression of emotions can be altered by brain lesions (19). There is also the emotional adjustment to having and living with a disability. There have been numerous reports of the emotional sequelae of brain injury (11, 20–22). Recently, researchers have also paid particular attention to grief as distinct from depression (23).

Professionals can use clinical acumen and psychometric assessment to determine emotional functioning. They should decide how to balance these two approaches based upon the setting and the level of functioning of the persons with brain injury with whom they are working. For instance, in a community-based setting with higher-functioning individuals, psychometric evaluation may be feasible, but at Rancho Los Amigos Level V (24) it is untenable with people newly arrived from an intensive care unit fresh out of coma.

Clinical assessment of emotional functioning occurs through a combination of diagnostic interview and observation. Interview can provide clues as to what persons with brain injury are experiencing. How persons with brain injury express emotions can provide insight into their coping abilities. Of course, professionals need to be aware of deficits in the expression of emotion, such as aprosodia (the loss of speech tone that conveys affective data), that might mislead professionals in their judgment regarding emotional status. Observation when persons with brain injury demonstrate emotional dyscontrol provides clues as to what they are feeling. Fluctuations in emotional intensity throughout the day, from day to day, or across events offer professionals the opportunity to study emotional patterns. Professionals must observe the antecedents and the consequences of emotions as well as the qualitative and quantitative aspects of the emotions to fully understand the expression of emotions. Experienced professionals, for example, might determine upon close observation that a diagnosis in the chart of depression is, in fact, anxiety. Trained observation of emotional events is often worth much more than only obtaining professionals' reports or reading the record. A combination of

interview, providing leads in regard to emotional status, and observation of emotions in practice during behavioral events can assist professionals in the exact delineation of emotional functioning.

In the case of psychometric assessment, there is an unending array of published psychological test instruments for the determination of emotional functioning. These range from measures of particular emotional variables (e.g., Beck Depression Inventory) (25, 26) to broad personality inventories (e.g., MMPI). There are also rating scales, questionnaires, and interview formats that include emotional or adjustment variables (e.g., Neurobehavioral Rating Scale-Revised, (27, 28) Functional Assessment Measure, (29–31) Mayo-Portland Adaptability Inventory (32–34)). Interview, observation, or both ought to accompany any psychometric assessment of emotional variables. Qualitative variables can be crucial in emotional assessment: how persons with brain injury experience or express emotions provides insight into their functioning beyond psychometric tools.

Professionals must consider the appropriateness of any instrument for the evaluation of emotional status for persons with brain injury. First, it is helpful when there are norms for persons with brain injury for the particular instrument. While it is important to be able to determine if persons with brain injury deviate from the general population, it is also useful for rehabilitation to know if they diverge from the normal experiences of other persons with brain injury. Publishers of standardized, mass-marketed tests of emotional adjustment generally fail to include a subgroup of persons with brain injury during test development. Furthermore, when they include persons with brain injury in a sample, the subject characteristics in any particular study of the brain injury population may differ in some significant fashion from the persons with brain injury being seen by a given professional. Important distinctions may exist on variables including the nature of onset, location of damage, time post onset, pre-morbid personality dimensions, etc.

Second, cultural variables can play a critical role in the psychometric assessment of adjustment after brain injury. Professionals may be aware of the impact of cultural factors on personality assessment in mental health populations, but they are potentially less in tune to the intersection of culture and coping with disturbances in physical health, particularly various cultures' differing views on appropriate approaches to brain injury. Behaviors that may appear pathological in one culture may represent normative beliefs in another culture (35). In light of the alterations in personality and cognitive functioning that can occur after brain injury, people have a complex emotional response to brain injury symptoms based on their social and cultural views of the symptoms.

Third, the neurological experiences of persons with brain injury are unique contaminants to the assessment

of emotional status. Many markers of emotional states in mental health populations include neurological or physiological functioning (e.g., impaired concentration or memory, sleep disturbances, alterations in initiation or energy level). However, for many persons with brain injuries these are normal reflections of organic impairment and may be unrelated to emotional disturbance. There have been investigations of the impact of such factors on emotional assessment, for example for depression, and the effect of these variables varies (36–38).

Yet, many persons with brain injury have had experiences that would indicate clear emotional pathology in mental health populations. When persons with brain injury report histories of periods of “blacking out” or “out of body episodes,” they could be due to coma or seizures; reports of hallucinations may be recollections of emergence from coma; acknowledgment of “delusional thoughts” could be confabulations during rehabilitation. While it is certainly possible that persons with brain injury have had blackouts, out of body episodes, delusions, hallucinations, etc. as a function of emotional pathology, the attribution of these symptoms ought to include the differential diagnosis of normal brain injury sequelae. Professionals must adjust their interpretations of psychometric instruments that utilize symptoms commonly occurring after organic brain injury.

Self report by persons with brain injury can also be a concern due to the injury. Memory deficits, in particular, can be a barrier to psychometric assessment of coping. When a test requires recall of personality based preferences, coping styles, past emotional experiences, or previous behavioral episodes, persons with brain injury may not be able to remember what they have done or what type of people they were in the past. It is common for persons with brain injury to relate that they are unable to remember how they were feeling at a particular point in time. Sometimes denial or lack of awareness can have a global effect on self report measures. A person with brain injury might self report an emotional picture that substantially conflicts with the one that professionals would obtain from significant others about their loved one with the injury (e.g., a person with brain injury might fail to report depression that is clearly present to other observers). Since many tests rely on self-reported recall of preferences, emotions, and behaviors, professionals must be cautious in the interpretation of psychometric test results of adjustment and coping styles for some persons with brain injury.

Finally, professionals must take care in the actual administration of psychometric tests of adjustment to persons with brain injury. Cognitive deficits can impair the ability of persons with brain injury to complete the tests or they can lead professionals to misinterpret the results because the findings are affected by cognitive deficits during test administration. Reading ability is one obvious

determinant for the suitability of a test. Other factors range from concentration (partial attention paid to test items as well as variable effort in completing the test) to comprehension and aphasia (understanding the directions and the test items) to even visual-perceptual ability (for visual analog or Likert scale measures). Even difficulty with decision making can interfere with responding to test items.

*Assessment of Behavior* It is essential that professionals formulate any intervention program for behavioral problems on sound behavioral assessment. The principles of behavioral analysis and assessment are well-established (39–41). Furthermore, their application to brain injury care has been detailed for some time (42, 43). Behavioral assessment routinely begins with decisions about which behaviors to assess. This is crucial. If professionals fail to appreciate the nature of their raw observations before measurement, they will operationalize and measure the wrong events or the unimportant aspects of events. Good clinical judgment must precede behavioral measurement. Next, behavioral assessment entails professionals defining in operational terms the behaviors they select. They then can observe behaviors and record frequency, severity, duration, etc.

Standardized rating of behavior is an alternative to individualized assessment of operationally defined target behaviors unique for each person. In this approach, behaviors such as aggression, noncompliance, or irritability are rated using predefined definitions of behaviors. Ratings can be completed by professionals, families, persons with brain injury, or someone else. The Agitated Behavior Scale (44) is an example of a rating scale with items covering impulsivity, violence, wandering, etc., as is the Neurobehavioral Rating Scale (45) with items including disinhibition, agitation, hostility/uncooperativeness, etc.

Regardless of the approach, two hurdles loom large related to the nature of behavioral dyscontrol after brain injury. First, the behaviors that most concern professionals, families, and others after brain injury are exceedingly complex. The process of defining behaviors in operational terms takes considerably more time and effort than many professionals anticipate. Second, overly simple behavioral assessment that involves just recording easily correctable aspects of behavior will miss important antecedents and qualitative variables that provide clues to treatment. This is especially so in light of cognitive and emotional impairments after brain injury that complicate behavioral etiology. Unfortunately, professionals in rehabilitation settings often approach record keeping for behavioral problems with ambivalence (46). The combination of needing excellent assessment, with the difficulty of knowing what to assess, and professionals' challenges in implementing assessment procedures can defeat efforts at treatment.

*Assessment of Cognition* A keystone for successful behavioral treatment of persons with brain injury is evaluation

of their cognitive functioning. Cognitive disturbance has far reaching implications. It affects emotional coping, behavioral dyscontrol, participation in physical and medical care, and return to independence and productivity. The foundation of cognitive assessment is neuropsychological evaluation. Neuropsychological evaluations are addressed in the chapter by Drs. Taylor, Livingston, and Kreutzer; however, there are two aspects of cognitive evaluations that are particularly pertinent to the current discussion.

The first aspect is the utilization of neuropsychological information to help formulate the treatment of emotional issues and behavioral dysfunction (47). Neuropsychological data greatly facilitates the treatment of emotional and behavioral problems, (48) though care must be taken to not rely solely on neuropsychological data (49). Still, many emotional and behavioral problems are partially based upon cognitive difficulties. For example, paranoia can be a reflection, in part, of attentional and memory deficits when persons with brain injury have perceptions of other people that are inaccurate because of a failure to attend to and recall all of the elements of an interaction. Similarly, speed of processing deficits can cause anger outbursts when persons with brain injury are unable to keep up in conversations, leading to frustration with getting their needs heard. Any study of behavioral dyscontrol or emotional distress ought to include cognitive processing assessment.

Second, professionals need to realize the importance of clinical observation for the determination of cognitive deficits. Sometimes issues of injury severity or non-cooperation render formal neuropsychological testing impractical, forcing professionals to rely solely on observation of cognition, while at other times observation of cognitive deficits is a crucial adjunct to testing. Experienced professionals should watch an emotional or behavioral event with an eye towards noticing how cognitive deficits influence the timing, severity, and nature of the event, as well as the effect of cognitive deficits on coping strategies. Also, observation of the impact cognition has on emotion and behavior provides excellent hypotheses for neuropsychological testing. The converse is also true: neuropsychological data can help refine professionals' observations, making the time spent on observation more productive.

## Intervention

*Contingency Management* The rubric contingency management, in brief, refers to the application of reinforcement and punishment to alter and control behavior. The principles of contingency management are well delineated, (40, 50) and professionals traditionally use these procedures for the treatment of behavioral dyscontrol after brain injury. It behooves professionals, however, to be certain that they correctly apply these procedures.

Many professionals across disciplines who attempt to utilize contingencies assume that they are simply to apply, whereas, in fact, they are quite complicated.

Technically, a reward is something that increases a behavior and a punishment is something that decreases a behavior. Professionals can explore a wide range of rewards and punishments (e.g., social, tangible, tokens/points) (51). Unfortunately, sometimes professionals independently believe something is a reward or a punishment and then apply it to change the behaviors of a particular person. This is problematic because the consequence may not be a reward or a punishment for that individual. Professionals should observe behaviors and discuss rewards or punishments with the person before plan implementation. It can be helpful to use access to naturally occurring behavior as a reward for the performance of lower probability behaviors that professionals want to encourage (52).

A positive reinforcer, when *presented*, increases a behavior; a negative reinforcer, when *removed*, increases a behavior. Many professionals often misunderstand the latter: negative reinforcement is not punishment! Both positive and negative reinforcement are rewarding. Punishment also can occur in two ways: the *application* of something unpleasant (positive punishment) or the *removal* of something pleasant (negative punishment) (52). Both forms of punishment decrease behavior. Table 44-1 summarizes the relationship between reinforcement and punishment, with examples.

Punishment is frequently misapplied. Punishment will not increase a desired behavior. Professionals cannot teach correct behavior with punishment. Moreover, punishment typically suppresses a behavior, but can be impermanent: when the punishment stops, the behavior may return (40). Also, as punishment begins behavior may

worsen. There may be significant emotional responses and punishment may lead to aggression (39, 52). If professionals endure the period of worse behavior, persistent application of punishment may eventually suppress behavior. However, the severity of aggression or other behaviors that adults with brain injury can produce in response to punishment is usually beyond what most professionals or programs are willing to tolerate.

Punishment can be detrimental to the process of treatment. It can impair rapport. Professionals may find that those persons to whom they are administering punishment avoid them (39). At the same time, however, persons with brain injury receiving punishment may learn from professionals to use punishment to change the behavior of other people. Professionals who provide punishment may be seen as models for how to act (52).

Punishment carries with it numerous significant ethical and moral concerns, beyond its ineffectiveness in teaching adaptive compensation strategies. In addition, there are regulatory standards regarding the use of aversive or psychologically risky procedures (53). Skilled professionals generally advise against the use of punishment (54). It is unnecessary, and it is fraught with risk for misuse. Still, punishment requires discussion because professionals working with persons with brain injury can slip into punitive paradigms. Punishment can even be reinforcing for professionals because it may rapidly decrease unwanted behaviors (52). Punitive acts may include discharge from rehabilitation by overwhelmed professionals who label persons with brain injury as dishonest or unmotivated (55).

In contrast, professionals can utilize reinforcement to teach appropriate behavior because it works to increase behaviors. However, the pattern of reinforcement influences how subsequent behavior occurs. There are four primary schedules of reinforcement. The first one is “fixed ratio:” the frequency of responses required to achieve reinforcement is set, and reinforcement occurs based on that frequency (e.g., every fourth time). This schedule encourages fast bursts of responding because the faster people perform, the more reinforcement they receive. However, there tend to be behavioral pauses after reinforcement. Typically, reinforcement is given every time (continual reinforcement) at the start of treatment and faded over time to a less frequent rate (intermittent reinforcement).

The second schedule of intermittent reinforcement is called “variable ratio.” Professionals provide reinforcement on a schedule with an average frequency of required responses (e.g., on average every fourth time), but with random variation around the average. This produces a higher rate of responding with more uniformity than fixed ratio schedules.

The third intermittent schedule is “fixed interval.” In this schedule, reinforcement happens after a set interval

**TABLE 44-1**  
*Positive and Negative Reinforcement and Punishment*

TYPE	ACTION	
	PROVIDE	REMOVE
<b>Desirable</b>	<i>Positive Reinforcement</i> Increases behavior (Salary at work)	<i>Negative Punishment</i> Decreases behavior (Revoking driver's license)
<b>Undesirable</b>	<i>Positive Punishment</i> Decreases behavior (Spanking)	<i>Negative Reinforcement</i> Increases behavior (Potential early prison parole)

of time. This schedule can cause a “scallop” effect in which appropriate behavior increases as the time for reinforcement approaches and then declines after reinforcement.

The fourth intermittent schedule is known as “variable interval.” Variable interval schedules eliminate the scallop effect because reinforcement happens after the passage of an average amount of time, not a consistent, set amount of time. Learning with variable intervals of reinforcement is fairly resistant to extinction (the cessation of a desired behavior during periods of a lack of reinforcement). Variable interval schedules produce a more uniform response than fixed interval schedules.

It can be difficult for professionals who are unfamiliar with reinforcement schedules to keep in mind the various options. Table 44-2 provides familiar examples of the four basic schedules of reinforcement to help identify them. Of course, there are other schedules of reinforcement and professionals may even form schedules including conjunctive schedules that require adherence to two or more performance requirements to receive reinforcement or they may chain different schedules together (52). The variations are countless.

Professionals must carefully examine how they deliver reinforcement compared to how they intend to provide it. There must be consistency in reinforcement across all professionals. Problems surface when a single professional is inconsistent or there is variability among many professionals. When one professional is inconsistent, treatment effectiveness will decline and may induce confusion or anger from persons with brain injury. If some professionals provide reinforcement, but other professionals do not, staff-splitting by persons with brain injury will likely ensue. Similarly, professionals may be pitted against family members, for example, when one group reinforces or extinguishes behaviors and the other set does not. Reinforcement will fail when there is inconsistency across professionals or between professionals and families.

Professionals must also be certain that the way a team of professionals reinforces behavior matches the treatment plans. For example, suppose a person with brain injury is to be encouraged whenever the person attempts a particular desirable behavior or coping strategy

(fixed ratio/continual reinforcement). Instead, busy or unaware professionals provide encouragement at the end of their workday in the late afternoon for efforts during that shift (fixed interval). Chart entries note better behavior in the afternoon with gradual improvement as time passes (scallop effect). This is occurring because of the inadvertent change in the schedule of reinforcement.

Consistency with plans is essential when using reinforcement. Furthermore, social attention (positive reinforcement) in response to maladaptive behavior (e.g., aggression) or escape from unwanted activities (negative reinforcement) such as difficult rehabilitation treatment due to behavioral dyscontrol (e.g., noncompliance) can unintentionally maintain undesirable behaviors (56).

The use of reinforcement is more complicated than just deciding on reinforcement schedules. A behavior must first occur for professionals to reinforce it. Professionals can prompt behaviors using cues and instruction so as to initiate behaviors; once behaviors have begun, professionals can reinforce them. Thereafter, professionals can gradually discontinue the prompts. Also, desirable behaviors may begin in rudimentary forms. Professionals must shape the behavior by reinforcing successive approximations of the behavior, progressively requiring more sophisticated approximations of the final behavior before reinforcement occurs. Professionals can also chain behaviors together.

Generalization occurs when behaviors that one learns in a particular setting occur in other settings, even without reinforcement of the behaviors in the new setting. Of course, professionals can encourage generalization with prompting and initial reinforcement. Professionals may also observe response generalization of the behavior to similar behaviors: learning a behavior influences the frequency of similar behaviors. This can be quite beneficial. For example, increased willingness to take showers may generalize to increased room cleaning.

Extinction is an additional tool. When professionals fail to provide reinforcement following behaviors they are using an extinction paradigm. When professionals ignore an emotional outburst on the part of a person with brain injury, they are extinguishing the behavior. As powerful as extinction can be, professionals must appreciate crucial factors in its use. Often, after extinction begins, there is a surge in the behavior. If the behavior is dangerous (e.g., aggression or self-injurious behaviors), the burst of behavior carries increased risk. There may also be periods of spontaneous recovery: after the behavior declines or stops, it may temporarily reappear. Professionals must take care to avoid unintentionally reinforcing either a burst or spontaneous recovery of the behavior. It is important to note that the schedules of reinforcement under which behaviors were acquired influences their resistance to extinction. Finally, extinction is best paired with reinforcement of alternative behaviors.

**TABLE 44-2**  
*Examples of Reinforcement Schedules*

SCHEDULE	EXAMPLE
Fixed Interval	Weekly paycheck
Variable Interval	Good performance on pop quizzes
Fixed Ratio	Factory piecework
Variable Ratio	Slot machine payouts

Behaviors often must be situation specific. As well as learning what to do, persons with brain injury must learn where and when to act. Professionals must reinforce behaviors in certain settings and not in others, teaching when and where behaviors ought to occur. Persons with brain injury often need instruction in reading social cues and context. Otherwise, they may do behaviors appropriate for home, for example, in other settings or they may attempt conversations acceptable with intimate friends when they are with strangers.

Professionals can use contingencies selectively. There are at least four useful procedures: differential reinforcement of other behavior (DRO), differential reinforcement of incompatible behavior (DRI), differential reinforcement of alternative behavior (DRA), and differential reinforcement of low-rate behavior (DRL) (57). In DRO, professionals provide reinforcement when an identified undesirable behavior does not occur. Using DRI, professionals reinforce a behavior that interferes with or prohibits an undesirable behavior. For DRA, reinforcement happens for a desirable behavior while ignoring an unwanted behavior. Lastly, in DRL, reinforcement occurs in response to the reduction of an unwanted behavior.

Token economies are a special format for the implementation of contingency management treatment. In token economies, professionals establish explicit rules for the delivery, withholding, or debiting of tokens (or some other accounting system, such as points) based upon the performance or absence of behaviors that professionals delineate. These tokens can be exchanged by persons with brain injury for reinforcing items, activities, etc. that professionals specify. In essence, the tokens substitute for money in a real economy (41). Tokens serve as conditioned (or secondary) generalized reinforcers (41, 52). They are conditioned or secondary in that people learn to associate them with things that are reinforcing (i.e., tokens by themselves have little inherent value without a relationship to what one can exchange for them). They are generalized because one can exchange them for several sources of reinforcement. Of course, unlike money, tokens can only be redeemed within the closed token economy of defined rewards.

Token economies have a number of advantages over simpler contingency management efforts (40). There may be less satiation than would occur with a set reward because a variety of reinforcers may be purchased with the tokens. For persons with brain injury this can also provide a sense of choice. They may choose diverse rewards or settle on particularly desirable ones. The flexibility may help persons with brain injury feel engagement with the process of behavioral change, though professionals should similarly involve persons with brain injury in the selection of reinforcers in even simpler contingency management plans.

Since persons with brain injury can accumulate tokens toward a valuable or large reinforcer, professionals can use them to permit a measured acquisition of a valuable reinforcer. A corollary of this is the specification that a person can choose to save tokens, as permitted by the economy rules, or to spend the tokens shortly after they earn them. Still, tokens can prove to be strong reinforcers because of their power to translate into significant rewards. Also, tokens can decrease the delay between behavior and reinforcement because professionals can provide them expeditiously. Rather than disrupting the flow of behavior by immediately giving a reinforcing item or event, professionals can easily provide tokens. Professionals must take care, however, in that tokens can become a stimulus for when to perform well and behavior may be different when they are not available (40).

Professionals must recognize that in many ways they are administering an *actual* economy. In the real economy people sometimes under perform and expect to be paid, use legalistic arguments regarding precise procedural concerns to reduce debits for improper behavior (e.g., financial penalties for crime), seek ambiguities in the specification of permissible behavior (e.g., analysis of tax code loopholes) to retain more money, commit theft to increase funds, hide inappropriate behavior, blame other people for their own acts, etc. In a token economy, persons with brain injury may also attempt to outfox the rules through procedural challenges, loopholes, theft, hiding behavior, blaming others, etc. For example, they may seek tokens for behaviors close to those behaviors that professionals specify as due reinforcement or they may claim that certain behaviors do not warrant a debit because the behaviors are not exactly the behaviors listed in the token economy behavioral descriptions (e.g., touching someone's hair does not count as touching the *person* or standing three inches away from someone does not count as *touching* them).

Professionals must consider devoting extra time to the design and implementation of token economies. Token economies can be intrusive in care environments and they can be cumbersome (39). Professionals must delineate each behavior. They must carefully codify in detail what they will use as tokens, how much each behavior earns or costs, how many earned tokens can accumulate, what reinforcers tokens can purchase, how tokens will be exchanged for reinforcers, how the token economy will terminate, etc (39). Obsessiveness helps. However, once in place token economies can provide professionals with a structure to address behavioral dyscontrol (58) and can be used across disciplines (59).

Token economies can be helpful for behavioral issues arising from brain injury. Professionals can implement a token economy with a single person with a brain injury (60) or in a programmatic fashion (61). However, as with any treatment, professionals must individualize treatment.

The use of any contingency management procedure is complex. There is no practical cookbook to guide professionals about which procedure to utilize with which symptom or person. Since treatment must be founded on individual, multifaceted symptom patterns and causes, any pre-determined treatment algorithms will fail to capture the extraordinary diversity of clinical presentations and etiological variables upon which professionals should base treatment. Moreover, as has been reviewed in the preceding discussion, contingency management encompasses a breadth of actual procedures that are highly intricate. Still, contingency management is likely to work best when three conditions are met.

First, they are more effective when persons with brain injury accept the idea of explicitly receiving reinforcement from another adult to alter their behavior. Not surprisingly, many persons with brain injury reject the idea that professionals are intentionally reinforcing their behavior. They dislike the manipulative feeling that apparent contingency procedures engender. While adults may use consequences to alter the behavior of children, adults in our society resist the idea that other people may attempt to apply contingencies to their own behavior. Persons with brain injury feel similar in this regard to any other adult and may resist contingency paradigms that remind them of being treated by professionals as if they are children whose behavior is to be controlled by others. Certainly, using contingencies with persons with brain injury who are suspicious or paranoid is contraindicated (62).

Second, when persons with brain injury act in their own best interests contingency management is more effective. Some persons with brain injury fail to do so because of their cognitive impairments, even when they understand and recall the likely consequences. Despite their awareness, factors such as lability, rigidity, nonverbal processing deficits, impulsivity, and executive dysfunctions lead to the failure of consequences to change behavior. Persons with brain injury may strike someone and later acknowledge having had awareness of the consequences, but they still proceeded. These persons may report either they could not stop themselves or could not think about the consequences quick enough to change their behavior. Sometimes they will state that the need for emotional release overrode their reflections about consequences.

Third, contingency management is likely to be more useful when memory difficulties do not interfere. Professionals must consider the impact of memory deficits on the effectiveness of contingency procedures. Many persons with brain injury forget their own behavior before professionals have an opportunity to respond with consequences. This defeats the purpose of linking behavior with consequences. Some persons with brain injury, when they are in a situation where they might choose a behavior that professionals have previously reinforced, forget the previous event. Because they forget that there were

consequences last time, the previous consequences have no influence. Both of these scenarios can defeat the use of consequences. However, there is evidence that in younger persons with brain injury consequences can work even when there exists impairment in explicit memory (memory of consciously recalled information) (63). Still, consequence-oriented behavior management outside of controlled environments can be relatively ineffective (64).

*Errorless Learning in Intervention* The errors people make at the start of learning are an additional concern in the use of contingency techniques. There are potential cognitive (e.g., interference with acquisition) and emotional (e.g., frustration, self-esteem) issues that arise with persistent errors. In contrast, errorless learning provides structure and cues, with initial performance demands set at an achievable level, so that as task complexity increases persons with brain injury perform correctly at each step. Correct responses can be provided to insure avoidance of errors. When applied to cognitive learning tasks, there is evidence of the benefit of errorless learning procedures (65–67). Professionals can apply errorless learning procedures to behavioral concerns (68). In doing so professionals insure that the situations persons with brain injury confront are of a type and level of complexity they can handle, with adequate prompts and training, before proceeding to more difficult emotional and behavioral challenges. Comprehensive programs can be built around errorless learning that adopt a holistic approach (69). Of course, contingency techniques, including reinforcement, stimulus fading, and cueing, can be incorporated into errorless protocols.

*The Impact of Modeling on Intervention* People receive vicarious reinforcement from observing other people receiving contingencies (70). Therefore, persons with brain injury may benefit from their observations of other people receiving reinforcement. If they see other people obtaining desirable consequences for certain actions, they may imitate the same behavior in anticipation of obtaining the same results. Moreover, they may determine that certain behaviors are socially acceptable upon observing the results of those behaviors. Professionals must take care, therefore, that they publicly encourage only behaviors that they wish to have emulated.

There are two issues, in particular, that professionals have to attend to regarding modeling. First, in some instances, professionals will reward one person with a brain injury for a particular behavior when doing so is part of the treatment plan, but not the same behavior from another person. Suppose professionals award a particular reward to someone who achieves a relatively low behavioral milestone, but one that is difficult for that person to reach. A much higher level functioning person with brain injury, who has loftier goals, observes this.

The second person, who is capable of much better behavior, demands rewards for behaviors similar to those of the first person, despite that behavior being well below the second person's capabilities. Individualized treatment plans based upon ability and goals are essential, but professionals must be astute in their application of the plans so that they avoid cross contamination.

Second, professionals must be cognizant of the modeling effect of their own behavior (46). Professionals are being watched: persons with brain injury notice professionals' behavior. For example, professionals may have difficulty teaching physical boundaries when persons with brain injury observe them patting each other on the back; professionals who are heard telling each other off-color jokes may struggle to teach sound sexually appropriate behavior; professionals who make an offhand comment about another professional contribute to staff-splitting and noncompliance by persons with brain injury. There are no off-the-record statements, attitudes, or behaviors on the part of professionals if they can be observed, detected, or implied by the persons with brain injury whom they serve. Professionals must constantly be attentive to the powerful impact of modeling.

Of course, modeling can also be a very powerful positive influence. Professionals can model appropriate behavior, emotions, and skills. Modeling can range from specific skills to more pervasive attitudes. Appropriate modeling can accelerate learning (71).

*Environmental Intervention* Environmental change strives to influence behavior by alteration of antecedent conditions. In general, how other people act toward persons with brain injury and physical elements in the environment comprise the antecedent conditions. Of the two, how other people act is probably the more crucial. In one estimate, 95% of maladaptive behaviors were felt to be a function of how professionals acted (72).

Environmental control emphasizes the establishment of environments conducive to appropriate behavior. The correct environment will vary for persons with brain injury depending upon their cognitive and emotional functioning. Ideally, professionals' attention to neuropsychological and psychosocial factors will permit the creation of a "Neuropsychosocial Environment," (48) one based on the etiological "phenomenology of dyscontrol" of each person. In "Neuropsychosocial Intervention" all of the elements that contribute to the occurrence of behaviors constitute the phenomenology of dyscontrol, including the obvious — cognition and emotions; the discoverable — self image, values, family influences, expectations, pre-morbid personality; and the subtle — noise tolerance, privacy needs, responses to others' appearance, sleep cycle effects, professionals' attitudes, etc. Once professionals comprehensively consider all of the factors that determine the occurrence of each behavior, they can

formulate the neuropsychosocial environment, a psychological and physical world, for each person that obviates the need for undesirable behaviors or interferes with their occurrence. The goal is to create a world consisting of the behaviors of others and physical plant elements that matches the capabilities of each person (48). In essence, persons with brain injury encounter only situations they can handle.

An environmental approach can address severe behaviors. However, there are two challenges: the need for careful observation and generalization (73). Systematic observational assessment is necessary to precisely determine the antecedent conditions leading to behavioral dyscontrol. Professionals must decipher the exact behavioral triggers in a complex social world for persons with impairment in cognitive and emotional functioning. Second, since the approach is not skill building, but environmental engineering, generalization can be a concern. Professionals must therefore strive for changes that are effective, transferable to additional settings, and doable by core people constituting the natural environment.

Environmental change is useful on its own or as an adjunct to other treatment. For example, it can be beneficial until skill building can take place (68). Positive behavioral supports (64, 74) designed to organize antecedent conditions combine skill building with environmental structuring. Moreover, professionals can arrange specific environments that match the abilities of persons with brain injury and then modify them as they can tolerate changes (75). Finally, professionals can use environmental control early in recovery as persons with brain injury emerge from coma (76).

In general, an environmental approach is proactive (before an episode of behavioral dyscontrol happens) in contrast to contingency management, which is reactive (after behavior occurs). Persons with brain injury encounter a positive world, one they can handle, individualized for each person. This creates a framework for success. One notable effect of an environmental approach is that treatment plans describe how professionals should act before behavioral dyscontrol occurs, not merely how they should act afterwards (74).

*Counseling and Intervention* Psychotherapy is an information exchange. Professionals convey ideas or, at least, encourage certain ideas. With new information, or enhanced awareness of previously known information, persons with brain injury, or anyone else in counseling for that matter, gain insight and skills. The usual intent is to influence emotion and behavior, although sometimes experiences during counseling sessions can be beneficial emotional events.

For many persons with brain injury the insights and skills they learn through counseling are invaluable. After all, most persons with brain injury arrive at their injury

with little or no knowledge of what to expect. They are often afraid and worried. It is very difficult to cope and adjust without knowledge, and they must do so with a brain that is impaired in its information processing skills.

There are a myriad of issues that persons with brain injury must face. These concerns begin in the acute rehabilitation center. Professionals need to be aware of how persons with brain injury perceive rehabilitation. From the professionals' perspective, rehabilitation professionals are the "good guys," there to help people who are critically injured become healthy enough to leave the hospital with the skills and knowledge to thrive. In fact, excellent rehabilitation centers seek to help persons with brain injury achieve goals that they have set for themselves to reintegrate into society.

From the perspective of persons with brain injury, there may be a very different reality. The rehabilitation center can be an unfamiliar, busy place with procedures and rules that are implicit, not explicit, or confusing. Persons with brain injury can feel uncertain in the rehabilitation center, not just because of their lack of experience with the physical space, but because of inexperience with the operational characteristics of rehabilitation: roles, schedules, regulations, procedures, and culture. Treatment environments following brain injury are alien places to most people (77). Also, professionals are strangers and therefore, at least initially, are untested sources of reassurance.

Persons with brain injury can struggle early with their sense of loss of control. Professionals must appreciate how hard it is for persons with brain injury to cope with the imposition of rules and schedules for sleep, nursing care, meals, therapies, and visits from family or friends. Even when professionals provide choices, the professionals set the parameters for the decision-making. Professionals assign the label "non-compliant" to persons with brain injury who fail to adhere to the choices that professionals permit.

Counseling can assist persons with brain injury to adapt to the rehabilitation experience. Early reassurance regarding how the rehabilitation team functions is essential. Counseling can provide rationales for professionals' decisions and place them within the context of recovery. It can also address issues of self-esteem that arise when formerly independent adults find themselves dependent on other people who make decisions about them.

Alternatively, counseling can assist persons with brain injury to learn to assert their desires in an effective manner. Professionals traditionally conduct rehabilitation with assumptions about processes, values, and goals that persons with brain injury might not share. Counseling can help bridge paradigm mismatches that would otherwise lead to conflicts between persons with brain injury and professionals. It can help persons with brain injury to delineate their perspectives with the intent of influencing

how rehabilitation professionals provide services to them and what services they want.

Counseling should continue after discontinuation of acute rehabilitation. Major life issues that professionals ought to have broached during rehabilitation typically come to the forefront of attention after hospitalization. Being confronted by the reality of a situation is emotionally different than preparatory, theoretical discussions. Issues that loom large usually include interpersonal relationships, work, driving, finances, sexuality, chemical use, supervision, and living arrangements. Some of the most important counseling happens after acute rehabilitation.

Professionals who provide counseling can face a difficult situation when persons with brain injury confront these issues. Many persons with brain injury want to assert themselves by returning to previous activities. In part, the role of professionals should be to help fulfill this desire when possible, but when persons with brain injury have limitations that require them to adapt to alterations in lifestyle or when society will not adjust to their strengths and weaknesses, it can fall upon professionals to facilitate awareness and coping. This is a complex challenge. Poor awareness is a highly complex symptom often with multiple aspects and determinants; (78–83) its treatment can be exceedingly difficult. Professionals must learn to be the voice of insight and, simultaneously, the source of support.

It is crucial that professionals build rapport with persons with brain injury before helping them confront reality. An empathetic treatment ambiance is essential when counseling persons with brain injury (84). Trust is essential to help persons with brain injury through the rapids of life. However, professionals should prepare for persons with brain injury to reach the point in time when they no longer want guidance. Many persons with brain injury want to strike out on their own, trying out their own ideas and abilities. Professionals must know when to prohibit plans and when to permit trial and error learning. Dangerous plans require professionals' prohibitions. For example, professionals should intervene when someone lacking the required skills intends to drive or return to a dangerous job, such as welding. On the other hand, even if neuropsychological and other data suggest a person may struggle with a particular endeavor, it can be a learning experience for the person to try it. If the person is resolved to make an attempt, professional resistance may lower rapport just when the person needs the most guidance. Professionals can help the person succeed to the degree possible. Still, the real world imposes consequences (e.g., being fired) with a stronger impact than the consequences that professionals can manipulate. The role of professionals in such circumstances is to be available for emotional support and to renew realistic planning. A non-judgmental approach is essential to accomplish this.

Professionals must modify counseling for the cognitive abilities of persons with brain injury (4). Professionals

have to consider the neuropsychological status of each person and adjust accordingly. There are numerous variables to weigh, including length of session (attention span), speed of speech (processing speed), sophistication of concepts or use of analogies (verbal reasoning), use of gestures (nonverbal processing), diagrams on a white board (visual-spatial ability), etc. One size does not fit all. Too often in health care for persons with brain injury, professionals pay insufficient attention to how well they are truly communicating; inadequate reflection on the actual impact of communication can destroy counseling effectiveness. Finally, it is important that there be consideration of professionals' characteristics and approach to counseling to insure a good match between professionals and persons with brain injury (55).

There are innumerable counseling approaches. It is impossible to discuss the application of all of them to brain injury. Still, many fall into one of three schools of thought: (85) cognitive-behavioral (e.g., Ellis' Rational Emotive Therapy and Beck's Cognitive Therapy), humanistic (e.g., Roger's Person Centered Therapy and Perl's Gestalt Therapy), and psychodynamic (e.g., Freud's Classical Psychoanalysis and Jung's Analytic Therapy). Very briefly, approaches from the cognitive-behavioral school focus on the facilitation of suitable, observable behavior and the alteration of thoughts that directly influence behavior; humanistic approaches emphasize self actualization, the growth of human potential, and the enhancement of the ability to experience one's feelings; professionals using psychodynamic approaches seek for people to increase control over unconsciousness influences and to understand the relationship between mental structures (85). Parenthetically, many rehabilitation professionals may be surprised at the inclusion of psychodynamic approaches. Yet, psychodynamically oriented therapists are increasingly addressing persons with brain injury (86). There are efforts to link research in brain function with psychoanalysis (87). Of course, psychoanalytical case conceptualization of emotional and behavioral functioning must recognize those issues that derive organically and not just attend to psychoanalytic formulation (88), but this is true of any psychological approach.

Professionals may choose to use approaches from any of these schools to assist persons with brain injury or they may decide to combine elements from more than one school. In the case of the more insight-oriented approaches (i.e., humanistic and psychodynamic) the premise is that insights garnered in treatment will change the perspectives of persons with brain injury. Such alterations should subsequently lead to emotional and behavioral improvement. This works best when persons with brain injury have sufficient cognitive processing ability to accomplish two aspects of this treatment. First, they should be able to formulate and express their thoughts and feelings. Second, they should be able to utilize changes in perspectives

to effect change in emotional responses and behavioral repertoire.

Threats to the former include aphasia, impaired vocabulary, verbal reasoning deficits, memory impairment, etc. Obstacles to the latter include deficits in divided attention, set shifting, memory, impulsivity, rigidity, etc. Sometimes, in fact, persons with brain injury can articulate, and believe, insightful perspectives, but organic impairment interferes with real world performance.

In contrast, cognitive-behavioral approaches seek to more directly correct actions and those thoughts that immediately attend upon behaviors. The principle is that efficacious behavioral improvement happens by a straight forward focus on requisite behavioral changes. This occurs most successfully when existential issues are less prominent, though professionals can use cognitive interventions to address existential issues. Furthermore, professionals vary in their emphasis on the cognitive versus behavioral end of the spectrum, either philosophically or on a case by case basis. In the more cognitive range, persons with brain injury often need abilities similar to those necessary to participate in insight oriented therapy. At the more behavioral tail, deficits in memory and learning can be impediments. In addition, recognition of the need to change is important, particularly for sophisticated behaviors that require complex social skills.

Skill building can be a corollary of counseling. This can entail skills that persons with brain injury develop implicitly from new insights gained in counseling or skills taught to them explicitly in counseling. Skill sets may range from cognitive compensation techniques to anger management skills to social skills (the latter will be discussed later in this chapter). In regard to cognitive rehabilitation, it behooves professionals to avoid artificial barriers between counseling and training in cognitive compensation methods. An integrated approach, using counseling combined with cognitive rehabilitation, should be part of professionals' armamentarium (89). For anger management skills, professionals should adapt the skills for the abilities of persons with brain injury (90).

## REHABILITATION PROCESS CHALLENGES

### The Importance of Early Attention to Psychological Variables

Rehabilitation is a formative time for persons with brain injury. Professionals can set the tone for the future experience of living with brain injury (91). Often, later in life, persons with brain injury still reflect on their early experiences (92–94). Sometimes there is gratitude; sometimes there is anger; sometimes there is disappointment.

Early assessment and intervention for emotional and behavioral concerns can help influence the direction of care and the perspectives of persons with brain injury.

In some settings, consultation on emotional or behavioral variables occurs only after there is a problem. In such places, prophylactic evaluation and case involvement by professionals with expertise on these issues is deemed secondary to initiation of physical, occupational, speech, and recreational therapies. This is unfortunate.

The gold standard for rehabilitation ought to be the automatic inclusion of evaluation and treatment of emotional and behavioral variables. Treatment teams should act proactively and avoid waiting for these problems to develop (46, 47). It is an error to assume that rehabilitation and accompanying adjustment on the part of persons with brain injury will proceed smoothly. Rather, professionals should function with the premise that brain injury is likely to be devastating, entailing cognitive, behavioral, and emotional traps, until the course of a case proves otherwise.

There are numerous benefits that accrue from this perspective. To begin with, professionals can detect behavioral and emotional issues as they start to initiate early intervention. For example, professionals can address depression before it becomes overwhelming or noncompliance before it is entrenched. It is easier to gently help re-conceptualize concerns as they emerge than to have to terraform the emotional and behavioral landscape.

Furthermore, guidance in how persons with brain injury conceive rehabilitation and their interactions with professionals can enhance the impact of other therapies. Professionals can facilitate motivation and effort in treatment. Willingness to perform necessary skills may otherwise be given less attention in rehabilitation than is acquisition of those skills. Knowing *how* to do something does not automatically imply *wanting* to do something, even if it is beneficial and necessary.

Finally, it is advantageous to include emotional and behavioral assessment and intervention at the start of rehabilitation so that persons with brain injury view attention to those variables as a natural part of everyone's rehabilitation. This removes the stigma of being singled out for help with emotional and behavioral responses to rehabilitation and brain injury. It also allows time to build rapport before any difficulty starts so that a relationship is in place on which to build further treatment, if necessary. In essence, evaluation and treatment of behavioral and emotional issues ought to be a standard, automatic component of rehabilitation, initiated upon admission to rehabilitation.

### Goal Setting

Rehabilitation is a collaborative effort requiring input from professionals, families, and persons with brain injury, among others. In intensive care units, the relationship of professionals to persons with brain injury is one of parent to infant, with professionals keeping the person alive.

In acute care settings, the relationship is one of parent to child, with professionals providing care and nurturance. However, in rehabilitation the relationship ought to be adult to adult, with professionals bringing knowledge and experience to a shared endeavor that includes recognition of the contribution of persons with brain injury. Fortunately, there is an increasing awareness of the importance of viewing treatment as a joint venture. For example, in the realm of behavioral treatment, the model of utilizing positive supports (74) to achieve successful behavioral functioning is based on an alliance with the person with brain injury. It takes a conceptual shift to view persons with brain injury as partners (95). Professionals' attitude toward persons with brain injury can have a large impact on treatment (46). In addition, it is essential that professionals be cognizant of cultural variables (96).

Professionals have a responsibility to avoid interpreting system problems, including societal attitudes or funding challenges, as organically imposed limits, while still facilitating awareness of organically determined limits. On one hand, it is unfair for professionals to be overly restrictive because of system issues or biases while, on the other hand, it is a failure of treatment to ignore anosognosia or unawareness, allowing pursuit of goals that really are unobtainable. Accurate feedback is good care, but being accurate (not over- or under- inclusive of limits) and compassionate (not too harsh in one's presentation) can be a challenge for professionals.

### Family Issues

Families are ordinarily unprepared to cope with brain injury. In part, there is a mismatch between their expectations for treatment outcome and the reality of recovery after brain injury. In our society, families expect the health care system to cure people after injury or at least leave them with minimal residual problems. Mass media, such as television, promulgate this expectation. Television portrays miraculous recoveries after all sorts of injuries, including brain injury. Rarely do shows demonstrate the true aftermath of brain injury. In addition, families' own experience with health care after acute illnesses fosters this expectation. When families take a child with an earache to their physician, they anticipate that the physician will cure the child, not that the child will be permanently deaf. When people break bones, they expect their physician to fix them, and they anticipate they will have little residual difficulty. However, when families experience the onset of a chronic condition in a loved one (e.g., spinal cord injury, kidney failure requiring recurrent dialysis, diabetes, AIDS, brain injury), there is no eventual cure and families do not know what to do. Persons with brain injury are not cured even when families, employees, friends, insurers, physicians, professionals, etc. all fulfill their roles and provide excellent help.

Families are unequipped for a health condition that violates all of their expectations and that requires them to adopt roles for which they had no previous training. They can feel resentment at the failure of the societal compact regarding health care. They perform their *acute* care roles (visits to the hospital, time off work, support of compliance with the treatment and medications, etc.), and yet the health care system fails them (i.e., there is no cure). Dr. Sanders' chapter on family intervention addresses family issues more thoroughly, but the impact of families' functioning is pertinent here in so far as it affects the psychological and behavioral status of persons with brain injury.

It is incumbent upon professionals to provide assistance to families if they wish to achieve successful rehabilitation. They should address the families' anger and frustration with the health care system. In addition, families may need help with their own guilt over their failure to protect their loved one from harm before onset and their powerlessness to obtain a cure afterwards (97). Professionals can help by exploring reasonable expectations for families and encouraging appropriate roles.

For example, many families attempt to be ever-present during rehabilitation, similar to their behavior during acute illnesses. This is detrimental to families because they are unable to maintain such vigilance indefinitely, despite feeling that they should be able to do so, and they burn out. Professionals can assist families to accept that involvement at a reduced level that can be maintained for years is better than total involvement early, with burn out shortly past acute rehabilitation.

Families may ignore their own needs (98). Yet, all aspects of caregivers' lives may be altered after brain injury (9). Moreover, there can be stressful changes not just for the primary caregiver, but for other relatives as well (99). While some family members may do relatively well, (100) the greatest stressors relate to behavioral, personality, and emotional changes in their loved ones after brain injury (101). Families may go through a crisis in how they relate and interact (102).

Professionals should also be alert for another scenario. Sometimes families have unresolved issues regarding the nature of behavioral care of their loved one, either during hospitalization or in the years following rehabilitation. When family members struggle with the necessity of implementing behavior plans, their needs merit attention. Their untoward reactions to behavior plans can range from disagreement accompanied by withdrawal to efforts that directly undermine behavior plans. This problem is similar to the challenge that professionals encounter with family agendas, sometimes hidden, that are at odds with professionals' other treatment efforts. For example, families may render assistance with return to work ineffective because of their own emotional needs (55) or there may be enabling issues interfering with chemical

dependency treatment. Of course, usually family members are strong allies in the implementation of behavioral treatment, and they are frequently quite insightful about how to proceed, but occasionally families need help to engage appropriately.

Despite the overwhelming nature of brain injury for families, professionals can greatly impact family perspectives after injury onset. For instance, a structured program that focuses on helping families can positively address the need families have for health information and emotional, community, and professional support (103). Obviously, families' need for help continues after acute rehabilitation. Families can benefit from ongoing support and guidance, even when professionals provide it by phone (104). Still, it can be very difficult to relieve family stress when behavioral dyscontrol persists (105).

## SELECTED APPLICATIONS

For a variety of issues in rehabilitation, emotional, behavioral, and neuropsychological assessment underlie the application of contingency, environmental, and counseling techniques, in conjunction with family intervention. The need to assess and treat some issues seems to arise repeatedly. A comprehensive review of all psychological difficulties is unfeasible here, but selected topics are worthy of mention.

### Aggression

Physical aggression may be the most distressing of all brain injury symptoms to other people. People will tolerate memory problems, depression, or the need for a wheelchair, but they will not permit physical assaults. When physical aggression occurs it commands attention.

As the severity of aggression increases, it requires an increasingly comprehensive approach. Environmental change can address the antecedents of aggression. The main variable to manipulate in a stimulus control paradigm is the behavior of professionals and other people. As already noted, their behavior often proves to be the primary antecedent for physical aggression.

Contingency techniques can be used after physical aggression, though they may prove more useful as an adjunct to antecedent control. Recall, however, the challenges in applying contingency procedures after brain injury. Moreover, when persons with brain injury direct aggression at professionals, it is particularly tempting for some professionals to be punitive. In this sense, contingency techniques can be notably difficult for professionals to positively and correctly implement.

Counseling with persons with brain injury can be essential to facilitate interpretation of antecedent and

contingency changes, the utilization of skill based techniques for anger management, cognitive restructuring of frustrating events, and preparation for future stressful events. Counseling can decrease errors and enhance error-less learning.

It is essential that professionals attend to variables that influence the expression of aggression. Treatment is less likely to be successful if two different people who apparently exhibit the same behavior receive the same treatment without an understanding of the behavioral etiology. Professionals must attend to the contribution of emotional variables leading to aggression and not just focus on the superficial behavioral symptom of aggression. Similarly, cognitive processing often plays a crucial role in the expression of aggression.

Families need particularly attentive support when there is physical aggression. Aggression may embarrass or frighten family members, especially when it is directed at the family. Professionals may need to encourage family members to consider their own safety. Alternatively, professionals may need to work with them regarding their own stimulus value and behavior as an environmental antecedent.

### **Noncompliance**

Noncompliance is a difficult problem for professionals. The obstacle to avoid is the automatic assumption that noncompliance is an intentional challenge to authority. Noncompliance can be due to a variety of factors. These include true dyscontrol (in which refusal is based on post-onset organic difficulty with acquiescence), manipulation for secondary gain, communication or memory deficits, pre-morbid oppositional personality, or attempts to reassert self-determination. It is also easy to miss the contribution to noncompliance of fatigue and poor sleep, depression, and initiation or impulsivity problems. As with all behaviors, determination of behavioral etiology is paramount for intervention.

Intervention may be multifaceted. Avoidance of power struggles is important. Education about the implications of noncompliance can be useful, particularly when unawareness is present. Sometimes negotiation can determine alternatives to achieve creative solutions. Alterations in schedules or the use of reminders, as well as other environmental changes can be successful.

Unfortunately, noncompliance can lead to paradoxical outcomes for persons with brain injury. Other people may view noncompliance as evidence for the need to restrict independence, despite its occurrence as an effort by persons with brain injury to expand their choices. They want the freedom to choose, and other people want to control poor choices. Treatment of noncompliance requires a careful balance of necessary rules and maximization of personal choice.

### **Impulsivity**

Impulsivity can be a particularly frustrating behavior for professionals and families, and, for that matter, for persons with brain injury. For professionals and families, impulsivity is difficult to address because it crosses other behaviors (e.g., social inappropriateness, risk to elope, suicidal ideation, noncompliance, hoarding, physical and verbal aggression) causing a worsening of whatever symptoms would occur anyway. For persons with brain injury, impulsivity can be embarrassing if there is sufficient self-awareness, because they act contrary to how they might otherwise behave. Oftentimes, upon post hoc guided reflection, persons with brain injury will express regret regarding impulsive behavior.

Two scenarios exist regarding impulsivity. First, persons with brain injury may act too intensely or prematurely. The resulting behavior appears as "too much, too soon." The behavior is too much of a good thing. Professionals find themselves trying to modulate behavior that would be acceptable if performed in a different setting, more slowly, or less intensely. Second, persons with brain injury may fail to stop inappropriate behavior, acts that ought not to occur at all. Professionals tend to describe these behaviors as risky or dangerous to persons with brain injury or to other people. There is a failure to inhibit impulses toward aggression, elopement, suicide, etc. Behavior in the first scenario appears as overly activated responses, and behavior in the second situation presents as uncontrolled behavior. Persons with brain injury find themselves being told to slow down in the first instance and stop in the second case. Impulsivity, therefore, may represent over activation or under control (48).

Impulsivity would appear to be a prominent component of the complaint of personality change after brain injury (106). It is likely to contribute to some of the more troublesome behaviors of aggression, sexual acting out, verbal abuse, etc. Moreover, the negative consequences associated with such behaviors tend not to alter their occurrence when impulsivity is a factor (74). As such, environmental changes, decreasing stimuli associated with impulsive responding, and skill building, when appropriate, may be more effective.

### **Depression, Grief, Catastrophic Reaction, and Post-Traumatic Stress Disorder**

Many persons with brain injury experience depression, (107) and the risk of suicide increases after brain injury (108). Depression can worsen as time passes post onset (109) and may correlate with increases in awareness or setbacks in the real world. Depression may be related to loss of self-esteem, uncertainty about the future, disruption of social supports, or particular events (e.g., loss of job). There are neuroanatomical and neurochemical factors as well, (11) and it is unclear as to whether depression after

brain injury is the same phenomena as depression without brain injury (107). Moreover, grief ought to be considered separate from depression *per se* (23). In light of experimental findings of brain activation during grief, (110) persons with brain injury may experience or demonstrate grief differently than others.

Furthermore, the typical stages of grief seen when people contemplate death may not apply well to the experience of brain injury (111). Rather, the emotional responses to brain injury may be better conceived as an identity crisis (112). However, the crisis may persist as the injury requires continual adaptation. There is an ongoing dynamic between brain injury and changing life circumstances, and it requires recurrent adjustment. This is characterized by uncertainty and has been described as a “mobile-mourning” process (113). Even after acute recovery, brain injuries do not appear static for many persons with brain injury. As they counter new life situations, unsuspected aspects of their injuries emerge to challenge them.

In addition, the people in the support system available to persons with brain injury are usually unprepared for survival of the person with alterations in cognitive, emotional, and behavioral functioning. They are unprepared to help. There is no known societal role for them to follow (114). As with persons with brain injury, family grief does not follow an orderly progression to resolution (97).

Persons with brain injury may also experience a catastrophic condition (115). They face lack of self actualization. This arises when impairment in abstract conceptual ability interferes with their accounting for performance failure on various tasks or activities. The resulting discord between impaired ability and an acceptable self-formulation of their shortcomings leads to the catastrophic condition and anxiety.

Deft handling of the catastrophic condition, or reaction, is important for successful rehabilitation. Pushing activities that highlight deficits and enhances struggles, or failures, can be contraindicated. In fact, two of the foundations of “Holistic Habit Retraining,” (69) a neurorehabilitation methodology, are errorless learning and a supportive approach, to help avoid the anxiety, frustration, despair, and resignation of the catastrophic condition that would otherwise interfere with learning.

Professionals must remain cognizant of the potential of catastrophic reactions as person with brain injury become more aware of deficits. There is the potential for catastrophic reactions as they advance from impaired self awareness to some awareness or to denial of deficit (116). Professionals may encounter accusations that they are making persons with brain injury worse during rehabilitation as awareness increases. This may be accompanied by a range of responses including withdrawal, noncompliance, resistance, anger, hostility, and aggression as persons with brain injury struggle with a mixture of perplexity and increasing despair.

Catastrophic reactions may vary in their presentation (117). In one scenario persons with brain injury may feel overwhelmed while experiencing shame, anxiety, and hopelessness. The loss of sense of self can drive frustration. Alternatively, in a second situation professionals may primarily observe passivity and withdrawal. Affect can appear flat. In a third variation persons with brain injury may respond with aggression and acting out behaviors (e.g., chemical abuse). There is likely to be hostility and resentment. In a fourth presentation there may be efforts to mask anxieties through superficial acquiescence and attempts to hide difficulties. This may prove difficult to maintain, however, since it requires persistent concealment of problems. In all instances persons with brain injury are attempting to cope with the underlying loss of integrity of the self. Finally, it should be apparent that any given person may have a combined clinical picture.

The development of post traumatic stress disorder (PTSD) is an additional factor that can complicate the care of persons with brain injury (118). There is documentation of PTSD after brain injury; (119) yet, there is debate regarding the co-occurrence of PTSD and brain injury (120) since traumatic brain injury can result in loss of consciousness and amnesia. Researchers have proposed avenues for the evolution of PTSD, however (121, 122). PTSD could arise from implicit memories occurring without conscious recall. Conditioned fear could cause PTSD in some cases. There may be later cognitive representations that lead to PTSD symptoms. Also, stressful events subsequent to immediate onset may be the basis for PTSD. Finally, neurobiological changes may contribute to PTSD.

### Social Skills

Social skills are a broad set of human interaction variables. They range from relatively narrow elements, such as eye contact or gestures, to broader factors including sensitivity to context and language-communication skills. Professionals need to address social self regulation (e.g., disinhibition, inertia), social self awareness (i.e., knowledge of one’s impact on other people), social insensitivity (i.e., understanding another person’s perspective or emotions) and social problem solving (i.e., interpersonal issue resolution) (123). Without social skill competency, brief, seemingly simple, everyday exchanges become episodes of miscommunication and sources of frustration. Worse, the lack of proficiency in social skills impairs the establishment or maintenance of ongoing supportive relationships.

It is important to recognize that social skill enhancement is challenging for a number of reasons. First, underlying cognitive deficits can impair learning new skills or remembering to apply them. Second, emotional factors, such as anger or frustration, or social pressure, such as

the desire to perform in a certain fashion to impress someone else, can distort how persons with brain injury perform skills. Third, persons with brain injury may relapse back to older, more over learned, dysfunctional skills.

Fortunately, research shows that persons with brain injury can learn skills for the social setting (124). This may involve specific skills, though there may be an increased difficulty in acquiring complex skills (125). When behavioral dyscontrol has resulted in the attainment of desirable goals in the past, then training in socially acceptable alternative methods to reach the same goal can mitigate behavioral problems (68). In the broader context of the utilization of social ability, social participation is also a function of perceived self-efficacy and determination, as well as energy level (126). Training can focus on general social competency that involves learning underlying principles for communication and social skills (127).

### Substance Abuse

Psychological considerations play a role in the treatment of substance abuse following brain injury. Professionals are likely to encounter three common patterns: social users whose use remains unchanged, but whose brain can no longer tolerate even a social level of consumption; social users whose use increases after onset, becoming abusive; and pre-onset abusers whose use remains abusive (and whose use may have contributed to their injury onset). Regardless of the amount and pattern of use, the best advice is abstinence: "zero, forever."

Still, it can be a considerable challenge for professionals to help persons with brain injury achieve abstinence. There are tremendously strong factors encouraging the use of alcohol and illicit drugs, including poor insight, denial, lack of information, peer pressure, depression, addiction, etc. Some persons with brain injury even report that the place they feel most normal is a bar, where their brain injury symptoms, including slurred speech, balance problems, memory difficulties, and social-sexual forwardness are commonplace among patrons without brain injuries. Hence, early discussion of chemical use and integration with other rehabilitation efforts helps set the stage for any future more comprehensive intervention.

Elsewhere in this book, Dr. Corrigan devotes a complete chapter to substance abuse. However, from a behavioral standpoint two concerns bear comment. The message of abstinence should be consistent across all professionals and family members. To be successful, professionals have to be attentive to issues of co-dependency (128). Moreover, professionals should be aware of any family members who may also have substance abuse problems and who will be unreliable participants in providing a united front on this issue.

Second, at times persons with brain injury may reject treatment advice. There are three typical objections: past adverse treatment experiences, claims of familiarity with chemical dependency treatment messages, or resistance to time away from community integration. Professionals must prepare to answer these concerns. Specialized programs for persons with brain injury who have substance abuse problems should differ from past treatment programs sufficiently enough so as to address the first two objections.

Persons with brain injury often experience frustration in traditional programs because of cognitive processing variables. They struggle in group treatment that fails to accommodate comprehension, language, memory, and processing speed variables. Furthermore, many persons with brain injury require help with abstinence because of their injury, not because of pre-morbid life devastation due to drugs or alcohol (e.g., alcohol use may have been at acceptable social levels prior to onset). It is important to remember that many persons with brain injury incur their injuries unrelated to any chemical use on their part (e.g., falls, sports, motor vehicle crash victims). Hence, traditional program messages regarding the need to redesign a dysfunctional life seem inappropriate to many persons with brain injury.

The integrated inclusion of a spiritual aspect in some programs can also be a difficulty. Some persons with brain injury, while accepting the need for treatment to achieve abstinence, reject faith-based messages in their brain injury recovery. This may be a function of their religious beliefs or the course of their emotional or psychological healing.

Finally, traditional follow-up support groups do not always readily welcome persons with brain injury and other participants may relate poorly to the experiences of persons with brain injury. Persons with brain injury may find that their social skill difficulties are at times misunderstood. Their cognitive problems can frustrate other group members.

Therefore, specialized programs can help after brain injury by structuring care around the cognitive needs of persons with brain injury and by tailoring their message to fit the circumstances of persons with brain injury. Also, professionals should have available materials that cover chemical use and brain injury. For example, it can be helpful to use workbooks specifically designed for chemical use after brain injury (129–131) or, if using a 12-step program, to use the 12-steps modified for persons with brain injury (132).

Professionals will find it easier to respond to the third objection (time away from community reintegration) when they link chemical health treatment to rehabilitation for brain injury. If professionals present it as a component of the overall plan of brain injury recovery, persons with brain injury may view it as more acceptable.

## SUMMARY

Issues of emotional and behavioral functioning require significant attention on the part of professionals. These concerns can influence the outcome of rehabilitation and can have a significant impact on persons with brain injuries and their families. Yet, there are forces ranging from insurers' perspectives to the inherent complexities in addressing psychological variables that impede treatment. Professionals will most benefit the people they serve when they are diligent about providing care for psychological needs.

Professionals should base intervention on solid assessment. This ought to include clinical observation, interview, and psychometric assessment of cognitive, behavioral, and emotional functioning. There is an array of possible intervention strategies. Treatment techniques include contingencies, environmental manipulation, counseling and skill building. Professionals should be aware of the advantages of starting care early after onset, the needs of families, and the nature of goal setting after brain injury. In fact, throughout behavioral care, during every type of evaluation and treatment for all emotional and behavioral problems, professionals must keep in the forefront of their decision making the unique nature of brain injury and its interaction with psychological functioning.

## ACKNOWLEDGMENT

Grateful acknowledgment is due Marti Beltz, Ann Reese, and Lindsey Schafer for their assistance with library research and manuscript preparation.

## Neuropsychiatric Aspects of TBI

*Thomas W. McAllister*

### INTRODUCTION

To the casual observer deficits in speech and language function or ambulation may be the most readily apparent changes after a traumatic brain injury (TBI). However it is often changes in personality and behavior that cause the most distress to survivors and their family/caregivers. Such alterations in the core sense of who the individual is, or who their loved ones believe them to be, can be devastating. Frequently these issues are the rate-limiting step in various rehabilitation settings, interfere with return to work and the ability to achieve the maximum quality of life within the least restrictive environment (1–6). The cost to the nation in care expenditures, lost productivity and family disruption is staggering (7).

Some individuals with mild traumatic brain injury and virtually all individuals who survive moderate and severe TBI are left with significant long-term neurobehavioral sequelae (8–10). The reduction in TBI-associated mortality rates over the last several decades (11) has led to a significant increase in the number of individuals with long-term neurobehavioral disorders related to TBI (5, 12). In addition to the agitation, aggression, and confusion often seen in the acute recovery period, TBI is associated with an increase in the relative risk of developing many psychiatric disorders including mood disorders, psychotic disorders, anxiety disorders, obsessive-compulsive disorder

and others (13–16). TBI may well be a critical risk factor in the development of schizophrenia in those with a genetic vulnerability to this illness (17).

Even apart from formal psychiatric disorders, behavioral challenges abound. Syndromes such as apathy, disorders of impulse control and affect, though perhaps not meeting formal criteria for specific psychiatric disorders are a source of excess disability. Environmental and psychosocial factors play key roles in the genesis and maintenance of these neurobehavioral problems, but so does the profile of regional brain injury.

The overarching theme of this chapter is that the assessment and treatment of the neurobehavioral sequelae of TBI follow logically from an understanding of the typical profile of traumatic injury. Thus the relationship of the neuropathophysiology of TBI to the neurobehavioral sequelae commonly encountered by individuals with TBI is outlined. An approach to the evaluation and treatment of these sequelae is suggested.

### RELATIONSHIP OF PROFILE OF INJURY TO NEUROBEHAVIORAL SEQUELAE

Our knowledge of the neuropathophysiology of TBI has increased dramatically over the last decade (18). Advances in molecular biology, molecular genetics, neuroimaging,

neuropsychology, and other neurodiagnostic techniques make possible a much finer resolution of brain injury profile associated with specific neuropsychiatric sequelae. The neuropathophysiology of TBI is more thoroughly discussed in chapters 6–8 (18). It is important to highlight some features of the neuropathology of TBI in that they help to explain the special vulnerability to neurobehavioral challenges seen in TBI survivors.

In brief, most injuries result from the brain coming into contact with an object (which might include the skull, or some external object) or from rapid acceleration or deceleration of the brain. Contact mechanisms often result in damage to scalp, skull, and brain surface (e.g., contusions, lacerations, intracerebral hematomas) (18). Acceleration/deceleration mechanisms are associated with shear, tensile, and compression forces that have maximum impact on axons and blood vessels resulting in axonal injury, tissue tears, and intracerebral hematomas. Injury from both mechanisms occurs immediately (referred to as primary injury) and may also evolve over time due to a variety of factors including massive release of neurotransmitters with subsequent triggering of excitotoxic injury cascades, and other injury-related factors such as hypoxia, edema, and elevated intracranial pressure (referred to as secondary injury).

With respect to brain tissue, contact mechanisms tend to produce focal injuries such as surface contusions and lacerations. In addition, rapid acceleration or deceleration results in differential motion of the partially tethered brain within the skull. Surface contusions can thus be seen where the swirling motion of the brain comes into contact with bony protuberances on the interior of the skull. Frequent sites of such injury are the anterior temporal poles, the lateral and inferior temporal cortices, the frontal poles, and the orbital frontal cortices. Acceleration and deceleration mechanisms also produce more widespread or diffuse injury (“diffuse axonal injury”) to white matter. Particular areas of vulnerability include the corpus callosum, the rostral brainstem, and sub-frontal white matter (18).

Secondary injury appears to occur at least in part from mechanical distortion of the neurons resulting in massive release of neurotransmitters. Although this probably occurs throughout the brain, the excitotoxic cascades and other forms of secondary injury such as hypoxia/ischemia have a disproportionate effect on certain brain regions such as the hippocampus, even in the context of an otherwise fairly mild injury (19).

Thus the typical profile of injury involves a combination of primary injury (occurs at time of application of force) and secondary injury (evolves over time subsequent to the primary injury) as well as a combination of focal and diffuse injury. Furthermore, although the damage may be diffuse or multi-focal, there are certain

**FIGURE 45-1**

Results of voxel-based morphometry demonstrating areas of reduced gray and white matter density in individuals with TBI compared to controls. Red areas show frontal and temporal abnormalities. Used with permission

brain regions which are highly vulnerable to injury and account for the high rate of challenging behaviors and the increased rates of psychiatric illness that are associated with TBI. These include the frontal cortex and sub-frontal white matter, the deeper midline structures including the basal ganglia, the rostral brainstem, and the temporal lobes including the hippocampi (see figure 45-1).

### RELATIONSHIP OF TBI INDUCED NEUROTRANSMITTER CHANGE TO NEUROBEHAVIORAL SEQUELAE

In addition to the profile of regional brain injury described above there is evidence that neurotransmitters with important roles in modulating common neurobehavioral sequelae of TBI (such as regulation of mood, anxiety, motivation, impulse control, and aggression) are altered in TBI. This evidence is briefly summarized to set the stage for rational psychopharmacological interventions for these sequelae.

**Catecholaminergic System Changes** There is significant evidence for dysfunction of catecholaminergic systems associated with TBI (20–22). This is important because the catecholamines (epinephrine, norepinephrine, dopamine)

play critical roles in a variety of domains important in behavioral homeostasis. Animal studies and observations from the use of catecholamine agonists in clinical practice suggest that epinephrine and norepinephrine play important roles in arousal, cognition, reward behavior, and mood regulation (23–25). Deficits in central adrenergic tone and thus associated with deficits in arousal, attention, memory, motivated behavior (apathy), and mood regulation. Dopaminergic tone and proper dopamine signaling are particularly important in the modulation of motivated behavior, attention, and working memory (see (22, 26, 27) for reviews).

As noted there is evidence of disruption of catecholaminergic homeostasis after injury. TBI results in activation of the sympathoadrenomedullary axis with subsequent alterations in hemodynamic parameters and cardiopulmonary function. Plasma norepinephrine (NE) levels are elevated after TBI and this elevation correlates with injury severity indicators (28). Circulating levels of dopamine, norepinephrine, and epinephrine may be markers of injury severity and likelihood of recovery (20, 21). Animal models of TBI have also shown a relationship between injury severity, increasing circulating levels of epinephrine and norepinephrine, and secondary complications such as cardiac arrhythmias (29). Transient hypoxia, common in more severe injuries, can result in dramatic releases of hippocampal norepinephrine (30).

Animal studies suggest that alterations in dopamine, norepinephrine, and epinephrine levels can be prolonged after TBI, associated with alterations in catecholaminergic receptors in damaged cortical areas, and can impair catecholaminergic function after trauma (29, 31). Administration of certain catecholaminergic agents may enhance recovery from brain injury (32–34), even after one-time doses (32, 35–37). Conversely, catecholaminergic *antagonists* can slow rate of recovery from certain types of brain injury (38). Some agents that augment catecholaminergic tone reduce the cognitive effects of TBI in animal models. For example Zhu et al. (39) administered L-deprenyl, a selective and irreversible MAO-B inhibitor to rats subjected to combined fluid percussion TBI and entorhinal cortical lesions and found significantly reduced cognitive impairment (Morris water maze performance) compared to the rats treated with vehicle only. There is good evidence that in individuals with TBI, methylphenidate, which augments both the dopaminergic and adrenergic systems, is effective in ameliorating certain cognitive deficits (40). Another study (41) showed significant improvement in executive function tasks with bromocriptine, a dopamine agonist.

*Cholinergic System Changes* Central cholinergic tone is critical to the modulation of most cognitive and behavioral domains, appearing to facilitate signal to noise ratios. It is of particular importance however with respect to attention and memory (Perry and Perry 2004).

Alterations in central cholinergic tone may also play a role in the genesis of mood disorders, particularly depression (see (42)). Cerebral cholinergic neurons and their ascending projections are vulnerable to trauma (43). Acutely, cholinergic neurons release large amounts of acetylcholine. Subsequently there is evidence for long-term reductions in cerebral acetylcholine levels (44). Sudden release of acetylcholine at the time of injury may contribute to the extent of injury through facilitation of excitotoxic cascades. Cholinergic antagonists can be neuroprotective in models of TBI (see (43) for review). Several studies have shown damage to the nucleus basalis of Meynert, as well as reduced levels of choline acetyl transferase (a marker of cholinergic afferents) in brain regions vulnerable to trauma including temporal cortex, cingulate and posterior parietal regions in humans who died within several weeks of injury (43, 45–47). Post-synaptic muscarinic and nicotinic receptors remained intact (45–47), suggesting cholinergic agonists as a potential point of intervention for cognitive deficits (43).

*Serotonergic System Changes* Central serotonergic tone is important in the modulation of normal mood states and aggression. Medications that increase serotonergic function are effective antidepressants and anxiolytics, and can reduce the frequency and intensity of aggressive behavior. As with the catecholaminergic and cholinergic systems, the serotonergic system is activated in TBI with increased levels of serotonin evident in areas of significant tissue damage, and in association with lowered regional cerebral glucose utilization (18, 48–50).

*Summary* Several cortical regions including frontal cortex, temporal cortex, and hippocampus are particularly vulnerable to TBI. Furthermore sub-cortical white matter, particularly in frontal regions and the corpus callosum, are often damaged. In addition catecholaminergic, cholinergic, and serotonergic systems are vulnerable to disruption acutely and chronically in TBI. This profile of structural and neurochemical injury plays a direct role in the common neurobehavioral sequelae associated with TBI.

## CHANGES IN PERSONALITY

Survivors and family/caregivers frequently describe the effects of the injury as “changes in personality”. Lifelong patterns of responding to external cues, situations in the environment, and internal drives or motivations, can be significantly altered. This takes two different forms: exaggeration of pre-injury traits, or fundamental changes in response patterns. Within the latter category, careful inspection usually reveals that this can be further parsed into alterations in the frequency or intensity of predictable responses to environmental cues or stimuli, or unpredictable response patterns. Several common clusters of symptoms that characterize the “personality changes” are recognizable.

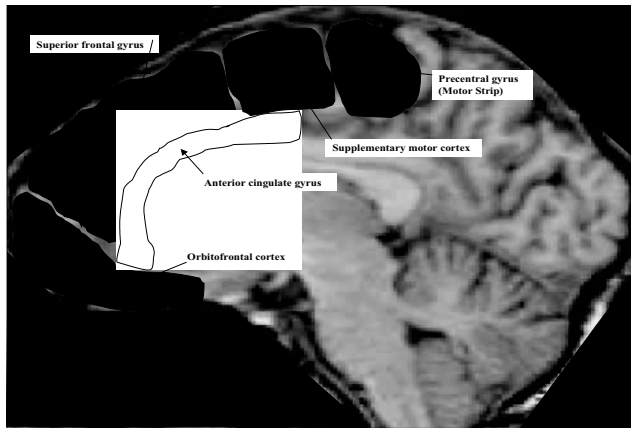

FIGURE 45-2

Mid-sagittal view of the brain showing prominent regions associated with executive functions. From McDonald et al. *Executive dysfunction following traumatic brain injury: Neural substrates and treatment strategies NeuroRehabilitation* 17 (2002) 333–344. Used with permission

**Dysexecutive Syndromes** Motivated behavior can be thought of as sets of behavioral responses that are more likely to occur than can be accounted for by chance alone. There are generally three components to motivated behaviors including initiation, procurement, and self-monitoring. These components, along with decision making, and mental flexibility are often referred to as executive functions. In fact much of the altered and distressing changes in behavior or personality after TBI can be subsumed under the rubric of impaired executive function (or “dysexecutive syndromes”) (see (51) for review).

Three broad (and somewhat overlapping) domains comprise executive functions:

- (i) *higher order cognitive function* (including mental flexibility, problem solving, set-shifting),
- (ii) *social comportment* (including context specific awareness of one’s behavior relative to past individual and societal norms, self-monitoring and self-correction), and
- (iii) *motivated/ reward-related behavior* (including initiation, sequencing, achieving/consuming).

As noted, these are not fully distinct domains but rather are more interactive and overlapping. This complex relationship is mirrored clinically in the observation that one can see individuals with prominent deficits in one, two, or all three domains to varying degrees. From the clinical standpoint, the prominent challenging behaviors brought to the clinician’s attention flow from these domains and can be usefully grouped into the following categories:

(i) Cognitive Syndromes

Cognitive deficits after TBI are covered in greater detail in Chapter 44. It is worth highlighting that initial and

FIGURE 45-3

Activation of working memory regions as shown with functional MRI. The above image shows the mean group image of 40 participants performing a WM task (3-back). Note extensive yet selective bifrontal, biparietal, and cerebellar activation associated with the task

persistent cognitive deficits are the most common complaints after traumatic brain injury (TBI) (52, 53) and the major hindrance to normalization in the areas of independent living, social re-adaptation, family life, and vocational endeavors (54, 55). There are several predictable areas of impairment including short-term memory, speed of information processing, and attention (56–66). Obviously these are not completely independent domains, and in fact the typical profile of attention and memory deficits could be reasonably subsumed under the construct of working memory (WM), the ability to hold information in mind and manipulate that information in light of incoming information. Much progress has been made defining the circuitry and neurochemistry of WM (see McAllister et al. 2004 for review; (26, 67–69) and suggests that (1) the parietal cortices (70–73), (2) the frontal speech areas such as Broca’s area (inferior frontal gyrus) and the supplemental motor areas, and (3) the prefrontal area (74, 75) play major roles in WM function. The conceptualization of WM as a core deficit in TBI may have particular significance in that the brain regions implicated in WM circuitry are the same regions that are vulnerable to injury in the typical TBI.

(ii) Social Comportment

**Impulsivity** One of the more common concerns of patients and family/caregivers alike is that survivors have difficulty with impulse control. This can be manifested in verbal utterances, physical actions, snap decisions, and poor judgment flowing from the failure to fully consider the implications of a given action. This is closely related to the concept of stimulus boundedness in which the individual responds to the most salient cue in the environment or attaches exaggerated salience to a particular cue

without regard to previously determined foci of attention or priorities.

*Irritability* Another very common concern of patients and family/caregivers pertains to the modulation of anger. Survivors describe themselves as more irritable or more easily angered. Although a particular cue might be perceived as a legitimate aggravation of some sort, the response is characteristically out of proportion to the precipitating stimulus. Responses can range from verbal outbursts to dangerous aggressive and assaultive behavior. This modulatory deficit differs in intensity, onset, and duration from the pre-injury pattern for any given individual.

*Affective Instability* Survivors and family/caregivers frequently describe a change in affective stability characterized by exaggerated displays of emotional expression which seem out of proportion to both the precipitating stimulus and the injured individual's previous range of response to similar stimuli. Cues or events that previously might have elicited momentary sadness may now precipitate weeping or crying. Events which in the past might have provoked a frown or reply laced with irritation now result in loud angry verbal outbursts associated with marked sympathetic arousal. The hallmarks of this instability typically include a paroxysmal onset, brief duration, and an exaggerated intensity of response out of proportion to the precipitating stimulus. This phenomenon is common to a variety of disorders affecting the CNS and has been given a variety of terms including pathological affect, affective lability, pseudobulbar affect, and affective incontinence (see (76) for review).

*Awareness Deficits* The burden of the above changes in personality and behavior is often complicated by a surprising and at times devastating lack of awareness of these changes (see (77, 78) for reviews). The injured individual may be unable to appreciate that their behavior is different since the injury, in stark contrast to family/caregivers and providers who may be painfully aware that the injured individual has changed in fundamental ways and can often provide detailed lists of these changes.

Alternatively an individual with TBI may have a vague sense that he or she is different or "not who I used to be" and yet struggle to define the specific ways in which their behavior or personality differs from prior to the injury. Awareness is not a unitary concept (79) and thus it is important to characterize the nature and extent to which an individual suffers from this problem. Of particular interest to this discussion is that individuals with TBI are less likely to be aware of changes in behavior and executive function than changes in more concrete domains such as motor function (e.g., (80)). Furthermore the degree of awareness has been found to correlate with functional and vocational outcome in many (81–84) though not all studies (85).

As is the case with disorders of affective stability, problems with awareness of deficits are not unique to individuals with TBI but rather occur in a broad range of disorders of the CNS including severe and persistent mental disorders such as schizophrenia (78). The literature suggests that lack of awareness of illness is not simply a function of global cognitive deficits but perhaps is more related to frontal-executive dysfunction (86–88, 89–92). Studies of the neuroanatomical correlates of illness awareness deficits in these disorders, and in overlapping syndromes such as anosagnosia suggest that injury to certain brain regions carries a heightened vulnerability to awareness deficits (78). Stuss (93, 94) suggests that frontal systems generate self-awareness, self-reflectiveness, and self-monitoring. Other work has suggested that lack of awareness in schizophrenia is associated with selective structural brain changes, including smaller brain size and selective atrophy of certain subregions of the frontal lobes (77, 95). Furthermore, using a self-reflective task while undergoing functional MRI, Flashman et al. have been able to show very high correlations of degree of unawareness with frontal activation in individuals with schizophrenia (78). Because frontal systems also play a critical role in the modulation of key social skills and behaviors (e.g., initiation, motivation, problem solving, and affective modulation), frontal lobe damage can affect the ability to understand the impact that deficits have on day-to-day function and how to apply that knowledge to a current situation. In individuals with TBI, this dimension is frequently the focus of family/caregiver concern yet is often not recognized by individuals with TBI (5, 96–100). Even when the individual admits to some difficulties, he or she is often unable to predict the implications of these deficits in current or future social situations.

### (iii) Disorders of Motivation

*Apathy* The underlying deficit associated with apathy is in the realm of motivated behavior (101). Although not as overtly disturbing or alarming as some of the other changes in personality described above, it can be disturbing to family/caregivers, and is frequently the reason that injured individuals fail to progress in rehabilitation programs. Furthermore it is often misinterpreted as either laziness or depression and may be somewhat paradoxically linked to aggression when for example attempts to engage the individual in activities in which they have little interest can precipitate assaultive behavior (25).

Apathy is quite common after TBI. Kant et al. (102) found that apathy (mixed with depression) occurred in 60% of their sample of individuals with TBI. Andersson et al. (103) found that almost half of their sample of individuals with TBI had significant degrees of apathy. Deficits in motivated behavior can occur in association with injury to the circuitry of "reward" which includes behavior specific (thirst, sex, hunger) hypothalamic

centers (25, 104), and a more general reward system linking the forebrain to the midbrain. Key nodal points in this circuitry include the amygdala, hippocampus, caudate, entorhinal and cingulate cortices, the ventral tegmental area and the medial forebrain bundle. Catecholaminergic systems, particularly the mesolimbic dopaminergic system appear to play critical roles in the modulation of the reward system (see (25, 104) for reviews).

### RELATIONSHIP OF PROFILE OF INJURY TO PERSONALITY CHANGES

A full discussion of the neuroanatomical substrates of the above behaviors is beyond the scope of this chapter. However the link between the injury profile in a typical TBI and some of these behaviors is fairly simply understood.

Five major frontal-subcortical circuits have been identified, one orchestrating primarily motor function, one primarily oculomotor function, and three that have significant roles in non-motor forms of behavior (see (105, 106) for reviews). Each of the latter three circuits can affect motivated behavior, though in somewhat different ways. Each circuit is named for its site of origin in the frontal cortex (e.g. the dorsolateral frontal-subcortical circuit, the orbitofrontal-subcortical circuit, and the anterior cingulate-subcortical circuit) (see Figure 45-4). Each circuit follows a similar path starting from the site of origin in the frontal cortex projecting to the striatum, from there to the globus pallidus, then to the thalamus and back to the frontal cortex. Each circuit is thought to be a more or less closed loop with some additional input

from other functionally related brain regions. The circuits differ from each other with respect to exact pathways through the key nodal points. Thus for example the dorsolateral frontal circuit projects to the dorsal caudate, the orbitofrontal circuit to the ventral caudate, and the anterior cingulate to the medial striatum/nucleus accumbens respectively. Similar topographic differences can be traced through the globus pallidus and the thalamus as well.

Examination of the brain regions vulnerable to injury in the typical TBI and the neuroanatomical substrate of core cognitive and behavioral domains (executive functions, social comportment, motivation) suggests why these areas are so often a source of distress to survivors and their family/caregivers after TBI. The frontal-subcortical circuits responsible for these critical domains of higher intellectual function and empathic, motivated, nuanced human behavior are highly vulnerable to injury in the typical TBI. Damage to the dorsolateral prefrontal cortex and its circuitry impairs executive functions such as working memory, decision making, problem solving and mental flexibility.

Damage to the orbitofrontal cortex and related nodal points impairs intuitive, reflexive, social behaviors and the capacity to self-monitor and self-correct in real time within a social context.

Damage to anterior cingulate and related circuitry impairs motivated and reward-related behaviors. Injury to medial temporal regions further impairs other aspects of memory and the smooth integration of emotional memory with current experience and real-time assessment of stimulus salience. In short the profile of injury vulnerability predicts the neuropsychiatric sequelae of injury (see Figure 45-5).

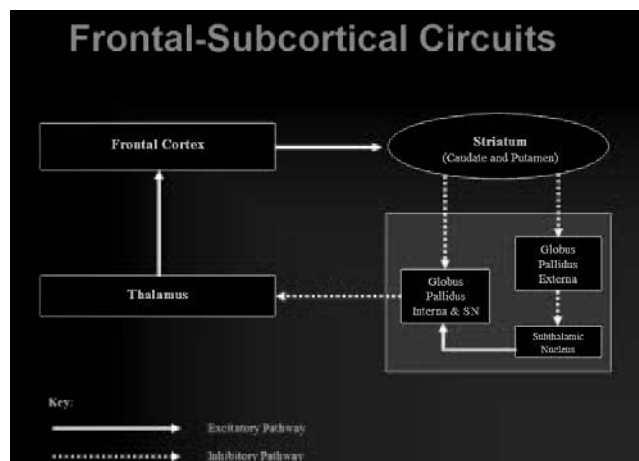

FIGURE 45-4

Outline of key nodal points in the five major frontal-subcortical circuits. Adapted from Arciniegas D, Beresford T. *Principles of Neuropsychiatry: An Introductory Approach*, Cambridge University, 2001. Cambridge, UK. p. 62. Used with permission

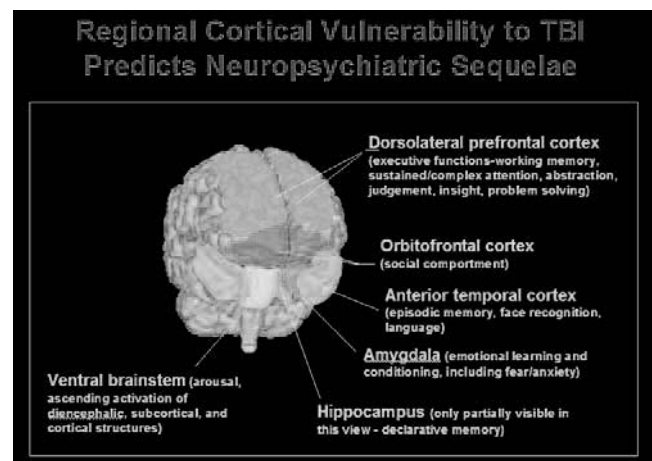

FIGURE 45-5

Relationship of brain regions vulnerable in typical TBI to predictable neurobehavioral sequelae. Adapted from Arciniegas D, Beresford T. *Principles of Neuropsychiatry: An Introductory Approach*, Cambridge University, 2001. Cambridge, UK. p. 370. Used with permission

This principle then should be the foundation on which a good neuropsychiatric evaluation is based. The process of elucidating the profile of injury, the profile of current signs and symptoms, and mapping the latter onto the former to assess goodness of fit is the work of the neuropsychiatric evaluation. Signs and symptoms which are not accounted for by the profile of injury must be explained on another basis or the profile of injury should be re-assessed. The clinical picture should make sense in the context of the brain damage.

### RELATIONSHIP OF TBI TO PSYCHIATRIC DISORDERS

In addition to the changes in cognition, behavior, and personality described above, a significant body of evidence suggests that TBI results in an increased relative risk of developing psychiatric disorders including mood and anxiety disorders, and psychotic syndromes (13, 15, 16, 107) (see Table 45-1). For example Koponen et al. (16) studied 60 individuals 30 years after their TBI and found that almost half (48%) developed a new Axis I psychiatric disorder after their injury. The most common diagnoses were depression, substance abuse, and anxiety disorders. Rates of lifetime and current depression (26%, 10%), panic disorder (8%, 6%), and psychotic disorders (8%, 8%), were significantly higher than base rates found in the Epidemiologic Catchment Area (ECA) study (108).

Hibbard et al. (15) studied 100 adults on average, 8 years after TBI. A significant number of individuals had Axis I disorders prior to injury. After TBI, the most frequent Axis I diagnoses were major depression and anxiety disorders (ie, PTSD, OCD, and panic disorder).

Almost half (44%) of individuals had two or more disorders. More recently (109) this group reported a longitudinal study of 188 individuals enrolled within four years of injury and assessed at yearly intervals on at least two occasions. Once again they found elevated rates of psychiatric disorders prior to injury. Subsequent to TBI, there were increased rates of depression, PTSD, and other anxiety disorders. This was particularly true of those with pre-injury psychiatric disorders. Furthermore, the rates were greatest at the initial assessment point after injury and stabilized or decreased over time (see Table 45-2). Van Reekum et al. (13) carefully reviewed the literature on the relationship of TBI to a variety of psychiatric disorders and using the ECA data for baseline rates concluded that TBI was associated with an increase in the relative risk for several psychiatric disorders (see Table 45-1).

Fann et al. (110) recently published findings on a cohort study of the medical records of about 1,000 HMO members who sustained a TBI classified as either mild (LOC <1hr) or moderate to severe, and followed for three years. Compared to non-injured controls, the individuals with TBI had increased indicators of psychiatric illness, especially in the first year after injury, and there was some evidence of a biologic gradient (49% in the moderate-severe group, 34% in the mild group, 18% in the non-injured comparison group). In injured individuals without history of psychiatric illness the Odds Ratio of developing psychiatric illness in the first 6 months was 4.0 in the moderate-severe group. Wei et al. (111) in a study of Medicaid beneficiaries in four states found that 18% of ~3,600 individuals diagnosed with TBI suffered severe mental illness, and another 16.5% had other mental disorders. Those with mental illness had significantly higher expenditures.

\*Bourdon et al.

†Includes major depression, depression not otherwise specified, and dysthymia.

‡Includes alcohol abuse, alcohol dependence, drug abuse, and drug dependence.

§Includes obsessive-compulsive disorders (OCD), panic, phobias, and generalized anxiety disorder (GAD).

¶Excludes depression disorders, substance abuse and dependency, PTSD, OCD, panic, phobias, and GAD.

### Diagnostic and Labeling Issues

It is important to address several issues with respect to the above studies and the question of psychiatric disorders in general after TBI.

*Symptoms vs. Disorder* As with any potentially disabling condition, individuals with TBI report a variety of symptoms in a variety of domains (discouragement, frustration, fatigue, anxiety etc). Not all of these symptoms will rise to the level of a disorder. However symptoms that are consistent and sustained over time (usually weeks), and that are of sufficient severity to interfere with social or occupational function or quality of life, are legitimately considered disorders. In the studies cited above, standardized criteria encompassing those principles were used and thus argue strongly that TBI acts as a gateway to the development of many psychiatric disorders. The consistent observation that individuals who sustain a TBI have higher base rates of psychopathology prior to injury suggests that there is a reciprocal interaction: psychopathology predisposes to TBI, and TBI in turn predisposes the individual to develop psychiatric disorders.

*Labeling Issues* Many individuals resist the idea that they have an illness. This is not unique to individuals with TBI, but rather reflects a general dislike of being labeled as having a disease. There is an even greater resistance to seeing oneself as having a psychiatric illness. Again this is equally true of injured and non-injured populations. However effective treatment can follow appropriate diagnosis. To avoid a diagnosis because of a societal or individual resistance to it is not in the interest of the individual suffering with the symptoms.

*Use of Diagnostic and Statistical Manual of Mental Disorders (DSM) Nomenclature* As with most diagnostic schemes the DSM approach has strengths and weaknesses. Its reliance on standardized phenomenological criteria has been helpful, particularly when sorting

out idiopathic psychiatric disorders. It is less helpful when approaching diagnosis in neuropsychiatric populations, including those with TBI. There are several reasons for this. In the DSM, psychiatric disorders in the context of neurological illness can be coded as “diagnosis” x “secondary to a general medical condition”. The use of the modifier “secondary to a general medical condition” implies that it is possible to accurately assess causality when for example a depressive syndrome follows a TBI by some time interval. Although this may be true, (and probably often is the case), proof is lacking and thus such a label reflects the impression or bias of the clinician.

The terms used to describe the changes in behavior and personality flowing out of damage to the various frontal-subcortical circuits described above are “personality change secondary to . . .”. Although this represents a significant improvement over “organic personality disorder” (DSM III), it does not do justice to the subtle and nuanced alterations present after a brain injury.

Perhaps most importantly the current schema does not recognize or allow for the alteration of syndromic presentations by brain injury. The question of how to diagnose depression in a non-verbal individual for example is not addressed in the DSM. The idea that depression can be expressed in other ways is not reflected directly in the menu of symptom options. For example so called “depressive equivalents” must be inferred by creative clinicians. Thus the diagnostic schema requires further refinement that hopefully will be reflected in future editions of the DSM. Despite these limitations it is helpful to review what is known about the association of TBI and certain psychiatric disorders.

### MOOD DISORDERS

*Depression* Depression after brain injury is common, with estimates that 25–60% of individuals with TBI

experience a depressive episode (DSM-IV criteria) within 8 years of injury (15, 112). These rates do not take into account individuals who have depressive symptoms but who fail to meet DSM-IV diagnostic criteria. It is also important to note that depression is associated with poorer cognitive, social, and functional outcome (112, 113) and can act as an amplifier of other neurobehavioral challenges including anxiety and aggression (7, 15, 112). The increased rate of depression and associated symptoms in TBI compared to other injuries suggests that CNS trauma and/or factors in plasticity/repair may play a role in the genesis of mood disorders.

*Neural Circuitry of Depression* Over the last decade substantial progress has been made in outlining the brain regions and related circuitry of mood regulation (see (114–116)), and not surprisingly they overlap with the areas vulnerable to the typical TBI. A thorough review of this topic is well beyond the scope of this chapter but several points are worth noting. Much of the insights come from functional imaging studies (see Refs. 114, 117 for thorough discussion) that have indicated metabolic abnormalities in dorsolateral prefrontal cortex (DLPFC) and anterior cingulate (reduced activity), and ventrolateral prefrontal cortex (increased activity) associated with depression. Although there is some variability of findings, other regions including temporal lobe and basal ganglia have also been found to have reduced activity (114).

A second group of studies has explored induced changes in mood state in depressed patients before and after manipulations such as sleep deprivation and tryptophan depletion, or before and after induced sadness in healthy individuals. The weight of evidence from these studies suggests that interventions leading to a less depressed state are associated with increased activity in DLPFC and anterior cingulate, and decreased activity in ventrolateral prefrontal cortex – largely consistent with the resting baseline studies (see (114)). Taken together this evidence suggests that the two frontal-striatal-thalamocortical circuits originating in orbitofrontal and dorsolateral prefrontal cortex function abnormally in depression. It may be that the orbitofrontal circuit with its limbic connections is the substrate of disordered emotional processing and vegetative symptoms common in depression, whereas dysfunction in the dorsolateral circuit may result in the cognitive deficits associated with depression (114, 116, 117).

*Neurochemistry of Depression* Several neurotransmitter systems play key roles in normal mood regulation and depression. Evidence of monoamine dysfunction in depression comes from the putative mechanisms of action of antidepressant compounds, most of which increase release, block re-uptake, or interfere with metabolism of norepinephrine, serotonin, or dopamine (see (118) for recent review). Interventions that reduce central monoaminergic tone (for example the

medication reserpine) are associated with an increased rate of depression. However, it is clear that a simple “imbalance of monoamines” explanation is inadequate. Several drugs (e.g., CNS stimulants) increase release of monoamines but are poor antidepressants. The effects of antidepressant compounds on monoamine transmitters can be demonstrated within hours, yet the mood altering effects take several weeks and not all depressed individuals respond equally to the same antidepressant. Thus, much remains to be learned.

An alternative theory of the genesis of depression posits that there is an imbalance of cholinergic and adrenergic tone with a relative cholinergic hyperactivity (see (42)). There are several reasons to postulate a role for cholinergic systems in mood regulation. Relative to healthy controls, depressed patients have a variety of exaggerated physiological responses to cholinergic agonists. The cholinergic agonists arecholine and physostigmine induce dysphoria in normals and can worsen depressive symptoms in individuals with mood disorders (42). The majority of antidepressants, including the tricyclics and SSRIs, have anticholinergic properties. Recent magnetic resonance spectroscopy (MRS) studies suggest that there may be elevated levels of the acetylcholine precursor choline in orbitofrontal cortex and other brain regions of individuals with depression (119, 120). The nicotinic receptor blocker mecamylamine has also recently been shown to have some antidepressant properties (42, 121).

It is important to note that antidepressants can effect neural response to injury and repair. For example several recent reports have suggested that antidepressants may have neurotrophic effects including facilitating regeneration of catecholamine terminals in cortical and hippocampal regions (42, 122, 123).

*Treatment* With respect to treatment of depression after TBI, there is a lack of good data. A brief selective review of this literature is provided (see Silver and Arciniegas, Chapter 55 for detailed review). Several papers address the use of tricyclic antidepressants although this is a relatively old literature and the results are somewhat conflicting. Wroblewski and colleagues (124) reported a small randomized, placebo-controlled prospective study, in which 10 individuals with severe TBI and depression were given placebo and desipramine in a crossover fashion. Desipramine was found to be more effective than placebo. Dinan and Mobayed (125) in a cohort study of 13 patients with mild TBI matched with 13 depressed patients without brain injury found amitriptyline to be less effective in the TBI group. Saran (126) using amitriptyline in an open label design found less reduction in depression scores in a mild TBI group than a non-injured group. Significant methodological issues limit the strength of the evidence from all three of the above studies.

A large number of case series and case reports address the treatment of depression after TBI with a variety of

other agents. However methodological problems such as the use of mixed populations (e.g. stroke, penetrating brain injury, TBI, epilepsy) (127, 128), absence of clear diagnostic criteria (127, 129–131), absence of validated outcome measures (129, 130, 131–133), or the use of more than one intervention at a time, limit the conclusions that can be drawn from many of these reports.

Several similar reports have addressed the use of selective serotonin re-uptake inhibitors in this population, but again basic methodological flaws, and small numbers make it difficult to draw conclusions from these papers.

Overall several important points can be made with respect to depression after TBI. The brain regions and circuitry implicated in the genesis of depression overlap to a great extent with those regions at greatest risk for damage in the typical TBI. Furthermore, the major neurotransmitter systems felt to play key modulatory roles in the regulation of mood and affect are the same as those known to be altered by TBI (ie adrenergic, dopaminergic, cholinergic, and serotonergic systems). When one considers the additional roles of stress, loss, social isolation, and other common psychosocial insults common in TBI, it is surprising that the frequency of depression following TBI is not higher.

### MANIC SYNDROMES

Mania is characterized by episodes of sustained (longer than one week) changes in mood (euphoria or irritability) and increased psychomotor activity. It may be associated with increased energy, decreased need for sleep, and a penchant for dangerous behavior (reckless activities, increased spending, increased sexual activity). Some manic episodes can be accompanied by psychotic symptoms such as grandiose delusions or thought process disturbances such as loosened associations or flight of ideas. Mania is a well-described complication of many disorders of the CNS including TBI (134, 135). Robinson et al. (134) found 6 of 66 (9%) carefully characterized TBI patients developed manic episodes. In these patients mania was not associated with severity of injury, post-traumatic epilepsy, family or past personal history of mania. It was associated with lesions in the temporal and orbitofrontal cortices. Shukla et al. (136) reported on 20 individuals with TBI and mania and found that nine of their patients had epileptogenic activity on EEG. Irritable mood not euphoria was more commonly observed. Van Reekum et al. (13) reviewed the literature and suggested that TBI was associated with a five-fold increase in relative risk of developing bipolar disorder relative to base rates in the population. The role of genetic loading in the etiology of mania after TBI is not clear. For example Malaspina et al. (17) did not find an

increase in exposure to TBI in her large bipolar pedigree study.

A variety of other small series and case reports suggest that mania can be seen in association with all injury severities including some cases with brief or no documented loss of consciousness (133, 137–139). The full array of phenomenologic variants of mania can be seen including a bipolar course, rapid cycling, and triggering of manic episodes by antidepressant medications (132, 136, 138, 140, 141).

It is difficult to determine the exact role that profile of injury plays in mania as the underlying circuitry of this disorder is less well established than that for depression. In mania occurring after CNS disorders (not solely TBI) there is a marked preponderance of right fronto-temporal and basal ganglia injury (5, 134, 142).

*Treatment* Although there are many case reports and small series of TBI-related manic syndromes in the literature there are no systematic studies of this issue that one can use to inform treatment. Even the case series and case reports available do not give sufficient data to allow firm conclusions about treatment response. However the impression from this literature and clinical experience suggests that the same agents used in idiopathic bipolar disorder can be effective in TBI-related manic episodes. Thus the usual approach is to control acute manic episodes with an antipsychotic agent such as risperidone, olanzapine, or haloperidol while starting an anticycling agent such as valproic acid or lithium for longer-term prophylaxis of the illness.

### PSYCHOTIC SYNDROMES

The term psychosis refers to a cluster of symptoms, which includes problems in both thought content and thought process. Delusions and hallucinations typically characterize disorders of thought content. Alterations in the structure and flow of speech and language such as loosening of associations, flight of ideas, thought blocking, and production of nonsense words or neologisms, are characteristic of disordered thought process. Psychosis is often equated with schizophrenia, but is more accurately viewed as a syndromic manifestation of many neuropsychiatric conditions, including depression, bipolar affective disorder, delirium, and dementia, to name a few.

Although psychosis is a relatively rare complication of TBI, it does occur more frequently than in the general population. It is a good example of a low frequency, high impact complication of TBI, causing enormous distress to individuals and their caregivers. There are several contexts in which psychotic syndromes following TBI can occur including during the period of post-traumatic amnesia, as a complication of post-traumatic epilepsy, in

the context of TBI-related mood disorders, or associated with a chronic, schizophrenia-like syndrome. It is necessary to distinguish these different contexts, in so far as it is possible, to guide appropriate interventions (143, 144).

Relatively few studies directly address the association and causal connections between TBI and psychosis. Davison and Bagley (145) summarized the results of eight long-term (15 to 20 years) follow-up studies of individuals with brain injuries published between 1917 and 1960. Across these studies, the percentage of TBI patients developing a schizophrenia-like psychosis varies from 0.7% to 9.8%, suggesting an observed incidence of schizophrenia-like psychosis that is 2 to 3 times greater than that expected by chance in the TBI population. Van Reekum et al. (13) reviewed the literature and found a more modest relative risk associated with TBI. The role of genetic vulnerability is also not clear. Davison and Bagley found no evidence of increased genetic loading for schizophrenia in TBI patients who developed psychotic symptoms. Malaspina and colleagues (17) however studied 1830 individuals who were first-degree relatives of people with schizophrenia or bipolar disorder, looking for a relationship between these illnesses and TBI. Compared to other first-degree relatives with similar genetic vulnerabilities, those with a history of TBI were at significantly greater risk to develop schizophrenia. The authors propose a synergistic effect between TBI and genetic risk in families with two or more members with schizophrenia.

Based on the studies to date, it seems reasonable to conclude that psychotic disorders do occur in individuals with a TBI at rates greater than in the non-injured population. The more severe the injury, the greater is the likelihood of psychosis. Psychotic syndromes may occur soon after the TBI, or after a delay of months to many years (see Table 45-3). In cases with delayed onset, the injury is almost certainly not the only etiologic factor, although it is interesting to note the high rate of previous TBI in patients with schizophrenia. Furthermore, it appears that TBI can interact with genetic vulnerability

to greatly increase the risk of developing illnesses such as schizophrenia.

As noted, psychotic symptoms can occur in the context of a seizure disorder, a relatively common complication of TBI. A relationship between seizures and mental disorders, particularly psychotic syndromes, has been commented on for centuries (146) and is the subject of a somewhat confusing literature. In a comprehensive review of studies looking at the prevalence of psychosis in epileptic populations, McKenna and colleagues (147) found prevalence rates ranging from 0% to 27% in small clinic-based studies and rates of 2.8% and 3.2% in larger surveys of patients attending epilepsy clinics. Two large-scale Scandinavian community surveys of individuals with epilepsy found prevalence rates for psychosis of 2% (148) and 7.1% (149), both of which are higher than prevalence rates in individuals without epilepsy.

Epileptic psychosis is overwhelmingly associated with complex partial seizures, occurring four to 12 times more frequently in temporal lobe epilepsy than in other types of epilepsy. Psychotic syndromes are most likely to occur in conjunction with left-sided temporal lobe lesions (150–153). This is particularly the case for schizophrenia-like syndromes and paranoid syndrome.

Psychotic syndromes associated with posttraumatic epilepsy can occur predominantly in the peri-ictal period (either during seizures or in the immediate post-ictal period), or inter-ictally, in which case the psychotic symptoms are more commonly chronic rather than episodic (154). Most commonly seen is a post-ictal acute confusional state characterized by generalized confusion, fluctuating sensorium, agitation, hallucinations, and delusions, which is similar to the posttraumatic delirium described above. This condition generally resolves within a few hours of the seizure, although rarely it may persist for several days.

Less commonly psychotic symptoms occur as part of the seizure ictus. The clinical picture is one of paroxysmal onset of psychotic symptoms which can include auditory, visual or somatosensory hallucinations, delusions

**TABLE 45-3**  
*Interval of Injury to Development of Psychosis in Selected Studies*

STUDY	SAMPLE	LATENCY
Achte et al. 1969, 1991. (Psychopath 24:309–315)	WWII veterans, mainly penetrating TBI	2 days to 48 yrs, 42% occurring 10 yrs after
Fujii and Ahmed, 1996 (Neuropsychiatry, Neuropsych, Beh Neurol. 9:133–138)	State hospital sample	3 mos – 19 yrs, mean of 5.9 yrs
Feinstein and Ron 1998 (J Neuropsychiatry 10:448–452)	44 subjects with psychosis after neurological disorders	0–54 yrs, mean of 11.7 yrs

(often paranoid, grandiose or religious), as well as alterations in thought process (loosened associations, flight of ideas, cognitive disorganization). As with other seizure phenomena, these symptoms usually recede quickly (over several minutes) unless they are associated with repetitive seizures of a more prolonged inter-ictal psychotic syndrome. The most useful clue clinically is the time course of the psychotic symptoms, characterized by the paroxysmal onset, rapid resolution (most commonly), and relative absence of such symptoms in between events (155).

*Relationship of Profile of Injury to Psychosis* A full discussion of the neuroanatomical substrate of schizophrenia and psychotic symptoms is not possible. However a brief overview is instructive. No single brain region has been identified as the site or cause of schizophrenia, rather several brain regions appear to play important roles in the genesis and phenomenology of this disorder. These regions overlap with those vulnerable to injury in the typical TBI. Computed axial tomography (CT) scan and magnetic resonance imaging (MRI) studies of patients with schizophrenia have identified enlarged lateral and third ventricles (156, 157), reduced frontal and temporal lobe volumes (158), reduced thalamic volumes (159), and enlargement of basal ganglia, particularly the caudate and globus pallidus (160–162). Functional imaging studies have also focused on frontal, temporolimbic, and basal ganglia areas. Positron-emission tomography (PET) studies of drug-free schizophrenics have suggested reduced metabolism in the cingulate gyrus and hippocampus, (163, 164) and reduced metabolism in the basal ganglia (165, 166). Some schizophrenic patients have abnormal patterns of frontal activation when engaged in cognitive tasks that require frontal function (163, 166).

Recent neuropathological studies of patients with schizophrenia have suggested abnormalities in regions of the dorsolateral pre-frontal cortex and the hippocampus. Selemon and colleagues (167) reported prefrontal (Brodmann's area 9), as well as more widespread increased neuronal density in association with reduced cortical thickness. They thought this finding might be related to reduction of neuropil. Akbarian and colleagues (168, 169) reported abnormal distribution of nicotinamide adenine dinucleotide phosphate diaphorase-expressing neurons in both dorsolateral prefrontal cortex and temporal cortex. They postulated that these findings were consistent with altered (incomplete) migration of this population of neurons. Furthermore, these cells participate in subsequent guidance of other migrating neurons, pruning, programmed cell death, and overall modulation of proper "connectivity."

The temporal lobes, particularly the left temporal lobe and the hippocampal formation appear to play a role in auditory hallucinations and in delusions of passivity and control. Dysfunction of the prefrontal cortex is also implicated in delusion formation. It is not surprising then

that psychotic syndromes occur with increased frequency in patients after a TBI. There is significant overlap between the regions implicated in the etiology of schizophrenia and its prominent symptoms, and those regions which are commonly affected in TBI, including the frontal lobes (both dorsolateral cortex and orbitofrontal cortex), temporal lobes, basal ganglia, and thalamus. In some respects, it is surprising that psychotic syndromes are not seen more commonly after TBI.

*Treatment Issues* A critical first step in the evaluation and treatment of psychotic symptoms is making an accurate diagnosis and determining the etiology of the psychotic symptoms. This necessitates distinguishing psychotic symptoms from other brain injury-related symptoms such as confabulation, misidentification syndromes, and delusions (170). Once the presence of psychotic symptoms has been clearly established, a diligent search for underlying causes is necessary. A history of any earlier psychiatric illness must be aggressively sought. A positive family history of psychiatric illness can give valuable clues about the patient's diagnosis. It is important to determine whether the psychotic symptoms are related to a post-traumatic seizure disorder, a mood disorder (either depression or mania with psychotic features), concurrent or past substance abuse, or a manifestation of a schizophrenia-like disorder.

Treatment approaches follow logically from this differential diagnosis. Seizure-related symptoms are best managed with adjustment of the anticonvulsant regimen or consideration of surgical approaches in refractory cases. Mood disorders are best treated with antidepressants or anti-cycling agents (12, 171–173). Single agents should be tried initially, but a combination of drugs may be necessary. Antipsychotic agents may be needed in the initial phases of treatment of a mood disorder with psychotic features, but these should be tapered and discontinued once the mood disturbance has been successfully treated. Treatment of associated substance abuse can be very difficult, but must be attempted (174).

Should these initial treatments efforts fail, or when a psychotic syndrome is the primary psychopathology (i.e., the patient appears to have a schizophrenia-like disorder), then antipsychotic agents must be used. There are several potential problems with the use of these agents. It is therefore critical that they be used sparingly and for the treatment of true psychotic symptoms, not for the management of nonspecific agitation. Problems with motor function, gait, arousal, and speed of information processing are common in brain-injured patients and can be exacerbated by the sedation, psychomotor slowing, parkinsonism, and anticholinergic side effects associated with the common antipsychotic agents. TBI may also increase the likelihood of tardive dyskinesia (175). Clinicians often report this increased sensitivity to side effects of psychotropics, although there is little systematic evidence

to confirm these observations (5, 12, 171, 173, 176). It is prudent to start with one third to one half of the usual starting doses and to lengthen the interval between dosage increases. Newburn (177) reviewed the pharmacotherapy of psychiatric disorders associated with TBI, advising caution with drugs having prominent anticholinergic, antihistaminic, or antidopaminergic effects because of risk of adverse effects on cognition. Also, traditional antipsychotic drugs should be cautiously used because they might decrease synaptic plasticity.

*Atypical Antipsychotics* Atypical antipsychotic drugs have emerged as first line drugs for treatment of psychotic disorders. They are also being used with increasing frequency to treat ill-defined anxiety syndromes and mood disorders. Unless there is evidence that psychotic signs and symptoms are a direct result of some other treatable condition, such as cerebral dysrhythmia, one of these drugs should be employed. Six such drugs are currently available: clozapine, risperidone, olanzapine, quetiapine, aripiprazole, and ziprasidone. These drugs offer two main advantages over conventional neuroleptic drugs. They have greater efficacy, especially in decreasing negative as well as positive symptoms of schizophrenia, and in decreasing agitation and aggression. The latter effect can be of particular benefit in some individuals with TBI. Most importantly, the atypical antipsychotics carry significantly less risk of causing extrapyramidal symptoms (EPS) and tardive dyskinesia. Like all drugs with antipsychotic activity, the atypicals have some blocking effect on dopamine-2 ( $D_2$ ) receptors, but proportionally less so than conventional drugs. The atypical class also shows a preference for limbic  $D_2$  receptors with minimal nigrostriatal effects, and thus less risk of EPS. Affinity for 5-HT<sub>2A</sub> receptors is thought to also contribute to decreased EPS risk (178).

Clozapine is considered the most potent and effective of the atypical antipsychotic agents. However, it is also associated with the most side effects, including a heightened risk of agranulocytosis. Clozapine also has the most prominent anticholinergic effects and can cause orthostatic hypotension (178, 179). Drooling and sedation can be distressing problems with clozapine. Weight gain can occur with all of the atypicals but is probably more likely with clozapine and olanzapine. Clozapine carries greater risk of causing seizures, which is a consideration in treating patients with a history of brain injury. Due to this side effect profile, clozapine will not usually be the first of the atypicals to try. It is rational to try at least two of the other atypical antipsychotic drugs before beginning a clozapine trial. Among the other four, none shows clearly superior efficacy. A particular patient's history of previous response, minimizing certain side effects, and the clinician's familiarity with one drug or another all affect choice of drug. In some instances, one might wish to use a side effect, such as sedation or tendency to cause weight gain to advantage.

A variety of case reports and small case series that suggest most of the atypical antipsychotics can be used to effectively treat psychosis resulting from TBI (131, 180–183), though there are no randomized controlled trials to date. For example Butler (180) reported persecutory and nihilistic delusions, Capgras delusions, and depersonalization in a 17-year-old man after TBI. The delusions completely resolved within 2 weeks of beginning treatment with olanzapine, 5 mg daily. Feinberg and colleagues (181) reported a 61-year-old man who developed misidentification delusions of the Fregoli type after suffering right frontal and left temporoparietal contusions. Umansky and Geller (182) reported successful treatment with olanzapine of psychosis and affective disturbance after severe TBI with frontal lobe injury in a 42-year-old man. Laddomada and colleagues (183) reported successful treatment of psychosis after TBI with clozapine in a 25-year-old man. Previous treatment with clonazepam and carbamazepine had not helped.

Thus, psychosis in a brain-injured patient can be successfully treated, but requires a thorough diagnostic assessment to discern the underlying cause, and the rational pharmacotherapeutic approach that follows logically from this diagnostic process. Medication approaches must be adjusted for the particular characteristics and vulnerabilities of the patient with a TBI.

## ANXIETY DISORDERS

Anxiety is a common complaint in injured and non-injured populations alike. There are several different patterns of anxiety including generalized anxiety, panic disorder, phobic disorders, obsessive-compulsive disorder, and post-traumatic stress disorder. There are relatively few studies however addressing the incidence of these disorders after TBI and even fewer studies addressing treatment options (see (184) for review).

*Generalized Anxiety Disorder (GAD)* Van Reekum et al. (13) reported a 2.3 fold increase in relative risk for GAD based on five studies that met their inclusion criteria. For example in a study by Fann et al. (7), 24% of their sample (the majority of whom had mild TBI) evaluated 2–3 years after injury met criteria for generalized anxiety disorder. Many had co-morbid depression and many had symptoms that pre-dated their TBI. Robinson and Jorge (185) also found high rates of co-morbid anxiety and depression. 76% of their sample of depressed TBI patients also met criteria for generalized anxiety disorder (GAD). 22% of the non-depressed group also met GAD criteria.

Hibbard et al. (15) also found high rates of several different anxiety disorders (PTSD, 19%; obsessive-compulsive disorder, 15%; panic disorder, 14%; GAD, 9%) in their sample of 100 individuals with mixed injury

severity studied an average of 8 years after injury. Deb et al. (107) found a high rate of panic disorder (7%) but no change in rates for GAD or obsessive compulsive disorder relative to the general population.

The question of anxiety symptoms and their link to post-concussive symptoms is an important one. There is a significant overlap between many postconcussive symptoms and core symptoms in generalized anxiety disorder. Thus, many patients endorse complaints of headache, dizziness, blurred vision, irritability, and sensitivity to noise or light after mild brain injury (56, 186, 187). It is less clear how many patients actually experience anxiety and how many have diagnosable anxiety disorders. Although 55% of Dikmen's group (186) of 20 patients with mild brain injury complained of subjective anxiety, 45% of the matched control subjects had similar complaints (a statistically nonsignificant difference). Schoenhuber and Gentilini (188) were unable to find a significant difference in mean anxiety scores in their study of 35 patients with mild brain injury and matched control subjects.

*Obsessive-Compulsive Disorder* Three studies (13, 15, 189) assessed their TBI populations for obsessive-compulsive disorder. As pointed out by Van Reekum et al. (13) these studies represent a combined sample of 282 subjects followed for a maximum of 7.5 years. 6.4% had obsessive compulsive disorder which represents about a 2-fold increase in relative risk compared to the general population.

*Post-Traumatic Stress Disorder (PTSD)* There is an increasing awareness of the relationship between PTSD and brain injury. Initially it was assumed that the presence of post-traumatic amnesia prevented the development of PTSD by preventing the formation of what was felt to be a core component of the syndrome – the exquisitely vivid memories and re-experiencing of the traumatic life-threatening event. In fact there is evidence that individuals with loss of consciousness, particularly 15 minutes or more do have reduced rates of PTSD (184, 190, 191). However this is by no means an absolute rule. McMillan (192) reported on 10 individuals who met criteria for PTSD despite amnesia for the traumatic event and several others have reported similar findings (193–195). However it is more common to see PTSD and PTSD-like syndromes in individuals with at least partial recall of the events. Patients with a history of mild brain injury seem to manifest signs and symptoms suggestive of PTSD fairly commonly. Symptoms may include sleep disturbance, recurrent nightmares, exaggerated startle responses, daytime flashbacks, and avoidant behaviors such as refusing to drive or leave home. Driving phobias may become prominent. Lishman (1), in his review of the psychiatric sequelae of brain injury, refers to PTSD-like symptoms, concluding that “the circumstances of the accident may recur vividly in dreams, maintain states of

anxiety, or become the focus for obsessional rumination or conversion hysteria” (p. 306). McMillan (196) described PTSD symptoms in a woman with a severe brain injury despite amnesia for the event itself and a PTA of approximately 6 weeks.

Bryant and Harvey have reported a series of studies of individuals hospitalized after motor vehicle accidents, some with and some without TBI (usually mild TBI). They have shown that rates of acute stress disorder 1 month after an accident are comparable in the two groups, and that acute stress disorder is a good predictor of those who go on to develop PTSD 6 months after injury (197–199). For example, they studied 46 individuals admitted to a hospital after an MTBI (LOC with PTA <24 hours) and 59 survivors of motor vehicle accidents without evidence of TBI 6 months after their accidents (194, 200). Twenty percent of the TBI group and 25% of the non-TBI group had PTSD. The TBI group had more postconcussive symptoms than did the non-TBI group. Furthermore, the TBI group with PTSD was significantly more symptomatic than the TBI without PTSD group. This suggests that, like other psychiatric disorders such as depression, PTSD can amplify postconcussive symptoms after an MTBI and complicate recovery. In a sample of individuals with mild TBI (LOC <15 minutes), Mayou et al. (2000) found that almost half (48%) of those with definite loss of consciousness had PTSD 3 months after injury, and one-third of their subjects with MTBI had PTSD 1 year after injury. Although it might at first seem strange that those with LOC could develop PTSD with intrusive memories, it has been suggested that the intrusive memories are of events immediately before or after the accident, or there may be patchy amnesia with some islands of preserved memory.

Warden et al. suggest that a PTSD-like syndrome does occur after TBI but that the phenomenology may be different from that seen in individuals without TBI. They studied 47 members of the Armed Forces who sustained moderate to severe TBI. Using the strict definition of PTSD defined in DSM-III-R, none of the individuals met full criteria for PTSD. However when the re-experiencing criteria was dropped under the assumption that the traumatic amnesia would make this symptoms less likely, 13% met these revised criteria. This study is particularly instructive in that it raises the issue of sub-syndromal levels of PTSD. As Warden et al. described, patients who do not meet formal criteria for PTSD yet manifest many of the core symptoms (apart from the re-experiencing) are commonly seen. This highlights the fact that clinicians must be aware of the profile of injury through which psychiatric symptoms will be expressed following a TBI. In this case the injury associated memory loss alters one of the key components of PTSD seen in the non-injured population, and yet the rest of the core symptoms are present, can cause enormous disability, and

need aggressive treatment. Failure to appreciate this altered clinical phenomenology on the one hand, or excessively rigid reliance on DSM criteria developed without the TBI population in mind can lead the clinician astray.

Thus it seems that GAD, panic disorder, obsessive-compulsive disorder, and PTSD do occur at increased rates in individuals with TBI compared to the general population. As with the other psychiatric disorders discussed, the phenomenology of the disorders may be altered by the “filter” through which the symptoms are expressed.

*Treatment* Very little information is available with respect to treatment of these disorders in individuals with TBI (see Chapter 55). Warden and Labbate (184) suggest that education and cognitive-behavioral therapy have an important role in treatment. There are no systematic medication trials. Thus the usual approach is to follow the same treatment algorithm for anxiety disorders in the non-injured population. Selective serotonin re-uptake inhibitors such as sertraline or citalopram are useful first-line agents for both GAD and obsessive-compulsive disorder, and arguably for panic disorder and PTSD. Benzodiazepines can be useful but are often second line agents due to their effects on cognition and the high rate of substance abuse disorders in the TBI population. Atypical antipsychotics such as risperidone, quetiapine, and olanzapine are increasingly being used to treat anxiety. However these should be third line agents due to the potential for weight gain or full metabolic syndrome and the less likely but real concern for the development of tardive dyskinesia. Aripiprazole and ziprasidone may be better choices in individuals who are already overweight or at risk for metabolic syndrome. Buspirone can also be of benefit to some individuals. It is important to give this agent a several week trial before assessing efficacy as it takes this long to have an effect.

## SUBSTANCE ABUSE

Use of alcohol and other substances can play an important role in TBI including etiology, neuropathophysiology, recovery, and functional outcome (see Chapter 40). For example about half of all traumatic brain injuries involve the use of alcohol, and about one half of these individuals are intoxicated at the time of injury (174). The majority of these individuals have pre-injury patterns suggestive of addictive drinking (alcohol dependence)(201). In fact alcohol use is the single greatest risk factor for TBI, and TBI is often an irreversible consequence of alcohol and drug abuse (201). The presence of alcohol at the time of injury predicts longer durations of unconsciousness (202), increased challenging behaviors during the acute hospitalization (203), cognitive outcome (204) and overall outcome including mortality(205).

Individuals with pre-injury substance abuse problems often continue to struggle with these issues after their injury. Ashman et al. (109) found that their TBI population had an almost 2-fold increased rate of substance use disorders (drug/alcohol abuse/dependency) relative to the general population (32% vs. 17%) *prior* to injury. Subsequent to injury the rates went down initially probably reflecting enforced abstinence related to hospitalization and rehabilitation stays. However by the third assessment point the rate was identical to that seen in the general population (17%). In an earlier study of 100 individuals studied at least one year (mean 7.6 years) after injury, 28% of the sample struggled with substance use disorders (15).

*Treatment* A full discussion of this topic can be found in Chapter 40. In the acute hospitalization period it is important to be alert to the potential for substance withdrawal syndromes. Treatment of withdrawal from alcohol and drugs in addicted patients with TBI are similar to those employed in patients without TBI, with some important exceptions. The identification of alcohol and drug intoxication and withdrawal follows the general principles of pharmacological dependence. The use of blood and urine toxicology is important to identify the presence and levels of alcohol and drugs for assessment of intoxication and anticipation of withdrawal. The use of vital signs, particularly blood pressure, pulse, and temperature, are critical in determining the presence and severity of the withdrawal state (206).

After the acute and sub-acute rehabilitation phase, it is often desirable to prescribe aggressive treatment for substance abuse problems that appear likely to persist. However there are a variety of issues that complicate this process in individuals with TBI. Although counseling and the use of group therapy and 12-step recovery models remain the mainstay of treatment (see (201) for review) the cognitive deficits of many with TBI makes these interventions more difficult in that there is often relatively little or no carry-over of issues discussed from one session to the next.

There is often a significant problem with denial. Disorders of substance use are frequently associated with a resistance or psychological denial with respect to the impact that the substance use has on an individual's life. This can be greatly compounded by the deficits of awareness that were described earlier (see (78)). Thus there is a double denial (denial of substance abuse and TBI-related deficits) that can hamper establishment of a therapeutic alliance around the need for treatment.

There are also difficulties related to the usual treatment settings. Individuals with TBI can find group meetings (e.g. AA or NA meetings) over stimulating. This can result in further difficulties processing the informational content of the meetings. Furthermore the difficulties in social comportment described earlier can become quite apparent in group settings and when individuals are over

stimulated. This can result in the individual being asked to leave or not being welcome at future meetings. There can be a culture within groups that discourages or downplays the need for psychotropic medications and this can be detrimental to individuals who are already wavering in their commitment to medication compliance especially if they are not convinced that they have a problem in need of treatment.

Despite the above difficulties, the tried and true interventions remain the cornerstone of treatment. Thus additional supports are needed to enhance their efficacy in individuals with TBI. Basic principles used in working with individuals with TBI work in addiction treatment as well. Individuals will do better with concrete and structured settings. Whenever possible programs should be geared to the cognitive level of the individual. When this is not possible the use of a buddy system to help to translate or operationalize the information from individual or group sessions to real life can be effective. It is important for the treatment team to have a thorough understanding of both addiction and TBI to provide a consistent, cogent, and effective treatment plan (201).

Techniques such as keeping treatment interventions simple, focused, and concrete are critical in both patient populations (201). Clinicians may find a need to be more directive and supportive than they are accustomed to with other patient populations (174). Redirection using appropriate cues and reinforcers is often needed more than in other populations. It is important to teach substance use prevention skills that can be used in more than one life setting to maximize generalizability. As noted it is important to never assume understanding or memory of content from previous session. This requires the therapist to be redundant both within and between sessions. It can be helpful to summarize previous progress and then restate where the previous meeting left off (i.e. be redundant) (174, 201).

### Dementia

Dementia is defined in the DSM as a syndrome characterized by impairment in memory and at least one other domain of higher cognitive function (“memory plus”) that is of sufficient severity to interfere with social and or occupational function. Although progression is often inferred this need not be the case. Thus many individuals with TBI who have significant impairments in memory and executive function meet this definition of dementia. However the larger issue is whether exposure to a TBI increases the risk of a progressive dementing disorder such as Alzheimer’s dementia (SDAT) later in life (see Chapter 32 for discussion of the full scope of late complications of TBI). At this time it is not possible to say definitively whether TBI, particularly mild TBI is a risk factor for Alzheimer’s disease. This topic has been recently reviewed

by Jellinger (207) who concluded that both SDAT and TBI are associated with abnormalities in amyloid and tau protein deposition and that several epidemiological studies have suggested either that SDAT occurs with increased frequency in individuals with TBI or that the age of onset of SDAT is reduced after TBI relative to non-injured controls. Furthermore the possibility exists that the two conditions share common genetic vulnerabilities with respect to polymorphisms in the apolipoprotein E (ApoE) gene.

ApoE is a complex glycolipoprotein that facilitates the uptake, transport, and distribution of lipids. It appears to play an important role in neuronal repair and plasticity after injury (208). A four exon gene codes for ApoE on chromosome 19 in humans. There are three major alleles: e2, e3, and e4. These alleles differ in amino acids at positions 112 and 158: e2 (cysteine/cysteine), e3 (cysteine/arginine), and e4 (arginine/arginine). Animal models suggest a link between the e4 allele and increased mortality, extent of damage, and poor repair following trauma (208, 209). The human e4 allele has been associated with a variety of disorders with prominent cognitive dysfunction including normals with memory complaints (210), AD, and poor outcomes in stroke and TBI (208, 211). Several studies have reported that the e4 allele is associated with poor outcomes following TBI, using a variety of measures (212, 213). Crawford et al. (214), for example, found poorer memory performance in their sample of 30 individuals with TBI with at least one e4 allele compared to 80 TBI patients without an e4 allele. Lichtman et al. (215) found lower total functional independence measure scores in seven e4(+) patients with TBI compared to the 24 individuals with TBI but without an e4 allele. Friedman et al. (216) found a significantly higher percentage of poor outcome indicators both acutely (prolonged loss of consciousness), and at 6–8 months after injury (significant dysarthria, global functional outcome rating) in 27 individuals with TBI and the e4 allele compared to 42 individuals with TBI but without an e4 allele. Liberman et al. (217) found lower cognitive performance on several cognitive measures at 3 weeks but not 6 weeks after injury in the e4(+) patients. In a recent 30 year follow up study of individuals with TBI Koponen et al. (218) found that 6 of 19 e4 (+) individuals had definite or probable SDAT, whereas none of the 41 e4 (–) individuals had developed SDAT.

The mechanism by which the e4 allele exerts its negative effect is unclear. ApoE4 shows an increased affinity for beta amyloid and thus an increased propensity to promote aggregation of beta amyloid (216). Rather than an active detrimental effect, it may be that the ApoE4 is less effective than ApoE3 in promoting neuronal repair, and neuritic growth and branching. There may be a cholinergic link between the ApoE and cognitive impairment (see (219)). In AD, the degree of reduction of choline acetyl transferase, one of the markers for the disease, is correlated with the “dose” of e4 (208). Parasuraman et al. (220) have

argued based on accumulated neuropsychological, electrophysiological, and neuroimaging evidence that the cognitive effects of the e4 allele are mediated through reduced cholinergic input to posterior parietal systems regulating selective attention.

Thus similarities in neuropathological findings and response to neurotrauma, genetic vulnerabilities with respect to apolipoprotein E, and some (though not all) epidemiological studies suggest that there is a link between TBI and subsequent development of SDAT. However further clarification is needed. From a clinical standpoint the important issue is the stability of cognitive deficits over time. Any individual who has had stable cognitive function after the period of spontaneous recovery that begins to show evidence of cognitive decline must have an aggressive evaluation for the underlying cause as this is not the typical course following TBI.

## NEUROPSYCHIATRIC ASSESSMENT

It is clear from the above that a careful assessment of neurobehavioral concerns should be an important component of the evaluation and rehabilitation of individuals with TBI. A full discussion of all the dimensions of a neuropsychiatric assessment will not be attempted (see (221) for review). However it is worth highlighting several points.

*Need for Multiple Sources of Information* The cognitive deficits that frequently accompany a TBI alter the neuropsychiatric assessment, particularly the history taking. The presence of short-term memory deficits, problems with sequencing events in time, and difficulties with self-monitoring and self-awareness can make it very challenging for an individual to give a clear and consistent history. This puts the onus on the clinician to identify other sources of information (family members, friends, employers, primary medical/school/vocational records) that can help clarify the history and current clinical picture. The clinician must also obtain permission from the injured individual and work hard to explain the need for others to be involved in the treatment as observers and sources of critical information.

*Assessment of Pre-Injury Baseline* Assessment of the effects of an injury must start with a thorough understanding of what the individual was like prior to the injury. Absent such information there is a significant risk of mis-attributing life-long traits, characteristics, and behaviors to the brain injury. The following domains should be carefully explored and efforts made to gain primary records and reliable history with respect to:

- *Medical history*
- *Neurobehavioral traits and characteristics* (e.g. history of psychiatric illness)

- *Intellectual capacity* (indicators include educational history, vocational history, parental education)
- *Functional performance* (profile of personal, professional, and vocational accomplishments)
- *Personality style* (indicators include patterns of coping with stress, stability of key relationships)

Proper information on the above domains helps to paint a picture of life before the injury. Ideally such information is obtained shortly after the injury. The more time that passes from the point of injury, the greater the tendency to (mis) attribute more issues and life events to the injury. It is important to not simply take the word of injured individuals and their family/caregivers that “he was always perfectly normal” but make efforts to get primary documentation, not just “hearsay”.

*Assessment of Post-Injury Changes* Once the baseline picture is complete, the clinician is positioned to accurately assess the changes that have occurred since the time of the injury. It is important to carefully review the functional domains that are frequently affected by injury including cognition, personality, mood regulation, speech/language, mobility, and higher order domains such as vocational performance, major role performance within the family or equivalent context. It can be helpful to use standardized assessment scales and tools that serve to sample the full array of common problems such as the Neurobehavioral Rating Scale-revised (222) or the Neuropsychiatric Inventory (223). Alternatively one can use scales and instruments that offer a more detailed approach to a given problem area specific to the individual being assessed such as the Overt Aggression Scale (224) or Apathy Evaluation Scale (225). For bedside assessment of cognition it is helpful to supplement a standardized instrument such as the Mini Mental Status Exam (226) with something that helps to assess frontal executive functions such as the Frontal Assessment Battery or the Behavior Rating Inventory of Executive Function (BRIEF, (227, 228)), (see Table 45-4).

*Attribution of Etiology* It is important to emphasize that temporal association does not guarantee causality. There are several ways that neurobehavioral change can be associated with brain injury. Change may be a direct effect of the insult to neural tissue with subsequent disruption of the functions sub-served by the damaged tissue. For this to be properly assessed requires accurate, sometimes fine-grained knowledge of the profile of regional brain injury and the relationship of the related circuitry to the functional change in question (the “neural component”).

Alternatively the change may reflect the development of a new illness or disorder that is the driving force behind the behavioral change. For example an individual may develop various endocrine complications of their brain injury related to pituitary damage, chronic pain

**TABLE 45-4**  
*NeuroBehavioral Rating Instruments Useful in TBI*

<b>NAME OF INSTRUMENT</b>	<b>COMMENTS</b>	<b>FORMAT</b>	<b>NUMBER OF ITEMS</b>	<b>APPROXIMATE TIME TO ADMINISTER</b>	<b>OUTPUT</b>
<b><i>BEDSIDE MEASURES OF COGNITION</i></b>					
Mini-Mental Status Exam (226)	Not a good measure of frontal executive functions	Rater administered	30	5 minutes	Score range to 30
Frontal Assessment Battery (230)	Good measure of executive function	Rater Administered	6	5–10 minutes	Score range to 18
BRIEF-A (228)	Good measure of executive function	Self-report or Family/caregiver report	75	10–15 minutes	Total and subscales
<b><i>MEASURES OF SPECIFIC BEHAVIORS</i></b>					
Beck Depression Inventory (231)	Requires self-awareness, ability to read, some memory skills	Self-report	21	5 minutes	Normal score less than 10
Spielberger State Trait Anxiety Inventory (232)	Measures both current (state) and trait anxiety. Requires self-awareness, ability to read, some memory skills	Self-report	40	5 minutes	Scores range from 20 to 80
Overt Aggression Scale (224)	Good coverage of common aggressive behaviors	Rater administered	16	5 minutes	Total and domain scores
Apathy Evaluation Scale (225)	Good coverage of common symptoms suggestive of apathy	Self-report and informant	18	10 minutes	Total score
Scale to Assess Unawareness of Mental Disorders (233)	Assesses patient view of whether an individual is aware of problems in personality and behavior	Rater administered	20	10 minutes	Assess awareness and attribution of specific psychotic symptoms
PCL-S (234)	Assesses symptoms commonly associated with PTSD	Self-report	17	5–10 minutes	Total scores
<b><i>SURVEYS OF BEHAVIOR</i></b>					
Neuropsychiatric Inventory (223)	Excellent coverage of common symptoms. Somewhat lengthy	Rater administered	91	10–20 minutes	Total score and 12 domain scores
Neurobehavioral Rating Scale – Revised (222)	Excellent coverage of common symptoms	Rater administered	57	15 minutes	Total score, domain scores

from orthopedic injuries, or depression that more reasonably explains the behaviors in question (the “biological component”). It is equally plausible that behavioral change could be caused by the meaning of the accident or injury, a reaction to a loss of self-esteem due to disfiguring injury, loss of mobility, or unemployment (the “psychological component”). Finally, changes in environment such as living situation, change in caregivers, or change in routine or flow of daily life can have an enormous impact on the behavior and adaptation of an individual with brain injury (the “social component”).

*Formulation and Interpretation* All of the above factors can reasonably be attributed to the event of the injury. For example the individual would not have endocrine abnormalities save for the injury-related pituitary damage, or may well have not developed depression absent the injury. However the degree of linkage to neural tissue damage varies across these factors. An individual showing new, aggressive outbursts associated with a change in residential care providers may be better served by working to further train the residential provider rather than by the aggressive use of medications. On the other hand if this patient has clear evidence of orbitofrontal damage, it may be that their threshold for tolerating frustration is so lowered that treatment will require both medication approaches and environmental manipulation.

The proper assessment and formulation of the relative weighting or contribution of each of these factors to the genesis of the challenging behaviors frames what can be termed a neurobiopsychosocial paradigm. It differs from more traditional psychiatric assessments with respect to the critical importance placed on understanding the profile of regional brain injury, and the array of complex behavioral circuitry that this profile would reasonably disrupt. Thus the work of the neuropsychiatric assessment can be summarized as the process of matching the profile of brain injury with the changes that have occurred in cognition, behavior, and overall function, and gauging the “goodness of fit” between predicted and actual outcomes. This is followed by an interpretative process whereby the clinician assigns relative weights to the various contributions made by the neural, biological, psychological, and social components. Treatment interventions should flow logically from this formulation. It is important to point out that even experienced clinicians can make mistakes in this process due to the complexity of clinical presentations and the incomplete data available. Thus the final critical component to this process is the regular re-evaluation of intervention efficacy. Essentially each formulation should be hypothesis driven and each intervention flow logically and in an empirically testable fashion (e.g. “I believe the increase in aggression is due to depression, thus I will prescribe antidepressants”). Poor or incomplete response to the

intervention should prompt a re-evaluation and formulation of a new and testable hypothesis. It is acceptable to be wrong, it is not acceptable to engage in sloppy thinking.

## PRINCIPLES IN TREATMENT

A detailed approach to specific syndromes and disorders can be found in Chapter 55 (Silver and Arciniegas), and Chapter 56 (Arciniegas and Silver). However several general treatment principles are worth emphasizing.

*Variability in Presentation* It is important to be aware that the presentation of psychiatric syndromes in individuals with TBI may differ from the presentation in the non-injured population. In general, the more mild the TBI, the more similar the presentation is. However special challenges arise in more severely injured individuals with cognitive, motor, and speech/language deficits. There are three broad factors that contribute to variability in clinical presentation.

*Mood Instability and Affective Lability* Due to the instability in mood and affect accompanying disruption of the aforementioned frontal-subcortical circuits, it is necessary to pay attention to an extended baseline of behavior. Individuals with TBI are subject to more rapid fluctuation in mood and affect and this overall instability should not be equated with the more sustained alteration in mood that is the hallmark of depression. Attributing internal feelings to external behavior is more difficult due to the frequent presence of pathological or “pseudobulbar” affect (76).

*Alterations in Speech and Language Function* Varying degrees of speech/language impairment are commonly seen following TBI, particularly in individuals with more severe injuries. These changes can range from subtle problems with naming and word finding to global aphasia. Dysarthria and articulation problems can be seen. The ability to modulate the prosody of speech can also be altered (229). This is manifested by difficulties in modulating speech tone, pitch, and amplitude (expressive aprosody), or in decoding and interpreting these components in the speech of others (receptive aprosody). The result of these deficits is an uncoupling of the content or propositional component of speech from the emotional valence and related non-verbal components of language. Patients with receptive dysprosody may have difficulty reading social cues and this may contribute to problems in social comportment. Those with expressive dysprosody may express distressing thought content without seeming to have appropriate accompanying affect (e.g. “I am depressed and suicidal” expressed in a flat monotone without depth of feeling) leading the clinician to be somewhat confused about the clinical significance of what is being expressed.

### *Effects of Associated Neurological Impairments*

One must also consider the effect that injury-related neurological deficits may have on clinical symptoms of psychiatric disorders. For example how will depression be expressed or manifested in non-verbal patients? How will delusions and hallucinations be evident in these same patients? In an individual with quadriplegia, what does manic hyperactivity look like? How will PTSD present in someone with amnesia for the event? Thus the clinician must become adept at envisioning what the psychiatric illness would look like if expressed through the filter of the individual's neurological and functional deficits.

*Effects of Cognitive Impairment* Individuals with poor self-monitoring, impaired memory, distorted sense of time, or time-sequencing deficits will have significant problems presenting an accurate history. The clinician must rely not only on what the individual reports but must strive to get additional information from family/caregivers.

### *Heightened Vulnerability to Medication Side Effects*

Individuals with TBI as well as other neuropsychiatric disorders often manifest an increased sensitivity to medication side effects. This may take several forms. The first is a tendency to develop typical side effects associated with the given medication at a lower than usual dose. The second is a lowered threshold at which the individual develops a delirium or toxic encephalopathy. The third is a worsening of the neurological deficits associated with the TBI. For example it is not uncommon to observe worsening of tremor or gait problems, increased emotional lability, or increased slowing of speed of information processing associated with psychotropic drug use. In other words the very symptoms the clinician is treating may be made worse by the medications prescribed. This highlights the need to take a careful medication history encompassing not only the current medications but medications used in the past as well as the response to those agents. Furthermore it is important to clarify whether a history of "that medicine didn't help" reflects a true lack of response or more a manifestation of the heightened vulnerability to side effects just described.

The above issues contribute to diagnostic and treatment challenges that can be outlined as follows:

- (1) *Atypical Clinical Presentations* – As noted earlier, clinical presentations of common psychiatric disorders may not meet standard diagnostic criteria as outlined in the DSM. Thus it is reasonable to have a "relaxed fit" criteria when approaching diagnoses in individuals with TBI.
- (2) *Trait vs. State Presentations* – It is important to point out that there are two broad factors that contribute to the neurobehavioral sequelae of TBI; the injury induced changes in personality, and the increased rate of psychiatric disorders. A problem arises when the latter presents as a heightening or worsening of the former. For example it is quite common for an individual with TBI to have a baseline of increased irritability or lowered frustration tolerance. It is also quite common for these traits to be exaggerated in the presence of a superimposed episode of depression or mania (or some other psychiatric disorder). If the clinician does not carefully tease out the post-injury baseline and clearly ascertain whether there is a change in the frequency and/or intensity of the challenging behaviors, it is easy to misattribute challenging behavior to a dysexecutive syndrome only, as opposed to a dysexecutive syndrome exacerbated worse by the presence of an Axis I psychiatric disorder.
- (3) *Treat syndromes or disorders not symptoms (diagnosis before treatment)* – It goes without saying that it is best to have a clear sense of what is causing the challenging behavior before designing a treatment plan. Yet many clinicians are inclined to prescribe antipsychotics or SRI's without formulating a hypothesis for what they are treating. This is a symptomatic approach – similar to treating a fever associated with a bacterial infection with acetaminophen but not antibiotics. In the neuropsychiatric arena, the symptomatic approach should be a last resort after having carefully ruled in or out the presence of an Axis I disorder (e.g. depression, mania, psychosis), neurological conditions that would account for the behavior (e.g. complex partial seizures, pain, iatrogenic complications, medication side effects), or factors in the environment that are causing the change in behavioral symptoms. Again it is important to restate that being wrong sometimes is unavoidable, but sloppy diagnostic thinking is avoidable.
- (4) *Role of behavioral metaphors* – There are times, especially when data is difficult to obtain or when the neurological deficits through which challenging behaviors are being expressed are severe, that one is at a loss to account for the etiology of a given behavior or behaviors, and thus not clear about a treatment strategy. A fallback position is to attempt to conceptualize the cluster of behaviors as if they were a particular syndrome or as if they represented what Tariot et al. (235, 236) have termed a "behavioral metaphor". For example an individual expressing increased negativism, loss of interest in activities, and/or self-destructive or self-injurious behavior might be conceptualized as having a depressive syndrome (see Table 45-5) and thus could reasonably be prescribed an antidepressant regimen. An individual with increased irritability, increased arousal and activation, and a significant reduction in sleep might be conceptualized as having an irritable manic-like syndrome and thus be started on an anti-cycling

**TABLE 45-5**  
*Examples of Behavioral Metaphors*

TYPE	BEHAVIOR	INITIAL TREATMENT
Depressive	Negativistic, lack of interest in activities, Weepy, aggressive or self-injurious behavior	SSRI's or other antidepressants
Manic	Increased level of arousal and activity, irritability, decreased need for sleep, increased sexual activity	Mood stabilizers or anti-cycling agents (e.g. anticonvulsants, lithium)
Psychotic	Consistent misinterpretation of environment in a paranoid fashion, apparent response to internal stimuli, aggression that "comes out of nowhere" but may flow out of paranoid misinterpretation of events	Antipsychotics (e.g. low dose risperidone)
Anxiety	Challenging behaviors most apparent in setting of anticipation of events, change in routine, consistently difficult or novel situations	Anxiolytics

Adapted from: Ryan JM, Kidder SW, Daiello LA, Tariot PN. (2002) Psychopharmacologic interventions in nursing homes: what do we know and where should we go? *Psychiatric Services*. 53(11):1407-13.

regimen or mood stabilizers. The critical issue is that these are testable hypotheses and should be treated as such. Target behaviors and baseline frequencies should be identified prior to treatment and an adequate but time-limited trial prescribed. It should be clearly decided what the endpoint is and if the desired goal is not attained, the medication should be discontinued and an alternative conceptual scheme considered.

### **Role of Behavioral and Environmental Interventions**

It is important to point out that individuals with cognitive impairment of all kinds, including individuals with TBI have a heightened sensitivity not only to medications, but to the environment in which they live. This is related to several factors.

*Stimulus Boundedness* As mentioned earlier one of the characteristics of damage to frontal-subcortical circuits with attendant problems in executive function and social comportment is that individuals have great difficulty with components of attention including complex, selective, and sustained attention. This results in difficulty with prioritization of incoming stimuli and the gating out of stimuli that would ordinarily be deemed of secondary importance. At its essence this may be a problem assigning or decoding proper salience to the constant influx of environmental cues and stimuli. In any event the result is that the individual becomes hostage for at least very sensitive to, events in their immediate environment.

*Fondness for Routine* Individuals with cognitive deficits are often quite sensitive to changes in routine or

schedule. This may relate to the afore-mentioned deficits in executive function in which problems with problem solving and mental flexibility can be quite apparent. Over time individuals (injured or non-injured) develop routines that tend to maximize predictability and efficient function, and minimize stress. Changes in these routines call for mental flexibility and problem solving skills to maintain environmental homeostasis. Individuals challenged in these domains will often respond with anxiety, irritability, or even catastrophic reactions to these changes in routine. This tendency can be apparent in response to both changes in people in their environment or changes in time or schedule. The latter may relate to basic impairments in both sense of time and memory, resulting in ongoing anxiety and perseverative requests for information or re-assurance with respect to upcoming events or activities. Family/caregivers and staff often function as cognitive prosthetic devices that the individual relies upon to supply ongoing memory for events, maintenance of schedule, and overall sense of time. Being deprived of these human prosthetic devices is a frightening experience and can result in appearance of some very challenging behaviors.

*Predictability of Response* Injured and non-injured individuals alike base much of minute to minute and long-term decisions and actions on predictions of the response a given action will produce. Increasing the probability of favorable responses and decreasing the likelihood of undesirable responses are powerful forces in shaping behavior. However certain executive deficits such as inferential reasoning, self-monitoring, self-correction, and episodic memory are critical to the successful application of these experiences to shaping behavior. In this context predictability of response becomes even more critical to

maximize contextual learning and generalize these lessons to other novel settings. Individuals existing in an environment in which the same behaviors elicit different responses from different people at different times can become confused, anxious, and agitated.

Thus it is critical to carefully consider these factors when performing a neuropsychiatric assessment. To ignore the environment and factors that may be provoking challenging behaviors will greatly reduce the efficacy of any prescribed medication even if it is the proper medication. On the other hand, without the properly prescribed medication, even massive efforts at applied behavioral analysis and environmental manipulation may be in vain. The therapeutic issue should not be: "Do we prescribe a drug, or write a behavioral plan?" Rather the question is better framed as "Which medicine prescribed in the context of what changes in environment and strategies for shaping behavior has the best potential for success?"

## CONCLUSIONS

Attention to the diagnosis and management of the neurobehavioral sequelae of TBI can serve a critical role in advancing the rehabilitative process. It requires a knowledge and understanding of the profile of regional structural and neurochemical injury associated with the typical TBI and how that profile predicts the common neurobehavioral sequelae. Careful assessment requires an accurate description of the individual's functional and neurobehavioral status prior to the injury, and how that has changed subsequent to the injury. It is helpful to be aware of the problems in diagnosis in individuals who have a fluctuating behavioral baseline, who may have significant cognitive deficits, or in whom the usual connection between internal feeling state and external behaviors may be uncoupled. Treatment should follow from a clearly articulated diagnostic scheme and should be time-limited and re-evaluated in the presence of poor or incomplete response.

## Assessment and Treatment of Speech and Language Disorders in TBI

*Bruce E. Murdoch*  
*Brooke-Mai Whelan*

### COMMUNICATION DISORDERS FOLLOWING TBI: AN INTRODUCTION

Traumatic brain injury (TBI) is the result of impact-induced biomechanical forces upon neural tissue, including compression, acceleration–deceleration and rotational acceleration (1, 2). Associated neurological injuries may be focal, multifocal, or diffuse, involving direct trauma, as well as tension-related tearing of tissue and/or shearing as a consequence of rotational force (1). In relation to communication skills, the potentially wide-ranging and heterogeneous nature of TBI accommodates an infinite range of prospective motor speech and language disturbances, through effects on the cortical, subcortical, bulbar and/or cerebellar systems.

Of particular note, the integrity of an individual's communication skills subsequent to TBI is often a critical factor in determining post-injury quality of life (3). Indeed, it has been recognized that speech and language deficits resulting from TBI may impose substantial social (4, 5) and vocational (6) ramifications. In the case of adults, the speech and language corollary of TBI is accountable for social segregation, academic failure, and/or vocational demotion following injury (2). In the case of children, TBI has been documented to cause immediate communication deficits, as well as a potential predisposition to speech and/or language

impediments evident during the formative years, whereby infants fail to meet milestones as they proceed along an anticipated motor-cognitive developmental continuum (2). Until recently, the remediation of communication problems associated with TBI has been considered subordinate to the management of related medical conditions (7). In light of the potentially adverse psychosocial impact that a loss of an ability to communicate may impose upon individuals with TBI, however, it must be emphasized that effective speech-language rehabilitation can no longer be viewed as an ancillary treatment objective.

Dysarthria represents a frequently documented symptom of TBI. It reportedly constitutes more than one-third of the communication deficits within this population (8). Furthermore, a diverse range of dysarthric subtypes has been observed in individuals subsequent to TBI (8). Within these subtypes, reported levels of motor speech dysfunction have been documented to vary from mild articulatory imprecision to nonfunctional speech (9). In contrast, apraxia of speech constitutes a rarely documented motor speech anomaly associated with TBI (10–12); however, it has been reported to manifest in tandem with dysarthria and aphasic symptoms in some cases (11). We are precluded in this chapter from discussing this further due to the limited amount of research available pertaining to apraxia in TBI, and the frequently

encountered diagnostic conundrum faced by clinicians with respect to delineating between the symptoms of simultaneous motor programming and muscular control deficits.

Current knowledge about the impact of TBI upon linguistic function is somewhat secondary to that about influences upon motor speech control. This discrepancy may be attributed to the fact that individuals with TBI have been historically reported to perform within normal limits on assessments of general language function (13), largely resulting in the exclusion of this population from supplemental linguistic analysis. Utilizing appropriately sensitive measures of higher-order, in addition to primary language function, deficits at the cognitive–linguistic interface, have been recently identified in TBI subjects (14). Similarly to motor speech sequelae, the nature of linguistic impairments resulting from head injury have been reported as variable (13). Incidence rates with respect to language dysfunction, however, have been documented to be as high as 100% in some research (15), highlighting TBI patients as a clinically viable population for language screening and intervention.

Mild TBI (mTBI) has received attention in the popular media as a public health concern (16, 17). Despite the fact that the majority of neurobehavioral alterations that result from mTBI have been documented to resolve within months of the related trauma, recent evidence suggests that premorbid levels of functioning may never be returned to after an injury (16). Of note, speech and language constitute neurobehavioral domains implicated within this population (18). Clearly, TBI encompassing the full spectrum of severity levels has the capacity to have an impact upon communication proficiency. It is the aim of this chapter, therefore, to describe the speech and language deficits that may manifest in individuals with TBI, as well as to provide a summary of applied assessment and treatment techniques that may be readily integrated within contemporary rehabilitation programs.

## ASSESSMENT AND TREATMENT OF MOTOR SPEECH DISORDERS IN TBI

The variable nature of the neuropathology resulting from TBI predicts the potential involvement of isolated or manifold motor speech subsystems. Consequently, emergent motor speech profiles in TBI subjects may include articulatory, velopharyngeal, laryngeal and/or respiratory deficiencies. A characteristic common to the dysarthria associated with TBI, however, is its intractable nature (8). Of note, it has been documented that although frequently presenting in tandem with language impairments at onset, the dysarthria of TBI endures long after initial linguistic deficits have resolved (3, 19, 20). Recent outcome studies, however, have indicated that the dysarthria of TBI

may respond effectively to a range of treatment techniques, documented to facilitate improvements in clinical speech features, functional communication skills, and physiological substrates (21–28). The following section outlines the nature of motor speech impairments associated with TBI, suitable assessment techniques and relevant treatment approaches.

### The Dysarthria of TBI: Neuroanatomical Classification and Clinical Features

As mentioned previously, the precise nature of the dysarthria that manifests as a consequence of TBI is governed by the location and scope of neural damage endured (8). The inherently diffuse nature of TBI, however, typically accommodates potential disruption at exponential loci along the neural axis, implicating upper as well as lower motor neuron systems. Indeed, classifications of spastic (29), hyperkinetic/hypokinetic (30, 31), flaccid (32, 33), ataxic (27, 34, 35) and mixed (29, 36) dysarthria have been reported within the TBI literature (37); however, spastic (37) and more recently mixed (i.e., spastic-ataxic) (36) subtypes have been highlighted as the most prevalent motor speech disturbances in this population. This motor speech profile is consistent with diffuse bilateral hemispheric damage following head injury (37), potentially implicating terminal loci of the neural fulcrum, such as the frontal lobes (38–40) and cerebellum, as the neuropathological substrates of the dysarthria of TBI.

#### Spastic Dysarthria

Spastic dysarthria, resulting from upper motor neuron damage implicating cortical motor areas and/ or associated descending motor tracts (41), reportedly manifests as a result of wide-ranging disturbance across the motor speech subsystems, characterized by hypertonicity of the muscles and reduced range, speed and strength of muscle excursion (42). Perceptually, this physiological symptom complex is typically characterized by strained-strangled vocal quality, as well as reduced alternate motion and speech rates (42).

#### Hyperkinetic and Hypokinetic Dysarthria

Although less common than spastic dysarthria, upper motor neuron damage as a consequence of TBI has also been reported to result in hypokinetic or hyperkinetic dysarthric subtypes (37). Neuropathologically defined within extrapyramidal nuclei such as the basal ganglia and divisions of the brain stem, hyperkinetic motor behavior denotes aberrantly excessive movement and hypokinesia, diminished and decelerated movement (1). Clinically, hyperkinetic dysarthria is characterized by disturbances in the rhythm and rate of oromotor movements as a consequence of involuntary motor actions, and

variability in muscle tone (43, 44). Perceptually, this profile is most often distinguished by prosodic deviations including impairments in pitch and volume control, stress, rate, phrase as well as inter-word and phoneme duration, but may also include additional aberrant speech features such as sudden respiratory inhalations and exhalations, vocal arrest, strained-strangled vocalization, articulatory imprecision and hypernasality (43–46).

In contrast, the clinical characteristics of hypokinetic dysarthria embody oromotor deviations associated with rigidity, diminished range as well as force of movement, and variations in movement velocity (47, 48). Perceptually, these neuromuscular disturbances commonly manifest as monopitch, monoloudness, reduced stress, festinatory speech (i.e., short rushes), hoarse and/ or breathy vocal quality, articulatory imprecision, phoneme repetition, low pitch, overall increased but variable speech rate and diminished volume control (47–49).

### **Flaccid Dysarthria**

In keeping with the inherently heterogeneous nature of neurological damage associated with TBI, motor speech disturbances consistent with lower motor neuron lesions have also been observed within this population. Resulting from damage to the motor cranial and/ or spinal nerves, flaccid dysarthria is characterized by muscular weakness, absent or reduced reflexes, muscle atrophy and fasciculations (1). Clinically, the motor speech deficits associated with this neurological profile may vary, dependent upon the specific cranial nerves implicated (50, 51). A common assemblage of deviant speech features, however, has been observed in flaccid dysarthric populations including breathiness, audible inspiration, hypernasality, nasal emission, reduced phrase length, consonant imprecision, vocal harshness, monopitch and monoloudness (45). Of particular note, the resonatory and phonatory deficiencies frequently seen in flaccid dysarthria have been described as largely unique to this dysarthric subtype (50).

### **Ataxic Dysarthria**

Extending further along the neural axis, cerebellar damage has also been reported as a possible outcome of TBI (8). Ataxic dysarthria constitutes the resultant motor speech deficit and is typically characterized by articulatory and prosodic insufficiencies (52). Perceptually, these insufficiencies translate as articulatory imprecision (encompassing both consonants and vowels), articulatory breakdowns, excess and equal stress, prolongation of phonemes and inter-word intervals, diminished speech rate, monopitch, monoloudness and harsh vocal quality (53). This motor speech profile has been reported to specifically represent the neuromuscular effects of reduced tone and coordination, effecting slow and inaccurate motor behaviors

relevant to the force, range, timing and direction of speech musculature movement (52, 54).

### **Mixed Dysarthria**

The heterogeneous and often pervasive nature of TBI, respecting lesion location, has also been associated with the clinical presentation of mixed dysarthria, concomitantly encompassing the motor speech deviations of several dysarthric subtypes (1, 37, 55). Notably, a recent body of research identified mixed dysarthria as the most prevalent form of motor speech impairment in cohort of TBI subjects, including spastic-ataxic, spastic-hypokinetic, spastic-flaccid, flaccid-ataxic and spastic-flaccid-ataxic subtypes (8, 36). Of further interest, within this group individuals classified with mixed dysarthric subtypes demonstrated the most qualitatively severe motor speech disturbances, suggesting that more diffuse brain damage may correlate with more severe speech disturbances.

### **Dysarthria Acquired During Childhood**

The aforementioned neuroanatomical classification of dysarthric subtypes and associated clinical features largely relate to motor speech anomalies acquired in adulthood or at neurodevelopmentally stable life stages. Historically, this taxonomy has been adopted as a frame of reference to classify dysarthria resulting from TBI in childhood, however, not without recognised limitations (56). It has been eloquently acknowledged that the pathophysiological mechanisms underlying childhood TBI may be disparate to those which take hold within the adult brain, particularly when considered within the context of developmental hierarchies and neuroplasticity capabilities (56). Indeed, TBI in childhood has been documented to recover more rapidly than that endured in adulthood, as a consequence of distinctive neuroplasticity mechanisms (57). Furthermore, children have been reported to predominantly endure brain injuries as a result of low speed motor vehicle accidents or falls, in opposition to adolescents and adults, commonly involved in high-speed collisions (57). These factors suggest that the mechanisms of child versus adult TBI may be incongruent, with greater rotational acceleration effects and consequently more diffuse brain damage expected in adult populations (56, 57).

Until recently, the perceptual and physiological features of dysarthria resulting from TBI in childhood have been relatively unexplored (58). Contemporary research, however, has revealed similar dysarthric profiles in children as compared to adults following TBI, with respect to the presentation of a variable array of disturbances in prosodic, resonatory, phonatory and articulatory aspects of speech production (56). Despite these clinical parallels, future research investigating the nature of interactions

between developmental and acquired factors is considered critical to the better elucidation of mechanisms underpinning dysarthrias contracted in childhood (59). In particular, resultant motor speech impairments may represent a maturation-sensitive consequence of head injury, within the context of developmental neurological systems. As such, longitudinal monitoring of motor speech abilities in children with TBI is considered pivotal to the prompt identification and remediation of speech deficits that may potentially manifest at any point during the course of motor development.

### The Dysarthria of TBI: Perceptual, Acoustic and Physiological Evaluation

Conventionally, perceptual speech analysis has provided the main stay of dysarthria assessment (56). Despite offering qualitative insights into the audible deviations apparent in dysarthric speech, these methods proffer little with respect to empirically identifying the neuromuscular locus or neurophysiological basis of the presenting deficits. Recently, advancements in technology have catalysed the development of more objective motor speech assessment tools, affording the compilation of quantitative acoustic and physiological profiles by way of state of the art instrumentation. Notwithstanding the value of the data generated via instrumental assessments, speech is by its very nature an audible entity, its “normalcy” considered by some to be most efficiently judged by the human ear. To this

end, perceptual and instrumental techniques combined have been recommended as the most effective means of evaluating motor speech dysfunction (56), taking into consideration relevant pathophysiological substrates as well as deviant perceptual features impacting upon functional communication proficiency. The proceeding summary of assessment methods utilized in the evaluation of dysarthria is largely applicable to both adult and paediatric populations. Recommendations have been made, however, with respect to the screening of developmental articulatory/ phonological processes, and/ or accommodating literacy related limitations in children.

### Perceptual Assessment

Comprehensive perceptual evaluations of motor speech function have been described as those which evaluate the 5 major elements of speech production, including: respiration, phonation, resonance, articulation and prosody (56). The perceptual motor speech assessment battery utilized in our research laboratory adheres to this recommendation, providing qualitative judgements pertaining to deviant speech dimensions (i.e., speech feature analysis (60); Fisher–Logemann Test of Articulation Competence (61)), speech intelligibility (i.e., Assessment of Intelligibility of Dysarthric Speech (ASSIDS) (55)) and subsystem dysfunction (i.e., Frenchay Dysarthria Assessment (FDA)(62)). For a more detailed summary of specific assessments applicable to TBI, refer to Table 46-1.

**TABLE 46-1**

#### *Comprehensive Perceptual Motor Speech Assessment Battery Applicable to TBI*

- Assessment of Intelligibility of Dysarthric Speech (55)
  - standardized assessment of severity of dysarthric speech
  - incorporates measure of speech intelligibility at both single word and sentential levels, overall speech rate, rate of intelligible speech and a ratio of communication efficiency
- Frenchay Dysarthria Assessment (62)
  - standardized assessment of neuromuscular systems associated with motor speech production, including: reflexive, respiratory, articulatory, resonatory and phonatory mechanisms
  - provides composite profile relative to status of motor speech subsystem functioning
- Speech feature analysis (60)
  - following reading aloud of a standard citation such as “The Grandfather Passage” (45) or in the case of children who may not be able to read, an oral picture description task, speech samples are analysed and rated according to the presence and severity of 33 possible deviant speech dimensions
  - relevant dimensions encompass five domains of speech production, namely: prosody (i.e., pitch, loudness, phrasing, rate, stress); respiration (i.e., breath support for speech); resonance (i.e., nasality); phonation (i.e, vocal quality); and articulation (i.e., consonant precision, length of phonemes, precision of vowels)
  - also provides an overall rating of speech intelligibility
- Fisher-Logemann Test of Articulation Competence (61)
  - *relevant to childhood TBI*, this assessment generates an articulatory profile which may be further analysed relating to the nature of deviant speech productions within the context of developmental articulatory and phonological errors

### Instrumental Assessment

The instrumental evaluation of dysarthria encompasses both acoustic and physiological assessment techniques. Acoustic assessment is specifically dedicated to the evaluation of voice, providing measures of frequency, amplitude, perturbation and signal noise, as well as temporally constrained aspects of phonation (e.g., maximum phonation time and voice onset time) (63) and is certainly applicable to TBI populations. A number of acoustic analysis systems are available commercially, including the Computerised Speech Lab® (CSL) (Kay Elemetrics Corp.), VisiPitch® (Kay Elemetrics Corp.), CSpeech®, the Canadian Speech Research Environment® (CSRE), MacSpeech Lab II®, and Dr. Speech Science for Windows® (Tiger Electronics) (64, 65). The CSL and VisiPitch, however, represent the most commonly employed acoustic analysis programs, rated as user friendly via the provision of real-time visual displays of acoustic parameters and the facility to store and analyse data (63).

Physiological assessments represent a corpus of instrumentation dedicated to the evaluation of the neuromuscular control mechanisms underlying speech. Available physiological apparatus not only evaluate phonatory aspects of speech production, but also extend to the assessment of articulation, resonance and respiration, including devices such as the Laryngograph, Electromagnetic articulograph, Nasometer and RespiTrace. Refer to Table 46-2 for summary of physiological instrumentation that may be utilized in the assessment of individuals with TBI.

### Physiological Measures of Laryngeal Function

In relation to the physiological assessment of laryngeal function, electroglottography (EGG) and measures of laryngeal aerodynamics represent two of the most commonly applied physiological tools in the clinical assessment of voice (63). EGG provides a means of representing vocal fold vibratory patterns (66, 67) and aerodynamic measures generate information pertaining to the interaction of various phonatory parameters. Waveforms generated via electroglottographic methods (e.g., Fourcin® Laryngograph) correspond to the opening and closing phases of the glottal cycle, and the velocity at which the vocal folds adduct (65). Measures of laryngeal aerodynamics such as the Aerophone II®, provide indices relating to the interplay of various laryngeal mechanisms in the production of voice, such as subglottal pressure, phonatory air flow, sound pressure level and laryngeal airway resistance (63). In addition to the parameters mentioned above, the Aerophone II® is also capable of measuring vocal fold adduction-abduction rates (68). Of note, high variability rates in performance have been reported in studies of aerodynamic laryngeal function (63). In order to counteract these variability effects, it has been recommended that the average of at least 5 repetitive samples, should be established as a representative illustration of laryngeal function on such measures (69). Within the context of TBI, however, fatigue effects as a result of effortful or repetitive physiological assessment tasks must also be considered in the interpretation of such data (63).

### Physiological Measures of Respiratory Function

Assessments of laryngeal function routinely co-occur with an evaluation of respiratory mechanisms underlying speech production (63). Physiological measures of speech breathing may be divided into 2 broad categories: 1) spirometric (i.e., direct measures of lung volume and capacity) and 2) kinematic (i.e., indirect measures of lung function by way of monitoring chest wall activity during breathing cycles and speech production tasks). Dry spirometers provide a means of measuring a range of respiratory parameters, including: vital capacity, inspiratory capacity, expiratory and inspiratory reserve volumes, forced expiratory volume, respiration rate, tidal volume and volume/ flow relationships. Furthermore, each of the parameters obtained may be compared to predicted age, height and sex-based values by way of formulae weighted for age and/ or height (70, 71).

Kinematic measures of speech breathing provide independent yet simultaneous recordings of alterations in rib cage and abdomen volumes during speech and non-speech tasks. A range of kinematic instrumentation has been applied to the study of speech breathing in neurologically impaired populations (68), including magnetometers,

**TABLE 46-2**

strain-gauge belt pneumographs and inductance plethysmography (72–74). RespiTrace®, an inductance plethysmographic measure of respiratory function, is the instrument of choice in our research laboratory. This instrument monitors changes in chest wall circumference via electrical inductance. Wires contained within elasticised straps placed around the chest and abdomen register dimensional alterations during specified tasks. A visual display signal is generated for analysis purposes and may also function as a biofeedback tool during therapy.

### **Physiological Measures of Articulatory Function**

In relation to the evaluation of articulatory function, pressure transduction systems are commonly employed to measure lip and tongue strength, endurance, velocity of movement, and fine force control. Within our research laboratory a miniaturised pressure transducer (Entran Flatline®, Entran Devices Inc., Model EPL 20001–10) with factory calibration, mounted upon an aluminium strip, is used to measure interlabial pressures during speech and nonspeech tasks, resembling that initially described by (75). Similarly a rubber-bulb pressure transduction system is utilized to evaluate tongue function, in line with that described by (76–78).

Electropalatography (EPG) and electromagnetic articulography (EMA) represent measures of dynamic articulatory function. More specifically, EPG provides a means of evaluating the positioning and timing of tongue to hard palate contacts during speech, via a thin acrylic palate studied with miniature sensory electrodes, fitted within a subject's oral cavity. Contact patterns during speech are subsequently acquired and stored in an external processing unit for analysis. By way of transmitter and receiver coil systems generating electromagnetic fields, the Electromagnetic Articulograph® (EMA) AG-100 (Carstens Medizintechnik, Germany) provides a two-dimensional representation of articulatory movements (79). More specifically, the EMA has the capacity to generate kinematic articulatory parameters, including trajectory, velocity, duration and acceleration, via the tracking of displacement relative to receiver coils positioned on the midline of the tongue, upper and lower lips, velum and mandible.

### **Physiological Measures of Velopharyngeal Function**

Measures of nasal airflow, air pressure, vibration and oro-nasal acoustic output offer non-invasive, clinically viable methods of assessing velopharyngeal competence (80). Nasal accelerometry and measures of oro-nasal acoustic output ratios represent the assessments of velopharyngeal function utilized routinely within our research laboratory. Nasal accelerometry involves the placement of miniature,

vibration sensitive accelerometers upon the lateral nasal cartilage and thyroid lamina, which detect nasal and laryngeal vibrations during speech. The magnitudes of vibration detected are then used to calculate a ratio of nasal to laryngeal vibration, providing an index of nasality, the Horri Oral Nasal Coupling (HONC) index (81, 82). High HONC indices are considered representative of velopharyngeal incompetence.

The Nasometer® (Kay Elemetrics) offers a measure of nasality via the generation of oro-nasal acoustic output ratios (83–85). Two directional microphones separated by a sound-separating plate are positioned anterior to the nose and mouth which record acoustic output signals. Accompanying software calculates nasalance scores which effectively represent nasal to oral acoustic output ratios during various speech tasks. High scores are considered representative of velopharyngeal dysfunction.

### **The Dysarthria of TBI: Treatment Approaches**

The treatment of the dysarthria of TBI in both child and adult populations has been described as a convoluted and protracted process, necessitating consideration of individual deficits within the context of functional communication requirements (86). The International Classification of Functioning, Disability, and Health (ICF) offers a widely-accepted framework for intervention relative to domains of health (87), which encompass communication skills. Within this model, the treatment of dysarthria is viewed from a three-tiered perspective, including: (1) integrity of body function and structure; (2) associated activity limitations and participation restrictions; (3) contextual factors facilitating functional improvements/ reduction in disability.

The inherently heterogeneous nature of the dysarthria associated with TBI respecting lesion site and severity, has largely precluded the reporting of group outcome studies relative to individual treatment techniques (88). By and large, research pertaining to treatment effects has been conducted via single case study designs, reporting the impact of a range of behavioral, instrumental and prosthetic approaches (22–26, 89–97).

### **Behavioral Approach**

The behavioral approach to the rehabilitation of dysarthric speech involves the teaching of compensatory strategies via traditional methods, which encompass the presentation of therapeutic stimuli and the establishment of response contingencies (98). The principle goal of this approach is to facilitate functional gains in speech intelligibility (99) via neuromuscular therapeutic techniques (100). These therapies include active exercises (e.g., strength training), stretching (e.g., to increase or decrease

tone), passive exercises (e.g., massage to relax musculature), and the use of physical modalities such as heat (to reduce pain), cold (to reduce spasticity) and electrical stimulation (to elicit voluntary contractions) (100). Historically, traditional/ behavioral techniques have provided the mainstay of dysarthria therapy, given their economic viability and wide-ranging environmental utility (101). Although failing to constitute an unabridged stockpile of behavioral dysarthria therapy techniques, Table 46-3 represents a number of commonly utilized traditional approaches in the remediation of phonatory, respiratory, resonatory, articulatory and prosodic deficits.

### Instrumental Approach

The instrumental therapeutic approach incorporates techniques which offer direct physiological or biofeedback pertaining to motor speech subsystem function during therapy tasks. Biofeedback tools provide a means of re-establishing motor control patterns by way of unconventional or adjunct sensory channels (113). Sensory channels may incorporate auditory, visual or tactile modalities, however, visual feedback signals have been documented as the most effective in the remediation of dysarthria (114–116). Table 46-4 highlights a range of biofeedback techniques currently utilized in the treatment of

respiratory, phonatory, resonatory, articulatory and prosodic disorders.

### Prosthetic/ Surgical Approach

Prosthetic and/ or surgical interventions, which effectively modify the physical configuration of specific motor speech subsystems (98), are commonly employed in the remediation of severe dysarthria (101). Table 46-5 summarises a range of prosthetic/ surgical techniques utilized the treatment of motor speech impairments, usually employed subsequent to an ineffective trial of more traditional therapeutic approaches.

### CASE REPORTS: CLINICAL MANAGEMENT OF DYSARTHRIA FOLLOWING TBI

The ability to apply the previously highlighted principles of dysarthria assessment and treatment to the management of a clinical caseload represents a requisite skill for any clinician. Within the context of the framework for intervention outlined in the ICF (87), the following vignettes constitute proposed clinical management plans relevant to the treatment of dysarthria following TBI, in a 26 year old adult and a 14 year old child.

**TABLE 46-3**  
*Behavioral Therapeutic Approaches in the Treatment of Dysarthria Following TBI*

TARGETED MOTOR SPEECH SUBSYSTEM	METHOD
• Phonation	<ul style="list-style-type: none"> <li>□ <i>Hyperadduction reduction techniques</i>: aim to alleviate excessive vocal fold adduction by way of tension reduction techniques such as <i>chewing</i> (102), <i>yawn-sigh</i> and <i>gentle voice onset</i> methods (103)</li> <li>□ <i>Hypoadduction reduction techniques</i>: aim to achieve effective vocal fold adduction and effective phonation in dysphonic patients via the application of <i>push/pull</i> (104), <i>hard glottal attack</i> (105), and <i>increased phonatory effort</i> (106) methods</li> </ul>
• Respiration	<ul style="list-style-type: none"> <li>□ <i>Manipulating posture</i> to maximize respiratory control (107) via the provision of visual, tactile and/ or auditory cues</li> <li>□ <i>Inspiratory checking</i> (108) technique aims to increase breath support and enhance respiratory control during exhalation via drills which encourage the regulation of air flow and volume during vocalization</li> </ul>
• Resonance	<ul style="list-style-type: none"> <li>□ Exercises aimed at increasing range of movement and strength of velum including <i>blowing, gagging and sucking</i> (101), as well as palatal awareness via <i>visual feedback</i> (101), <i>palatal massage</i> (109) and <i>icing/ brushing</i> (110) techniques</li> </ul>
• Articulation	<ul style="list-style-type: none"> <li>□ Aim to normalise function of the articulators (i.e., lips, tongue and jaw) via the <i>modification of muscle tone</i> (e.g., hypertonia versus hypotonia), <i>maximising muscle strength</i> (i.e., isotonic and isometric oromotor exercises (109, 111)) and <i>articulation/ speech drills</i> of increasing complexity (98)</li> </ul>
• Prosody	<ul style="list-style-type: none"> <li>□ Methods aimed at remediating stress patterning (e.g., <i>contrastive stress drills</i> (109)), intonation (e.g., <i>altering respiratory capacity and patterning</i> (112)) and rate (e.g., <i>intersystemic reorganization</i> (109) involving therapist directed pacing of speech)</li> </ul>

**TABLE 46-4**  
***Instrumental Therapeutic Approaches in the Treatment of Dysarthria Following TBI***

TARGETED MOTOR SPEECH SUBSYSTEM	METHOD
• Phonation	□ Use of apparatus with the facility to display vocal parameters such as pitch, intensity and duration during speech output (e.g., Vocalite (117), Visipitch (112), Visispeech (118), Speech Viewer (91), storage oscilloscope (119))
• Respiration	□ <i>U-tube manometer</i> : requires patient to maintain specific water level over designated period of time via controlled exhalation (109) □ <i>Kinematic instrumentation</i> (e.g., <i>Respirace</i> ®): provides visual representation of chest wall movements during speech tasks. Feedback shown to be effective in increasing lung volumes, increasing abdominal contributions to breathing as well as enhancing co-ordination of speech breathing (95, 120)
• Resonance	□ <i>Endoscopy</i> and <i>flexible fibre nasopharyngoscopy</i> provides direct visual feedback pertaining to velar and posterior pharyngeal wall excursion during speech (121, 122) □ <i>Velograph</i> provides real time representation of velar movement via an oscilloscope (123) □ <i>Nasometer</i> ® provides bar graphs and/ or real time visual displays of nasalance during speech (101)
• Articulation	□ <i>Electromyography (EMG)</i> represents a biofeedback tool with applications for altering labial and lingual muscle tone and strength (26, 92, 124–126) □ <i>Electropalatography (EPG)</i> may be utilized as a biofeedback device to alter lingual postures during speech (127, 128)
• Prosody	□ <i>Speech Viewer</i> (129) provides both visual and auditory feedback pertaining to fundamental frequency and vocal intensity. Documented as successful device in improving pitch, intonation and rate of speech (130) □ Modification of speech rate during reading via <i>PACER computerised rhythmic cueing</i> (131) □ <i>Delayed Auditory Feedback (DAF)</i> documented as useful biofeedback device in reducing rate, increasing vocal intensity and enhancing overall speech intelligibility (132–134)

**TABLE 46-5**  
***Prosthetic and/or Surgical Approaches in the Treatment of Dysarthria Following TBI***

TARGETED MOTOR SPEECH SUBSYSTEM	METHOD
• Phonation	□ <i>Voice amplifiers</i> : electronic device aimed at increasing voice volume (112, 135) □ <i>Botox injections</i> (136), <i>laryngeal nerve resections</i> (137) in the treatment of hyperadduction □ <i>Reinnervation of paralysed vocal folds</i> (138), <i>collagen/ Teflon implants</i> (139, 140) and <i>arytenoid adduction</i> (141) in the treatment of hypoadduction
• Respiration	□ <i>Abdominal muscle girdling</i> by way of elasticised bandages (109). Enhances expiratory control during speech by facilitating recoil of the abdominal musculature. □ Postural enhancement by use of <i>overhead slings</i> (109). Provides surface upon which individuals may bear down to establish expiratory force for speech.
• Resonance	□ <i>Palatal lift prosthesis</i> aims to achieve palatopharyngeal closure (142, 143)
• Articulation	□ <i>Bite block</i> to increase jaw stability and maximize function of other articulators and/ or <i>palatal augmentation prosthesis</i> which aims to facilitate tongue/ palatal contacts required for articulation otherwise compromised by reduced range of movement or elevation of tongue (143, 144)
• Prosody	□ <i>Pacing</i> (145)/ <i>alphabet board</i> (146) encourages speech rate reduction

### **Case 1 (Adult): Moderate Spastic-Ataxic Dysarthria (86).**

*Case History:* Jacob is a 26-year-old male who sustained a TBI as the result of a motor vehicle accident. On admission to hospital a Glasgow Coma of score of 5 was reported, indicative of severe head injury. MRI investigations revealed bilateral subcortical hemorrhages and multiple contusions. At the time of his accident, Jacob was married and working as a practicing accountant. His family and employer were reportedly committed to his rehabilitation and return to the work force.

*Motor Speech Profile: Moderate Spastic-ataxic Dysarthria:* Perceptual assessment results revealed: reduced speech intelligibility, consonant imprecision, reduced breath support for speech, hypernasality, strained-strangled vocal quality, reduced pitch and loudness control, reduced speech rate and impaired stress patterning. Physiological assessment revealed wide-ranging motor speech subsystem dysfunction, incorporating: reduced respiratory support for speech, hyperfunctional laryngeal activity, velopharyngeal insufficiency and reduced range and speed of labial and lingual movement.

*Clinical Management Plan:* A multisystem approach was adopted in the rehabilitation of Jacob's speech, involving a combination of behavioral and instrumental treatment techniques. Consistent with the ICF, his presenting motor speech deficit was considered in relation to structural and functional impairments, imposed activity limitations and participation restrictions as well as manipulable contextual factors. Refer to Table 46-6 for the proposed rehabilitation schedule.

### **Case 2 (Child): Moderate Spastic Dysarthria (147)**

*Case History:* Max is a 14-year-old male who sustained a TBI following a pedestrian/ motor vehicle accident. On admission to hospital a Glasgow Coma of score of 5 was reported, indicative of severe head injury. Computed tomographic (CT) scan revealed soft tissue hematoma over right temporal and left zygomatic regions as well as an area of high attenuation in left lentiform nucleus and additional foci scattered over peripheral grey/ white region anteriorly and superiorly. No significant mass effect was observed. At the time of his accident, Max was a high-achieving year 9 high-school student with a range of extracurricular interests, including: debating, football and tennis.

*Motor Speech Profile: Moderate Spastic Dysarthria:* Subsequent to TBI, Max endured a 5-month period of mutism. Perceptual assessment of speech function following this period revealed: severely reduced range and

speed of lingual movement; moderately reduced range and speed of labial movement, consonant imprecision, strained-strangled vocal quality, hypernasality, reduced breath support for speech, slow speech rate, monopitch and moderately reduced speech intelligibility. Physiological assessment also revealed wide-ranging motor speech subsystem dysfunction, incorporating: reduced lung volumes and capacities as well as reduced abdominal excursion during speech, laryngeal hyperfunction, velopharyngeal insufficiency and reduced labial and lingual strength and endurance.

*Clinical Management Plan:* A multisystem approach was again adopted in the rehabilitation of Max's speech, involving a combination of behavioral and instrumental treatment techniques. Consistent with the ICF, his presenting motor speech deficit was considered in relation to structural and functional impairments, imposed activity limitations and participation restrictions as well as manipulable contextual factors. Refer to Table 46-7 for the proposed rehabilitation schedule. Furthermore, longitudinal monitoring of Max's speech and language abilities was considered pivotal in maximising educational and subsequently vocational potential, as he continued to mature from adolescence into adulthood.

## **ASSESSMENT AND TREATMENT OF LANGUAGE DISORDERS IN TBI**

Detailed investigations of linguistic integrity subsequent to TBI have been afforded limited consideration within the scientific literature thus far (13). The forerunning explanation for this lack of inquiry may rest with the observation that TBI subjects tend to perform within normal limits on tests of general language function, routinely incorporated within linguistic screening batteries. Despite this admission, however, recent evidence indicates that TBI proffers distinct ramifications for cognitive-linguistic substrates underpinning complex language processes, the rudiments of which fail to be adequately evaluated via standard aphasia tests.

Consequently, the proceeding sections of this Chapter highlight the nature of language impairments following TBI, appropriately sensitive assessments of linguistic function for use within adult and pediatric populations, as well as relevant treatment strategies.

### **Linguistic Deficits and TBI: Taxonomy and Neural Substrates**

Despite being reported to largely perform within the range of normal on assessments of general language function, individuals with TBI frequently demonstrate deficiencies in relation to functional communication

**TABLE 46-6**  
**Multisystem Approach to the Rehabilitation of Moderate Spastic Dysarthria Following TBI in an Adult: Jacob**

TREATMENT GOAL	METHOD
<ul style="list-style-type: none"> <li>• Reducing impairment in body structure and function. Remediate physiological dysfunction within motor speech subsystems.               <ul style="list-style-type: none"> <li>○ Enhance coordination of chest wall movements during speech</li> <li>○ Remediate hyperadduction of vocal folds</li> <li>○ Increase velopharyngeal competence</li> <li>○ Increase strength and range of labial and lingual movements</li> </ul> </li> <li>• Reducing activity limitations and participation restrictions. Enhance speech intelligibility.               <ul style="list-style-type: none"> <li>○ Modify stress and intonation patterns</li> <li>○ Increase speech rate</li> <li>○ Enhance articulatory precision</li> </ul> </li> <li>• Maximising communicative success across a range of communication environments               <ul style="list-style-type: none"> <li>○ Increasing communication partner awareness of conversational topics and contextual cues</li> <li>○ Repairing communication breakdowns</li> <li>○ Capitalizing upon situational and environmental recompense to maximize effectiveness of communication</li> </ul> </li> <li>• Manipulating contextual factors. Enhancing opportunities for participation across social and vocational contexts</li> <li>• Providing information to family/ friends/ workmates pertaining to nature of communicative disability and strategies to enhance communicative effectiveness within social and vocational environments</li> </ul>	<ul style="list-style-type: none"> <li>➤ Kinematic instrumentation to offer visual feedback of chest wall movement</li> <li>➤ Chewing/ yawn-sigh, gentle voice onset techniques</li> <li>➤ Use of Nasometer® to provide visual feedback of nasalance during speech</li> <li>➤ Isometric and isotonic lip and tongue exercises</li> <li>➤ Contrastive stress and intonation drills</li> <li>➤ PACER technique</li> <li>➤ Articulation drills</li> <li>➤ Practice routinely identification of contextual cues and establishment of topic of conversation</li> <li>➤ Clarify if communication partner has comprehended intended message and provide strategies for communication partners to request clarification</li> <li>➤ Limit communicative interactions when fatigued and maximize interaction when energy levels are at their peak; avoid noisy environments</li> <li>➤ Provide resources outlining: the cause and nature of presenting communication deficit; strategies to maximize communicative success with unfamiliar communication partners (e.g., sitting in front partner, requesting clarification in the event of misunderstood message)</li> <li>➤ Provide assistance in communicatively taxing situations (e.g., board meetings; face to face client contact)</li> </ul>
<p>*Note: References pertaining to individual treatment techniques may be located in Tables 46-3, 46-4, and 46-5.</p>	

skills (148–153). Furthermore, where TBI individuals do present deficits in primary language function such as naming, verbal association, reading and/ or auditory comprehension (150, 154, 155), error profiles generally fail to meet the criteria for classification within traditional Bostonian taxonomies (149). On the basis of these characteristics, a coherent conceptualisation of the nature of linguistic deficits associated with TBI has been hindered thus far.

Most recently, however, measures of high-level linguistic functioning including probes of metalinguistic ability, lexical-semantic manipulation and language

integration, have been recognised as sensitive indices of cognitive-linguistic breakdown in TBI populations (14). Tasks involving: the interpretation of ambiguous sentences, making inferential judgements, semantically constrained sentence generation, interpretation of metaphorical expressions and humour, formation of semantic associations, identification of semantic absurdities, synonym and antonym generation, definition and multiple definition formulation have been specifically implicated. These tasks are considered to be complex in nature, potentially necessitating the interplay of cognitive (e.g., attention, memory, executive

function) and linguistic processes (156). It is this interface that appears to be most susceptible to the effects of TBI, as opposed to more general language processes.

Overall communicative competence has also been postulated to necessitate the interplay of cognitive-linguistic processes which facilitate access to and manipulation of the semantic system within contextually defined environments

(13), extending well beyond the domain of operational or primary level language (157). Indeed, some research has highlighted frontal lobe dysfunction as the primary substrate underlying the language impairments associated with TBI, on the basis of diminished neuropsychological test results pertaining to frontal lobe integrity in tandem with reduced language performance (158). In support of this

postulate, closed head injury has been hypothesised to yield its greatest impact upon the prefrontal cortex, by virtue of skull configuration (159). It is plausible, therefore, that the interplay of frontal lobe-dependent cognitive domains such as attention, memory, executive function etc. with linguistic processes may be subsequently impaired as a result of TBI.

Linguistic deviations interwoven within a tapestry of cognitive deficits represents a commonly accepted view of the language symptom complex associated with TBI (13, 149, 155, 160). The precise nature of cognitive-linguistic interactions within this population, respecting a hierarchy of domain-specific influences upon language function, however, remains largely unknown (13). Recently, TBI performance profiles on tasks of lexical-semantic manipulation (e.g., TWT-R) have been strongly correlated with the cognitive variables of memory and attention (14), potentially earmarking these variables as integral to the mediation of certain linguistic operations.

In a similar manner to motor speech correlates, the linguistic sequelae of TBI have been documented as extremely variable from case to case (14), perhaps best attributed to variations in neuropathology across subjects. Despite this heterogeneity, however, several studies have identified subgroups within TBI populations respecting language performance (161–163). Global cognitive-linguistic impairment to near normal levels of functioning have been reported, with and without concomitant combinations of attentional, memory and/ or visuospatial deficits (162, 163). These profiles suggest that certain aspects of language are indeed influenced and perhaps directed by cognition, evidenced by distinct yet variable levels of discernable association subsequent to brain injury.

Thus far, the focus of the discussion pertaining to linguistic impairments associated with TBI has been directed at adult populations. Brain injury within childhood, or developmentally formative life stages with respect to cognitive skill acquisition, however, must be afforded special consideration. In a similar manner to adult language disturbances as a result of TBI, children with head injuries have been documented to present a form of “subclinical aphasia” (164), or rather, symptom complexes which fail to comply with the primary characteristics of traditional aphasic syndromes. For example, previous studies have specifically reported impairments on task of verbal fluency (165–168), confrontation naming (167, 169–171), verbal repetition (170, 171) and written expression (164, 172). Although not representative of frank aphasic deficits, it has been hypothesized that these atypical profiles may reflect the impact of TBI upon language processes in developmental ascendancy at the time of insult (164).

In line with adult research, post-TBI language profiles in children suggest impairment of a high-level linguistic nature, particularly when the aforementioned deficits are

considered within the context of well-documented neuropsychological deviations, including: disturbances of memory, attention, visuospatial ability and executive function (173–175). Indeed, following this line of investigation, reduced scores on sentence generation, as well as ambiguity and figurative language interpretation tasks have been identified in children with TBI (176).

Despite the many clinical parallels that may be drawn between language syndromes associated with adult and pediatric TBI, children potentially present deficits against a developmental backdrop, providing distinctive implications for assessment and treatment. Of most note, TBI in children has been documented to disproportionately disturb the acquisition of new language skills as compared to the recovery of already established abilities (177), and the younger a child is at the time of injury, the more profound the effect on language function (172, 178). Furthermore, latent behavioral deficits have also been reported to manifest in children with TBI (179, 180), posing definite ramifications for educational and vocational potential. These caveats indicate that assessment and treatment plans must be carefully mapped out in the treatment of paediatric head injury, as much as to enhance communicative competence as to maximize the quality of present and future life opportunities.

### Linguistic Deficits and TBI: Assessment

In general, individuals with TBI have been reported to demonstrate distinctive deficits on high-level language tasks which entail: (i) the application of metalinguistic competence; (ii) linguistic integration/ reasoning; (iii) divergent language production; (iv) lexical-semantic manipulation (i.e., judgement, organization, retrieval) (13). Subsequently, assessment batteries utilized in the evaluation of TBI individuals should incorporate such measures. Relevant assessments as they relate to adult and pediatric populations have been listed in Tables 46-8 and 46-9, respectively. Acknowledging the potential for varying levels of deficit severity in TBI populations, assessments of primary language function may also be required to delineate impairments in some individuals. As per high-level language evaluation, refer to Tables 46-8 and 46-9 for recommended assessments of general language function as they apply to adult and pediatric cases.

It has also been acknowledged that the conversational speech of TBI subjects is frequently characterized by verbosity, tangentiality and idiosyncratic phraseology (152). Parameters such as these are inadequately assessed via standard aphasia batteries. Consequently, contemporary research has begun to focus upon the assessment of more dynamic versus static linguistic functions in TBI, including discourse, or language in its most naturalistic form (181). A comprehensive summary of discourse and its analysis as it relates to TBI is beyond the scope of this Chapter. Suffice

to report that discourse analysis of non-interactive (e.g., narrative, procedural, expository) and interactive language samples has provided valuable insights into the nature of the functional linguistic impairments associated with TBI (181). Discourse analysis may involve the evaluation of syntactic, thematic and/ or information variables (181) as well as the more pragmatic aspects of communication, or the application of social rules (204), including turn-taking, maintenance of topic, comprehension of verbal and nonverbal cues etc. (205-207). Possible methods of language sample acquisition for discourse analysis have been listed in Tables 46-8 and 46-9, however, for a detailed discussion of analysis techniques, the reader is referred to (181, 208, 209).

### Linguistic Deficits and TBI: Treatment Approaches

The rehabilitation of cognitive disorders resulting from TBI, including language deficits, essentially involves three general approaches, including: restorative, compensatory and/ or behavioral techniques (210-213). Restorative techniques involve the undertaking of repetitive tasks targeting specific neural processes, with the aim of restoring function. Compensatory techniques involve the development of strategies and/ or competencies which overcome prevailing deficits via the acquisition of functional skills (213). Behavioral techniques engage behavior modification strategies in the development of targeted skills (210). In most cases, these strategies are used in combination, the restoration of behaviors and behavioral compensations representing the products of intervention.

#### Behavioral/ Restorative Approach

Specifically targeting impairments, traditional/ restorative approaches to language rehabilitation involve the repetitive undertaking of structured linguistic tasks, the nature of which are determined following a psycholinguistic evaluation of cognitive-linguistic integrity (214, 215). Refer to Table 46-10 for some examples of restorative therapy tasks.

#### Compensatory Approach

The compensatory approach to linguistic rehabilitation entails the development of self-initiated strategies to overcome particular communicative deficits, by way of physical props (e.g., written notes), external cues (e.g., requests for repetition of information) or internalized or self-cueing (208, 216). The success of compensatory approaches has been reported to rely upon the user's ability to apply them automatically (208). Consequently, compensatory strategies utilized naturally by a particular individual will be automatized more quickly than those strategies that are foreign or unfamiliar. For examples of compensatory strategies, please refer to Table 46-11.

**TABLE 46-10**  
*Restorative Therapeutic Strategies in the Treatment of Linguistic Deficits Following TBI (208)*

Deficit	Therapy Task
• Lexical-semantic Processing	<ul style="list-style-type: none"> <li>➤ Generating synonyms and antonyms</li> <li>➤ Word-definition matching</li> <li>➤ Convergent and divergent naming</li> </ul>
• Comprehension of complex linguistic information	<ul style="list-style-type: none"> <li>➤ Interpreting abstract expressions</li> <li>➤ Proverb/metaphor explanation</li> <li>➤ Discriminating between fact and opinion</li> <li>➤ Following instructions of increasing length and complexity</li> </ul>
• Organization of verbal expression	<ul style="list-style-type: none"> <li>➤ Sequencing tasks</li> <li>➤ Story retelling</li> <li>➤ Narrative production using specified schemas</li> </ul>

### TREATMENT APPROACHES: PEDIATRIC CONSIDERATIONS

By and large, the same treatment approaches may be applied to the rehabilitation of linguistic deficits as a consequence of TBI endured in childhood. In the case of pediatric populations, however, therapeutic hierarchies must not only focus on the remediation of skills already established at the time of injury, but must also take into account the future acquisition of developmental language processes. Of particular note, the impact of TBI on cognitive-linguistic functioning may not always manifest immediately following insult in children (208). Associated language deficits may only become apparent when the child fails to successfully acquire specific language processes relevant to a developmental continuum. As a result, children with acquired brain injuries should be monitored longitudinally in order to permit the prompt identification and remediation of potential cognitive-linguistic anomalies, with a view to promoting a sound educational and vocational platform.

### CASE REPORTS: CLINICAL MANAGEMENT OF LINGUISTIC IMPAIRMENTS FOLLOWING TBI

The following vignettes present clinical management plans relative to the rehabilitation of linguistic deficits following TBI in a 23-year-old adult and a 9-year-old child.

**TABLE 46-11**  
*Compensatory Therapeutic Strategies in the Treatment of Linguistic Deficits Following TBI (208)*

DEFICIT	STRATEGY
• Verbosity with good insight into maladaptive behavior	➤ Frequent clarification with communication partner that they are following conversation
• Verbosity with poor insight into maladaptive behavior	➤ Obtain assistance of external communication partner regarding relevance of verbal output
• Word retrieval problems with natural tendency to circumlocute	➤ Utilize circumlocution as a means of facilitating word retrieval
• Ineffective functional communication	➤ Identify where communication breakdowns occur (i.e., in what environments), formulate communication strategies for use in those environments and develop skills by way of functional therapy tasks (e.g., role playing)

### Case 1: Linguistic Impairment Following TBI in Adulthood

*Case History:* Kylie was a 23-year-old kindergarten teacher and part-time student at the time she sustained a TBI as the result of a motor vehicle accident. She was unconscious at the accident scene. However, no Glasgow Coma Score was recorded. Neuroimaging investigations failed to identify any focal neurological damage. At the commencement of her rehabilitation program, returning to work as a kindergarten teacher was her consummate goal.

#### *Language Profile:*

- Primary-level language largely intact with evidence of word retrieval deficits
- Natural inclination to utilize circumlocution as a means of facilitating word retrieval
- High-level linguistic deficits evident. Reduced performance on tasks of lexical semantic manipulation (e.g., forming semantic associations, defining words with multiple meanings, constructing semantically constrained sentences).
- Narrative discourse analysis revealed a proliferation of verbal disruptions, general verbosity

- Conversational discourse presented a similar profile, marked by intricate details in the presentation of information whereby the original theme of the message was often times forgotten. Kylie was insightful pertaining to her verbose communication style, frequently acknowledging her tendency to ramble.
- Often demonstrated overfamiliarity and inappropriate communicative behaviors with unfamiliar communication partners, with little insight pertaining to these character traits.

Based on the above information and within the context of the framework for intervention promoted by the ICF, a functional cognitive-linguistic communication plan for Kylie's rehabilitation was devised (208), 3 months subsequent to injury. This plan specifically targeted levels of impairment, activity limitation and participation restriction, and has been illustrated in Table 46-12.

### Case 2: Linguistic Impairment Following TBI in Childhood

*Case History:* Sally was a 9-year-old primary school student who sustained a TBI as the result of a fall from a horse. No loss of consciousness was observed at the time of injury but she was not responsive to commands. A Glasgow Coma Score of 7 was recorded at hospital admission. CT scan failed to reveal any focal neurological damage, however, a left occipital skull fracture was indicated.

Two days after hospital admission, Sally's condition deteriorated to a state of deep coma, requiring ventilation for a period of 1 week. Subsequent CT scan revealed right cerebral oedema, compressed ventricles and midline shift. Limited verbal output was observed post-injury with the gradual return of simplified yet socially appropriate language, 4 weeks following insult. Speech/ language evaluation at this time revealed:

#### Language Profile:

- Primary-level language largely intact with evidence of deficiencies in aspects of spoken language production, such as confrontation naming
- Conversational discourse was marked by circumlocutory behaviors, frequent repetition of utterances, difficulty interpreting humour and comprehending complex instructions
- Delayed responses to test items evident
- Overall, high-level linguistic impairment impacting upon communicative competence was diagnosed. General profile was characterized by reduced verbal fluency and word retrieval skills in the presence of impaired performance on tasks requiring comprehension of complex concepts and instructions.

**TABLE 46-12**  
*Cognitive-Linguistic Rehabilitation Plan Following Adult TBI: Kylie*

GOAL	METHOD
<ul style="list-style-type: none"> <li>• Providing effective instructions to children the preschool setting</li> </ul>	<ul style="list-style-type: none"> <li>➢ Maximize verbal retrieval and planning by way of: (i) utilising circumlocution as a means of facilitating word retrieval; (ii) plan one sentence explanations increasing hierarchically to more complex structures; (iii) structured lexical-semantic tasks (e.g., naming to definition; convergent naming; divergent naming etc)</li> <li>➢ Provide opportunities for role playing and rehearsal</li> </ul>
<ul style="list-style-type: none"> <li>• Reduce verbosity in conversation</li> </ul>	<ul style="list-style-type: none"> <li>➢ Discuss content categories such as relevant, irrelevant and embellishment</li> <li>➢ Discuss narrative structure</li> <li>➢ Identify presence and absence of content within conversations</li> <li>➢ Establish self-initiated cues to reduce verbosity</li> <li>➢ Provide opportunities for role playing, video feedback, group therapy</li> </ul>
<ul style="list-style-type: none"> <li>• Develop appropriate conversational style with unfamiliar communication partners</li> </ul>	<ul style="list-style-type: none"> <li>➢ Discuss various communication contexts, appropriate and inappropriate communication styles</li> <li>➢ Provide opportunities for role-playing and video feedback to enhance self-monitoring skills</li> </ul>

Based on the above information and within the context of the framework for intervention promoted by the ICF, a functional cognitive-linguistic communication plan for Sally's rehabilitation was devised (217). Refer to Table 46-13 for specific treatment schedule. Sally received 6 months of intensive speech pathology intervention with regular monitoring of progress including a formal language review at 12 months post-injury. At this point, the majority of linguistic deficits had resolved with the exception of subtle word finding difficulties in conversation. Ongoing speech pathology intervention involved monitoring of language recovery, as well as the implementation of compensatory strategies, tailored to changeable educational and social needs over the course of Sally's academic life.

**TABLE 46-13**  
***Cognitive-Linguistic Rehabilitation Plan***  
***Following Childhood TBI: Sally (217)***

GOAL	METHOD
<ul style="list-style-type: none"> <li>• Reduce word finding difficulty</li> </ul>	<ul style="list-style-type: none"> <li>➤ Convergent naming</li> <li>➤ Identify salient features relative to specified items</li> <li>➤ Utilize salient features strategy to facilitate word retrieval in conjunction with communication partner</li> <li>➤ Story retell/ story construction</li> </ul>
<ul style="list-style-type: none"> <li>• Enhance comprehension of complex material</li> </ul>	<ul style="list-style-type: none"> <li>➤ Following instructions of increasing length and linguistic complexity</li> <li>➤ Interpreting ambiguous sentences and figurative language; explaining jokes</li> <li>➤ Provide opportunities to request repetition of information when information not understood (e.g., role play in classroom environment)</li> <li>➤ Provide classroom strategies: request teachers to write complex instructions down when not understood; provide written summary of each class; engage in tutorials at end of lesson to ensure Sally has understood main concepts; regular contact with parents and monitoring of academic progress</li> </ul>

### **MILD TBI: MORE THAN MEETS THE EYE?**

To date, TBI research has largely focused upon the effects of moderate to severe level trauma, typically incorporating cases that have demonstrated extended periods of lost consciousness (18). It has been long acknowledged, however, that an absence of frank neurological disturbance subsequent to head injury does not guarantee an unmarred recovery (218). Indeed, physical, cognitive and affective disturbances constitute frequently documented sequelae associated with concussion or mTBI (219).

The majority of mTBI behavioral research to date has been neuropsychologically-based, lacking in-depth linguistic analyses (220). Reduced processing speed, concentration, attention and memory (219) have been identified as common cognitive deficits in mTBI patients.

Respecting language, deficits in verbal fluency, story recall/ verbal memory and anomaly detection (221–224) have also been reported, suggesting that higher-level linguistic processes may be implicated following mTBI. Indeed, a comprehensive language evaluation recently conducted within our laboratory was in support of this hypothesis. Deficits in lexical access, complex lexical-semantic manipulation at single word and sentential levels, as well as the organization and monitoring of responses were highlighted in a single mTBI case, nearly 2 years post-injury (225).

Potential high-level language implications in mTBI are supported by a neuroanatomical rationale. In an absence of frank neurological disturbance, dynamic imaging studies relating to cerebral perfusion and metabolism, have revealed frontal and temporal lobe abnormalities in mTBI cases (226–229). In terms of localisation theory, these findings have evident implications for language function. The mTBI language profile identified within our laboratory closely paralleled that of frontal lobe disconnection populations previously studied (230–235). This finding supports the notion that mTBI mechanisms may also preferentially implicate frontal lobe systems involved in the recruitment and directed interplay of the frontal lobes with other language areas, perhaps via neuronal fall out processes (236).

With respect to speech, it has been generally accepted that motor speech disturbances commonly accompany severe TBI (237). Within the domain of mTBI, however, speech deficits have also been documented (172, 238–240). The precise nature of these disturbances remains unexplored, with detailed perceptual and physiological investigations of motor speech function sorely lacking.

Acceleration-deceleration trauma without explicit neurological deficit has been recognized in simian research to evoke diffuse degenerative changes in axonal functioning (241). Shear strain (238) induced axonal injury has been hypothesised to result in the degeneration of synaptic terminals as well as disturbed neuronal input (242–244). Evidently, the extent of axonal damage subsequent to mTBI may involve the complete neural axis, extending from the cortical regions mentioned previously, to terminal aborizations within the brain stem (241). These neurophysiological alterations resulting as a consequence of mTBI, provide a platform for explaining the physical, cognitive and affective sequelae frequently associated with this syndrome. The potentially wide-ranging neuropathological profile of mTBI also offers possible ramifications for speech and language function, including manifestations of subclinical oromuscular and cognitive-linguistic alterations that may be undetected by standard assessments of fine motor control and cognitive abilities.

If we consider that the demands placed upon mTBI patients are greater at any given time after injury than that

of patients with severe brain trauma (245), the challenge lies ahead for researchers and clinicians to evaluate and apply appropriately sensitive methods of assessment to this population, in an effort to better delineate the nature of associated communication deficits. Special attention must be afforded to mTBI endured in childhood, considering that subtle symptoms may be easily camouflaged by inherent variabilities in maturational rates, particularly in regard to neuropsychological factors (18). Furthermore, ascertaining whether or not the communicative sequelae of mTBI demonstrate responsivity to traditional treatment techniques is yet to be determined.

The neuropsychological literature currently provides the mainstay of data pertaining to the assessment and treatment of mTBI cohorts (220). Contemporary studies have recently reported efficacious outcomes subsequent to a process-specific approach to the remediation of working attention/ memory deficits (246), and the implementation of compensatory strategies for functional impairments of memory, attention, reasoning and additional components of executive function (247). The development and application of cognitive communication rehabilitation techniques relative to this population, however, is much needed. To this end, it is anticipated that Speech-Language Pathologists may have a potentially valuable role to play in the future educational and/ or vocational rehabilitation of individuals with mTBI, as the precise nature of the motor/ cognitive sequelae associated with this syndrome continue to be unraveled.

## Evaluation and Treatment of Swallowing Problems After TBI

*Jeri A. Logemann*

**T**raumatic brain injury in children or adults can affect swallowing in a variety of ways (1–4). It is important for the clinician to investigate the history of the patient’s original injury and acute care for that injury in order to understand the type(s) of swallowing disorders that may be present. The neural damage resulting from traumatic brain injury and the incident causing the injury can vary tremendously from patient to patient. There is the direct neural damage at the site of trauma, the contrecoup injury or the opposite side of the brain trauma as the brain bounces in the brain case, and there is the twisting or torquing of the brainstem during the injury. Thus, there is rarely a direct relationship between the location of the trauma and the nature of the swallow disorders. However, the clinician should learn the locus of the direct injury and results of any other testing of neural function to identify other areas of damage (5).

In addition to the neural damage, there is potential structural damage during the injury that could affect swallowing. For example, if the patient’s neck is broken as their head is injured, they may exhibit problems in swallow related to cervical spine injury (6). If the patient flies from a motor vehicle and lands on a foreign body such as a stick or piece of metal, there may be penetrating wounds into the neck that affect swallowing. Thus, the exact nature of the patient’s damage at the scene of

the accident is quite important. Another factor in identifying swallowing disorders in the patient who has suffered a traumatic brain injury, is to define any emergency medical care that could affect swallowing (7). This would include an emergency tracheostomy, which might be placed higher in the neck than normal and damage laryngeal function. If intubation to establish an airway is done traumatically, it can cause dislocation of one or both arytenoid cartilages or other damage to the larynx, particularly the true vocal folds. Understanding the nature of the patient’s injuries and the medical care they received is important in accurately assessing dysphagia in the head-injured patient. The key to successful recovery/rehabilitation of dysphagia after brain injury is to define the exact structural or physiologic abnormalities in the swallow and to design the therapy program to address these disorders.

*Swallowing Disorders Seen in Brain Injury* A broad range of swallowing disorders is seen in patients after brain injury, probably because of the wide range of damage that can cause dysphagia in these patients. If the patient exhibits upper motor neuron damage with high muscle tone, there may be difficulty in opening the mouth, controlling the oral tongue and the soft palate. Most commonly, there is a delay in triggering the pharyngeal swallow or even an absent pharyngeal swallow. There may

be reduced motor control of the pharyngeal stage of swallow when it triggers, involving reduced movement of the tongue base to generate pressure to move the food into the pharynx, reduced laryngeal elevation because of scar tissue, tracheostomy, etc., or there may be reduced pharyngeal wall contraction resulting in reduced pressure generation. Dysfunction in the airway protection provided by the larynx does not occur frequently in head-injured individuals nor does a dysfunction at the upper esophageal sphincter at the entrance of the esophagus. However, patients with structural damage can have scar tissue in place that affects either airway closure or opening of the upper esophageal sphincter. Myoclonus may occur in any oral or pharyngeal structure including the oral tongue, tongue base, soft palate, pharyngeal walls, larynx, and completely discoordinate the swallow. It is critical that the speech language pathologist define the exact nature of the patient's swallowing disorder(s) in order to define appropriate therapy/management for the patient's swallowing problem(s).

*Counseling the Patient's Family* In a patient who has suffered a severe brain injury, swallowing is often one of the last things to be evaluated. Sometimes, patients are allowed to eat because they exhibit no symptoms of a swallow disorder such as coughing or choking. Then, later, as recovery progresses, the patient begins to exhibit some signs of dysphagia while swallowing particular types of food. It is important that clinicians talk with the patient's physician and family as soon as possible regarding the possibility of swallowing disorders and the potential need to evaluate swallowing. Families often think that if the patient is not visibly struggling to eat, coughing and choking, their swallowing is fine. If the patient is allowed to eat and then later has an assessment which identifies a significant swallow impairment, families and patients can become very angry, complaining that they were allowed to eat at an earlier stage in recovery sometimes at another institution, but now the clinician is "making them go backwards" and delaying their recovery. Because of this reaction, it's important that clinicians introduce the possibility of a swallow impairment early, even if evaluation isn't possible immediately because of the patient's medical status.

*Evaluation of Dysphagia in Brain Injured Patients: When and How* The evaluation of dysphagia in brain injured patients should begin as they are admitted to the acute care hospital. However, in some situations, the patient receives a severe enough injury that swallowing evaluation is not even considered until the patient has been stabilized and life is no longer threatened. **For some patients this may be days or weeks.** The initial screening assessment may simply indicate that the patient is not ready for a full swallowing assessment. Many patients are

in a coma initially. A small amount of data point to the fact that the longer the coma, the more severe the swallow problems are likely to be (3). When the patient is consistently awake and exhibits some level of alertness, dysphagia assessment should begin at the bedside. Formal swallowing evaluation and therapy have been found to improve dysphagia outcomes in brain injured patients (8)

Bedside assessment usually includes an oral motor assessment, a review of receptive and expressive language and ability to understand direction, history of medications used since the injury, and oral sensory testing to identify any abnormal oral reflexes or postural abnormalities (9). The major purpose of the bedside clinical assessment is to identify oral motor difficulties in the face, lips, tongue, palate, pharynx, and larynx, and to determine whether there is significant risk of a pharyngeal stage swallowing impairment. Pharyngeal stage swallowing impairments cannot be diagnosed at the bedside and require an instrumental assessment in order to define the exact nature of the swallowing problem and its sequelae such as inefficient swallow or aspiration. A review of the patient's medications may identify medications that could negatively affect swallow including tranquilizers, psychotropics, and medications that cause xerostomia (10). Oral sensory assessment examining two point discrimination and light touch sensitivity is important in determining the patient's ability to recognize where food is located in the mouth and whether or not all of the food has been cleared in any swallow attempt. Some brain injured individuals exhibit severely slowed oromotor control such that opening the mouth can take 3 to 5 minutes. In this situation, there is generally significant hypertonicity in facial musculature which requires rotary massage on one cheek while digital pressure downward is applied firmly to the chin and the patient is given repeated directions to try to open their mouth. Even with this assist to heighten sensory awareness, the patient may take 3 to 5 minutes to open their mouth. In such a patient who is also nonverbal, an instrumental swallow assessment must be delayed until they are able to open their mouth in under 30 seconds. The rotary massage and continuous digital pressure to the chin will facilitate faster oral opening as well as an understanding of the patient's neural and structural damage causing the swallowing problem. Family members should be counseled regarding the fact that the patient is not yet ready to have an instrumental swallow assessment but rather needs to build control over their oral mechanism instead. The patient's ability to manage their own saliva and awareness of their saliva is also an important component of the bedside assessment. At the end of a bedside assessment, the clinician should be able to describe the patient's level of alertness, their ability to follow direction, behavior control, their oral motor function and their saliva control as well as understand the patient's neural and structural damage

causing the swallowing problem. Patients should also be assessed for their ability to vocalize and to coordinate respiratory and laryngeal function. If the patient has been given food or is eating, the clinician should observe the patient swallowing to identify any dysphagic symptoms. Unfortunately, the bedside clinical examination cannot define pharyngeal physiology or pharyngeal symptoms of swallow disorders such as aspiration (11).

**Instrumental Assessments** Instrumental assessments may include a radiographic evaluation, fiberoptic endoscopic examination of swallow (FEES) or manometric assessment. Radiographic assessment is the simplest for the patient who has sustained a brain injury since no tube or other instrumentation must be placed into their nose or mouth. During the radiographic assessment, the patient must be able to be positioned into the fluoroscopy equipment so that the head and neck can be viewed in the lateral plane (Figures 47-1 and 47-2). Even this can be difficult for some low level patients. However, in many instances the patient can be moved into the equipment and positioned between the fluoroscopy tube and the table on a cart or gurney, thus requiring no voluntary motor control on their part.

The radiographic study is designed to define the anatomy and the physiology of the oral preparatory, oral and pharyngeal phases of swallow and to identify therapy procedures to improve the swallow if needed. The goal of the test is to find ways for the patient to swallow successfully, not to keep them from eating (12). The patient is given measured volumes of thin liquids, pudding and,

if the patient is capable of chewing, a material requiring mastication, generally a Lorna Doone cookie. Other foods can be given as needed. The patient is presented with measured volumes of thin liquid beginning with a small amount (1 ml) and asked to swallow it. The material is a flavored barium. The patient is given 2 swallows of each bolus volume or food type and the swallow is observed fluoroscopically. In total, the patient should receive 2 swallows each of 1, 3, 5, 10 ml of thin liquids, cup drinking of thin liquids, pudding and masticated material. The bolus volumes of thin liquid are increased sequentially as long as the patient swallows the smaller volume successfully, that is, without aspiration or large amounts of residual food left in the mouth or pharynx. If the patient exhibits a significant swallow impairment which results in aspiration or large amounts of oral or pharyngeal residue, the patient should be given treatment strategies during the x-ray study to improve the swallow and eliminate these sequelae of swallow disorders. Generally, when selected treatment techniques are introduced during the radiographic study, three types of techniques are attempted in the following order: 1) postural change; 2) heightening sensory awareness; and 3) voluntary swallow maneuvers. The specific postural techniques, sensory enhancements and voluntary swallow maneuvers to be introduced with a particular patient will depend upon the nature of their swallowing disorders revealed by the diagnostic portion of the test and the level of their ability to follow direction. The purpose of introducing therapy strategies into the radiographic diagnostic study is to determine which procedures are the most efficacious for the patient and to do so in a way that

**FIGURE 47-1**

Lateral radiographic view of the oral cavity and pharynx after a swallow in a brain injured patient who is also spinal cord injured and is wearing a neck brace. There is significant residue in the mouth and the tongue base is also coated with material

**FIGURE 47-2**

Lateral radiographic view of the oral cavity and pharynx at mid swallow in a patient post brain injury. The airway should be completely closed at this time but there is penetration and aspiration present

documents their effectiveness. If none of these strategies improve the safety or efficiency of the swallow, the clinician can introduce other food consistencies such as nectar- or honey-thickened liquids to determine whether or not the patient can gain a safe and fairly efficient swallow with a diet change. At the end of the radiographic study, the clinician should be able to define the patient's swallow physiology and safety, the best treatment procedures for the patient's swallow disorder(s) and the optimal diet as well as safety of the swallow. The report provided after the study should provide this information in a concise and accurate format.

Another instrumental assessment is the fiberoptic endoscopic evaluation of swallowing or FEES which involves the nasal insertion of a fiberoptic tube in order to view the pharynx from above. This procedure does not enable observation of the oral preparatory or oral phases of swallow, nor does it permit assessment of the pharyngeal stage of swallow during the moment of laryngeal elevation, tongue base retraction and upper esophageal sphincter opening (6, 13–14). It does enable observation of the bolus entering the pharynx over the base of tongue, the initial movements of the pharyngeal stage of swallow and any aspiration that may occur as the bolus appears in the pharynx. It also enables viewing of the pharynx after the swallow when any bolus residual may be aspirated. In summary, endoscopy provides a superior view of the pharynx and enables the clinician to observe selected aspects of the oral pharyngeal swallow (see Figure 47-3). Endoscopy has the advantage of involving no radiographic exposure and enabling the clinician to bring the equipment to the patient's bedside (15). The question the clinician must answer is whether or not the endoscopic examination will provide the information needed for management of the patient's swallowing disorder(s).

If the question the clinician needs answered in the swallow assessment is whether or not the pressure generated during swallow is adequate, then manometry may be the appropriate procedure to be used. Many swallowing disorders, including difficulties with the oral tongue, tongue base or pharyngeal wall, lead to reduced pressure generation in the pharynx including reduced movement of the base of tongue, reduced movement of the pharyngeal walls and reduced laryngeal elevation and forward movement. While the radiographic study or the fiberoptic endoscopic study can give a perception of reduced pressure to clear food through the pharynx, actual measurements of pressure can only be made with manometry. Manometry, too, involves placement of a tube transnasally into the pharynx and the top of the cervical esophagus. Generally, this is done under fluoroscopy in order to assure where the pressure sensors in the manometric tube are located (see Figure 47-4) and to determine what structures are touching the manometric tube that may create pressure changes (16).

**FIGURE 47-3**

A superior endoscopic view of the larynx and the pharynx with the false vocal folds closely approximated prior to swallow. The arytenoids and pyriform sinuses are also in view. The upper esophageal sphincter (UES) is located at the top of the image behind the arytenoids and is closed. Opening of the UES is not usually visible during endoscopy as the endoscopic image disappears as the larynx elevates during the first third of the pharyngeal swallow (24, 25)

**FIGURE 47-4**

Lateral radiographic view of the oral cavity and pharynx prior to a swallow with a solid state manometric catheter in place prior to swallow. The manometric catheter is a 3 mm diameter flexible tube containing the solid state pressure sensors represented by the dark elongated rectangles resting on the pharyngeal wall first at the level of the tongue base, and second at the level of the laryngeal entrance

Before scheduling the instrumental assessment, the patient should be screened for their readiness for an instrumental assessment. If the patient is unable to control their behavior or to tolerate leaning against the back of a cart during a radiographic study, then they are not ready for that assessment. Similarly, if the patient is easily upset or will not tolerate a tube placed in their nose, they are not ready for an endoscopic or manometric study in many cases.

Other procedures can be utilized in assessment of dysphagia in brain injured individuals including the use of ultrasound and electromyography. These procedures are not frequently used in the evaluation of swallow function in the brain injured individual because the information that they can provide has limited clinical utility. Ultrasound is an imaging procedure using high frequency sound waves which enables examination of tongue motion in the mouth but does not visualize the pharynx. Since many of the greatest concerns in the patient with dysphagia resulting from a brain injury are pharyngeal concerns, ultrasound will not provide the requisite information. Similarly, electromyography is a procedure that shows electrical activity in muscles being used during swallow but does not enable visualization of oral and oropharyngeal structures or their movement.

In summary, a radiographic study, that is, the modified barium swallow, is the most commonly utilized instrumental assessment to evaluate oropharyngeal swallow abnormalities in the patient who has sustained a brain injury.

## TREATMENT/MANAGEMENT OF DYSPHAGIA IN BRAIN INJURED PATIENTS

The initiation of treatment for dysphagia in the brain injured individual generally depends upon the outcome of the detailed physiologic assessment. In some cases, treatment may begin immediately with exercise programs to facilitate improved swallowing motor control. Or, treatment may involve compensatory strategies in an attempt to direct the flow of food in a more safe or efficient manner. Exercises to reestablish a coordinated swallow may also be appropriate. Each of these will be discussed below.

*Compensatory Treatment* Compensatory strategies to manage swallowing disorders typically involve changes in head or body postures. There are 5 different head and body positions which have known effects on pharyngeal dimensions, the bolus and structural movements during the oropharyngeal swallow: 1) chin down; 2) chin up; 3) head rotated; 4) head tilted; and 5) lying down. Table 47-1 presents these 5 postures and their known effects on the anatomic relationships of structures in the pharynx and

also on the oropharyngeal swallow. Postural techniques are usually attempted first because they are relatively easy for most patients to achieve and can have dramatic effects on the oropharyngeal swallow (17–19). Table 47-1 presents a list of swallow disorders and appropriate postural techniques along with the effects of the posture on swallow function.

*Enhancing Sensory Input* Another set of management procedures involve enhancing sensory input in the patient's oral cavity prior to the attempt to swallow (20–22). Generally, these procedures include thermal tactile stimulation and enhancing the bolus taste, texture, volume, carbonation, or viscosity. The sensory enhancements are appropriate for patients with sensory swallowing disorders which are: 1) a delay in recognition of food in the mouth and a delay in the oral onset of the swallow, and 2) a delay in triggering the pharyngeal swallow. Both of these disorders must be identified in the careful swallow assessment. Sensory treatment procedures such as intensifying or changing bolus taste or presenting carbonation have not been adequately studied. The small amount of available data indicate that such procedures are not effective in patients with impairment in motor control of the oral or pharyngeal stages of swallow.

*Swallow Maneuvers* Swallow maneuvers are voluntary controls applied to selected motor characteristics of the oropharyngeal swallow. There are 4 voluntary swallow maneuvers that have known effects during the motor control of swallow: 1) supraglottic swallow; 2) super-supraglottic swallow; 3) effortful swallow; and 4) the Mendelsohn maneuver. The supraglottic swallow involves a voluntary breath hold lightly before and during the oropharyngeal swallow. This closes the airway at the level of the true vocal folds. The super-supraglottic swallow closes the airway entrance between the arytenoids, base of epiglottis and false vocal folds, thus closing the entrance to the airway. This is done by breath holding with effort. The effortful swallow increases the known pressure exerted during swallow by the oral tongue and tongue base. The patient is instructed to squeeze hard with all of their muscles during swallow. This improves tongue base and oral tongue action and the resultant pressures during swallow. The Mendelsohn maneuver is designed to increase laryngeal elevation and forward movement during the swallow and thereby to increase opening of the upper esophageal sphincter. The sphincter is controlled by hyo-laryngeal movement. The patient is told to swallow normally and as they swallow feel their "voice box" or "Adam's apple" elevate during swallow. When they can feel their larynx elevate, they should grab the larynx with their muscles in the neck and hold the larynx up. The effort of holding the larynx up extends its elevation and increases opening of the upper esophageal

**TABLE 47-1**  
**Postural Techniques Generally Most Appropriate for Each Swallow Disorder and the Physiologic/Anatomic Effect(s) of the Posture on Pharyngeal Dimensions or Bolus Flow**

DISORDER OBSERVED ON FLUOROSCOPY	POSTURE APPLIED	PHYSIOLOGIC/ANATOMIC EFFECT OF POSTURE
Inefficient oral transit (Reduced posterior propulsion of bolus by tongue)	Head back	Utilizes gravity to clear oral cavity
Delay in triggering the pharyngeal swallow (Bolus past ramus of mandible but pharyngeal swallow is not triggered)	Head down	Widens valleculae to prevent bolus entering airway; and narrows airway entrance
Reduced tongue base retraction (Residue in valleculae)	Head down	Pushes tongue base backward toward pharyngeal wall
Unilateral laryngeal dysfunction  (Aspiration during swallow)	Head down  Head turned to damaged side	Places epiglottis in more posterior, protective position  Pushes damaged side toward midline
Reduced laryngeal closure (Aspiration during the swallow)	Head rotated to damaged side and chin down	Increases vocal fold closure by applying extrinsic pressure; narrows laryngeal entrance. Places epiglottis in more protective position
Reduced pharyngeal contraction (Residue spread throughout pharynx)	Lying down on one side	Eliminates gravitational effect on pharyngeal residue
Unilateral pharyngeal paresis (Residue on one side of pharynx)	Head rotated to damaged side	Eliminates damaged side from bolus path Pulls cricoid cartilage away from posterior pharyngeal wall,
Cricopharyngeal dysfunction (Residue in pyriform sinuses)	HEAD ROTATED	reducing resting pressure in cricopharyngeal sphincter

sphincter. These maneuvers can be used during eating or as an exercise. There is another swallow maneuver, the tongue holding maneuver which is an exercise maneuver and cannot be used to eat. During the tongue holding maneuver, the patient holds their tongue tip between their teeth to stabilize it, thereby pulling the tongue base forward and putting extra pull on the muscle which contracts the pharynx at the tongue base level and pulls the tongue base backward, the glossopharyngeal muscle.

All of these maneuvers require the ability to follow direction and thus may not be appropriate for the most severely damaged individuals who have suffered a brain injury. Data on nature of swallow disorders among the brain injured indicate that disorders of airway closure or upper sphincter opening occur relatively infrequently (3). When these disorders do occur among patients with brain injury swallow maneuvers can be very helpful if the patient is able to follow the directions necessary.

**Exercise Programs** Exercise programs can also be very helpful to improve structural range of motion, muscle

strength, and coordination (20). Range of motion exercises are helpful in patients with neurologic or structural damage to the brainstem or to the periphery and are available to the facial muscles, tongue, laryngeal elevation, and laryngeal adduction (20). Strengthening or resistance exercises for the tongue can result in significant improvements (23–24) in tongue function for swallowing. Swallow maneuvers can be used as exercises to improve swallow coordination (25–26). When prescribed, these exercises should be done for short periods (5 minutes, 10 times per day). These exercises can be difficult for brain injury patients with language or cognitive deficits who may not be able to follow directions. Such patients may more successfully use postural changes, sensory enhancements, or diet change.

**Diet Change** Sometimes patients can only swallow safely on a particular viscosity of food, such as thin liquid, nectar thick liquids, honey thick liquids, pudding, etc. Limiting a patient's diet should be the clinician's last choice in management because most patients dislike diet

**TABLE 47-2**  
***Bolus Consistencies and the Swallow Problems for Which They Are Usually Most Appropriate. The Patient Should Be Tested Radiographically with Each Bolus Type to See Which Can Be Most Efficiently and Safely Swallowed***

FOOD CONSISTENCIES	DISORDERS FOR WHICH THESE FOODS ARE MOST APPROPRIATE
Thin liquids	Delayed pharyngeal swallow *Reduced tongue base retraction *Reduced pharyngeal wall contraction *Reduced laryngeal elevation Reduced cricopharyngeal opening *Oral tongue dysfunction
Thickened liquids (nectar and/or honey) Purees and thick foods, including thickened liquids	Delayed pharyngeal swallow Reduced laryngeal closure at the entrance Reduced laryngeal closure throughout the larynx

\*All of these disorders affect generation of pressure to drive the bolus through the oral cavity and/or pharynx. Thinner foods (liquids) require less pressure to swallow.

changes such as thickened liquids. However, there are patients for whom there is no other feasible management and diet change is necessary. Or the patient is recovering and can initially only swallow safely and efficiently on a particular food consistency. Table 47-2 presents food consistencies that are particularly helpful for patients with various oropharyngeal swallow disorders.

*Experimental Treatment Procedures* There are a number of treatment procedures currently being discussed in the area of dysphagia therapy that are experimental in nature because these procedures have no efficacy data to support them. They should be used carefully and only with a very strong rationale. These procedures include neuromuscular electrical stimulation to various points on the neck, deep pharyngeal neuromuscular stimulation (DPNS) and myofascial release. None of these procedures have been identified as effective with any specific swallow impairments or with patients with a specific diagnosis. Therefore, clinicians should approach their application with care, particularly in patients with seizures or muscular hypertension in the head or neck.

### SHORT- AND LONG-TERM FOLLOW UP

It is important that patients who have sustained a brain injury are regularly seen after discharge if therapy has not returned their swallow to a functional status, i.e., no aspiration and only minimal residual food left in the mouth or pharynx after the swallow. There are numerous instances in which patients who have sustained brain injury with subsequent dysphagia have received

swallowing therapy and shown improvement but have ultimately plateaued and have not been able to return to full oral intake. Some of these individuals have been found to have functional swallowing at 3, 6 or 9 months after their original discharge from swallowing treatment. It is clear that we do not know enough about recovery from swallow disorders caused by brain injury. Therefore, it is best to reassess the patient's function at 6 months or a year post discharge from treatment if the patient is left non oral.

### RESEARCH NEEDS

There is a great deal more research needed in the area of brain injury and swallowing disorders. The pattern of recovery of swallow disorders post brain injury has not been clearly defined though it is clear that most patients do recover swallow abilities over the first 3 to 5 months post injury (27). There are some patients, however, who do not achieve functional and safe swallowing or who require much longer rehabilitation (28) and the exact nature of their neural damage or resulting swallowing disorders in comparison to individuals who have achieved faster recovery have not been defined. There have been no clinical trials in the comparative effectiveness of specific strategies for swallowing therapy in patients with brain injury. One reason for this is the wide variety and high variability between brain injured patients with dysphagia. There are numerous patient characteristics that must be controlled but such research is much needed. The relationship between coma duration and severity and the nature of swallowing disorders and recovery time for dysphagia deserve further attention as well.

Factors associated with development of pneumonia in severely brain-injured patients with and without dysphagia have been examined (29). These authors found that a Glasgow Coma Scale Score of less than 5, evidence of swallowing disorders and aspiration and field intubation were risk factors for early pneumonia in the brain-injured patient. However, this issue and others related to recovery of full oral intake in the dysphagic head-injured patient require a great deal more research.

## Cognitive-Communication Deficits Following TBI

*Carl A. Coelho*

**L**anguage is best defined within the context of communication. Human communication involves the sharing and exchange of information between people. Language refers to communication through the use of words or other symbols and entails the use of multiple modalities such as: speaking, auditory comprehension, reading, writing, and gesture (1). Language use is frequently displayed through speech. Speech has developed into a highly efficient system for the exchange of even the most complex ideas. However, speech is the end product of a multifaceted cognitive process. For example in a situation in which two people are interacting; the speaker has to organize his thoughts, or communicative intent, decide what he wants to say and put what he wants to say into an appropriate linguistic form. This occurs by selecting the right words and phrases to express the intended meaning, and then placing these words in the correct order specified by the grammatical rules of the language. The next stage involves the formulation of motor commands necessary for programming the speech mechanism (i.e., the neural and muscular activities for activating respiration, phonation, resonance, articulation, and prosody) to produce an acoustic signal that accurately represents the words selected to communicate the speaker's intent. The final step in this process is the

execution of the commands resulting in the production of speech (2).

Brain injuries may disrupt the process of communication at a variety of levels. Speech disorders (e.g., apraxia of speech or the dysarthrias) will not be discussed in the present chapter. The reader is referred to chapter 46 for a thorough discussion of that topic. Rather this chapter will focus on language disorders following traumatic brain injury (TBI).

### **LANGUAGE DISORDERS FROM A SITE OF LESION PERSPECTIVE**

The nature of a brain injury will in large measure determine the characteristics of the subsequent language disorder. For example, strokes are typically associated with focal lesions to either hemisphere or subcortical structures, resulting in fairly predictable deficit patterns. By contrast, TBI may result in focal injury to specific regions of the brain (e.g., coup and contrecoup sites of impact), diffuse axonal injury (i.e., stretching, tearing, shearing of nerve fibers), or a combination of both. This mechanism of injury yields a far less homogenous array of deficits. Language disorders resulting from lesions to the left hemisphere, right hemisphere, subcortical regions, and diffuse damage are reviewed separately below.

### **Focal Left Hemisphere Damage—Aphasia**

McKinley and colleagues (3) have noted that language is disturbed in 75% or more of individuals with TBI. However, the nature of this language disturbance, that is, whether it is aphasic or nonaphasic, is not clear-cut. Aphasia is defined as an acquired impairment of language processes underlying receptive and expressive modalities caused by damage to areas of the brain that are primarily responsible for language function (4). Aphasia is characterized by grammatical disturbances, deficits of word retrieval, auditory comprehension, reading, and writing, in the presence of relatively intact cognitive abilities (e.g., orientation, attention, memory). Lesions associated with aphasia are usually located in the left hemisphere in the region of the posterior frontal lobe, anterior temporal lobe, and/or inferior parietal lobe (i.e., anywhere along the distribution of the left middle cerebral artery). The incidence of aphasia secondary to TBI reported in the literature varies greatly. Reports range from approximately 2% of 750 (5) and 614 (6) consecutive admissions to two city hospitals, to nearly 50% (7, 8). Sarno, Buonaguro, and Levita (9) reported on a group of 125 individuals with closed head injuries admitted to a rehabilitation center. The individuals studied fell into three groups: those with classic aphasia (30%), those with dysarthria accompanied by subclinical aphasia (34%), and those with subclinical aphasia (36%). The authors classified individuals as aphasic if their use of speech for expression and/or reception was impaired. Subclinical aphasia referred to evidence of linguistic processing deficits on formal testing in the absence of clinical manifestations of linguistic impairment. The apparent discrepancies regarding the incidence of aphasia following TBI are difficult to resolve because of the lack of consistency in the descriptions of the individuals with TBI studied, the different aphasia assessment tools employed, as well as the varied definitions of aphasia applied. An examination of specific linguistic deficits following TBI reported in the literature indicates that anomia, difficulty retrieving words, (5, 7, 9–13) and impaired auditory comprehension (7, 9) are the most commonly observed symptoms. Holland (14) noted that there is overlap in these deficit areas between individuals with aphasia and those with TBI, as well as in the associated reading and writing deficits both groups often demonstrate. However, it is the qualitative differences in the naming errors between the two groups which may be most useful in distinguishing between aphasic and nonaphasic responses. Both individuals with aphasia and those with TBI (particularly those in the acute stages) produce circumlocutions and various paraphasias and have reduced fluency in the generation of category-specific words; individuals with TBI, however, demonstrate additional naming errors. For example, they may also produce naming errors related to their personal

situations or make errors of confabulation (i.e., sometimes bizarre responses related to the individual's disorientation). Milton and colleagues (15) have described a system for qualitatively evaluating naming behavior for individuals with TBI. The system permits descriptions of correct responses, and, when responses are incorrect, descriptions of their semantic, phonemic, and other relationships to the target. For example, for the target stimulus "apple" semantically-related responses might include such utterances as: "fruit", "Granny Smith", or "pear". Phonemically-related responses might include such utterances as: "able" or "ubel". Other responses might include such things as "saw" or "We grew them in our backyard".

### **Focal Right Hemisphere Damage**

As noted by Myers (16) it has only been in the last 25 years that the cognitive and communicative deficits associated with the right hemisphere have been considered. As was the case for left hemisphere damage most instances of focal lesions to the right hemisphere are the result of cerebrovascular accidents (CVA). Localization of specific functions related to language processing in the right hemisphere has been a confusing endeavor. Some investigators have observed that the difficulty localizing the component processes involved in maintaining semantic information may be attributable to the involvement of both anterior and posterior cerebral regions and their interconnections (17). Although it is beyond the scope of the present chapter to discuss in any detail the nature of deficits that result from right hemisphere damage (RHD), this section will summarize some of the characteristic features. Generally speaking the range of deficits linked to RHD may be placed into five broad categories (16). The first is attentional deficits which includes problems with: arousal, orientating, vigilance, sustained and selective attention. The next category is neglect which involves a reduction of: attention to left-sided input, use of left limbs, awareness and recognition of left-sided body parts, and awareness of illness. The third category involves visuoperceptual deficits including: visual attention, integration, and memory, and spatial and topographical orientation. A fourth category is affective and emotional deficits including reductions in: the use of facial expression to convey emotion, sensitivity to facial expressions of others, use of prosody to convey emotion, and comprehension of emotional prosody. The final category is cognitive and communicative deficits, included here are reduced: discourse comprehension and production, communicative efficiency and specificity, processing of complex inferences as well as alternative and ambiguous meanings, sensitivity to contextual information, and appreciation of shared knowledge.

With regard to specific linguistic impairments, individuals with RHD typically perform adequately on

language tasks that involve convergent processing (i.e., those requiring a limited number of responses and familiar word meanings) such as confrontation naming, yes/no questions, and providing definitions. Divergent language tasks (i.e., those involving a wide range of meanings which diverge from a single semantic concept such as verbal fluency, open-ended questions, or resolving ambiguities) present more difficulty for this group. They often have trouble understanding intended meanings because of a decreased ability to generate, maintain, or inhibit additional, alternate, and related meanings when the dominant meaning is inappropriate to the context (16).

### **Focal Subcortical Damage**

There is a growing body of literature which documents that right-handed individuals who sustain damage to the left basal ganglia or left thalamus can also develop aphasia (18–20). Three subcortical aphasia syndromes have been described by Naeser and associates. The first, anterior syndrome, results from damage in the internal capsule, lenticular nucleus, and anterior white matter. This syndrome is characterized by hemiplegia; slow, dysarthric speech with near normal phrase length and prosody; poor confrontation naming; good repetition; good comprehension; and poor oral reading and writing. The second is posterior syndrome, which is associated with damage in the putamen and internal capsule, and the posterior white matter. Features of this syndrome are hemiplegia, fluent speech without dysarthria, good single word repetition but poor sentence repetition, impaired confrontation naming, poor comprehension, reading and writing. The third pattern described, anterior-posterior syndrome, results from capsular-putamenal damage with anterior and posterior white matter involvement. Characteristics include a combination of symptoms seen in both Broca's and Wernicke's aphasias. Robin and Scheinberg (21) have cautioned that aphasia caused by lesions in the basal ganglia result in a variety of speech and language impairments that are not all accounted for by the three syndromes described by Naeser and associates.

Aphasia resulting from damage to the left thalamus is typically characterized by hemiplegia and difficulty initiating spontaneous speech. In addition, speech may be echolalic and contain neologistic errors. Fairly good auditory comprehension and reading are usually noted, while writing and word retrieval are impaired. These individuals have also been observed to be perseverative with fluctuating performance moment to moment (22).

### **Diffuse Axonal Damage**

Although individuals with TBI may incur focal lesions, a far more common type of brain pathology following TBI, and specifically closed head injury, is diffuse axonal

injury. This pattern of injury is typically associated with what has been termed confused language (10, 23–25). Confused language is described as receptive/expressive language that may be phonologically, syntactically, and semantically intact, yet lacking in meaning because responses are irrelevant, confabulatory, circumlocutory, or tangential in relation to a specific topic, and lacking a logical sequential relationship between thoughts (26). Such language dysfunction may be mistaken for a fluent aphasia but is more appropriately considered cognitive in nature as opposed to linguistically-based, that is, as a symptom of cognitive rather than linguistic deficits. Traumatic brain injuries frequently result in significant disruption of cognitive processes such as (attention, memory and executive functions). More recent considerations of language disruption following TBI have suggested use of the term cognitive-communicative disorders as being a more accurate description of these impairments. Cognitive-communicative disorders involve difficulty with any aspect of communication secondary to cognitive dysfunction (27). Some individuals with TBI exhibit language disorders most consistent with aphasia, some with communicative deficits comparable to those seen in RHD, and some, particularly in the acute stages of recovery from TBI, demonstrate language behavior consistent with confused language. Regardless, a primary component of language dysfunction in the majority of TBI survivors pertains to disordered language use (i.e., pragmatics). Pragmatics refers to the set of rules which govern the use of language in context (28). Sohlberg and Mateer (29) observed that whereas individuals with aphasia may communicate better than they talk, individuals with TBI appear to talk better than they communicate. Pragmatic deficits are probably most prevalent in those individuals with frontal lobe injuries. Although the frontal lobes are not thought to be responsible for primary cognitive functions, it appears they are involved in coordinating and actualizing many functions involved in cognitive processing such as attention, motivation, regulation, and self-monitoring (30). Individuals with prefrontal injury frequently demonstrate problems, among other things, with: disorganized discourse; inappropriate social interactions (e.g., difficulty interpreting social cues); and abstract forms of language (e.g., irony or sarcasm) (31).

### **DISCOURSE ANALYSIS**

Just as predominant impairments of language caused by focal lesions may mask subtle cognitive disturbances, primarily cognitive disturbances resulting from diffuse brain injury, may mask subtle language deficits (32). Such deficits typically go undetected, or are incompletely delineated by the traditionally used language assessment tools, such as aphasia batteries. In an effort to document such

pragmatic deficits many investigators of verbal communicative ability following TBI have chosen to analyze *discourse* (33–43). Discourse is a series of related linguistic units that convey a message. The length of a given discourse is determined by the communicative function of the message. There are various types of discourse and each type has different cognitive and linguistic demands (44). It has been suggested that discourse is the most natural and basic unit of normal verbal communication (45). Furthermore, accurate production or comprehension of a narrative requires a complex interaction of linguistic, cognitive, and social abilities (i.e., language use) that are sensitive to the particular disruption following TBI.

Discourse analyses begin with the elicitation of a spoken *narrative*, minimally five sentences in length. A variety of types of discourse may be studied including *procedural* (e.g., describing how to change a tire), *descriptive* (e.g., describing a favorite activity), *story narratives*, and *conversational*. The discourse samples are audiotaped and transcribed verbatim. Once transcribed, the narratives are divided into basic units for analysis, such as T-units (i.e., an independent clause plus any dependent clauses associated with it). A T-unit is similar to a sentence but is more reliably identified. Segmenting narratives into sentences is often problematic because of the tendency of some speakers to link sentences of a narrative with conjunctions such as *and*, *or*, and *then*, making it difficult to delineate sentence boundaries (46). Depending on the type of discourse and the focus of the analysis, the actual discourse analysis may be done at a variety of levels (see Table 48-1). For example, in a narrative story, at the sentence level the number of T-units may be tallied as a measure of narrative length, or the number of subordinate clauses may be

counted as a measure of grammatical complexity. Across-sentence analyses may involve examining how speakers link meaning units across several sentences (e.g., counting complete or incomplete ties), referred to as intersentential cohesion. In story narrative analysis, episodes may also be examined. Episode components are defined as information units pertaining to stated goals, attempts at solutions, and consequences of these attempts. Additional analyses include productivity measures such as total words produced or total speaking time, content measures such as accurate or irrelevant content units, and measures of conversational speech, for example, appropriateness of an utterance or topic maintenance.

### DISCOURSE DEFICITS FOLLOWING TBI

Functional communication requires language competence in a variety of settings ranging from informal social interactions to formal educational or work-related tasks (42). Findings of recent investigations have demonstrated that individuals with TBI experience difficulty with communicative effectiveness across a number of discourse genres (see 47–49 for reviews). What follows is a summary of several studies of discourse in individuals with TBI. Prior to beginning, a clarification on the use of the term TBI is offered. Although both closed and penetrating head injuries are classified as TBI, there are distinct differences between the two types, both in terms of array of deficits and recovery, the discussion of which is beyond the scope of this chapter. Throughout the review, which follows, the generic term TBI will be used because in many instances authors have not specified whether the individuals with brain injuries studied, had a penetrating or closed head injury. This review is organized by the level analysis. Prior to beginning this summary a brief overview of the levels of analysis for discourse production is provided. The most basic distinction in the analysis of discourse is whether the discourse genre of interest involves a monologue (narratives such as telling a story) or is interactive in nature (such as participating in a conversation). At the most general level, analyses of narrative discourse are focused on within-sentence processes, termed microlinguistic, or between-sentence processes, referred to as macrolinguistic. Under each of these broad categories are sublevels such as, lexical, syntactic, and lexical-semantic for the within-sentence analyses, and under the between-sentence analyses are the sublevels of local (microstructure) and global (macrostructure). Each of the sublevels has corresponding measures or analyses (see Table 48-1). Conversational analyses can be broken down in terms of the role of the participant during an interaction, that is, whether the individual functions as an initiator or as a responder. In each role there sublevels again with corresponding measures in the analysis.

**TABLE 48-1**  
*Various Levels in the Analysis of Narrative Discourse Production*

GENERAL LEVELS	SUBLEVELS	EXAMPLES OF MEASURES
Within-Sentence microlinguistic	Lexical	Lexical errors
	Syntactic	Completeness Complexity
	Lexical-semantic	Propositional analysis
Between-Sentence macrolinguistic	Local (microstructure)	Cohesion Local coherence
	Global (macrostructure)	Global coherence Story grammar

**TABLE 48-2**  
*Examples of Narrative Story Analyses (Coelho, 2002)*

DISCOURSE MEASURES	DESCRIPTION	EXAMPLE
<b>Sentence Production</b>		
Words per T-unit	Total words in story divided by number of T-units	118 words/6 T-units = 19.7
Subordinate clauses per T-unit	Number subordinate clauses in story divided by number of T-units	3 subord. clauses/6 T-units = .5
<b>Cohesion</b>		
Cohesive adequacy—Percent complete ties of total ties	Each occurrence of a cohesive tie judged as to its adequacy. Number of complete ties in story divided by total number of cohesive ties.	<b>Complete tie</b> – The girl was hungry. <i>She</i> ate her lunch. <b>Incomplete tie</b> – The boys walked home from the mall. <i>They</i> stopped at his house for a snack. <b>Erroneous tie</b> – Dave and Joe drove to the game. <i>He</i> forgot the tickets.
<b>Story Grammar</b>		
Number of total episodes	Total number of complete and incomplete episodes in a story.	<b>Complete episode</b> – <b>[Initiating event]</b> and this fly comes in and the Father's bothered by this. <b>[Attempt]</b> so he decides to swat or hit the fly. and he hits his wife. <b>[Direct consequence]</b> and she goes down. <b>Incomplete episode</b> – <b>[Attempt]</b> and he hits his daughter <b>[Direct consequence]</b> and the daughter goes down to the floor.
Proportion of T-units within episode structure	Number of T-units in episode structure divided by total number of T-units in story.	10 T-units in episodes/ 16 total T-units = .62

### Narrative Discourse

For each of the levels of analysis for narrative discourse a brief description is provided of each analysis followed by a summary of the findings from the TBI discourse literature. Examples of some of the more commonly used narrative analyses appear in Table 48-2. This will be followed by a comparable discussion of the analyses of conversational discourse.

### Microlinguistic Analyses

**Lexical Production** Examinations of lexical production typically involve measures such as lexical diversity (i.e., number of different words produced) and the occurrence of paraphasic errors. The literature on lexical problems in discourse following TBI has been somewhat equivocal. For example some authors have reported a reduction in the number of different words produced (50) or a greater frequency of verbal paraphasias (51) following TBI, while others have noted that lexical production was not a

problem for the individuals with TBI they studied (52, 53). Difficulties with verbal fluency and word retrieval following TBI reported in the discourse literature must be interpreted cautiously. Some of these studies have included, within their participant groups, individuals with TBI who were aphasic (e.g., 37, 51).

**Syntax** Syntactic aspects of discourse have been examined in several studies with mixed findings. Syntactic complexity, as measured by percentage of T-units containing dependent clauses (33), embeddedness of subordinate clauses (51), subordinate clauses per T-unit (54), and words per T-unit (55), was comparable to that of normal controls. Further, syntactic complexity was not judged as being a primary deficit when rated on various pragmatic rating scales (52, 53, 56). By contrast, other investigators have reported syntactic impairments in the discourse of individuals with TBI. For example Campbell and Dolaghan (50) noted that syntactic complexity, as measured by percentage of utterances containing two or more lexical verbs, was decreased in six of nine participants they

studied. In addition an increased incidence of grammatical errors (e.g., omissions of the subject, main verb and other required grammatical morphemes, word order transpositions, verb tense and agreement errors) have also been noted for participants with TBI versus normal controls (51, 57). Once again these findings may have been partially contaminated by the presence of aphasia for some of the brain-injured participants.

*Lexical-Semantic* The contradictory findings, noted for lexical production and syntax, have prompted other investigators to examine the microlinguistic dysfunction in the discourse of individuals with TBI through semantic analyses, specifically propositional analysis. The advantage of propositional analysis is that it permits the examination of semantic complexity of an utterance apart from sentence structure and grammaticality (58). Propositions are meaning units identified with respect to a predicate (i.e., verb, modifier) and its arguments (i.e., agent, instrument). Any sentence may contain several propositions (59). Using a measure of words per proposition, Chapman and colleagues (33) did not find deficiencies in information flow for a group of adolescents with TBI. However, McDonald (39) tallied unspecified propositions in explanations of a board game by two individuals with TBI and found that one participant provided less detail than the non-brain-injured controls. Another study that applied propositional analyses, noted that individuals with TBI appeared to have difficulty with the planning and organization of language (60). Similarly, individuals with TBI were noted to produce significantly fewer propositions per T-unit than normal controls. In other words, they demonstrated a decreased ability to insert multiple ideas into single sentences (61). By contrast, the non-brain-injured (NBI) participants' appeared to chunk information, and that appeared to be a mechanism for linking propositions together, which increased the likelihood that the listener might understand multiple ideas as a connected semantic unit. The participants with TBI appeared less adept at applying this strategy to facilitate discourse organization.

### Macrolinguistic Analyses

Continuing with the review of narrative discourse analyses, the focus now shifts to the macrolinguistic analyses which examine discourse performance between or across sentences.

*Cohesion* Sentences are connected by various kinds of meaning relations described as cohesive markers or ties. A word is considered a cohesive marker if its meaning cannot be adequately interpreted without the listener searching the text, beyond that sentence, for the completed meaning. Cohesional analyses, as described by Halliday and Hasan (45), have been undertaken in several studies of discourse and TBI. Discourse samples of

individuals with TBI have been described as lacking continuity as evidenced by their production of fewer cohesive ties than normal controls in both narrative and procedural discourse tasks (37, 40). However, other investigators have reported that individuals with TBI produced a comparable number of cohesive ties as NBI participants in narrative discourse (39, 51, 54, 62). Differences in the proportional use of ties across discourse tasks have been reported for individuals with TBI (40, 54). Mentis and Prutting observed that their TBI participants used different cohesive patterns which appeared to be related to their reduced linguistic processing abilities, their reduced pragmatic abilities, as well as their attempts to compensate for the linguistic deficits. Liles and colleagues noted that, in a story retelling task, similar proportions of referential (e.g., *Tom is an engineer. He works in Ohio.*), lexical (e.g., *I gave Frank our tickets. The idiot lost them all.*), and conjunctive (e.g., *Bill worked all night. And his hammering kept the rest of us awake.*) markers occurred for both the TBI and NBI groups. In the story generation task however, a distinction between the groups appeared in which the individuals with TBI showed a reversal of the pattern used in the story retelling task. In story generation all of the TBI participants decreased the proportional use of reference and increased the proportion of lexical ties. This shift in the proportional use of types of cohesive ties across the story tasks was attributed to the TBI groups' apparent direct reference to the stimulus picture. These direct references were characterized as interjected descriptors of the picture that were unrelated to the rest of the text. The individuals with TBI rarely integrated these lexical items into the text structure and consequently they were often judged to be incomplete ties. The TBI participants' tendency to refer outside their texts suggested that they were unable to detach themselves from the perceptual salience of the stimulus picture in order to organize their language for story development. In a final study, Coelho and colleagues (35) examined cohesion in discourse samples from a story generation task gathered longitudinally from two individuals with TBI. One individual demonstrated poor cohesive adequacy with meaningful content, as measured by story structure, and the second, fair to good cohesion with poor content. These findings emphasize the clinical utility of monitoring discourse abilities longitudinally and of employing a multilevel analysis procedure.

*Coherence* Coherence refers to the conceptual organization of discourse. The coherence of a text depends on the speaker's ability to maintain thematic unity (63). Coherence is typically considered from two perspectives, global and local. Global coherence pertains to how discourse is organized with respect to a general goal, plan, or topic. Local coherence refers to the maintenance of meaningful conceptual links between individual sentences within a text. Coherence has been specifically examined

in the narrative discourse of individuals with TBI (39, 51, 62) and the findings have been mixed. With the exception that the participants with TBI produced more unexplained references, McDonald (39) noted that their texts were as coherent as those of the normal controls. Similarly, Van Leer and Turkstra (62) found no differences in the coherence ratings for their groups of TBI and NBI participants. However, Glosser and Deser (51) reported that the individuals with TBI they studied were significantly impaired relative to the normal controls in measures of local and global coherence, with global coherence most impaired. These authors suggested that coherence depends on intact access to semantic memory representations of real-world knowledge, as well as perceptual and conceptual integration necessary to maintain the plan and overall organization of discourse. In addition, the ability to produce discourse perceived as coherent requires simultaneous attention and mental manipulation of several bits of information including integration of the speaker's plan and the listener's perspective. The TBI participants' greater impairment with the maintenance of global versus local coherence, suggested that their discourse impairment was more related to a disruption of macro-organizational abilities as opposed to problems with meaning relationships between contiguous concepts (51).

*Story Grammar* Story grammar pertains to the purported regularities in the internal structure of stories that direct an individual's comprehension and production of the logical relationships between people and events. Story grammar knowledge is typically measured by complete episodes. An episode consists of (a) an initiating event that prompts a character to formulate a goal-directed behavior, (b) an action, and (c) a direct consequence marking attainment or nonattainment of the goal. An episode is considered complete only if it contains all three components (64). A variety of difficulties with story grammar has been reported for individuals with TBI. For example, Chapman and colleagues (33) noted that their severely impaired group of individuals with TBI demonstrated a reduction in the number of essential story components, failed to signal new episodes with setting information, and often omitted essential action information. These authors commented that it was unclear whether this difficulty was a reflection of an underlying impairment of the internal story schema or difficulty implementing story schema during discourse production. In another study NBI participants and those with TBI produced comparable numbers of complete episodes in a story-retelling task, but three of the four individuals with TBI produced no episodes in story generation (54). The TBI participants' apparent inability to use episode structure in the story generation task, in spite of having been able to produce complete episodes in the story retelling task, suggested that the story generation task required an interaction of cognition and language use in which the

TBI participants could not consistently engage. A reduction in the number of total episodes produced was also noted in a later study by the same authors (35). Finally, Coelho (65) noted that a group of 55 TBI participants produced fewer T-units within episode structure (i.e., the proportion of total T-units that contributed to episodic structure) than did a group of 47 NBI individuals. Although the TBI and NBI participants were not different in terms of the number of total episodes produced, which had been reported in previous studies (35,54), the NBI participants produced more T-units within the structure of episodes. In other words, the NBI group produced fewer extraneous T-units—that is, T-units that did not contribute to episodic structure. This measure was considered to be an indication of participants' ability to use story grammar as an organizational plan for language.

### *Miscellaneous Measures*

*Informativeness.* The measurement of informativeness in discourse production has focused on three aspects primary aspects: amount of information communicated, quality of information (incompassing such descriptors as irrelevant, redundant, off topic, over personalized, etc.), and efficiency of information (66). The discourse output of TBI participants has been described as reduced in a number of studies as measured by number of words (and/or meaningful words), utterances or sentences; mean length of utterance in morphemes or communication units (comparable to T-units); or some combination of these measures such as number of words per T-unit or syllables per story grammar element, and percentage of syllables or utterances in mazes (33, 37, 42, 50, 55, 65, 67). Individuals with TBI have also been described as comparable to normal controls in terms of the amount of pertinent content expressed and in narrative length, but significantly slower in the rate of information produced (36, 55). These individuals appeared to “talk past the point of diminishing returns”, their oral narratives were lengthier and slower relative to the amount of content provided (36, p. 6). Other investigators have reported normal productivity for individuals with TBI in terms of the number of T-units or sentences in narrative tasks (40, 54).

Other indices of informativeness have included such measures as: number of essential steps included in a description of a procedure (42), amount of pertinent content (36), content units (37), amount of essential information, accuracy of story, and implied meanings (68) and number of concepts introduced (55). In general mixed findings have been noted with essential steps and pertinent content the TBI participants being comparable to the normal controls (36, 42), but in other studies the individuals with TBI produced fewer content units and concepts and demonstrated some difficulty with implied meanings (37, 55, 68).

### *Summary of Findings on Narrative Discourse*

Numerous investigations have illustrated the clinical utility of narrative discourse analyses with the TBI population (33–37, 39, 40–42, 50, 51, 54, 55, 60, 62, 65, 67, 68). In terms of microlinguistic processes, findings on lexical production and syntactic aspects of discourse have been noted to be somewhat ambiguous. Some investigators have reported difficulties in these areas for individuals with TBI, and others have observed that these abilities remain intact following injury. Results from some of these studies have been confounded by the inclusion of individuals who were also aphasic as a result of their TBI. Although some individuals with TBI in the acute stages of rehabilitation may demonstrate impairments with word retrieval and syntax, such discourse deficits are not characteristic of this population in the chronic stages (65). When microlinguistic processes are examined by means of semantic analyses the findings are more straightforward. Individuals with TBI demonstrate consistent problems with the planning and organization of language as reflected in their difficulties inserting multiple ideas into single sentences (60, 61).

Narrative discourse performance has also been evaluated extensively in terms of macrolinguistic processes, namely cohesion, coherence, and story grammar. Cohesion has been noted to be an area of inconsistent impairment and performance may vary considerably depending on the discourse elicitation task presented (40, 54). For example, the cohesive adequacy of individuals with TBI has been reported to be comparable to that of normal speakers in story retelling, but impaired for story generation (54). Similarly, the proportion of types of cohesive ties used by participants with TBI changed from story retelling to story generation, which was not the case for the normal speakers (40, 54). Similar to cohesion, TBI participants' ability to generate complete episodes was frequently effected by the nature of the task, with story retelling being easier than story generation. Story generation required a complex interaction of language and various cognitive abilities that were difficult for even mildly impaired individuals with TBI (54, 65). It has also been noted that TBI participants produced more T-units that did not contribute to episodic structure. It appears that these individuals have difficulty using story grammar to organize language (65). Along similar lines, conceptual organization of discourse (i.e., coherence) has also been noted to be problematic for individuals with TBI. Specifically, their greater difficulty with the maintenance of global (i.e., general plan or goal) versus local (i.e., conceptual links between sentences) coherence suggests a disruption of macro-organizational processes for discourse (51). Analyses of story grammar (i.e., the generation of episodes) and cohesion enable discourse samples to be examined at multiple levels allowing for the delineation of distinct discourse patterns (35).

Finally, the applicability of findings on narrative discourse productivity and content analysis of individuals with TBI have also been limited by the inclusion of individuals with aphasia and dysarthria in the groups studied. However, in general terms, the TBI participants studied demonstrated decreased discourse efficiency, generating information at a slower rate in lengthier utterances than controls (36, 55).

### **Conversational Discourse**

The analysis of conversational discourse is of particular interest for the study of the TBI population because of its importance in the process of socialization. The development and maintenance of social relationships has been noted to be challenging for survivors of TBI. The consequences of this difficulty are social isolation, increased reliance on family for social support, and significant problems returning to work, school, and premorbid avocations. It has been suggested that these interactional problems are the result of social skills deficits, and that these deficits in social skills are felt to be a reflection of subtle impairments in pragmatic language use during conversation (69, 70). There have been numerous reports pertaining to the analysis of conversational discourse following TBI. These reports are summarized below by type of analysis.

#### *Response Appropriateness*

The appropriateness of TBI participants' utterances within conversations utilizing procedures described by Blank and Franklin (71) has been described (72, 73). A greater number of turns per conversation were noted for the participants with TBI than for the normal controls. This increased number of turns resulted from their shorter length of utterance per turn and their conversational partner's higher percentage of oblige production (i.e., utterances for which a response is expected, as in a question) (72). In a follow-up to the original study, which involved 5 individuals with TBI, Coelho and colleagues (73) studied 32 individuals with TBI, all of whom had recovered a high level of functional language, and were all rated as Rancho Los Amigos Level of Cognitive Functioning (74) VII (automatic-appropriate) or above. As a group the individuals with TBI did not initiate a great deal and appeared dependent on the examiner to maintain the momentum of the interaction. They produced fewer spontaneous obliges and comments (i.e., utterances for which a response is not required) than did the NBI controls and functioned primarily as "responders". Further, when they did respond, they provided more information than was requested. Although this extra information was not inappropriate or bizarre, it did not facilitate disclosure on the part of the conversational partner. The function of disclosure in social interaction is to allow the opportunity to

talk about oneself or subjects of interest to oneself, in order to establish, sustain and enjoy social interaction (69).

### *Analysis of Topic*

The proficiency by which participants manage conversational topics is critical to the success of an interaction. Topic management pertains to how participants in a conversation extend or maintain a given topic, as well as how discussion of a topic is discontinued, and how and when participants change topics (75). The specific contribution of speakers and their conversational partners to topic maintenance and development through analysis of ideational intonation units has been examined (76). Ideational describes a concept borrowed from Halliday (77) and pertains to the idea that discourse is about something or contributes some content. Therefore, ideational units can be assumed to represent what speakers contribute to topic maintenance and development, and to exist as a function of cognitive processes. For example, there are categories of ideational units for new information appropriate to the topic contributed by a speaker and categories representing no new information but still maintaining a topic. Thus it is reasonable to assume that production of ideational intonation units is likely to be disrupted in persons with brain injuries and cognitive impairments. Mentis and Prutting (76) found differing patterns of production between an adult with TBI and a NBI control in their intonation unit analysis across unspecified, concrete, and abstract conversational contexts. The individual with TBI produced fewer units containing novel information not specifically requested, fewer clarification and confirmation requests, and more agreement and acknowledgement units. In a follow-up study this analysis procedure was applied to conversational samples of a group of ten individuals with TBI and ten NBI controls (78). The intonation unit analysis did not distinguish high functioning individuals with TBI from controls matched for age, gender, and socioeconomic status. The method of eliciting conversation, with the examiner directing the conversation, may have constrained the context and, thereby, masked deficits commonly attributed to this population's difficulty in social interchanges.

Other approaches to the analysis of topic management have involved the examination of how topics are introduced and changed during a conversation (73, 79). Any participant in a conversation may introduce topics. Topics are changed in one of three ways: (a) at the beginning of the conversation, or by ending discussion of one topic and initiating another, referred to as a novel introduction; (b) by means of a smooth shift, in which discussion of one topic is subtly switched to another; or (c) by means of a disruptive shift, in which discussion of one topic is abruptly or illogically switched to another

topic. Findings on this measure have been mixed. Coelho et al. (79) observed that five individuals with TBI demonstrated difficulty initiating and sustaining topics compared to five matched controls. However, when a group of 32 individuals with TBI were compared to an NBI group of 43 individuals, the group with TBI produced comparable numbers of Novel Introductions and Smooth Shifts as the NBI group during their conversations with an examiner. Neither group produced many Disruptive Shifts (73).

### *Systemic Functional Linguistics*

Systemic Functional Linguistics (SFL) describes language use as a series of choices (77, 80). When a speaker produces an utterance, choices are made pertaining to what will be said and how it will be said. The listener and the situation in turn, influence the what and the how of the utterance. The impact of context on language use is an important consideration of SFL. Context has been described as a combination of three components: field, mode, and tenor. Field pertains to the nature of the social interaction taking place (e.g., a speech or a conversation with friends). Mode refers to the modality by which the discourse is produced (e.g., written or oral). Tenor describes who is involved in the interaction, their relationship to each other, and their roles or status (e.g., teacher and student, two strangers, clerk and customer) (43). Two additional components of SFL are genre, which pertains to the influence of culture on language (i.e., the step-by-step structure that are followed to achieve goals) and ideology, which involves the participants' biases and personal perspectives. Three types of SFL analyses have been used to study the nature of language structures, which are used to establish and maintain interpersonal interactions of individuals with TBI. These have included: exchange structure analysis, generic structure potential, and mood and modality analysis. Each of these is described briefly below.

Exchange structure analysis. Exchange structure analysis (ESA) involves the examination of who has the knowledge (i.e., the primary knower) in an interaction and how that information is transferred (to the secondary knower). This approach has been applied to interactions of individuals with TBI during a variety of service encounters (e.g., calling about: bus schedules, getting a driver's license, therapy schedules, and therapy goals) (43, 81, 82). Investigators studied whether TBI participants and NBI controls altered their communicative behavior with different conversational partners who varied in terms of familiarity (e.g., an information operator, a policeman, their mother, or a therapist). In reviewing the findings from this analysis the authors examined the communication partners' responses to the TBI versus control participants. Results indicated that the therapists gave more

information to the normal controls than to the TBI participants. The mothers tended to provide more information to their NBI sons than to their sons with TBI, but this difference was not significant. In terms of requesting information therapists asked more questions of the normal controls than of the individuals with TBI, while the police asked more questions of the TBI participants than of the NBI individuals. Finally, therapists generated more clarifications and checking utterances with the individuals with TBI than with the NBI group. There were no other significant differences for the communication partners. In comparing the individuals with TBI to the NBI controls across the four conditions a number of significant differences were reported. First of all the TBI group produced more information in the police encounter than did the control group. Some of the information offered was inappropriate (i.e., more information than was requested, which was similar to the findings of Coelho and colleagues (72, 73)). The individuals with TBI provided more information in their interactions with the police than in those with the therapists and the operators at the bus station. This was felt to be due in part to the greater number of questions produced by the police. Because the mothers did not request much information from their sons with TBI, that group provided less information to their mothers as compared to the NBI group. In addition, the TBI group requested more information from the therapists than did the controls. The individuals with TBI generated more requests for clarifications than the NBI groups when conversing with the therapists. Finally, the TBI group asked for clarifications more with the police than with their mothers or the operators at the bus station (81, 82). Overall, results indicated that the discourse performance of the participants with TBI varied according to their conversational partner.

Generic structure potential analysis. This analysis addresses the issue of which aspects of language use appear to be influenced by particular dimensions of the context. Togher and colleagues (82) examined the core structural elements (e.g., greeting, address, service initiation, service request, service compliance, close, goodbye, etc.) that would be expected in two types of interactions (i.e., the bus information operator, and the police) for TBI and NBI participants. Results indicated that the generic structural elements in the TBI service encounters were different in terms of length and content than those of the controls. The TBI group had difficulties opening sequences and with the main service requests. This group also produced repetitious and at times inappropriate elements not seen with the NBI group. There were several significant differences noted between the police and bus information encounters as well. When the control participants interacted with the police the greeting sequences were shorter and promptly followed by succinct service requests. In addition the closing/goodbye sequences were

longer when they spoke to the police than when they interacted with the bus information operator. By contrast, when the participants with TBI interacted with the police they had longer greeting sequences and shorter goodbyes (82). The authors comment that opening and closing sequences facilitate the development of interpersonal relationships by establishing credibility, confirming the success of the encounter, and encouraging future contact. During the longer closing sequences of the NBI participants, the police encouraged them to call again, however this was not observed during the shorter closing sequences of the TBI group. This analysis of the overall structure of an interaction facilitates the identification of specific structural elements that may be problematic. These can then be further analyzed in terms of mood and modality.

*Mood and Modality Analysis* The analysis of mood may be used to study the lexical and grammatical choices made at the clause level to establish the degree of directness being expressed (e.g., statements such as "I will be home on Tuesday" are direct, whereas a declarative statement with rising intonation such as "You'll be home Tuesday?" are less direct and considered to be more polite). A direct statement may be either positive or negative (e.g., "I will be home" or "I won't be home"). Between these two poles a speaker may indicate uncertainty or directness through expressions of modality such as *might*, *must*, *possibly*, *probably*, or comments such as *I think*. Definiteness decreases as the speaker's expression of modality increases. Mood and modality has been examined in the interactions of TBI and NBI speakers in four interactions (with: a bus information operator, police, mother, therapist). Results indicated that the TBI participants were able to access a variety of politeness strategies, however they appeared less adept at applying these strategies across the four different interactions when compared to the NBI group (83).

### *Conversation Analysis*

Other highly structured analyses have also been applied to conversational samples. One such system is conversation analysis (CA) which was developed to delineate the structural organization and sequential ordering of talk. Friedland and Miller (84) have applied CA to conversational samples of an individual with TBI. The authors commented that CA was sensitive for identifying pragmatic deficits in this individual. Specifically it identified the precise locale of conversational breakdowns and how these were repaired or not. Further, it demonstrated how one conversational partner adapted to these breakdowns and was successful during interactions with the TBI participant and another was not.

### *Pragmatic Rating Scales*

In contrast to the very structured analysis procedures of SFL and CA a number of investigators have utilized

pragmatic rating scales to investigate conversational abilities (56, 85–90). Although some of the pragmatic dimensions rated within these scales are redundant, each scale has a rather novel approach to looking at conversation. For example, some scales rate both nonverbal (e.g., intonation, facial expression, eye contact, gesture) and verbal (conversation initiation, turn taking, topic maintenance, response length, presupposition and referencing) communication (87). While others focus on specific aspects of the verbal message such as intelligibility, sentence formation, and coherence of narrative (56). Some theoretically-based scales focus on aspects of pragmatics such as utterance acts (e.g., vocal intensity, voice quality, prosody), propositional acts (e.g., lexical selection, word order, stylistic variations), and illocutionary and perlocutionary acts (e.g., speech acts, topic, turn taking) (88). Other scales are questionnaires completed during an observation or from personal knowledge which deal with such issues as “Does client: make rapid and inappropriate changes in conversational topic without clues to the listener? or fail to attend to cues for conventional turns, interrupting frequently or failing to hold up his or her end of the conversation?” (85, 91). Observations on the use of such pragmatic rating scales for assessing individuals with TBI have been generally positive. The scales are not labor intensive, which is the case for most of the other formal analysis procedures, and they are useful for assessing selected communicative behaviors unobtrusively, in real-world settings.

### *Social Information Processing*

A final category of analysis views communication as an integral aspect of social pragmatic skills. A universally accepted definition of social skills is absent from the enormous literature on this topic. Similarly, numerous conceptual models of social skills have been described (92). The ability to communicate effectively is the basis of socially skilled behavior, and in humans, language is the primary method of communication. Ylvisaker, Urbanczyk, and Feeney (93) suggested a conceptualization of social skills following TBI that specifically incorporated the dimension of communication. Five components are included: (a) the individual’s knowledge of self; (b) the extent to which an individual attends to their personal appearance; (c) social cognition (i.e., social perception, social knowledge, and social decision making); (d) communication, and (e) the social environment (i.e., significant people in the individual’s natural environment). Analysis procedures pertaining to social cognition have examined such skills as cooperation, turn-taking, politeness, negotiation, topic management, and sensitivity to role and status of all participants. For example, McDonald (39) studied two individuals with TBI and 12 NBI participants explaining a novel procedure to a blind-folded

third person. The productions of the TBI participants were rated as disorganized, confusing, and ineffective as compared to the controls. The disorganization was attributed to errors in sequencing and inclusion of irrelevant propositions. In a second study individuals with TBI and NBI controls participated in a barrier task, which required that the participants explain a board game to a listener not present in the room (94). The authors noted that the TBI participants appeared to be bound to the physical properties of the stimulus before them, and omitted important details from their explanations that the listener needed to understand the game. Similar findings were noted for adolescents using the same task (95). The investigators concluded that overall performance was limited by the TBI participants’ decreased ability at role taking which in turn was associated with frontal lobe damage. In a final study, Turkstra and colleagues (96) studied social cognition of 10 adolescents with TBI and 60 NBI peers. Two tasks were presented: emotion recognition and conversation judgment. In the emotion recognition task, the participants were asked to identify the emotion depicted by an actor (happy, sad, peeved, angry, disgusted). For the conversation judgment task, six conversation skills were depicted: (a) attentive listening; (b) perception of nonverbal cues; (c) detection of sarcasm; (d) sharing the conversational burden; (e) humility; and (f) speaking at the listener’s level. Each participant was asked to make judgments about the actor during videotaped vignettes (e.g., “Is the person a good listener?”, “What makes you think so?”). Results indicated that the TBI group differed significantly from the NBI group for both recognition of emotion and the conversational judgments. Most of the errors on the conversation skills task were related to the detection of sarcasm and the feelings it might evoke in a listener. This finding was consistent with those of McDonald (97) which demonstrated impaired understanding of sarcasm and other forms of social inference in adults with TBI.

### *Summary of Findings on Conversational Discourse*

The analysis of conversational discourse has been conducted from a variety of perspectives and the procedures applied have ranged from rating scales or check lists to highly structured analysis protocols. Although not entirely consistent, results from various pragmatic rating scales, and analyses of response appropriateness and topic management suggest that individuals with TBI experience difficulty when called upon to function as a partner in communicative dyads, whether in conversation or referential communication. These individuals demonstrate problems initiating and sustaining topics in conversation and frequently rely on their discourse partner to assume a greater proportion of the communicative burden to ensure a successful interchange of information (39, 56, 72, 73, 76, 91).

The role of individuals with TBI as participants in conversational dyads will vary according to the tenor relationships. In addition, the factors of familiarity and status appear to influence the language choices made by conversational partners during these interactions. These language choices are the result of the different roles the conversational participants assume and how conversational partners respond to the disability of the participant with TBI (43).

Finally when conversation is considered as a component of social skills or social cognition, a decreased ability for role taking has been identified as a primary deficit for individuals with TBI. Problems with the recognition of emotion and interpretation of sarcasm and inference also compromise their social functioning (96, 97).

### INTERPRETATIONS OF DISCOURSE DEFICITS FOLLOWING TBI

The present review has indicated that individuals with TBI frequently demonstrate discourse impairments. These difficulties cross discourse genres and are revealed by a variety of discourse analyses. This chapter has focused primarily on descriptions of narrative and conversational discourse deficits. If it is assumed that these types of discourse are different in terms of underlying requisite processes, then the reasons for difficulty with narrative and conversational discourse should also be different. What follows are interpretations of narrative and conversational discourse impairments following TBI.

#### Narrative Discourse Impairments

Kintsch and van Dijk (98) have proposed that semantic information may be represented at multiple levels. These levels include: the surface structure, the text base; consisting of the microstructure (i.e., meaning contained in words and phrases) and macrostructure (i.e., topic- or gist-level information), and the mental model where the listener constructs a representation of the situation described (i.e., comprehends the text). The notion that a text's representations occur at a number of levels implies that discourse analysis must be performed at multiple levels as well. The primary division in such structural analyses occurs between the analysis of linguistic (e.g., lexical, syntactic, and cohesion analyses) and of conceptual or semantic representations (e.g., propositional and frame [i.e., higher level of semantic structure specifying constituents and relations among constituents]) levels (99). Two broad types of cognitive functions, assumed to be involved in discourse processing, further characterize these levels of analysis, that is whether an analysis is micro- or macrolinguistic in nature. Microlinguistic functions are language-specific procedures for processing

phonological and syntactic aspects of single words and sentences in the absence of context. Macrolinguistic functions involve cognitive procedures for integrating linguistic and nonlinguistic knowledge for the purposes of maintaining the conceptual, semantic, and pragmatic organization of discourse. The critical distinction between these two categories is that the macrolinguistic processes involve analyses of language units as contextual events (63).

With regard to microlinguistic analyses, the TBI participants have been noted to have comparable scores to normal controls on measures of lexical diversity (100) and syntactic complexity (65). For measures of macrolinguistic processes, no consistent differences between the groups have been noted for cohesive adequacy, however TBI participants typically have lower scores on measures of story grammar performance than normal controls (65). In addition, individuals with TBI demonstrate lower propositional density scores (61). As a group TBI participants demonstrate relatively preserved microlinguistic discourse functioning. The impairments noted in their narrative discourse production are associated with problems in macrolinguistic functions, that is, with the interaction of linguistic and conceptual structures. The finding that the TBI participants present with predominantly macrolinguistic discourse deficits is consistent with the diffuse pathology associated with TBI and closed head injury in particular. Glosser and Deser (51) have specified that microlinguistic, language-specific, functions are dependent on the integrity of a specialized neural system within the left hemisphere. Conversely macrolinguistic functions depend on different neural systems that are non-focal and bilaterally distributed.

To better understand how macrolinguistic discourse functions are disrupted in TBI, Huber's (101) description of text processing may be considered. Two distinct modes are involved: macroprocessing in which the speaker focuses primarily on the critical ideas in a text, and microprocessing in which the speaker deals with individual meaning units and their relationships as conveyed by various syntactic devices. Microprocessing requires linguistic knowledge and an algorithmic processing mode that is rule governed facilitating the analysis of linguistic elements. Macroprocessing involves general world knowledge and pragmatic reasoning and the mode of processing is heuristic. Lexical information, such as key words and idioms, is picked from the text and matched with experiential knowledge and expectations about persons, events, and situations. As soon as a plausible match is obtained, the interpretation process ends (101). This macroprocessing mode is the likely source of narrative discourse breakdown among the group of TBI participants reported on above (61, 65, 100).

There are a variety of cognitively-based explanations for this breakdown that are also reasonable avenues to pursue in future studies of narrative discourse following

TBI. First, optimal discourse processing involves simultaneous micro- and macroprocessing. However, such processing will be hindered by limitations of working memory, potentially resulting in incomplete integration or understanding of all propositional elements within a text. Previous findings of significant correlations between working memory and linguistic cohesion in discourse of individuals with TBI support this notion (37). Other investigators have also emphasized the critical role working memory plays in discourse (102–105). Secondly, individuals who are proficient at discourse processing are able to integrate prior real-world knowledge to facilitate interpretation of the ongoing discourse. This integration of prior experiences is facilitated through the use of story schemas and script knowledge. Schemas and scripts are cognitive structures that generate expectations about the way a story might progress and organize the understanding of real-world events and their consequences. Both scripts and story schemas are attempts to characterize prerequisite memory representations of contextual information. Inclusion of irrelevant information during the production of discourse may reflect attentional or memory problems (106). Finally, the formation of story macrostructure requires knowledge about goals and actions, difficulty with story grammar may reflect problems with executive functions or goal-directed behavior in general. The relationship between executive functioning and discourse would appear to be quite logical. It has been suggested that discourse proficiency involves an interaction of cognitive and linguistic organizational processes, which requires executive control (107). Recent findings have demonstrated several significant, but modest, correlations between scores from the Wisconsin Card Sorting Test (WCST) (108, 109), a purported test of executive functioning, and measures of story narratives (65). This relationship between executive functioning and narrative discourse production in adults with TBI corroborates findings of previous investigations (68, 110).

### **Conversational Discourse Impairments**

The complexities of conversational discourse have been well described in a number of studies (43, 49, 111–113). Effective participation in a conversation is dependent on a variety of factors such as: topic maintenance, turn taking, appropriate referencing, sensitivity to the conversational partner, and general cognitive abilities such as attention, vigilance, and memory. Social cognition (i.e., social: perception, knowledge, and decision making) will also have important influences on conversational skill. Galski and colleagues (114) have commented that the success of an individual's social, vocational, familial, and academic integration rests on the recovery of effective communication.

Although individuals with TBI demonstrate difficulty with many narrative discourse tasks, conversational

discourse appears to be more difficult for this population. This may be attributed to the interactive nature of conversation. Consistent with this explanation, is the report that individuals with TBI produced more discourse errors in conversation than in a structured referential communication task. The authors suggested that conversations are more complex because due to social aspects, such as the relationship between conversational partners that is, familiarity, status, and role, as well as the face-saving strategies used for politeness when communication breakdowns occur (115). Such factors typically are not at issue in non-interactive types of discourse. Additional support for the contention that conversation may be more challenging than narrative discourse for individuals with TBI comes from a study which entered measures of both narrative and conversational discourse into a discriminant factor analysis (DFA). The goal was to determine which type of discourse analysis would best discriminate TBI from NBI participants. Results of the DFAs run with both sets of discourse data indicated that the conversational measures were most accurate in discriminating the groups (116). It appears that because the conversational measures were pragmatic in nature and more sensitive to the communicative dysfunction displayed by individuals with TBI than the more structurally focused narrative measures.

An additional explanation pertains to the potential cognitive factors that have been suggested to be important for meaningful participation in conversation. For example, topic maintenance and appropriate referencing requires both selective and sustained attention. Further, functional memory is required to recall what the speaker has said as well as the listener (112). Social competence requires the ability to apply social skills flexibly in accordance with the rules of an interaction. It has been argued that the inability to flexibly apply behavior according to rules, which entails executive functioning, may account for conversational difficulty following TBI (70). Support for the notion that executive functioning may be an important factor in conversational proficiency comes from findings of significant correlations between measures of conversational performance and scores from the WCST (117). Finally, comprehension of sarcasm and implicit language may also influence the effectiveness of a conversational participant (97).

### **CONCLUSIONS**

This chapter has reviewed the nature of language dysfunction following TBI. Although some individuals with TBI will demonstrate aphasia, most will present with language deficits that are cognitively-based versus linguistic, referred to as cognitive-communicative impairments. The majority of these individuals will present with pronounced difficulties with pragmatics, that is with the use

of language in context. These pragmatic deficits are not readily apparent when the assessment of language is focused on single words or isolated sentences. Rather, language should be evaluated in terms of discourse. Discourse permits the analysis of language at multiple levels (i.e., micro- and macrolinguistic, micro- and macroprocessing) which may be differentially impaired after TBI. Further, the analysis of interactive discourse (i.e., conversation) will reveal difficulties with social cognition that cannot be observed in the typical acontextual assessment settings.

Most survivors of TBI will demonstrate a variety of narrative and conversational discourse deficits. The underlying bases for these impairments are probably different but in many ways similar as well. Problems with narrative discourse are attributed to disruption of macrolinguistic processes involved in the organization of semantic information. This organizational process more than likely involves executive control. Meaningful interactions involve the flexible application of social rules which is also associated with executive functions. Delineation of the processes which subserve discourse will provide important treatment implications for cognitive-communicative impairments.

## Neuroscientific Basis for Occupational and Physical Therapy Interventions

*Randolph J. Nudo*  
*Numa Dancause*

### INTRODUCTION

The field of neurorehabilitation is currently undergoing a fundamental change in approach to therapy after central nervous system injury. In the past, occupational and physical therapy after stroke or traumatic brain injury (TBI) was based almost exclusively on empirical data and without a full understanding of the neural processes or correlates of recovery mechanisms. Since the early 1980's, experimental data has been accumulating to provide compelling evidence that the adult brain is capable of significant anatomical and physiological plasticity. These data have contributed to a renewal of the long-debated theory of vicariation, or the taking over of function of damaged brain regions by spared, healthy regions. It has become clear that in both humans and in experimental animal models, the injured brain compensates in a variety of ways that contribute to the spontaneous return of function, and that behavioral interventions are perhaps the most powerful modulators of post-injury plasticity.

Based on this growing evidence for behaviorally-driven neural plasticity after brain injury, and the increasing number of scientists and clinicians that have begun to design therapeutic approaches grounded in the latest neuroplasticity principles, some have suggested that we are fast approaching an impending paradigm shift in neurorehabilitation therapy (1). In the coming years, advances

in behavioral principles, robotics, pharmacotherapeutics, brain imaging, genetics, genomics, nanoelectronics, and neural prosthetics are likely to change the landscape of functional restoration after brain injury. The purpose of this chapter is to introduce the reader to the underlying principles of functional brain plasticity and how they may be applied to restoration of function after brain injury. What circumstances gave rise to the fundamental changes in emerging therapeutic principles? What factors modulate brain structure and function in the healthy and injured brain? How can contemporary therapeutic interventions be improved based on principles of neural plasticity? What does the future hold for further development of therapeutic approaches? While the answers to these questions are still fragmentary, it is hoped that this chapter will help to prepare students and practitioners of neurorehabilitation for the paradigm shift that is already in progress.

It is important to note that most of the clinical examples and animal models of plasticity are based on recovery after ischemic infarct, rather than on TBI *per se*. This is primarily because the vast majority of the literature on post-injury plasticity associated with recovery focuses on stroke or ischemia. In many ways, post-stroke plasticity is an easier phenomenon to investigate and understand. The injury is typically focal and well-circumscribed. The surviving cortical and subcortical tissue is essentially

undamaged. In TBI, injuries may be diffuse or multi-focal. Whether these same plasticity principles based on post-stroke recovery generalize to TBI is still an unanswered question. However, the description of the various modulators of post-stroke plasticity and their neuroanatomical and neurophysiological bases provides a fundamental understanding of the potential for the role of neuroplasticity in post-TBI recovery.

### MATURATION OF OUR UNDERSTANDING OF BRAIN PLASTICITY AND RECOVERY PRINCIPLES

The modern era of the application of brain plasticity principles to recovery after injury began in the mid-1980s with

a series of experiments demonstrating use-dependent modulation of the functional organization of somatosensory cortex (2–6). These studies demonstrated that after amputation of a digit or transection of a peripheral nerve in experimental animals, the deafferented cortex quickly became responsive to inputs from adjacent skin surfaces. While later studies eventually showed that these functional alterations could be attributed, in part, to modulation of pre-existing divergent connections in the lemniscal pathway (such as diverging thalamocortical arbors), other changes, such as alterations in local cortical circuits and long-term anatomical changes have also been reported within the cortex, thus making it clear that the functional organization of the cerebral cortex is modifiable (Figure 49-1).

Results demonstrating use-dependent (and skill-dependent) modulation of auditory cortex, visual cortex,

FIGURE 49-1

Classic neurophysiological studies in primary somatosensory cortex (area 3b) of non-human primates demonstrating that the functional topography of cerebral cortex is modifiable after peripheral injury and after repetitive use. Top experiment shows the area 3b hand map before and a few months after amputation of a single digit. Prior to the amputation, area 3b displays the normal topographic pattern, with neurons responding to light touch on individual digits progressing from ulnar to radial aspects of the hand as a microelectrode is introduced from more medial to more lateral locations. Each digit's representational territory in cortex is demarcated by a sharp border. After a digit 3 amputation, neurons in the former digit 3 cortical territory become response to stimulation of skin surfaces adjacent to the missing digit, i.e., to stimulation of digits 2 and 4. Adapted from (2, 6). Bottom experiment depicts changes in the digit 3 representation in area 3b following several weeks training on a sensorimotor task in which digit 3 is repetitively stimulated. The representation of the stimulated digit expands and receptive field sizes become smaller (132)

and motor cortex eventually erased any lingering doubts that topographic plasticity may be a methodological epiphenomenon, or specific to only certain portions of the cerebral cortex. Behavioral improvement appeared to correlate with neurophysiologic map plasticity, suggesting that these changes were an adaptive response of the cerebral cortex to novel behavioral requirements.

However, even in the early 19th century, clinicians and scientists began to ask specific questions regarding brain plasticity, though their knowledge of underlying neuronal mechanisms was rudimentary. While better known for his study of phrenology (with Gall), Johann Spurzheim wrote that brain and muscles can increase with exercise “because the blood is carried in greater abundance to the parts which are excited and nutrition is performed by the blood”. In the mid-19th century, Jean-Pierre Flourens, one of the first experimental brain researchers, asserted that after restricted lesions of the cerebellum, recovery could occur as the result of compensation by other brain areas. This view was later to be incorporated in Lashley’s principle of equipotentiality that states that all parts of the neocortex (or at least, all parts within a localized functional area, such as visual cortex or somatosensory cortex) play an equal role in memory storage, or in a particular physiological function (7).

Several other investigators took up the question of brain recovery mechanisms throughout the first half of the 20th century, including Sherrington, Franz, Glees, Denny-Brown, Kuypers and others using behavioral and neurophysiological techniques (8–13). But it was in the final two decades of the century when solid evidence from experimental animal models accumulated to give adequate credence to the notion that cortical functions are not static in adulthood (14). Parallel human neuroimaging studies confirmed that these same processes could probably be generalized to humans (15).

Thus, the recent intensive interest in recovery after brain injury has come about as a result of two nearly simultaneous events: 1) the maturation of our understanding of brain plasticity principles, and 2) the rapid development of sophisticated neuroimaging techniques. In addition, specifically with regard to stroke recovery, interest has been spurred by the initial effectiveness of pharmacologic and physiotherapeutic interventions introduced during the acute or chronic stages after stroke (i.e., thrombolytic agents, amphetamine, constraint-induced movement therapy) (16–18). These recently developed interventions were largely based on neuroscientific and behavioral principles developed from animal models of post-injury recovery.

While results demonstrating neuroplasticity in healthy brains as a result of experience, and in injured brains as a result of trauma or stroke were largely phenomenological in the initial stage of discovery, the molecular and cellular mechanisms regulating these events are now

being investigated intensively. The coming decade will be important in defining which of the many potential features of neuroplasticity represent adaptive mechanisms, which represent maladaptive mechanisms and which are epiphenomenal.

## NEURAL CORRELATES OF SKILLED MOTOR CONTROL

Because many of the same underlying adaptive neurological processes are thought to occur in both normal and injured brains, to appreciate the events that shape anatomical and physiological plasticity and promote functional motor recovery after brain injury, it is first necessary to understand how repetitive use and motor skill acquisition modulate the structure and function of the normal, uninjured brain. In this section, the organization of the motor cortex will be reviewed briefly. Then, the modulatory role of sensorimotor behavior will be discussed.

### Organization of Motor Cortex

The motor cortex is composed of a number of interconnected cortical regions that are distinguishable from surrounding areas primarily on the basis of cytoarchitecture, thalamocortical and intracortical connectivity (hodology), and electrophysiological properties. In addition to the extensively studied primary motor cortex (M1) located in the precentral gyrus, there are several other motor areas that play important roles in motor control. These include the premotor cortex (dorsal and ventral premotor cortex, or PMd and PMv, respectively), the supplementary motor area (SMA), and the cingulate motor cortex (CM). Each of these motor regions can be further subdivided based on histochemical, hodological and neurophysiological properties (Figure 49-2).

The primary pathway through which the motor cortex directs motor commands to the spinal cord motor neurons is the corticospinal tract. Corticospinal neurons originate from each of the cortical motor regions in the frontal cortex, i.e., from CM, PMv, PMd, SMA and from M1. Additional corticospinal neurons originate from parietal cortex, though their precise function in motor control is still unclear. Monosynaptic corticomotoneuronal neurons (i.e., neurons with somata located in cerebral cortex with fibers terminating directly onto motor neurons in the spinal cord) are thought to originate primarily from M1.

Each of the cortical motor areas is reciprocally interconnected with the others, though to varying degrees. Thus, M1 receives input from premotor, supplementary motor and cingulate motor areas, and emanates corticocortical axons to terminate in these same regions. In addition, cortical motor areas receive substantial input from

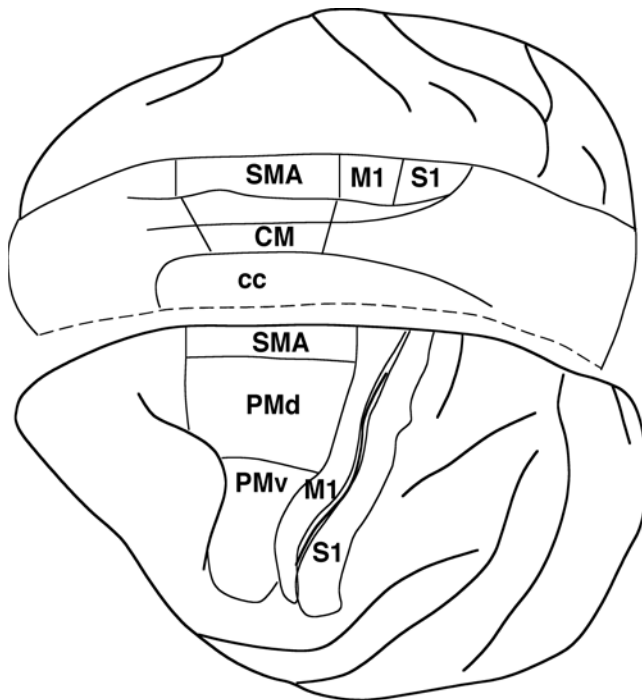

FIGURE 49-2

Location of motor areas in the cerebral cortex of a macaque monkey. At least five subdivisions can be recognized on the basis of structural and functional properties. These include the primary motor cortex located in the precentral gyrus (M1), the dorsal and ventral premotor cortex located anterior to M1 (PMd and PMv, respectively), the supplementary motor area located medial to PMd on the medial aspect of the cortex (SMA) and the cingulate motor areas located in the cingulate gyrus on the medial wall (CM). Each of these main motor areas can be subdivided further based on cytoarchitectonic, neurophysiologic, and chemoarchitectonic criteria. Note that much of the M1 representation is buried in the central sulcus (i.e., on the anterior bank of the precentral gyrus) in most primates (including humans). Thus, access for detailed neurophysiological mapping studies is limited. Certain non-human primate species (e.g., squirrel monkeys, marmoset monkeys) possess a relatively shallow central sulcus allowing more access to the posterior aspect of M1

parietal cortex, specifically from somatosensory regions. Thus, the motor cortex cannot be considered strictly as a motor structure, but instead, is a site of somatosensory-motor integration, with a primarily motor output function based on its corticospinal connections, primarily its monosynaptic connections with motor neurons. In fact, when focal ischemic lesions are made in either the primary somatosensory cortex (S1) or M1 of non-human primates, deficits are quite similar when performance on sensorimotor tasks is assessed (17, 18). For example, in addition to a decrement in manual skill, monkeys with lesions in either S1 or M1 display a type of sensory agnosia. The sensory agnosia eventually subsides, possibly due to the

FIGURE 49-3

Anatomical divergence and convergence of corticospinal neurons. Upper: Example of a motor map of evoked movements in the primary motor cortex (M1) derived from intracortical microstimulation techniques. The map shows the intermingling of evoked digits (red), wrist and forearm (green) movements clustered in the middle of more proximal (elbow and shoulder; blue) movements. Lower left: Corticospinal divergence. One cell located in the digit representation of M1 projects to several motoneuronal pools in the spinal cord that, in turn, project to different arm muscles. This result has been demonstrated using both axonal tracing and spike-triggered averaging techniques (133, 134). Functionally, this illustrates that one very small area of the motor map can have a very widely distributed influence on the musculature of the arm. Lower right: Corticospinal convergence. Several cells located at various locations within the wrist and forearm representations in M1 all project to the same motoneuronal pool in the spinal cord, which then projects to a single muscle of the arm. This has been demonstrated using both intracortical microstimulation and stimulus-triggered averaging techniques (135, 136). Functionally, this illustrates that a wide surface area of the motor map can have a very focal influence on the musculature of the arm

use of visual guidance to compensate for deficits in somatosensory-motor integration (19).

The functional representation of the skeletal motor apparatus is represented in cortical motor areas in a topographic fashion, with the contralateral leg represented

more medially and the hand and face represented more laterally in M1. However, due to anatomical divergence of corticospinal neurons, a strict topography is not apparent when the spatial organization is examined on a more refined scale. It has been estimated that each corticomotoneuronal cell innervates about four or five separate motor neuron pools (20). Further, neurons originating corticomotoneuronal fibers innervating a single motor neuron pool are located in multiple sites within a topographic region in M1 (Figure 49-3). This anatomical divergence and convergence of corticospinal fibers, along with a dense network of local intracortical connections within M1 results in a substrate that provides a great deal of flexibility in its functional arrangement. In other words, it appears that motor cortex is expressly designed to allow for plastic reorganization of its local circuitry and ultimately, of its functional outputs.

### Use-Dependent and Skill-Dependent Modification of Motor Cortex Topography

A common technique for demonstrating the detailed topography of cortical motor areas in experimental animals is known as intracortical microstimulation (ICMS) (21). Based on ICMS results in non-human primates, the general topographic representation of specific body parts is quite consistent in M1, but substantial individual variability exists in the detailed topography on a more refined level, e.g., within the hand representation (Figure 49-4). The size of the hand representation can vary by over 100% in different monkeys, a difference that cannot be accounted for on the basis of the animal's size alone. It has been hypothesized that individual variation in motor maps is a result of each individual's sensorimotor experiences leading up to the motor mapping procedure (22).

The modifiability of the motor map has now been studied extensively in M1 of humans, non-human primates and rodents (caudal forelimb area) (23, 24). Soon after the learning of a new fine motor skill, the representations of the movements involved in the skilled task are enlarged. At least in experimental animals, specific combinations of movements used in the task emerge in ICMS maps (25). Presumably, local functional networks are established within the reorganized cortex, potentially reflecting the emergence of muscle and movement synergies within M1. Long-term potentiation of intracortical connections is likely to play a role in the emergent properties of reorganized cortex (26, 27). Plasticity in motor maps resulting from the acquisition of motor skills is both progressive and reversible.

Plasticity in motor cortex organization as a result of motor skill learning has also been shown in humans using fMRI techniques. While neuroimaging results represent a very different form of data, skill-dependent changes can be demonstrated during the acquisition of skilled motor

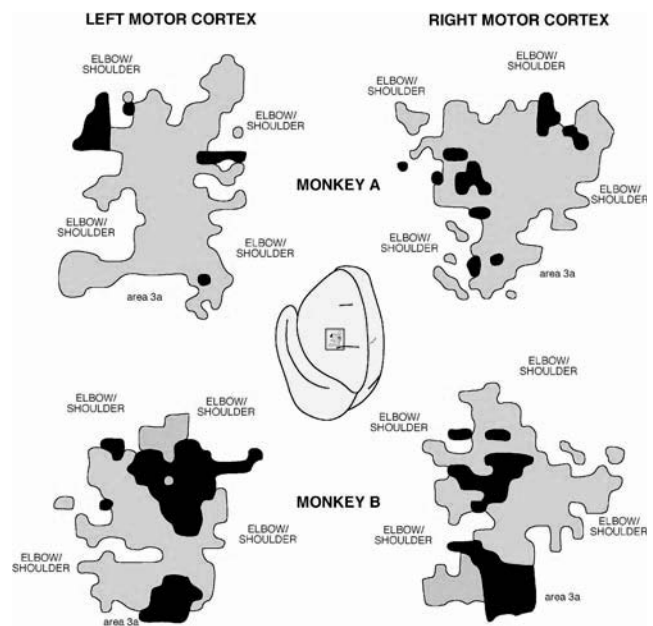

FIGURE 49-4

Individual variability in M1 maps in non-human primates. When the M1 maps of the hand representation are compared between hemispheres of the same animal, the mosaical patterns are similar on the two sides. For example, in both Monkeys A and B, the pattern of digit flexion representations (black) in the left motor cortex is roughly a mirror image of the pattern in the right motor cortex. However, when the digit flexion representation is compared between Monkeys A and B, the patterns are strikingly different, if not complementary. This high degree of individual variability in motor maps may result from the differential motor experiences of the animals prior to the mapping experiment. Graig denotes non-digit distal forelimb areas. Adapted from Ref. 22

tasks. However, the timing of the learning events may be critical to the particular changes that are observed (28). While the relationship between acquired skills and the size of motor representations holds for M1, the story may be more complex for other motor areas or for other motor tasks. For example, during the sequential learning of foot movements, cerebral blood flow was increased bilaterally in the dorsal premotor cortex and cerebellum during the execution of the movement. After a one-hour training session, blood flow in these regions was no longer increased during foot movement (29). As the authors suggest, these areas may be involved in cognitive strategies and motor routines to execute the foot movements, but are no longer involved once the sequence of movements is learned.

Structural changes in motor cortex also occur during the acquisition of motor skills. In rodents assigned to a skilled reaching task, reaching accuracy increased significantly at 3, 7 and 10 days of training. However, synaptogenesis (synapses per neuron) increased after 7 or 10 days of training, but not after 3 days of training. Motor map

plasticity occurred at 10 days of training only. Motor learning-dependent synaptogenesis is localized only to those motor regions undergoing the motor map changes (30) (Figure 49-5). Thus, structural and functional changes in motor cortex are co-localized, and are evident only in late stages of training, possibly related to the consolidation of motor skills rather than their initial acquisition (31). This late change in motor maps and motor cortex synaptogenesis is important in interpreting differences between fMRI results in human motor learning studies with electrophysiological and anatomical results in animal studies. The typical human studies are conducted over relatively short time intervals (minutes to hours), and thus, may be reflecting very different aspects of motor learning-dependent neuroplasticity.

From the standpoint of developing new rehabilitative interventions based on neuroplasticity principles, it is important to contrast the effects of skill learning with repetitive, but non-skilled motor activity (Figure 49-5). In

experimental animals, repetitive motor activity that does not induce improvements in motor skill or motor learning fail to alter motor map topography or synapse number (30, 32, 33) albeit induces angiogenesis (34, 35). This phenomenon has not yet been extensively studied, but may play a very important role in recovery at particular stages after brain injury.

### ACUTE AND CHRONIC CHANGES IN PERI-LESIONAL AND REMOTE REGIONS AFTER BRAIN INJURY

Following injury to the brain via trauma or stroke, a cascade of molecular and cellular events is set into motion in the surrounding tissue that results in both temporary and permanent changes in the anatomy and physiology of the affected structures (36). Many of these changes are pathological consequences of the injury (e.g., edema) and

FIGURE 49-5

Functional and structural changes in motor cortex related to improvements in motor skill. As rats develop skill at a reach and retrieval task (upper left), distal representations occupy a progressively greater portion of the forelimb area (upper right), while proximal representations occupy a progressively smaller portion (lower left). In addition, synaptogenesis occurs during motor skill acquisition, especially during the later phases of motor learning (i.e., mostly at 10 days, but not substantially at 3 or 7 days; lower right). Simple repetitive tasks that do not require acquisition of new motor skills result in no neurophysiological map changes or synapse changes. Adapted from Ref. 31

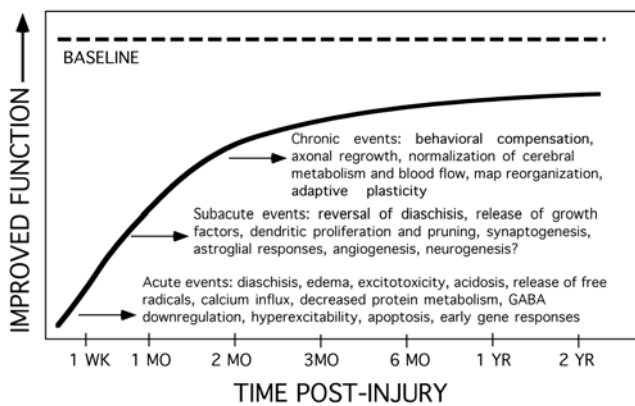

FIGURE 49-6

Cascade of acute, sub-acute and chronic events that are triggered by cortical injury. As acute pathogenesis subsides, improved sensorimotor function occurs. During the subacute phase, presumed restorative mechanisms are set in motion, such as dendritic arborization, release of growth factors and angiogenesis. Finally, functional and structural changes are consolidated in chronic phases as evidenced by alterations in axonal pathways and functional map configuration

have potentially damaging results. However, many adaptive processes may begin early in the post-injury stage and result in reduction of pathophysiological events or in neuroplastic changes leading to at least some restoration of function (37, 38) (Figure 49-6). While a thorough understanding of these processes at the molecular, cellular and network levels is just beginning, sufficient knowledge is now available to begin testing hypotheses about the effects of specific post-injury interventions on functional recovery and its underlying neuroanatomical and neurophysiological bases.

### Theories of Recovery

At least three general theories have been proposed to explain the substantial recovery that often follows brain injury, referred to here as reversal of diaschisis, compensation and adaptive plasticity (or vicariation of function) (Figure 49-6). As early as 1914, von Monokow discussed the role of diaschisis, or the temporary reduction in function of structures interconnected with an injured brain region, in the acute stages after injury (39). It is well known that both cerebral blood flow and metabolism are decreased in the region immediately adjacent to the injured tissue. Further, structures anatomically connected with the injured region undergo similar reductions in blood flow and metabolism. Gradually, blood flow and metabolism returns to the connected regions. Since this disruption is temporary, functional recovery is likely to be related, in part, to a gradual reduction in diaschisis.

Compensation in motor behavior is a common consequence of brain injury as the individual attempts to

supplant lost functions with alternative strategies. As an extreme example of compensatory behavior, a stroke survivor may begin to use the less-impaired limb for completing common tasks. However, more subtle changes in movement patterns occur even during use of the impaired limb. Stroke survivors with impaired function of the arm and hand may use proximal musculature in compensatory strategies to propel the limb forward (40). Depending upon the specificity of the motor endpoint that is assessed, such compensatory behavior could be missed, leading to the suggestion that motor performance has normalized. Even with the smallest experimental ischemic infarcts that can be made reliably in experimental monkeys, subtle changes in the kinematics of motor strategies take place, leading to the question of whether “true recovery”, i.e., return to normal, pre-lesion behavior, ever occurs (41). This is an extremely important, but often overlooked aspect of recovery that is critical for interpreting studies of neuroplasticity mechanisms after injury. Since use-dependent and learning-dependent changes are observable in the anatomy and physiology of normal, intact brains, it must be presumed that the development of compensatory motor patterns post-injury also alter brain structure and function.

A third general theory posits that functional recovery is largely dependent upon adaptive plasticity of intact, remaining brain structures. Various alternative terms have also been used to describe this theory, including “vicariation of function” and “neural compensation”. While this theory is also at least a century old, it has received considerable support in the past two decades from correlative studies in both experimental animals and in humans after brain injury. Underlying mechanisms thought to be involved in adaptive plasticity include unmasking of existing connections, long-term potentiation, long-term depression, axonal sprouting, dendritic sprouting, synaptogenesis and angiogenesis. Also, while the role of neurogenesis after brain injury is still controversial, some studies now suggest that brain injury can induce this process at least in some regions, and that neurogenesis may contribute to functional recovery (42).

### Neurophysiologic Alterations in Intact Structures After Brain Injury

Focal injury to the cerebral cortex does not simply result in a “hole” in the affected structure. Adjacent, intact cortical regions, as well as more remote cortical regions interconnected with the damaged area, undergo substantial physiological and anatomical changes. As early as 1950, Gles and Cole, using cortical surface stimulation techniques, demonstrated that if the motor representation of the thumb in primary motor cortex (M1) was destroyed in experimental monkeys, it reappeared in the adjacent, intact motor cortex (10). Later, it was demonstrated that a focal ischemic infarct in the primary somatosensory

cortex that eliminated the sensory representation of a single digit resulted in the eventual re-emergence of the digit representation in the adjacent tissue (43). These results would seem to support the adaptive plasticity or vicariation hypothesis. However, when newer intracortical microstimulation (ICMS) techniques were applied to M1, the vicariation phenomenon could not be replicated (25). Instead, when small, focal infarcts were made in the digit representation of M1, a further loss in digit representation occurred in the adjacent M1. While it may be tempting to dismiss the earlier results of Glee and Cole based on the spatially crude surface mapping techniques that were used, another important factor was found to contribute to the findings. This factor – the post-injury motor experience of the animal – has great impact on the ultimate, chronic condition of the motor map, and, very likely on the ultimate motor performance that can be achieved.

To determine the effects of post-injury experience on reorganization of motor maps, Nudo and colleagues encouraged the use of the impaired limb by placing a restrictive jacket on experimental monkeys. The jacket contained a long sleeve that extended the length of the less-impaired forelimb, and ended in a soft mesh mitt on the hand. The restricted hand could still be used for climbing, but was ineffective for grasping small objects, a task that was difficult to perform with the affected hand. Beginning about five days post-injury, two half-hour sessions of reach/grasp training were conducted each day. Several days to weeks were required to retrain skilled use of the affected hand, but eventually motor performance on the experimental task was similar to pre-lesion levels. Following this recovery period, the ICMS-derived motor maps revealed that the digit representations in the intact areas were maintained. In some cases, they expanded into regions where prior mapping revealed proximal representations (44). Thus, motor experience after injury can drastically alter the ultimate functional organization of motor cortex (Figure 49-7).

This phenomenon is not limited to the adjacent cortex. In other non-human primate experiments employing slightly larger lesions encompassing the entire M1 hand area, hand representations in the premotor cortex were enlarged several months later, even in the absence of post-injury training. Further, the magnitude of the premotor enlargement was directly related to the size of the injury in M1 (45) (Figure 49-7). Since premotor cortex has reciprocal connections with M1, it is not surprising that this region is altered. But the enlarged representation related to the size of the M1 injury suggests that it may play a significant vicarious role in recovery.

### Anatomical Alterations in Intact Cortical Structures After Brain Injury

In concert with behavioral recovery and neurophysiological remodeling, injured brains undergo significant

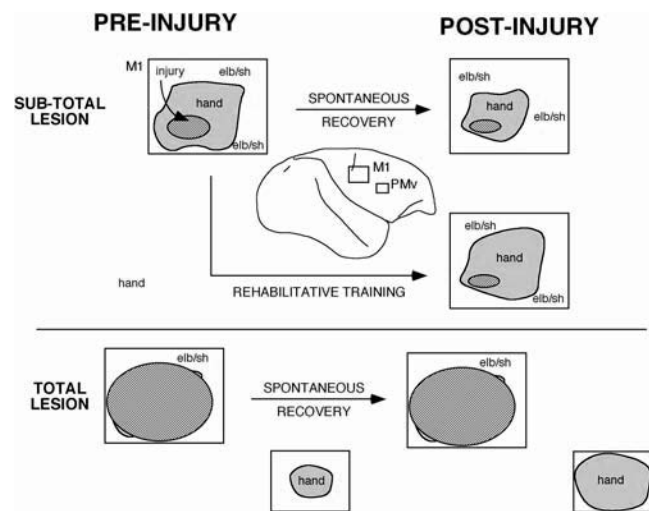

FIGURE 49-7

Functional alteration of local and distant cortical organization following focal injury. Sub-total lesion: If the injury is small enough, reorganization is primarily confined to the local adjacent tissue. For example, a subtotal injury to the M1 hand area results in changes in representational maps in the spared hand area adjacent to the injury. Post-injury rehabilitative training can have a profound influence on the inevitable map configuration. Total lesion: After a total lesion of the M1 hand area, other motor regions interconnected with M1 are stimulated to reorganize. For example, the hand representation in the ventral premotor cortex (PMV) enlarges. This premotor area normally has reciprocal connections with the injured M1. Adapted from (45)

anatomical plasticity in neuronal and non-neuronal structures. In rat motor cortex, intracortical fibers in the bordering intact tissue display orientations different from those seen in normal animals, suggesting that injury induces local axonal sprouting (46). Arteriolar collateral growth and new capillaries also form in the ischemic border (47). Significant neuroanatomical changes also occur in the contralesional (intact) motor cortex, but the role of this cortex in functional recovery of the affected limb is still a subject of debate. Recent results from animal studies suggest that the neuroanatomical changes in the intact cortex occur as a use-dependent or skill-dependent change due to increased use of the less-affected limb (48).

The latent potential for enhancing neuroanatomical plasticity mechanisms after stroke has been demonstrated by the use of mutant mouse strains that lack the Nogo receptor. Nogo is a protein involved in the inhibition of axonal growth. Mice lacking the Nogo receptor recover motor function after stroke better than controls. Further, rats subjected to anti-Nogo antibody treatment initiated one week after stroke resulted in better behavioral recovery compared with controls. Further, sprouting

of contralateral corticorubral and ipsilateral corticospinal fibers was observed (49). Pharmacologic treatment with D-amphetamine after stroke has also been shown to enhance neocortical sprouting, synaptogenesis and behavioral recovery after stroke (50).

### **PHYSIOTHERAPEUTIC TREATMENT FOR MOTOR DISABILITY AFTER BRAIN INJURY: CURRENT PRACTICE**

Since it is now clear that certain types of behavioral and pharmacologic interventions have the potential to alter neurophysiological activity and neuroanatomical structure, it may be helpful to examine the various therapeutic approaches used in post-injury rehabilitation, and consider their potential for maximization of recovery based on neuroplasticity principles. This discussion may lead to a better understanding of the underlying mechanisms of rehabilitative therapy by pointing out the current gaps in our basic knowledge. It also may help us to refine therapeutic interventions to take advantage of the modulatory role that specific behavioral and pharmacological therapies play.

#### **The Maximization of Motor Recovery Through Diverse Approaches**

Treatment of upper limb impairments following brain injury (such as that occurring after stroke) follows either: 1) principles of neurofacilitation or 2) principles of functional retraining. Traditionally, the choice between these rehabilitation strategies has been based on the phase of stroke recovery. Whereas in the acute/subacute phase, therapy typically focuses on the prevention of maladaptive compensatory strategies while promoting the recovery of normal function, in the chronic phase, the emphasis is placed on maximizing function, often through the teaching of compensatory strategies (51).

*Principles of Neurofacilitative Approaches* Neurofacilitative approaches, such as Rood, Brunnstrom, Bobath, Proprioceptive Neuromuscular Facilitation (PNF) and Sensory Integration (SI) therapy, are usually used in early post-injury stages to favor motor recovery following a stroke, when most of the recovery seems to occur (52). These approaches focus on the recovery of normal movement. Unwanted movements and spasticity are inhibited and normal patterns are facilitated under the assumption that regaining of voluntary control over key movements will transfer to functional improvement. These approaches are based on empirical assumptions that motor impairments are a consequence of a disruption of central nervous system (CNS) hierarchical and reflex motor control

(53–57). In the traditional view of these approaches, recovery of motor function follows the same chronology that is observed in neurodevelopmental stages, supposedly reflecting the CNS efforts to reestablish its internal hierarchical order that was disrupted by the neuronal loss consequent to the injury. Therefore, these approaches utilize neurophysiological phenomena (e.g. reflex pathways) to favor ‘normal’ motor behaviors and are largely based on neurodevelopmental knowledge (58). Whereas largely used and trusted by therapists (59, 60), in general they have not resulted in substantial impact on patients’ recovery when examined in controlled trials (61–64) and seem to result in similar behavioral outcomes when compared to each other (65–67).

Currently, to our knowledge no studies have explored physiological or morphological effects of neurofacilitative approaches on the CNS. This contrasts with the large number of mechanistic studies that are related to approaches based on movement repetition and retraining. However, it should be noted that the current absence of basic research investigating the effects of these approaches may be due to technical challenges rather than a weaker scientific rationale. Among the technical difficulties, because the NDT approach is specifically adapted for the individual’s particular needs and because it involves a high level of therapist manual expertise, inter-subject and inter-therapist variability is very high, making it quite difficult to standardize protocols. Hopefully, in the near future, the mechanisms of action of these approaches will be investigated. Currently, the urge for experimental support for the widely used clinical practice is felt and underlined by the NDT community (68). The desire to provide an evidence-based practice is supported by the Neuro-Developmental Treatment Association, which is currently providing financial support for research and favoring the development of a consistent knowledge base among therapists.

*Principles of Functional Retraining* Recently, studies evaluating the mechanisms underlying motor acquisition and motor control have resulted in the elaboration of behavioral treatment approaches based on practice (51, 69, 70). In these approaches, it is believed that the hemiparetic subject has distorted central motor programs resulting from CNS cell death. Based on the assumption that repetition of movements has the same effects as the ones reported for normal individuals (71), it is believed that practice establishes novel motor plans for the resolution of encountered motor problems (72). Additionally, it is taught that movement repetition improves behavior by affecting muscle weakness, an important problem affecting upper limb function (73–75).

Initial evaluations of the efficacy of repetition of movement, in order to improve motor outcomes following stroke, have provided encouraging results. Several studies have shown that repetitive, concentrated practice

improves motor outcomes (14, 76–80). Additionally, diverse practice approaches have been explored in order to maximize retention and transferability (81–88). At this point, whereas it is well established that practice improves motor outcomes and function following stroke, currently a consensus on a precise and consistent protocol to use to maximize the recovery is far from established. The elaboration of standardized training protocols based on principles of motor learning, retention and transferability specific to the hemiparetic population, is one of the most urgent needs for patient management.

While animal models have frequently been used to optimize basic therapeutic strategies in preclinical drug trials, their utility has been under-appreciated. Surely, animal research allows investigation of mechanisms through which practice favors recovery and the identification of morphological and physiological processes that accompany improved motor performances. Whereas physiological changes at the level of the motor cortex induced by practice following stroke has been shown (44), the impact of diverse types of practice, intensity or even the time at which practice is most beneficial for the modulation of adaptive physiological and or morphological changes has yet to be investigated. For example, it was recently shown that rats undergoing training consisting of repetitive movements demonstrated functional and structural plasticity within the same cortical regions (30). This study provides strong evidence that synapse formation and physiological expansion of cortical representation of movement are concomitant and probably inter-dependent adaptive processes playing important roles in learning. Knowing that learning and practice are so influential in the recovery from stroke, the investigation of the parallel changes of dendritic arbors and physiological reorganization of motor maps in M1 or in premotor cortex will be of great interest. In the near future, the choice of treatment, intensity and schedule of therapy at different stages of stroke (e.g. acute, chronic) could be directed to take advantage of the most prolific stages of morphological and physiological reorganization.

Although it is a long held belief that most of the rehabilitation of stroke patients occurs in the first few weeks to months following stroke (Duncan and Lai, 1997), there is little evidence available indicating that physical rehabilitation is effective for patients with chronic CVA, and the literature is even equivocal on the value of physical rehabilitation for sub-acute patients (89, 90). However, the fact that some patients with a given extent and locus of lesion recover more movement than others suggests that additional factors may be involved. Taub and colleagues suggested that some motor abilities were possible, but were not reinforced. In the vernacular of classical conditioning, these behaviors were extinguished or actively inhibited (89). From this assumption, it was

stipulated that function could be improved in chronic stroke patients. In particular, this group has developed an innovative approach known as constraint-induced movement therapy (CIT) that has received a great deal of attention in the last decade. The idea behind the application of CIT originates from fundamental experiments conducted in non-human primates following peripheral deafferentation (91). In these experiments, disuse of the affected upper limb of non-human primates was observed following the injury. This maladaptive behavior persisted if no manipulation was introduced, even after a three to six month spontaneous recovery period. At that point, the function of the deafferented limb could be greatly enhanced by forcing its use by restraining the non-affected limb (92). This led to the ‘learned non-use’ hypothesis which stipulates that non-use, or less than maximal use, of the deafferented limb results from negatively reinforced attempts to use the affected limb. This negative feedback would consist of unsuccessful behavioral consequences of attempts to use the affected upper limb (e.g., absence of reward for goal-directed activity, or painful execution). After the initial recovery period, when the ability to use the affected limb is stable, behavioral sequelae caused by the learned non-use remain. Therefore, because of the phenomenon, the actual use of the affected limb is much less than its true potential (89, 93, 94). Strong support for the learned non-use formulation came from a study where restraint was applied directly following the deafferentation of the upper limb of an animal for a 3-month duration, therefore preventing the learned non-use phenomenon to occur (95). When the restraint was removed, the animals used their deafferented limb. Also, when deafferented prenatally, animals exhibited purposive use of the deafferented limb from the first day of extrauterine life (96, 97). In that experimental paradigm, the use of the upper limb following the lesion was also restricted because of the limited intrauterine space, thus preventing the negative feedback from unsuccessful usage of the limb and supposedly the learned non-use phenomenon from developing.

Physiologically, it can be assumed that deafferentation is a lesion which, like potentially many others, such as traumatic brain injury or stroke, creates a disruption of sensorimotor integration loops (98–100). By this logic, disruption would result in initial poor motor behavior. The progressive reestablishment of sensorimotor integration loops through motor behavior favoring CNS adaptive mechanisms may underlie a substantial amount of spontaneous recovery from these lesions. However, during the adaptive period, the learned non-use phenomenon would negatively intervene, making the subjects subconsciously or consciously learn that the use of the affected limb results in poor behavioral outcomes. The negative feedback from these outcomes would reinforce preferential usage of the non-affected limb. In that view,

the learned non-use phenomenon would not only be present following deafferentation, but also following any injury disrupting sensorimotor integration loops. Therefore, the application of a restraint on the unaffected limb, to force the use of the affected limb, should result in improvement of motor outcomes in numerous neurologic, and even orthopedic, conditions (101).

In the original application of the learned non-use hypothesis to the hemiparetic population, a simple arm-restraint was employed (102). In that study, stroke and head-injured patients were required to keep their uninjured upper extremities within a hand-enclosed sling during waking hours over a two-week interval. Functional improvements in diverse tasks and in force were reported, and most of them were maintained when examined in a one-year follow-up assessment. The results supported the hypothesis that learned non-use occurs in select neurological patients and that this maladaptive behavior can be reversed through application of a forced-use paradigm. In a second experiment (103), use of the sling for 14 days was combined with six hours of practice of functional movements with the impaired limb for 10 of those days. The behavioral training paradigm consisted of operant conditioning (104). Patients demonstrated improvements beyond what had been reported with the sole use of the sling, and improvements in motor performance were maintained during a two-year period of follow-up. The increase of motor improvements obtained from the combination of behavioral training with the wearing of the sling is a strong indication that, in addition to reversal of learned non-use, additional factors may be involved in the recovery in chronic stroke patients<sup>1</sup>.

Positive results using the CIT paradigm have been reported in several experiments (94, 105, 106) and by unrelated research groups (107, 108), repeatedly demonstrating large effect sizes for the Motor Activity Log (MAL) and for the Wolf Motor Function Test (WMFT). In addition, more recent studies using a modified CIT demonstrate that upper extremity function can be improved after TBI. Most importantly, improvement in motor skill made by the patients has been shown to be transferable to other activities in their daily lives. It should be pointed out that the constraint increases the time of treatment to up to 90% of waking hours of the subject. Thus, it imposes a discipline that might otherwise be difficult to achieve in practice. It can be argued that it probably is the simplest and most reliable way to reach such a high level of intensity for a clinical intervention. In the absence of constraint, if a task introduces too many obstacles to execute with the affected limb, the subject will naturally have the tendency perform it with the other limb, therefore limiting the learning

experience with the impaired limb. The constraint forces the patient to immediately apply the motor skills he is learning during daily treatment in a natural and very significant location: at home. Learning is context-dependent, meaning that an important factor in the retention of motor skills is the relationship between the context of practice and the context of application (109). Therefore, the level of intensity of intervention and direct context-dependent application of the learned motor patterns during the day might explain why the therapy has such a high impact on the performance level on tests evaluating functional motor state of the patient (e.g. MAL; WMFT).

The paradigm used in non-human primate experiments is strikingly similar to CIT. Monkeys wore a jacket with a long sleeve restricting fine control by the less affected limb. Thus, these animal experiments may be very useful for evaluating various aspects of the CIT protocol (e.g., timing, intensity, specific behavioral factors, etc.). From the monkey studies, it would appear that the repetitive behavior is the more important factor in CIT, rather than the presence of the constraint device. Recovery of hand representations in primary motor cortex is very rapid when the use of the restraint jacket is combined with repetitive training. However, when the restraint device is the sole source of motivation to use the impaired limb, normalization of motor maps occurs extremely slowly, if at all. Monkeys that wore a restraint jacket for up to one year did not display as much map recovery as monkeys engaged in repetitive training for only two weeks (110).

A series of experiments to evaluate the presence of cortical representation changes, paralleling the behavioral changes resulting from CIT, has also been performed (91, 111, 112). These studies reported increased cortical representation areas of the affected arm following treatment, an upper limb representational map size that was similar in both affected and less-affected hemispheres at a 6 months follow up, and shifts of the center of the output map, suggesting recruitment of adjacent brain areas examination. This last result has been related by the authors to the phenomenon that has been reported in monkeys undergoing repetition of movement therapy following a cortical ischemic lesion (44). Therefore, human studies now support the hypothesis that CIT modulates recovery through processes that are similar to the ones that are known to occur following motor learning through practice and repetition.

As previously mentioned, one of the interesting results that came from these studies was that, in addition to the reversal of the learned non-use phenomena, other factors appeared to be involved in the motor recovery of chronic stroke subjects. In fact, it was even shown that subjects that were undergoing intensive physical therapy, consisting of aquatic therapy, neurophysiological facilitation,

<sup>1</sup>Discussion of this particular topic can be found below.

and task practice showed a level of improvement similar to that of sling restraint of the less-affected arm, combined with intensive task practice or shaping (94, 105). However, in these experiments, the intensive therapy control groups showed higher levels of decrement of arm use at the two year follow up in comparison to the CIT group. Therefore, it appears that one of the advantages of the usage of a sling is the higher retention of use of the affected limb at the two-year follow-up, and that the common factor in all techniques producing an equivalently large treatment effect is repeated use of the more-affected upper extremity (89). It thus can be suggested that chronic hemiparetic patients have the capacity for functional motor learning and that they have not maximized their motor potential after traditional acute care.

In conclusion, we would tend to consolidate the preceding literature into one treatment hypothesis: Intensive treatment based on repetition creates plastic changes that are associated with learning (which might include reversal of learned nonuse). This probably acts through positive behavioral conditioning of the use of the impaired limb resulting in learning and amelioration of the general motor schema of the upper limb.

### **Too Much, Too Early?**

After injury to the sensorimotor cortex in rats, extreme use of the affected limb can result in an enlargement of the lesion and further motor impairment (113). If the unimpaired limb is placed in a restrictive cast after cortical injury, rats must rely heavily on the impaired limb for posture and locomotion. Forced overuse of the impaired limb during the first week after injury results in expansion of the injury and poorer motor performance (114). Forced overuse during the next seven days does not result in injury expansion, but nonetheless resulted in poorer motor performance. More recently, it has been shown that after TBI in rats, neuroplasticity-related intracellular signaling proteins are disrupted if voluntary exercise is provided within the first week post-injury (115). These studies strongly suggest that there are specific vulnerable periods for maladaptive effects of use after injury. Timing of these maladaptive effects must be considered along with timing of adaptive effects in any rational therapeutic design for treatment of motor deficits after injury.

### **Assessment of Efficacy**

The assessment of efficacy of clinical approaches is an important issue, not only for stroke and brain injury recovery, but for the entire field of neurorehabilitation in general. Particularly in the cases of stroke recovery, one important question surrounding this topic is: Should we focus on the return of “normal” movement (true recovery) or just on return of function at any cost (i.e., compensatory

strategies)? This question extends beyond the clinical field and is also debated in the literature discussing animal models of stroke (40, 41, 116). It also raises the question of evaluative tools. Obviously, very different tools are needed to evaluate the divergence from ‘normality’ of movement and functional capacities of a patient. Whereas evaluation tools focusing on the ‘abnormalities’ of movements are much more useful and appropriate to the practice of neurodevelopmental approaches, newer, strictly functional scales are used in several research protocols to measure the impact of movement repetition based treatments. Particularly, in the cases of CIT, the validity of the clinical tests they traditionally use to assess motor recovery has been questioned (106, 117, 118). These tests only evaluate function and use, and do not evaluate the use of compensatory strategies. In fact, the treatment effects become much more uncertain when using evaluation tools monitored by trained therapists, such as the Fugl-Meyer (119) or the Barthel index (118). It can be argued that the WMFT and MAL are self-reports that could circumvent the blinding process (118); familiarizing patients with the MAL questions on a daily basis may permit recollection of previous responses, thereby narrowing the choice points on the MAL. This effectively reduces the variability, and enhances the effect size (119). On the other hand, it can also be argued that the ultimate goal of therapy, specifically at a chronic stage, is to improve function and use of the affected limb and that the WMFT and MAL are specifically designed and were shown to do this well (117). Alternatively, for the validation and evaluation of learning processes, movement kinematics could be assessed. A recent study showed that in chronic patients, when immobilizing the trunk, the subjects use their shoulder and elbow joints in a more normal way (120). The use of the trunk helps patients to create end-point trajectories that are more similar to healthy subjects. This study underlines that compensatory behavior can potentially be detrimental to maximization of function, in this case, limiting the range of reaching. Whereas maximization of function is the goal of rehabilitative approaches, the identification of these detrimental compensatory strategies is necessary to achieve this goal. Novel evaluation scales are being developed (121) and will hopefully help clinicians in that task.

### **Treatment Groups and Valid Controls**

It now seems obvious that the evaluation of treatment outcomes must take into consideration the type of treatment and the initial level of function of the targeted population (52, 122). Intrinsic, non-treatment-related elements are key determinants in the level of potential benefits a patient derives from a particular treatment. Whereas the initial level of function (as reflected by clinical assessments such as the Fugl-Meyer) has traditionally

been used as the main predictor for recovery, other factors are now identified as better predictors. The initial grade of paresis appears to be the most important clinical predictor for motor recovery (123). Additionally, motor evoked potentials (MEP) seem to be highly predictive for the occurrence of motor recovery (124–126). It was shown to be a much better predictor than clinical examination, infarct size and location, age, gender, and stroke type (infarction versus hemorrhage). Also, preservation of the corticospinal tract with MRI imaging was also found to correlate with good recovery, confirming the TMS studies (127). This confirms that studies evaluating the efficacy of different clinical approaches need to have stringent selection criteria for their subjects. Recovery from strokes can vary largely between individuals. For example, purely cortical stroke survivors recover better than purely subcortical or mixed cortical-subcortical strokes. Decreases in the level of recovery can be observed from cortex, corona radiata, and posterior limb of internal capsule (128). This suggests that recovery of upper limb movement is heavily dependent on the preservation of corticofugal fibers (128, 129). Also, the recovery period is approximately twice as long for patients with severe paresis (15wk), compared to patients with mild paresis (6.5wk) (130). Therefore, to truly evaluate the impact of a treatment on stroke survivors, studies should be designed to include patients with similar predicted outcomes in each experimental group. Additionally, if some subjects have intrinsic conditions rendering them unable to benefit from a certain approach, they should be studied separately to identify the substrate of this failure and the potential alternative approaches from which they could benefit more. For example, a preliminary study to investigate the integrity of short-term motor memory in stroke subjects indicated that patients with low Fugl-Meyer and executive function scores had problems modifying their motor commands based on previous experience (131). Such results raise important questions concerning the use of movement repetition in this particular population of hemiparetic patients.

### SUMMARY

Our understanding of recovery from damage to the central nervous system has evolved tremendously in the last few decades. Fundamental research on the diverse physiological, morphological, molecular and genetic changes resulting from ischemic damage and the association of certain phenomena to behavioral recovery has drastically impacted stroke management. Evolving knowledge of plastic changes accompanying functional recovery coming from both animal studies and technological advancements in humans (e.g., fMRI) might create a entire new set of outcome predictors and or surrogate markers of

recovery states useful for both study design and patient treatment choices. These novel indicators might also direct the type, intensity and duration of treatments. For example, cortical representation of body segments evaluated with TMS could become a means to identify the endpoint for treatment. When patients demonstrate a plateau in physiological reorganization, this could imply that most of the adaptive changes have already taken place. Whereas much work has been done, obviously, many questions are still unanswered. Most of the experiments that have been performed so far have included only subjects showing high functional scores. Unfortunately, a large proportion of hemiparetic stroke patients show mild improvements with currently available treatments. Surely, significant work in both animals and humans needs to be accomplished to better understand and provide more efficient treatments to individuals with brain injury.

## Therapy Interventions for Mobility Impairments and Motor Skill Acquisition After TBI

*Katherine J. Sullivan*

**I**nnovations in mobility rehabilitation after brain injury derive from recent advances in neuroplasticity and neurorecovery. In particular, our understanding of motor recovery after brain injury is being influenced by basic science work that demonstrates that the process of motor skill acquisition is essential to promote both behavioral changes in motor performance and morphologic changes in neural structures within the motor cortex. (Please refer to Chapter by Nudo & Dancause for discussion of neuroplasticity and effects on brain injury recovery). The complexities of rehabilitation after brain injury comes from the usual situation that both neural structures that interfere with normal movement (i.e., corticospinal neurons and their connections) as well as those that impact the cognitive processes associated with motor learning are affected. Therefore, physical neurorehabilitation needs to include intervention strategies that address impairment level motor deficits that result after brain injury such as weakness, abnormal movement synergies, and abnormal tone as well as the intrinsic and extrinsic factors that promote motor learning and the acquisition of motor skills needed to increase function.

The field of neurorehabilitation needs to experience a paradigm shift. Advances in basic science research provide important understanding of the physiologic events that occur after brain injury and the neural processes that modify and impact recovery. The challenge

for neurorehabilitation specialists who work with individuals with brain damage is to incorporate the strategies that are elucidated by the animal studies and ultimately design the clinical trial studies that will systematically examine these treatment paradigms within the clinical setting. Unfortunately, clinical trials that specifically examine treatment efficacy in human populations with traumatic brain injury (TBI) are sparse. However, evidence from the work done in individuals with stroke-related brain damage may provide a basis for the design of future TBI trials.

The intent of this chapter is to focus on rehabilitation approaches that address motor recovery; specifically, primary and secondary impairments that affect mobility and the process of motor skill acquisition after brain damage. This chapter will discuss factors that affect motor skill acquisition after brain injury, review traditional treatment approaches that address physical impairments that affect mobility, and present some examples of innovations in therapeutic interventions that address the acquisition of skills and promotion of meaningful functional recovery.

### **DISABLEMENT MODEL**

Recovery from brain damage is multi-factorial and involves more than just the recovery and reorganization of neural structures. Contextual factors such as environmental

influences like physical barriers, social support system and access to funds and services or personal factors such as age, gender, health status and personal lifestyle behaviors are all powerful predictors of outcome after TBI. For this reason, it is helpful to use an organizing framework such as the International Classification of Functioning, Disabilities, and Health (ICF) disablement model when approaching problem identification, goal formulation, and treatment planning. Additionally, the multiple dimensions of this model reflects the need for an interdisciplinary team to adequately address all of the contributing factors to disability after TBI.

The ICF disablement model is a classification system developed and disseminated by the World Health Organization (WHO) (1). The ICF characterizes the impact of a condition such as TBI according to the following dimensions: body function and structures, activities, and participation.

- *Loss of body functions and structures* include the impairments that result as a primary or secondary consequence of the brain injury. The neuromuscular motor impairments that will be discussed in this chapter include such things as impairments in voluntary movement, balance and postural control, and abnormal tone that result from direct insult to brain structures. Secondary impairments are the musculoskeletal conditions that result from immobility or excessive muscle tone such as muscle contractures, restricted joint mobility, and disuse weakness and deconditioning.
- *Activities* are the tasks that the individual performs such as walking, feeding, dressing, and other self-care related functions. Activity limitations reflect the difficulty that the person has in functional task performance.
- *Participation* reflects the individual's involvement in life and societal activity. There are 9 participation domains that include: personal maintenance, mobility, exchange of information, social relationships, home life and assistance to others, education, work and employment, economic life, and community, social, and civic life. The focus of this chapter will be therapeutic approaches associated with improving participation in mobility related tasks and activities.

Disablement models are a meaningful way to determine and evaluate the consequences of disease or injury. The original intent of the ICF classification (and its predecessor the ICIDH-2) was to evaluate the process of health care delivery, which required the need to develop and measure outcomes at each level of the disablement process (2). Because of this, recent trends in rehabilitation literature (particularly in randomized clinical trials that examine the efficacy and effectiveness of rehabilitation interventions)

include levels of measurement that reflect outcomes at the impairment, activity, and participation levels.

Another application of the disablement schema is to provide an organizing framework for rehabilitation intervention such that rehabilitation approaches could be developed and standardized in order to identify goals that are aimed to address problems at the levels of impairment, activity, or participation. Designed to assess the consequences of disease or injury, the disablement classification system has an implicit assumption that interventions that improve impairments will lead to improvements in functional limitations, and hence, reduce disability. Quinn and Gordon (3) propose that one of the limitations of using the disablement model as a framework for intervention is that it takes a reductionist approach to rehabilitation. A reductionist approach would emphasize that disease or injury leads to disablement; therefore, reduction of disease or injury-related impairments would be the focus of rehabilitation. In contrast, they suggest that the process of rehabilitation is the reverse, such that, rehabilitation interventions are designed to lead to recovery (Figure 50-1). A physical rehabilitation approach that emphasizes recovery would 1) identify the roles related to self-care, social and recreational pursuits, and occupation that an individual desires to assume or reassume after injury, 2) identify the skills required to successfully achieve these pursuits, 3) determine the physical limitations and cognitive processes that are impaired and contribute to the functional deficits, and 4) design interventions that address physiologic mechanisms of recovery at both the impairment and skill levels.

Recent advances in neuroplasticity provide mechanistic validation to a rehabilitation approach that emphasizes

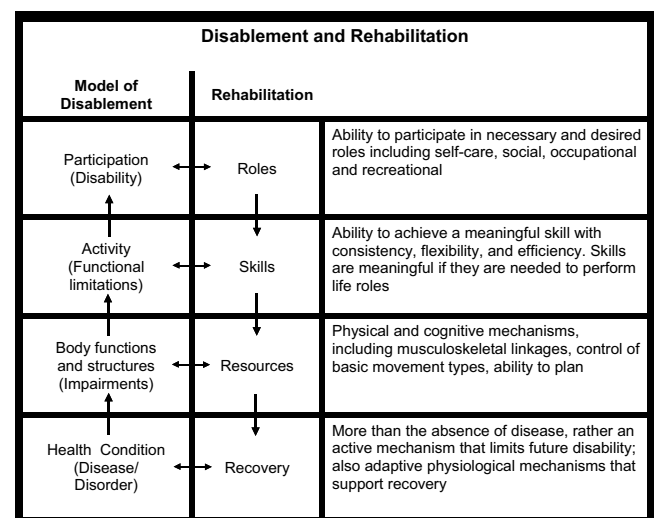

FIGURE 50-1

Conceptual framework of functioning and health in rehabilitation. Adapted from Quinn and Gordon (79)

recovery and skill acquisition. Consistently, animal models of recovery after brain damage demonstrate that the process of motor skill acquisition is a critical component that subserves both functional and neurological recovery (4–11). One of the major premises of a paradigm shift in physical rehabilitation of individual’s with brain injury is the need to design therapeutic interventions that promote the acquisition of motor skill as well as address the direct and indirect impairments that occur to the neuromuscular system.

**PRINCIPLES OF FUNCTIONAL TRAINING AND MOTOR SKILL ACQUISITION**

The recent advances in neuroplasticity discussed by Nudo and Dancause in Chapter 49 of this book provide substantial evidence for the neurophysiologic and neuroanatomic mechanisms that underlie the process of motor skill acquisition and the importance of skill acquisition in recovery after brain damage. Clinicians in the neurorehabilitation field need to develop strategies to integrate the concepts

of neuroplasticity and motor recovery with the clinical environment where the learning of motor skills occurs. Figure 50-2 proposes a Theoretical Model for Neurologic Therapeutic Intervention that incorporates our current understanding of neuroplasticity and neurorecovery. This model is based on the assumption that neuroplasticity is driven by the acquisition of motor skills. What are the therapeutic principles that should be incorporated into therapy sessions in order to optimize the learning experience and maximize the level of skill acquisition for our patients? Recent research in neurorehabilitation suggests that key principles of motor skill acquisition and learning and principles of exercise can be applied to increase neurorehabilitation effectiveness and include the importance of practice and feedback, task-specificity, and training intensity. These principles provide important guidelines for the design and delivery of therapeutic interventions. Another important aspect of the neurotherapeutic model is at the level of assessment, whereby, the therapist analyzes functional task performance and determines the primary and secondary impairments that contribute to functional deficits. The organization of this chapter is to elucidate each of the critical factors that guide the clinician in the design of therapeutic programs that drive neuroplasticity through the process of skill acquisition. In addition, this chapter discusses the mechanisms and intervention strategies of the primary and secondary impairments of the neuromuscular and musculoskeletal systems that most commonly affect mobility after TBI.

**Process of Motor Skill Acquisition After Brain Injury**

Motor skill acquisition is the process by which an individual learns a motor skill. As with other cognitive processes such as language, verbal learning or declarative memory, motor learning occurs within various regions of the cortical and subcortical structures that are involved in the formation of a motor program that is parameterized in time and space to accurately meet a task goal. For example, a child learning to hit a baseball has to develop the strength and coordination to swing a bat with the speed and accuracy to meet the ball as it passes over the plate. The development of the sensorimotor representation of an action plan occurs in cortical sensorimotor structures such as the primary and secondary motor and sensory cortices. However, the initiation and retention of an action plan occurs in prefrontal, basal ganglia, and cerebellar structures. Therefore, motor skill acquisition and retention occurs throughout a neural network that involves all of these movement-related cortical and subcortical areas (12–14). Obviously, the impact of TBI on motor skill acquisition is profound since individual’s post-TBI can have involvement with structures that directly impact force production (i.e., motor cortex and direct connections to

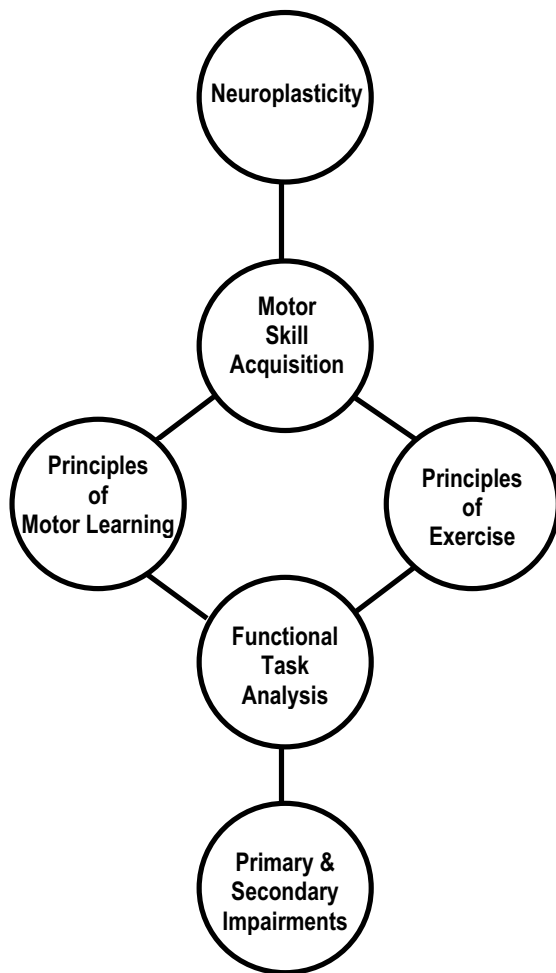

FIGURE 50-2

Theoretical model for neurologic therapeutic intervention

corticospinal tract of spinal cord) and coordination (i.e., cerebellum and basal ganglia effects on motor control) as well as with other cortical and subcortical areas associated with action plan development, initiation, and retention.

When working on motor skill learning with individuals with TBI, it is particularly important to appreciate the distinction between declarative (explicit) and non-declarative memory (implicit) systems since it is common that patients will present with cognitive deficits which interfere with their ability to have declarative recall but may not interfere with their ability to learn motor skills. The explicit and implicit learning systems are functionally and neuroanatomically distinct (15, 16). Declarative memory is memory for facts and events and is mediated by the medial temporal areas that include the hippocampus and diencephalic nuclei. Patients' post-TBI who are in the period of post-traumatic amnesia have declarative memory deficits as a result of damage in this neural system. In contrast, implicit or non-declarative memory is a collection of abilities that includes the formation of skills and habits, priming and perceptual learning, classical conditioning, and nonassociative learning. The implicit learning systems are not dependent upon the medial temporal areas that support declarative learning. Motor skill learning is a form of implicit learning in which changes in motor performance with practice can occur without conscious awareness of all of the movement-related abilities that are being learned. The areas associated with implicit learning are those that participated in the original learning; therefore, the sensorimotor, prefrontal, basal ganglia, and cerebellar areas, which comprise the neural network for movement, are the areas that are most likely to subserve the implicit motor skill learning system.

The dissociation between declarative awareness and skill learning has been demonstrated in healthy individuals (17) as well as those with brain damage due to Alzheimer's disease (18, 19), Parkinson's disease (20, 21), encephalitis and anoxia (22), and TBI (23, 24). Clinically, this dissociation is significant since it reveals that there is not a direct relationship between the ability to learn new declarative information and the ability to learn motor skills. This dissociation between learning systems confirms that the ability to learn motor skills is retained even in the presence of profound declarative memory loss. Clinical strategies that can be effective when working on motor skill acquisition with individuals who have profound short term declarative memory loss include task-specific training that focuses on the direct acquisition of skills, adaptation of daily routines or the environment such that cues for functional skills can be provided that do not require declarative recall (e.g., memory boards, prearranged functional setups, pictures), and monitoring responsiveness to therapeutic interventions by more sensitive measures of motor performance such as measurement of the time to complete tasks (25).

Motor skill acquisition occurs as a result of practice. The process of motor learning occurs in stages. Fitts and Posner (26) described three stages of motor skill acquisition. The *cognitive* phase is the initial phase of learning where the learner develops the execution requirements of the skill to be learned. During the *cognitive* phase, the learner has frequent errors and variable performance as he/she develops an understanding of what to do. The learner is dependent on visual and verbal environmental cues to organize the movement. As errors decrease, other forms of feedback such as kinesthetic information will be used for error detection and correction. In this early stage of learning, therapists serve as important sources of augmented verbal, visual or tactile feedback. Feedback that provides information of movement outcome is knowledge of results (KR) and information of movement errors is knowledge of performance (KP) (27). When a therapist reports the time it took to complete a 10-meter walk they are providing KR; a description of the gait deficits during that walk is an example of KP. Due to the high cognitive and attentional demands during this initial phase of skill acquisition, practice in an environment with few distractions is recommended. This is particularly relevant when working with individuals with brain damage who have impairments such as slowed information processing, attention deficits, and high distractibility.

With additional practice, the learner shifts to the *associative* phase of learning. In this phase, the learner shifts from what to do to how to best complete the action. The learner begins to rely less on visual and verbal cues and attends to kinesthetic cues in order to develop an internal reference of correctness. As kinesthetic awareness develops, the learner has a greater ability to detect movement errors and their consequences. After extended practice, the learner shifts to the *autonomous* phase in which motor tasks are performed more automatically and with less error. During this phase, cognitive effort is less and attentional demands directed to the task are reduced. Patients with brain injury can be introduced to more environmental complexity and distraction as they advance to these later phases of skill acquisition.

In summary, motor skill learning is a purposeful, problem-solving thought process in which the learner develops the coordination of perception and action in order to perform motor skills efficiently and effectively (28). Physical practice of a motor skill is the most important requirement in order to promote skill acquisition and motor learning. Therapists are instrumental in setting up the therapeutic learning environment in such a way as to promote the process of skill acquisition. Understanding that motor learning occurs in stages that have varying cognitive demands is especially important when planning a therapeutic session for someone with brain injury. In addition, it is important to be aware that the level of performance proficiency (i.e., cognitive, associative,

autonomous) will vary with the task and environmental demands (29). In other words, a functional task such as a wheelchair transfer may be performed at an autonomous level in the structured and quiet atmosphere of an individual treatment room. However, on the nursing unit where environmental demands are high or during a car transfer where task demands are more difficult performance proficiency may regress to a lower level until sufficient practice with these additional challenges has occurred.

### Principles of Motor Learning

Motor learning is a process associated with practice or experience that leads to a relatively permanent change in the ability to produce skilled movements (27). However, in the clinic, learning processes are not directly observed since learning is a reflection of internal neural processes such as enhanced synaptic efficacy within motor-related neural networks. Motor performance is the level of skill execution or how a person completes a movement or functional task. Motor performance is the directly observable action. Motor learning is inferred when an individual reliably and accurately performs a motor skill in various settings and across various points of time. We can infer that an individual has truly learned a motor skill when motor performance can be retained or transferred to a novel situation. The motor performance versus motor learning distinction is very important since conditions of practice and feedback, which can positively impact motor performance, can interfere with the cognitive processes that are required to promote motor learning.

Practice and feedback are two of the most important training variables that can affect motor performance and learning. Motor learning research of both healthy controls and individuals with brain damage demonstrates that practice and feedback can be manipulated in such a way that performance gains during training can be very high; yet, measures of learning such as performance during a retention or transfer test can be detrimentally affected. Clinically, we observe motor performance as a patient practices a task during a therapy session. How would a therapist determine if the patient learned the motor task? In the clinical setting, a retention test would be the observed performance on the following therapy session with no feedback or cueing provided. Performance at this moment would reveal the task-related learning that occurred from the previous therapy session. In contrast, a transfer test reveals the generalizability of what was learned in one condition to another similar but different condition. For example, it has been demonstrated in individuals with stroke that practice in a static balance activity did not transfer to the balance requirements needed during walking (30). In contrast, practice of treadmill walking at speeds closer to normal walking speeds

results in very good transfer in that walking speed increases are observed overground (31).

Practice conditions can be manipulated to vary the presentation of tasks (i.e., practice schedule) across a training session or the presentation of feedback within a training session of a particular task. Conditions of practice or feedback that invoke greater cognitive effort appear to be more effective for motor learning. Cognitive effort involves the perceptual and motor as well as decision-making processes that occur during skill acquisition (32). When cognitive effort is high during task practice, performance may be degraded; however, retention performance is better compared to task practice with less cognitive effort. Cognitive effort as a construct that underlies motor learning processes has profound implications for the generalizability of motor learning principles derived from young, healthy adults to motor skill learning in individuals with impaired cognitive processing. What is the interaction between practice or feedback conditions that require greater cognitive effort in individuals who have impaired cognitive ability? It is not yet clear what the impact of cognitive processing deficits post-brain injury will have on mental processes associated with motor learning. The following section will review the limited literature that investigates the manipulation of practice and feedback on motor learning in individuals with brain damage.

*Effects of Practice Conditions* Structuring the practice session includes the determination of the tasks to be practiced and the order of this task practice during the therapy session (33). Part-task vs. whole-task practice is one example of a practice schedule where either a task is practiced in its separate components or is practiced in its entirety. Consistently, it has been demonstrated in young, able-bodied individuals that the effectiveness of whole-vs. part-practice relies upon the nature of the task being learned (34). If a task is serial in nature, a part-task practice schedule can be effective. A serial task is a task that can be broken into discrete tasks that when ordered appropriately result in a meaningful functional outcome. For example, a patient learning to brush his teeth in the morning must learn to unscrew the toothpaste and apply it to the brush, move the brush to clean his teeth, and reach for a glass in order to rinse his mouth. Each discrete component of this functional task sequence can be practiced individually then practiced as a whole. In contrast, continuous tasks such as walking, pushing a wheelchair, or steering a car cannot be parsed into discrete components since successful task performance requires interaction and responsiveness to environmental conditions.

Variable and random-order practice are two practice conditions that have been demonstrated to be more effective for motor learning in young, able-bodied populations. Variable practice reflects the variety of conditions

in which a task is practiced such as walking on a treadmill at different speeds or practicing a transfer to different surfaces. This is in contrast to constant practice where the same task and conditions are repeatedly practiced. Theoretically, variable practice is a more effective method of invoking the cognitive processes to establish a motor program and the flexibility of processing needed to parameterize this program to meet environmental goals (35). Unfortunately, there are very few motor learning studies in populations with brain-damage that have tested these hypotheses. In fact, there is some evidence that variable practice effects in healthy, able-bodied populations may not be as applicable to individuals with profound declarative memory impairments (18) or motor deficits (31).

Random order practice is a practice schedule in which the order of, for example, 3 different tasks are scheduled throughout a therapy session. This is in contrast to a blocked schedule where the 3 tasks would be ordered and practiced in a block such that practice of task 1, is followed by task 2 and so forth. The effectiveness of random-order practice in comparison to blocked practice has been attributed to the *contextual interference effect* (36, 37). Contextual interference is the cognitive interference introduced when several tasks are practiced together. Random practice induces a form of forgetting that requires the learner to reconstruct the motor memory from a previous, but not immediately preceded, practice trial. The evidence for random-order practice in individuals with brain injury is limited and not consistent. Random practice has been demonstrated to be effective in individuals with stroke learning a series of functional grasps (38) but has not been investigated in individuals with more profound declarative memory and cognitive processing deficits. It is not clear how brain injury that affects various higher-level cognitive processes such as memory and attention may influence practice condition effectiveness. Further work is needed to determine if practice conditions that promote deeper levels of information processing will be as effective in individuals with brain injury that have information processing deficits.

**Effects of Feedback** Feedback has a powerful influence on motor performance. A patient learning a motor skill receives intrinsic feedback from visual, auditory, and proprioceptive systems that may or may not be impaired due to brain injury. In addition, a patient receives augmented feedback from the therapist in the form of KR or KP as the therapist provides verbal, visual, or tactile information during a therapeutic procedure or functional training session. Augmented feedback can interfere with the more permanent learning effect that one hopes to achieve with practice. If given too frequently or continuously, feedback can interfere with the problem solving thought process that should occur during practice and instead “guide” the patient to the optimal response (39). Studies

that have examined the effects of feedback in healthy subjects (40), older individuals (41, 42), individuals with stroke (43), and TBI (44) demonstrate that post-response feedback (feedback provided after the skill is performed) given with less frequency can result in motor performance during a retention or transfer test that is more accurate or consistent than feedback provided more frequently or concurrently. In these types of studies, feedback is provided after every trial (100%), with reduced relative feedback (i.e., 50% of trials), or concurrently in which feedback is provided at the same time as the task is performed.

Concurrent feedback consistently degrades learning compared to post-response feedback with less frequency (45). Yet, therapeutic interventions that use biofeedback, computer-generated feedback, or continuous physical guidance by a therapist are examples of concurrent feedback that is typically observed in the clinical environment. One method that appears to be particularly effective in clinical settings to promote motor learning is the use of a faded feedback schedule in which the relative frequency of feedback is decreased within or between practice sessions. With a faded feedback schedule, feedback presentation is high during early learning and then decreased in frequency in the later phases. In this way, feedback is provided in the early stages when the learner needs much information to learn what to do and how to perform the task but feedback is faded as the learner is encouraged to develop the problem solving and self-discovery needed to actually learn a motor skill.

**Summary** The importance of practice, the effective scheduling of practice and the frequency of feedback are important principles of motor learning that can be applied to the treatment of individuals with brain injury. However, evidence guiding clinical application is limited and at times inconsistent. In particular, there is a need for motor learning studies that examine the interaction between the cognitive processes invoked during the motor learning process with the cognitive impairments that result from brain injury. Sherwood and Lee (32) propose that the depth of cognitive processing and the degree of cognitive effort have a profound effect on motor learning processes. This has implications for the application of motor learning principles in the rehabilitation of individuals with brain damage. Individuals with profound cognitive impairments in attention and memory may respond differently to conditions of practice or feedback frequency that require greater depths of information processing or cognitive effort. Further work is needed to understand these relationships; however, therapist can take concepts presented here and apply it to the clinical setting. Blocked practice and frequent feedback, which have lower information processing demands, may be more appropriate for individuals with severe cognitive processing deficits. However, over the course of recovery,

conditions of practice and feedback that require greater cognitive effort would be appropriate.

### Principles of Exercise

Therapeutic exercise is the method most commonly used to address mobility problems after brain injury. Therapeutic exercise incorporates exercise principles into the design of therapeutic interventions in which the goal is to increase functional performance and decrease specific movement-related dysfunction. Traditionally, therapeutic exercise programs have been designed to remediate impairment specific mobility problems. For example, if range of motion is limited due to muscle shortening, exercise techniques can be used that will effectively lengthen the shortened muscle. While impairment-focused interventions may be effective in the rehabilitation of specific impairments (evidence for impairment-focused interventions will be discussed later in the chapter), there is building evidence from meta-analysis that impairment-focused interventions have no effect on functional performance (46).

A recent trend in therapeutic exercise is to incorporate sport physiologic training principles in the design of exercise programs that increase aerobic capacity and strength in individuals with brain damage (47, 48). This is an important consideration since the dosing of exercise can influence treatment outcome. Task-specificity (what is the nature of the task or skill to be learned?) and training intensity (what is the frequency, duration, time, and demand of the activity?) appear to be 2 important factors that affect therapeutic exercise effectiveness after brain injury.

*Task-Specific Training* Since the writings of Bernstein in the early 1900's (49), the importance of movement and task-specific learning has been well recognized in the psychological sciences. It has only been in the past 10–15 years that the emphasis on task-specific training has been incorporated into the rehabilitation setting.<sup>1</sup> The effectiveness of task-specific training derives from the specificity of learning hypothesis proposed by Henry in the 1950's who suggested that the most effective conditions for motor learning occur when performance during practice is well-matched to the performance requirements needed during retention or transfer conditions (50). Motor learning reflects a neural specificity of practice since motor skill acquisition involves the integration of

the sensory and motor information that occurs during practice, and ultimately, leads to the sensorimotor solution that results in accurate, consistent, and skillful movements (27).

The importance of repetitive, task-oriented practice in the recovery of upper limb function (51–53) and walking (31, 54–57) has been consistently demonstrated in clinical trials of stroke-related brain damage and is beginning to emerge in TBI populations as well (58–61). In these studies, interventions are designed that involve specific task practice that incorporates the upper limb in various functional activities or in repetitive activity such as walking on a treadmill.

A recent and comprehensive systematic review compiled by Van Peppen et al. (46) of physical therapy interventions post-stroke demonstrated strong evidence for greater patient benefit due to functional task practice than impairment-focused interventions. Functional improvement was associated with interventions such as aerobic training, constraint-induced movement therapy, transfer training, and treadmill training with or without body weight support. In contrast, exercise programs that focused on muscle strengthening, muscular re-education with biofeedback or neuromuscular stimulation showed improved impairment level outcomes such as strength and range of motion but failed to result in significant functional outcomes. In addition, Van Peppen et al. (46) demonstrated no evidence for improved functional outcomes to support the use of neurophysiologic treatment approaches such as neurodevelopmental treatment (NDT), proprioceptive neuromuscular facilitation (PNF) or Brunnstrom (62–64).

Our understanding of the mechanisms that subserve functional recovery and responsiveness to task-specific training is elucidated by eloquent animal work that demonstrate that repetitive task practice that involves the acquisition of a motor skill results in neuroplasticity in both synaptic and neuronal morphology and in cortical reorganization (6, 65, 66) These findings of experience-dependent neuroplasticity are corroborated in humans with brain damage through recent neuroimaging studies that use transcranial magnetic stimulation (TMS) and functional magnetic resonance imaging (fMRI) to demonstrate the potential for cortical reorganization as a result of task-specific therapeutic interventions for both upper limb and lower limb recovery (67–70).

*Training Intensity* Time spent in exercise training and increasing the difficulty or physiologic demands of the exercise session are examples of methods to increase training intensity. Exercise dosing can have differential effects that vary as a function of the time in the activity (min/day), frequency of sessions (times/wk) and the duration of training (weeks of training). Kwakkel et al. (71) demonstrated that specific skills training post-stroke for

<sup>1</sup>Note that task-specific training is distinguished from ADL training. Task-specific training implies that the training event is designed to improve motor skill acquisition in a specific task. ADL training implies that the training event is designed to decrease the level of physical assistance to complete a functional task; therefore, ADL training may allow the use of compensatory strategies or assistive devices in order to enhance task completion.

30 min/day, 5 days/wk for 20 wks in addition to a standard rehabilitation program was most effective if the specialized training was specifically focused on active arm or leg focused training. Winstein et al. (53) have also demonstrated the preferential effect of additional therapy time in functional task training. The added significance of this study is that functional training in the early rehabilitation period post-stroke resulted in significant differences in both strength and function at 9 months post-injury compared to strength training or usual care groups. This study illustrates the impact that early functional training in the period immediately post-injury may have on future limb use and function later in the recovery process.

A recent systematic review specifically investigated the effects of exercise intensity as measured by time in therapy on ADL, walking, and dexterity in patients with stroke (72). The results of this meta-analysis suggests that more intensive therapy that includes approximately 16 hrs of additional task-specific training in the first 6 months post-brain injury particularly dedicated to lower limb and ADL activities is more effective than standard therapy programs. Limitations of this meta-analysis include the inability to determine the precise treatment contrast that separates the longer time in therapy from the control comparison. At this time there is insufficient literature in TBI populations to conduct a meta-analysis; however, there is some evidence that the findings from stroke may be somewhat generalizable to individuals with TBI. Eng et al. (73) in a prospective study in the inpatient rehabilitation setting compared mobility outcomes between patients with stroke and TBI. Overall, patients with TBI had higher mobility status at admission and discharge; however, the improvement in mobility status per day was not different between the diagnostic groups. Cifu et al. (74) specifically examined the effect of therapy intensity (time in therapy/ length of stay) and found that therapy intensity predicted the amount of motor function improvement a discharge. While the level of evidence may not be as high as the evidence from stroke, there is clearly a trend that shows similar responsiveness in patients with TBI. Collectively, this literature reflects the need for studies that investigate the optimal dosing of exercise programs designed to improve mobility especially in populations with brain beyond stroke.

Incremental increases in task difficulty and increasing the physiologic demand of the exercise are additional methods to manipulate training intensity. Adaptive task practice is a method whereby the therapist adjusts the difficulty of the task as they observe performance and provide feedback during practice. Task difficulty is adjusted such that the patient experiences progressive challenge across training. Adaptive task practice is one of the practice strategies used in CI therapy as the optimal movements develop or a “shaped” during therapy. Strong evidence exists for CI therapy as a treatment to increase dexterity

of the hemiparetic arm and appears to be related to the high intensity dosing of task-specific upper limb training (46). Case study series in individuals with TBI using a modified CI therapy approach are beginning to demonstrate a similar responsiveness to this type of training (60).

Increasing physiologic demand is another effective strategy to increase training intensity. In studies of treadmill training with and without body weight support, it has been demonstrated that treadmill training at higher speeds is more effective than training at constant or variable speeds that are within the range of the patient’s typical overground walking speed (75, 76). In addition, fast walking results in improvements in body and limb kinematics and muscle activation patterns in individuals that have impaired walking due to hemiparesis (77). Training within a task at maximum capability is one of the tenets of training specificity and appears to be applicable to individuals with brain injury relearning a functional task. The equivocal evidence found in the recent Cochrane review of treadmill training with or without body weight support may be due to the high degree of variability between studies in the frequency, duration, and timing of the intervention as well as the level of physiologic intensity used across studies (78).

*Summary* Task-specificity and intensity are important principles of exercise that can be applied to the treatment of individuals with brain injury. There is strong evidence that intensive, functional task training is effective in individuals with stroke-related brain damage; however, there is limited (yet developing) evidence in populations with TBI. Most likely, principles of exercise incorporated into therapeutic interventions will extend to other populations with brain damage such as those with TBI. It is unknown if cognitive and behavioral problems, common post-TBI, will interfere with the compliance needed to achieve the desired training effect.

## THE LINK BETWEEN ACQUISITION OF SKILLS AND AVAILABLE RESOURCES

At this point, we return to the rehabilitation model proposed by Quinn and Gordon (79) (Figure 50-1). This chapter has focused on the acquisition of skill including the evidence that neuroplasticity and neurorecovery are promoted through the skill acquisition process, conditions of practice and feedback frequency affect the retention and generalizability of motor skill learning, and training intensity and specificity appear to be important parameters that drive functional training effectiveness. Skills are required in order for our patients with brain damage to participate in desired roles related to self-care, social and recreational pursuits, and occupation. However, post-TBI there is a myriad of physical, behavioral, and cognitive

limitations that contribute to the functional deficits. Typically, rehabilitation specialists classify these limitations as impairments that have to be remediated. The perspective developed by Quinn and Gordon suggests that the goal of therapy is to determine what resources the patient needs to successfully accomplish the functional task. In essence, the diagnostic challenge for the therapist is to identify the impairments that prevent functional task performance and develop an intervention program that develops the necessary resources to successfully complete the task. This section of the chapter will address the therapeutic interventions and strategies used to develop patient resources and address impairment level problems.

**Behavioral Treatment Strategies**

In the days, weeks, and months after TBI, patients present with a variety of potential behavioral disorders that may impact their ability to participate in therapy. This can be compounded by organic deficits in cognition (e.g., confusion and disorientation, decreased short term memory, decreased problem-solving and reasoning ability, delayed processing, motor and verbal disinhibition, lack of initiation and concrete reasoning), perception (e.g., visual, auditory or tactile hyper- or hypo-sensitivity, neglect, visual-field deficits, right-left discrimination problems), and communication (e.g., expressive or comprehension aphasia, decreased understanding, delayed responsiveness) as well

as their personal reactions to injury and disability such as loss of control, frustration and anger, lack of insight, and depression. The challenge for the therapist working on mobility issues is to adjust performance expectations and to adapt the therapeutic learning environment. The Table 50-1 summarizes common therapeutic strategies that can be applied as the patient progresses through the various behavioral and cognitive phases associated with TBI recovery.

The overall therapeutic goal is to progress the patient through the various stages of cognitive function recovery through systematic and graded stimulation and activity (29). The following descriptions provide an overall behavioral strategy that would be appropriate as specific mobility training or preventive maintenance of musculoskeletal deformity is being applied. It is important to note that the stages of motor learning discussed earlier have applicability within each of these stages particularly at the mid- and high-level management phases. Motor performance proficiency increases as the learner moves from the cognitive, associative, and autonomous phases of skill acquisition. Similar strategies such as monitoring environmental distraction and task complexity apply as well when an individual with brain injury is progressing through the levels of cognitive function (80, 81).

It is important to note the level of evidence for most recommendations on cognitive management used for physical rehabilitation are primarily at the level of clinical expertise. A recent Cochrane review of sensory stimulation for individuals with TBI in a coma or vegetative state revealed that most of the literature in this particular area of cognitive-physical rehabilitation is primarily at the level of case study or case series (82). Three studies met inclusion criteria for an RCT; however, there were serious methodological limitations that led the authors to conclude that there was no reliable evidence to rule in or out the use of sensory stimulation in patients in coma. Given the need for additional RCT's that address the issue of cognitive and physical management post-TBI, the following summarize what is regarded as best available practice in this area using the Rancho Los Amigos Levels of Cognitive Function (LOCF) Scale to delineate low-, mid-, and high-level cognitive groups (80).

*Low-Level Cognitive Management* Patients who are considered within the LOCF levels of I, II, and III have low-levels of responsiveness that range from unresponsive to any stimulation (LOCF I), generalized response that is limited and non-purposeful (LOCF II), to localized responsiveness in which the patient may follow simple commands (LOCF III). This decrease level of responsiveness is often accompanied by severe postural tone and paralysis that can lead to secondary musculoskeletal impairments. Specific strategies to address these secondary impairments will be discussed later. In addition, to preventing complications due to immobility and impaired

**TABLE 50-1**  
*Behavioral Treatment Strategies*

LOCF	RECOVERY PHASE	APPROACH
I, II, III	Minimal response	Sensory stimulation Preventative maintenance Monitoring response to early mobilization
IV	Confused, agitated	Structured environment Directed activity Monitor response to stimulation Brief, frequent activity changes
V, VI	Confused	Structured environment Directed activity Consistent approach Complexity to tasks varied gradually Environmental distractions varied gradually
VII, VIII	Automatic	Reduce structure Greater self-monitoring Progressively challenging tasks

LOCF – Levels of Cognitive Function from Rancho Los Amigos Rehabilitation Hospital (Hagen, 1079).

motor control therapists, in collaboration with other team members, usually begin some form of sensory stimulation program to encourage arousal and responsiveness. Once the patient is medically stable, upright mobility activities are initiated progressing from bed mobility to upright postures in a wheelchair or tilt table. Observationally, changes in posture and upright positions appear to be effective in evoking increased levels of responsiveness in patients in these lower levels.

**Mid-Level Cognitive Management** The transition from unresponsiveness to LOCF IV is often accompanied by confusion and agitation. A patient at this level is easily confused and disoriented and may present with aggressive and inappropriate behavior. His responses during this phase appear to be due to internal confusion. During this phase, the patient cannot readily engage in self-care activity and episodes of incontinence are frequent due to lack of internal and external awareness. The therapeutic strategy at this phase is to provide a structured and safe environment with minimal distraction that can allow the patient to move about. Within this structured environment, brief, directed activity can be introduced. Frequent, short treatments that are interspersed across the day would be the ideal therapy schedule for a patient in this phase.

Patients' post-TBI at LOCF V and VI are non-agitated but continue to present with confusion and profound declarative memory deficits. At LOCF V, the patient responds to commands and is more alert but is easily distractible with difficulty concentrating on tasks. Agitated outbursts and inappropriate verbal responses still occur when the patient is frustrated. At LOCF VI, that patient has more consistent goal-directed behavior but needs cuing. Greater participation in ADLs is evident as the individual is developing greater awareness of self and others. This level is associated with the period of post-traumatic amnesia in which the ability to develop new declarative memories is seriously impaired. The Rancho Cognitive levels state that during these phases individuals cannot learn new information. However, the distinction between the explicit (declarative) and implicit (non-declarative) memory systems would suggest that patients during post-traumatic amnesia do have the capability to learn new motor skills, and in fact, has been demonstrated in individuals' post-TBI during post-traumatic amnesia (23, 24).

The most effective therapeutic strategies during this phase would include task-specific training in structured environments. Treatment approach at this level would encourage successful performance through adaptive task practice in which task practice is challenging, yet, successful. The expectation is that repetitive task practice during this phase of recovery would lead to a gradual improvement in motor performance as the patient acquires motor skills that may be independent of any

verbal recollection of the task training. For patients with confusion, a consistent approach to the daily schedule, treatment setting, activities, instruction, and team members is most effective. Task complexity and changes in the structure of practice (i.e., increased variability) and feedback (i.e., decreased frequency) can be progressed as the patient's cognitive status improves.

**High-Level Cognitive Management** The progression from the previous levels to LOCF VII and VIII is marked by improvements in short term memory with more appropriate and purposeful behavior. During this phase, there is less confusion, better recall, and increased self-awareness and interaction with others and the environment. However, limitation in insight, abstract reasoning and problem solving can still exist, particularly for those in LOCF VII. At this level, it is realistic to expect completion of ADLs with relative independence. Therapy focuses on the tasks and skills needed to facilitate community integration. This phase is primarily focused on skill acquisition in the tasks that will assist the individual to participate in their desired self-care, social, occupational, and recreational goals.

### **Physical Impairment-Focused Interventions**

Mobility impairments after brain injury are either directly related to the damage of neural structures such as impairments in voluntary movement, abnormal tone, and balance or are secondary impairments that result from these neural system impairments. Secondary mobility impairments result in limitation of the musculoskeletal system such as muscle contractures, joint mobility restrictions, and disuse weakness. Both neural and musculoskeletal impairments can be major contributors to functional deficits after brain injury. The following section provides a brief overview of current therapeutic strategies to address these problems.

### **Neural System Impairments**

**Voluntary and Purposeful Movement** Impairments in voluntary movement associated with TBI can be due to an upper motor neuron weakness syndrome that includes inability to do selective joint movements out of synergy, decreased force production, and impaired initiation of purposeful voluntary movement. The primary mechanisms for these movement deficits post-TBI can be attributed to diffuse axonal injury due to scattered white matter infarctions in the descending motor pathways, focal cortical contusions or deep cerebral hemorrhage that results in direct damage to the corticospinal tract as it passes through the striatocapsular region, and transtentorial herniation where compression of motor pathways in the upper brain stem can occur (83). Diffuse axonal injury

and/or major brainstem contusion can result in low levels of consciousness in which reflexive movement patterns within decorticate and decerebrate postures can result from motor output of subcortical motor brainstem systems that include the rubrospinal, reticulospinal, and vestibulospinal systems (84).

In contrast to stroke where 70% of all stroke survivors will present with a motor hemiparesis (85), only 17% of patients post-TBI will have arm/hand paresis with synergistic movement and of these individuals motor recovery is good such that only 3% will have synergistic hemiparesis at 4 months post-injury (83). The predominant motor deficit in patients post-TBI is impaired force production leading to decreased power generation and strength and impaired integration of voluntary movement with the other cortical, subcortical, and cerebellar motor systems involved in the planning, initiation, completion and retention of accurate and consistent goal-directed movement. Weakness and impaired power generation can be a major factor along with sensory integration and cognitive deficits that interfere with performance of mobility tasks. The differential diagnosis and treatment of movement dysfunction after brain injury requires the therapist to determine what are primary contributors to impaired task completion (i.e., force generation, synergistic movement), how can these primary contributors be addressed (i.e., strength training, muscle re-education), and how can the learning environment be structured to result in the acquisition of skill when considering both the cognitive and motor deficits of the patient (i.e., task-specific training).

There are numerous therapeutic strategies employed by therapist to address issues of neural motor control that can vary in emphasis across the recovery continuum from the acute care phase (86) where lower level management strategies are needed to later in the recovery process where the focus is to incorporate motor control strategies with task training (81, 87–89). Current approaches to muscle re-education and therapeutic exercise use an interactive systems model that emphasizes that task accomplishment emerges from a complex interaction of biomechanical, motor, and sensory effects that are modified by environmental constraints (90). Typically, therapists interact with the patient as they manipulate the mechanical demand of the task within the sensorimotor conditions that optimize task performance.

Traditionally, neurophysiologic therapeutic approaches such as neurodevelopmental treatment (NDT) (91), proprioceptive neuromuscular stimulation (PNF) (92), and the Brunnstrom approach (93) were commonly used to facilitate motor and postural control. These approaches were derived from the neurophysiologic understanding of the time such as the hierarchical organization of the nervous system, that proprioceptive afferent sensory stimulation can be used to modify abnormal tone and

facilitate a patient's movement pattern, and that recovery from brain damage occurs in a predictable sequence that corresponds to development (94). With current advances in neuroscience (5) and greater understanding of motor control (95) as well as the trend for evidence-based practice, there is building consensus that the traditional neurophysiologic treatment approaches are not effective compared with usual care that emphasizes functional training (46). It would be remiss to treat patients with a traditional neurophysiologic treatment approach alone since it appears that these approaches emphasize impairment-focused intervention and have not been shown to be effective in improving functional gains. However, important therapeutic principles have emerged from these traditional neurophysiologic approaches that continue to influence practice today. The importance of proximal control and midline alignment, the use of resistance and developmental postures as ways to increase demand needed for functional tasks, and the quantification of recovery as patients develop more isolated joint movement and control all derive from these approaches. Current best practice would incorporate these important therapeutic principles with our understanding of motor learning and exercise physiology to promote skill acquisition in our patients with brain injury.

*Abnormal Muscle Tone* Clinically, therapists are confronted with two major problems related to the impaired regulation of muscle tone. Abnormal muscle tone includes problems with velocity-dependent increases in phasic stretch reflexes associated with the upper motor neuron syndrome (i.e. spasticity) (96) and abnormal postural control interfering with the ability to maintain upright head, neck, and trunk postures against gravity (86). Pierson (97) describes a wide range of clinical assessment tools that can be used to assess treatment effectiveness and functional outcomes as it relates to abnormal tone particularly spasticity. These tools include goniometry to assess range of motion limitations that can result from muscle imbalance, the modified Ashworth Scale that is an ordinal scale to quantify tone intensity, and functional tests such as the Jebsen Taylor Hand Function test, gait speed, and the Berg Balance scale to determine the effects of abnormal tone on function. These outcome measures are commonly used; however, a recent review of the reliability and validity of spasticity assessments suggest that further work is needed to develop more objective measures as well as measures that capture the real-world impact of spasticity on function (98).

The approach to abnormal tone management is twofold. One is to address the primary issues related to spasticity and postural control by providing therapeutic interventions that attempt to decrease tone or increase upright control in functional postures such as sitting and standing. The second approach is to address the secondary

musculoskeletal impairments that can occur when severe and unrelenting increases in abnormal muscle tone result in muscle contracture and joint deformity. Specific approaches to address these secondary tone-related impairments will be discussed in the next section.

Therapeutic interventions that use weight bearing through the extremities and trunk are often used in various functional positions to decrease tone as the patient develops appropriate motor control to maintain upright postures and to complete functional tasks (86, 88). The goal of the therapy is to facilitate more effective motor unit recruitment, and due to the task-oriented nature of the training, appears to be more effective than interventions that focus on the reduction of spasticity alone. For example, in a recent double-blind, placebo-controlled multi-site RCT, botulinum toxin intramuscular injections reduced muscle tone in patients with upper limb spasticity after stroke but there was no change in disability or quality of life (99). In a similarly controlled RCT, botulinum toxin injections to the gastrocs were effective at reducing muscle tone and limb pain but were no more effective than placebo in improving gait function (100). In both studies, no specific splinting or physical therapies were incorporated into the treatment. One explanation for the lack of functional improvement is that treatment only focused at the impairment level (i.e., the reduction of muscle tone) and did not potentiate the benefit of tone reduction with the process of skill acquisition. More effective approaches to tone management may include the integration of pharmacologic interventions with the task-specific training required to make significant functional improvements.

*Balance and Vestibular Disorders* Balance and vestibular disorders after TBI can be due to damage of the peripheral vestibular sensory apparatus or central structures that respond to the vestibular sensory inputs such as the vestibular nuclear complex, central pathways of the vestibulo-ocular and vestibulospinal reflexes, the brainstem, and cerebellum (101). Peripheral vestibular dysfunction after TBI can be reduced (hypofunction) which results in vertigo, dysequilibrium, and impaired gaze stability if the damage is unilateral. If bilateral, patients may have less severe complaints of vertigo but present with severe dysequilibrium and gait ataxia. Trauma to the head can also result in benign paroxysmal positional vertigo (BPPV) caused when otoconia either are displaced into the semicircular canals or is floating in the endolymph. BPPV results in distorted vestibular function that is gravity-sensitive; therefore, episodes of severe vertigo and positional nystagmus occur with head position changes. Central vestibular disorders can commonly occur as a result of diffuse damage to white matter tracts that interact with vestibular areas of the brainstem and the cerebellum. Severe episodes of vertigo and dizziness are not

as common with central vestibular disorders. Patients will usually have a wide range of symptoms, which include constant feelings of vertigo that are also accompanied by nausea, nystagmus, ataxia, or dysequilibrium. Whether from central or peripheral causes, balance deficits and dizziness have been identified as major factors affecting functional prognosis and return to work after TBI (102, 103).

Patients post-TBI commonly present with gait instability and are at high risk for falls. Balance deficits can be a result of the combined effects of visual, somatosensory, and vestibular impairments as well as motor control deficits that result in weakness and incoordination. The Dynamic Gait Index (DGI) is a clinical tool that can be used to assess fall risk in individuals with balance disorders (90). Whitney et al. (104) demonstrated that gait instability as measured by the DGI was related to falls history. Individuals with vestibular disorders that were either from peripheral (e.g., BPPV, labyrinthine concussion, labyrinthitis), central (e.g., stroke, head trauma, cerebellar dysfunction) or combined peripheral and central vestibular dysfunction were 2.58 times more likely to fall if they scored  $\leq 19/24$  on the DGI.

Vestibular rehabilitation post-TBI can include vestibular adaptation exercises such as gaze stabilization exercises, balance retraining, sensory organization exercises with progressively more difficult static and dynamic activity, and canalith repositioning maneuvers (101). There is good evidence that vestibular rehabilitation that incorporates various balance retraining strategies that are designed to address specific patient problems can be effective (105, 106). The two exercise approaches used for the treatment of vestibular hypofunction include vestibular adaptation exercises to improve gaze stability and balance exercises that foster the use of visual and somatosensory information to improve postural stability (see Herdman (105) for detailed description of vestibular, balance, and gait exercises used for balance rehabilitation). Canalith repositioning maneuvers are specific techniques used to treat patients with BPPV (107). It is beyond the scope of this chapter to discuss the appropriate application of all these various balance interventions since they are designed to address specific vestibular deficits based upon the patient's history, age, and diagnosis. Excellent sources are available to provide greater background in this rehabilitation specialty area (105, 108).

### **Musculoskeletal Impairments**

*Muscle Contracture and Joint Mobility* Impaired voluntary motor control and spasticity are the primary cause of muscle contracture and joint deformity after TBI. Hypertonia in combination with immobility due to paralysis and altered mechanical properties of muscle and connective tissues due to disuse can result in severe deformity of the upper and lower extremities. In addition, heterotopic

ossification can further complicate joint mobility management. Common patterns of deformity that result from spastic motor patterns includes shoulder adductor/ internal rotation, elbow flexion, forearm pronation, wrist and finger flexion contractures of the upper limb and equinovarus foot with clawed toes, valgus foot, stiff or flexed knee, and hip adductor and flexor contractures of the lower limb (109). Spastic deformities interfere with bed positioning, sitting and standing, transfers and walking as well as self-care activities such as hygiene and dressing. In addition to interfering with function, spastic deformities can be a major source of pain (97). The cumulative effect of these secondary musculoskeletal impairments can seriously impact quality of life or the potential for recovery especially for individuals who have been in coma for extended periods of time.

The primary therapeutic goal is to prevent or correct muscle contractures. Various preventative methods are employed in the acute care setting immediately post-injury such as performing passive range of motion and stretching or using preventive bed position including the use of wedges, splints, and pillows to improve limb alignment (86, 110). Various therapeutic interventions are effective to increase passive range of motion or to prevent its loss and include stretching (111, 112), serial casting (113, 114), dynamic splinting (110, 115), orthotic management (116), and, in combination with these types of physical approaches, pharmacologic management such as motor point blocks (116), and intrathecal baclofen (117). In severe cases, when more conservative management has not been effective, surgical management for tendon lengthening or releases may be indicated (110).

*Weakness and Deconditioning* One area that is beginning to receive more study is the effect of immobility on work capacity in individuals with brain injury. Peak exercise capacity and cardiorespiratory fitness of individuals with moderate to severe brain injury is reported to be 60–70% of the capacity of normal healthy adults of similar age (118). It is common in the acute phase that patients with TBI are confined to bedrest for days, weeks, or months depending upon the initial brain injury severity. The adverse effects of prolonged bedrest are well documented in humans but little attention has been given to the additive effects of immobility to chronic disease or injury (119). Immobility due to bedrest as well as a reduction in physical activity results in decreased muscular strength and aerobic capacity that leads to reduced work capacity. Additionally, prolonged immobility can result in osteopenia, which can interfere with fracture healing for patients who may also present with multiple fractures in addition to the brain injury (120).

Thirty days of bedrest can result in 18–20% reduction in knee extensor peak torque; however, strength can recover within 92% of pre-bedrest levels within 30 days

after bedrest (120). Findings such as these highlight the importance of active muscle contraction during bedrest and the introduction of early intermittent ambulation and physical activity to attenuate the effects of immobility in patients with TBI. Responsiveness and tolerance of individuals with moderate to severe TBI to aerobic or circuit training has been demonstrated in both the acute and sub-acute phases post-TBI (47, 48). Peak work rate improved in patients with TBI recruited within  $24 \pm 14$  wks of injury that completed resisted cycling for a goal of 30 min (actual cycling time achieved  $23 \pm 5$  min) at 60–80% age-predicted maximum heart rate for 24 sessions over 8 wks (47). Forty-five minutes of circuit training (combination of aerobic exercise, muscular strength, and endurance training) at 60% age-predicted maximum heart rate for 3 sessions per week for 12 wks increased peak power output and  $\text{VO}_2$  peak in 14 individuals approximately 17 wks post-injury (48). Clearly, exercise and early mobility training are indicated to lessen the impact of secondary causes of weakness and decreased endurance. With proper supervision and monitoring of cardiovascular responses to exercise, individuals with TBI can engage in intensive strength and conditioning training.

## INNOVATIONS IN PHYSICAL REHABILITATION

Constraint induced (CI) movement therapy and the use of treadmill training with body weight support (BWS) are examples of innovations in rehabilitation that are derived from basic science work in neuroplasticity and neurorecovery and incorporate principles of motor learning and exercise into the therapeutic intervention. The therapeutic goal of each of these interventions is to increase skill in functional tasks.

The scientific rationale for CI therapy is derived from studies in non-human primates in which 2 important findings impact the clinical application of this paradigm. First, Taub (121) observed that deafferented monkeys who wore a restraining jacket that constrained the non-affected limb had greater use of the limb than monkeys that were not constrained. However, Nudo (122) demonstrated that greatest amount of motor cortical reorganization and functional recovery occurred in primates who wore the restraining jacket *and* engaged in repetitive skills training. As a result, CI therapy has developed as a therapeutic intervention where use of a constraint device and intensive task practice is used to promote upper limb recovery in individuals who have hemiparesis due to stroke (Fig. 50-3).

The effectiveness of this approach in individuals post-stroke who meet a minimum motor criteria was first described by Wolf (123) and Taub (124) and is currently being investigated in a multi-site, RCT funded by the NIH

(125). The paradigm under investigation includes individuals post-stroke in either the subacute period (4–9 months post-stroke) or chronic period (>1 yr post-stroke) who at a minimum must be able to actively extend the wrist, thumb, and at least 2 other digits 10°. The intervention occurs 5 days/wk for two weeks for 6 hr/day in training with therapist supervision that combines the use of a constraint device (mitt on unaffected hand) with task practice and adapted task practice (shaping). The patient signs a behavioral contract and agrees to wear the mitt 90% of waking hours and to maintain a daily diary of activities. The results of the trial have not been published; however, smaller experimental trials have demonstrated the effectiveness of this intervention and the specific effectiveness of this practice schedule (126–128). Several recent studies have found that a modified CI therapy (Figure 50-3) can be effective after stroke (129, 130) and TBI (60). These researchers found that a modified practice schedule of CI therapy for 3 times/wk for 10 wks for 30 min/day of supervised therapist training in combination with the restraint use 5 dy/wk for 5 hrs/day during patient-identified times

**FIGURE 50-3**

Constraint induced (CI) movement therapy is a therapeutic intervention where use of a constraint device and intensive task practice is used to promote upper limb recovery in individuals with hemiparesis

of high frequency upper limb use results in improved motor function and self-perceived use of the limb. One of the advantages of a modified practice schedule is that it is more compatible with the delivery of services reimbursed for rehabilitation at this time.

Step training on a treadmill with body weight-support (BWS) is a neurotherapeutic intervention used to promote locomotor recovery in individuals with spinal cord or brain injury that is derived from basic science animal research. Adult cats with low thoracic spinal transection recovered the ability to step on a treadmill after training with trunk support and assistance with paw placement (131–133). These findings precipitated a movement in rehabilitation to use body weight support systems in locomotor rehabilitation of humans with spinal cord injury (134–136) and stroke (31, 56) (Figure 50-4). The effectiveness of this type of training is attributed to the intense and

**FIGURE 50-4**

Step training on a treadmill with body weight support is an example of intense, task-specific training that incorporates the repetitive practice of walking

task-specific nature of walking on a treadmill in which the appropriate afferent inputs associated with walking provide the input needed to induce experience-dependent changes in neuroplasticity at spinal and supraspinal levels (137–139).

Despite several investigations of treadmill training with or without BWS in individuals with stroke-related brain injury, a recent Cochrane review found weak evidence supporting the effectiveness of this approach (78). However, what this Cochrane report did reveal is that there is tremendous variability in the time post-injury that the intervention occurred and the frequency, duration, and intensity of the protocols being studied. In fact, subsequent studies that specifically addressed training parameters have demonstrated that training intensity as determined by treadmill speed is an important parameter of training effectiveness (31, 76), yet, none of the studies in the Cochrane review used speeds or other training parameters known to affect exercise effectiveness.

At this time, preliminary work in individuals with stroke-related brain damage does suggest that functional changes in overground walking velocity can occur with a training program that includes a minimum of 12 sessions for at least 3x/wk for 4 wks that results in at least 20 minutes of treadmill walking time at speeds within 1.5 – 2.0 mph (31). Clearly, more systematic work is needed to determine the most effective training parameters for this intervention. There is one study that has demonstrated both the effectiveness and challenge of applying this intervention in individuals with severe brain injury (61). The authors have developed the Missouri Assisted Gait (MAG) Scale to identify the small but significant changes in motor ability during gait recovery of patients with TBI.

What is it about these two rehabilitation innovations that make them distinctly different from usual therapeutic approaches? What is the active ingredient that appears to result in functional changes that appear to be more substantial than in other treatment paradigms? Both interventions incorporate the principles of motor learning and exercise that have been described in this chapter. First, the interventions focus on task practice with appropriate feedback monitored and graded by the therapist. In both CI therapy and treadmill training with BWS, the patient actively engages in task practice for periods of time that are substantially greater than what is typically provided in therapy. Second, the therapies focus on intense, task-specific training. It is more than just the time in task therapy that appears to be effective. The training must be a challenge or engage the patient in higher levels of performance than is normally experienced. Third, task-specificity is incorporated into training protocols that have defined training parameters for frequency, intensity, and duration. In order to achieve a training effect, the patient must engage in enough exercise or task practice,

which is systematically progressed in order to induce a physiologic or neural response. Finally, these interventions address the impairments and deficit in functional skills that are unique to the needs and capabilities of the individual patient.

The Theoretical Model for Neurologic Therapeutic Intervention presented in Figure 50-2 proposes that the theoretical foundation for physical rehabilitation after brain injury is based on the premise that 1) skill acquisition promotes neuroplasticity, 2) motor learning and exercise principles are used to enhance the acquisition and retention of motor skills, 3) skills to be learned are identified through functional task analysis and patient perspective (i.e., the individual's self-perceived goals and expectations), and 4) the differential diagnosis process for therapists involves the identification of the primary and secondary impairments that interfere with functional performance.

### Implication for Future Directions

This is a very exciting time for physical rehabilitation specialist since it is evident that physical activity, particularly the acquisition of motor skills, provides the stimulus that the nervous system needs to recover. The challenge for researchers in this area is to conduct the clinical trials that will define the tasks and training parameters that result in effective therapeutic interventions. In addition, these trials must be expanded to include other populations with brain damage in order to provide greater generalizability for clinicians. The challenge for clinicians is to incorporate an evidence-based treatment approach, which integrates their individual clinical expertise with advances in neuroscience and incorporates the perspective from patients and family members. The ability to learn the necessary skills our patients need to return to meaningful and productive roles are the changes that will truly improve the quality of life for our patients with brain injury.

## Therapy for Activities of Daily Living: Theoretical and Practical Perspectives

*Robin McNeny*

### **THERORETICAL PERSPECTIVES: FOCUS ON ADL ASSESSMENT AND INTERVENTION**

#### **Activities of Daily Living as Human Occupations**

The term “activities of daily living” was first introduced by a physical therapist in 1949 as part of a published checklist she designed to assess her patient’s performance of daily living tasks (1). Humans engage in activities of daily living in order to maintain themselves, create an outlet for self-expression, fulfill roles, and to bring meaning into their lives. Occupational therapists regard these activities as “human occupations”. As Fisher says *occupation* is the “action of seizing, taking possession of, or occupying space or time” (2). Therefore occupation is about doing and therapy directed toward resumption of occupational tasks is significant as it enables “people to perform the actions they need and want to perform so that they can engage in and ‘do’ the familiar, ordinary, goal-directed activities of every day in a manner that brings meaning and personal satisfaction” (3).

Engagement in occupation is vital to the human spirit and to health (4). Through engagement in occupation, we become competent. Engagement in occupation begins at birth and continues throughout the life span. Occupations are ordered around routines and patterns for living. Humans learn about and make adaptive responses to their world through the pursuit of occupation. Humans bring

rhythm to life as they engage in ordinary tasks through the course of days and weeks. This rhythm set within the appropriate context brings healthy balance to life. Healthy rhythm and balance includes involvement in what Adolph Meyer refers to as the “big four”: work, play, rest and sleep (5). These four areas of occupation form the core of human activity.

Assessment of and intervention for impairments in occupational performance are based on a view that clients are occupational beings. Because each person possesses an “occupational identity”, each person has a life centered on personal values, interests and roles. While values, interests and roles are abstract, occupational identity is concretely expressed through doing (6). Participation in everyday occupations develops skills, promotes competence, establishes connections with others, expands one’s sense of belonging and community while giving meaning and purpose to life (7).

Capturing the depth and meaning of ordinary daily tasks within the culture and context of an individual’s life is a central concept of occupation as a scientific guide to practice. Insight into the client’s culture and context for living are fundamental to an understanding of the client’s occupations. Because American clinicians are often entrenched in westernized middle-class culture, we have a tendency to view clients through that cultural bias (8). Modern rehabilitationists are challenged to analyze more

deeply the “whys” and “hows” behind the readily observed actions of our clients as they perform activities of daily living. Such an analysis helps the clinician understand the meaning the individual client assigns to the tasks the client chooses to do.

### Areas of Occupation

Clinicians practicing in acute rehabilitation settings usually focus on two areas of occupation: self care skills, often called personal activities of daily living (PADLs) and independent living skills, referred to as instrumental ADLs (IADLs). Occupations focused on work and play, while important, are usually addressed later in the continuum of care. PADLs include tasks commonly performed as part of a daily routine: feeding, dressing, grooming, toileting, bathing and transfers. More individual characterization and variation are found in IADLs. However, we do a disservice to our clients when we narrow the focus of the therapy program to a mere set of ADLs. Such a restricted focus minimizes the complexity and richness of occupational performance.

Brain injury interrupts life. Abruptly an individual loses his or her place in the world. Roles are disrupted. Rhythm and balance are lost. The capacity to engage in meaningful tasks is restricted. Occupational identity is shaken if not totally lost. The capacity to “do” is flawed or perhaps totally absent. Where once there was routine, now there is chaos. Where once there was satisfaction and meaning, now there is confusion. Suddenly participation in life becomes toil. In occupational therapy, the client engages in the process of “relocation of self” where skills required to resume essential life roles are taught (4).

To set the proper stage for this relocation process, the occupational therapist conducts a client-centered assessment of occupational performance. Law (7) states that each person “has unique interests and occupations through which they find satisfaction”. A client-centered assessment defines the client’s occupations while simultaneously determining how the brain injury has affected participation in valued activities. A well-conducted client-centered assessment provides the foundation for a client-centered treatment plan designed to promote occupational performance and in turn, health.

## ASSESSING OCCUPATIONAL PERFORMANCE

### Focusing the Assessment

Fisher (9) defines assessment as “a process of collecting, organizing and interpreting the relevant information that is necessary to plan and implement a meaningful, effective program of treatment”. Trombly recommends a

“top-down” evaluative approach (10) where the first stage of assessment is exploration of the client’s occupational performance issues.

Clinicians have access to a plethora of ADL assessment tools that “score” an individual’s performance on PADLs and in some cases, IADLs: the Klein-Bell Scale (11), the Barthel Index (12), the Kenny Self-Care Evaluation (13), the Assessment of Motor and Process Skills (14), the A-One Evaluation (15), the Canadian Occupational Performance Measure (16), the Allen Cognitive Test (17), Rabideau Kitchen Evaluation (18) and the Kohlman Evaluation of Living Skills (19). Table 51-1 explores some of these ADL assessment tools in greater depth.

Many clinicians employ “homemade” ADL checklists in their practices rather than using published checklists and assessments. These facility-developed evaluations are compatible with the program’s focus and mission. Many are derived from the Functional Independence Measure (20) commonly used by rehabilitation teams as a comprehensive tool for functional assessment of PADLs and IADLs.

The advantage of using a standardized and reliable tool for assessment of ADLs is the ability to retest the client’s performance over time, regardless of the testing environment. Communication between clinicians along the continuum of care is clearer when the same evaluative tool is used to assess performance. Improvements in ADL performance are apparent and reliable. However, standardized assessments often take longer to administer and to score. Though clinically important information is gained from assessments such as the AMPS and A-One, clinicians feel they lack the time to devote to such thorough, occupationally oriented evaluations.

With so many assessments available for use, clinicians must identify the goal of the ADL evaluation before selecting an assessment tool. The evaluation might have a descriptive purpose. That is, the therapist chooses to assess the client’s ADL performance at a given moment in time to describe the degree of impairment and need for therapy intervention. The evaluation could have a predictive purpose where the clinician ascertains through ADL performance the patient’s capacity to live alone, function in the community or support primary life roles. The ADL evaluation also might serve an evaluative purpose where the clinician documents progress in performance over the course of time (1, 21). Clearly some ADL assessments are better for descriptive assessment and others more appropriate for predictive assessment. Law and Letts provide a thoughtful, comprehensive comparison of 13 ADL assessments in their paper which may serve as a guide for assessment tool selection (21).

Undoubtedly, there is more to the assessment of activities of daily living than simply scoring patient’s performance using an ordinal scale. Though the scales and measures available for the rehabilitation clinician and

TABLE 51-1

ASSESSMENT	POPULATION	STANDARDIZATION	COMMENTS
Klein-Bell ADL Scale	Adults in a rehabilitation program	Good	Test-retest reliability is good; content validity is very good; lengthy evaluation to administer
Barthel Index	Adults in a rehabilitation program	Good	Test-retest reliability and content validity are excellent; lengthy to administer
Kenny Self-Care Evaluation	General adult rehabilitation	Good	Test-retest reliability poor; content validity is good; lengthy to administer
Assessment of Motor and Process Skills	A variety of populations; a school version is available and studies continue assessing the use of AMPS with different cultures	Good	Reliable and valid; can be individualized to the patient's occupations; new test items are being evaluated to expand utility of assessment
The A-One Evaluation	Adults with neurobehavioral impairment	Good	Reliable and valid however certification in the interpretation of the evaluation is recommended; can be administered during the course of routine ADLs
Canadian Occupational Performance Measure	Variety of ages and populations	Good	Reliable and valid; intended for use as an outcome measure; allows clinician to focus on client's goals
The Allen Cognitive Test	Adults with psychiatric diagnoses; some work has been done with adults with brain injury	Good	Based on Allen's Cognitive Theory, the instrument is reliable and valid but training in testing procedure and interpretation is recommended
Rabideau Kitchen Evaluation	Adults with rehabilitation diagnoses	Non-standardized	Face validity; good inter-rated reliability; provides standard way to evaluate patient performance on kitchen tasks
Kohlman Evaluation of Living Skills	Adults and adolescents, including adults with brain injury	Good	Reliable and valid; useful in determining client safety in the home/ community

\*more in-depth analysis is available in *A Critical Review of Scales of Activities of Daily Living* by Law and Letts (21).

team quantify and objectify the client's performance, a thorough assessment of ADLs requires clinicians to analyze the full spectrum of the patient's performance. The best assessment begins with an understanding of the client as an occupational being, therefore the occupational profile interview is a proper starting point.

**The Occupational Profile**

The occupational profile is a semi-structured interview conducted with the client to determine the client's roles, habits, interests, values and to confirm the client's goals for the rehabilitative process. Frequently, after a brain injury, the client is unable to reliably provide information for the occupational profile due to disorientation, cognitive deficits, language impairments or behavioral issues. In such situations, the clinician should interview family or close friends to gather this vital information.

The occupational profile promotes an understanding of the client (6). Following the interview, the clinician is able to answer the following important questions about the client:

- How does my client describe himself?
- How do my client's occupations define and maintain her identity?
- In what ways does my client's engagement in occupations allow for self-expression?
- What are my client's goals given her present disability and how do they relate to her occupations?

The occupational profile consolidates information on the client's environment, daily routine, educational achievement, social support system as well as primary areas of interest. This data defines the patient's and/ or significant other's goals for rehabilitation. These stated

goals become primary drivers for the treatment planning process yet to come.

### **Assessing Performance in Areas of Occupation**

The assessment of occupational performance involves analytically watching clients “do”, utilizing what Padilla, Barrett and Walker have identified as “mindful observation” (8). In the intensive care setting where persons with brain injury usually are dependent in ADLs, the therapist assesses the client’s PADLs while managing potential complications to minimize or eliminate the impact on later occupational performance. The OT working in the ICU monitors range of motion, muscle tone and provides splints and positioners as needed to prevent deformity and contracture. Often the occupational and physical therapists conduct co-evaluations in the ICU. As the patient improves and begins in-patient rehabilitation, the OT assesses the client’s performance of relevant PADLs. Information from the occupational profile provided by the client or family guide the performance evaluation process. Assessment begins with PADLs of greatest value and priority to the client and family. As therapy continues in day rehabilitation and outpatient therapy, the OT assessment of ADL performance is refined to focus on higher level skills to promote maximal independence in the home and community. Through the continuum of rehabilitation, occupational therapists, as “experts in occupation”, analyze the methods used by their clients to complete ADL tasks (1). The therapists discern whether observed errors are attributable to problems in range of motion, strength, coordination, balance, visual-perceptual function or executive skills and use this information to design treatment programs.

As clients transition from the hospital setting into the community, the therapist broadens the assessment of occupational performance. The home health occupational therapist has the benefit of assessing the client in his natural environment, which allows the therapist to ascertain the effects of the natural environment, culture, and support network on performance (1). Some studies suggest that assessment performed in a client’s natural environment provides the most accurate picture of ADL performance (22). Because assessment in the out-patient setting occurs in a clinical environment, the clinician must listen carefully to the client and family’s descriptions of specific ADL performance carried out at home in order to identify areas of performance breakdown or client/family concern.

Several of the evaluation tools previously mentioned comprehensively assess occupational performance, rather than just ADL skills. Use of these assessments enhances the clinician’s insight into the meaning, function and form of occupational performance for the individual client while elucidating performance components that

influence performance (6). The Canadian Occupational Performance Measure (16) assesses self-maintenance, productivity and leisure roles with an eye to those areas that the client regards as valuable and meaningful. The Assessment of Motor and Process Skills (14) guides the clinician’s observation of the client as he engages in tasks of his choice selected from an extensive list of varied occupations. During the course of task performance, the clinician identifies the motor or process skills that facilitate or impede task performance. The Arnadottir OT-ADL Neurobehavioral Evaluation (15), clinically known as the A-One, aids the clinician’s detection of potential neurobehavioral deficits that are impacting the quality of or completion of occupational task performance. Use of any of these occupationally-based assessment tools gives the clinician a fuller appreciation of the client’s occupational performance assets and impairments while promoting a more holistic and hearty assessment than that which is available through a simple ADL checklist.

### **Best Practice Methods for Assessing Occupational Performance**

The use of real versus simulated tasks during the assessment process is an important consideration. Simulated assessments lack the influence of context, which may shape, either positively or negatively, a client’s performance. Occupational performance is influenced by the context surrounding the occupation itself. Context includes physical elements such as the physical environment, the area’s topography or even the level of lighting or noise. Spiritual context involves the client’s sense of a higher being and purpose to life, both of which contribute to motivation and the inspiration to “do”. Temporal context, such as the time of year or a stage in life, have bearing on task selection and performance. A homemaker doing a cooking evaluation three days before Thanksgiving may engage with greater motivation in the preparation of apple pies for her family dinner than she would in the preparation of a soup-and-sandwich lunch for herself using a menu planned by her therapist (23). Context is an inescapable part of the assessment process.

Simulated activities as a form of assessment, while not ideal, are necessary in many clinical settings. Clinicians working in hospitals may employ several strategies to improve the quality of simulated assessments. Through interviews, clinicians may obtain detailed information about the client’s home environment and insert as many of these features as possible into the assessment. For example, the therapist might learn that the client’s bedroom contains a low chair routinely used for dressing. During the dressing assessment, the clinician utilizes a chair of the same height to determine the effect of sitting

on a lower surface during dressing. Some OT kitchens have moveable islands that allow therapists to configure the kitchen as similarly as possible to the client’s home. If the patient plans to use a regular bed at home, the therapist should perform all bed-related assessments with the hospital bed flat and the rails down. Real coins and bills improve the quality of money management skills assessment. Provision of the client’s own grooming tools and supplies in the bag or container used at home enhances the physical context of the task.

**Assessing Client Factors that Affect Performance**

At times, therapists find it necessary to assess specific components of functional performance further to identify the nature of or severity of an underlying problem. Known as client factors, these components are peculiar to the individual client and play a role in the client’s ability to perform functional tasks. Client factors include mental functions, sensory functions, neuromusculoskeletal and movement-related functions, visual and speech functions. Table 51-2 provides some examples of client factors (23). Perhaps the therapist notices while assessing bathing that the client cannot reach her lower back. A specific evaluation of the client’s upper extremity range of motion and strength reveals that though her shoulder range of motion is within normal limits, her antigravity strength is insufficient to support washing her lower back. In another case, during an assessment of a client’s self-feeding skills, the clinician notices that the client over-reaches for her milk carton, closes one eye when scooping food with her fork and sometimes closes both eyes when chewing. A quick assessment of ocular alignment reveals a diplopia that is interfering with the client’s comfort and precision during PADL’s.

Formal testing of client factors, such as visual-perceptual or memory assessments, is based upon an assumption that there is a relationship between the factor being tested and the client’s ability to perform the daily living task (9). Tests such as the Toggia Cognitive Assessment (TCA) (24), the Lowenstein Occupational Therapy Cognitive Assessment (25) and the Contextual Memory Test (26) are used to assess client factors. Researchers continue to seek evidence of a correlation between tests such as these and occupational performance (27).

The complete occupational performance assessment provides a picture of the client’s occupations within context, an understanding of the client’s and/or significant other’s goals for the therapy process as well as information on impairments in client factors that limit overall performance. Armed with a good assessment, the clinician proceeds to plan treatment to promote the client’s relocation of self, all the while keeping the client’s priorities and goals for the treatment process in mind.

**GOAL SETTING STRATEGIES**

In times past, health care providers paternalistically offered advice and treatment to clients to remediate their conditions or symptoms. This advice and the prescribed intervention was offered with the client’s best interests in mind. In most cases, clients accepted the health care provider’s advice and treatment without question, believing that the health care provider knew best. Whatever priorities the health care provider set were “fine”– even if they didn’t match the client’s own priorities.

Times have changed. Now individuals receiving medical services are more informed, more involved in decision-making and more vocal about their preferences. Client-centered goal setting is now routine in many health care settings. Major health care accrediting agencies, such as JCAHO and CARE, require evidence of the client’s and significant others’ input into the goal-setting process. Current research demonstrates that client-identified goals yield the best therapy outcomes. Therefore, goal setting with the client and caregiver is an integral part of the rehabilitative process. Often goals identified by clients and especially by caregivers focus on areas which, if improved, make return to home and care in the home easier. Those clients who initially are unable to state their rehabilitation goals must be given the chance to provide input once able (28). At times, clients set lofty long-term goals, such as driving, returning to school or work or staying home alone. In such situations, the clinician works with the client to outline realistic and attainable short-term goals, never losing sight of the client’s long-term goals.

Once ADL-related treatment goals are set, intervention focuses on the client’s ability “to do” (29). A well-defined treatment goal integrates the client’s expressed

**TABLE 51-2**  
*Examples of Client Factors*

Mental functions	Level of arousal, orientation, personality, motivation, attention, visual-perceptual function, judgment, mathematical calculations, motor planning
Sensory functions	visual acuity, hearing, balance, taste, smell, tactile discrimination, pain
Neuromusculoskeletal and movement-related functions	range of motion, mobility, strength, muscle tone, reflexive responses, eye-hand coordination, tics and tremors, ability to ambulate
Skin and related structure functions	skin integrity including the presence of wounds

**TABLE 51-3**  
**Examples of Goal with Qualifiers**

<p>Patient will place arms in sleeves of shirt with moderate assist while sitting in wheelchair.</p> <p>Patient will calculate money up to \$2.00 in coins with 40% accuracy.</p> <p>Patient will bring washcloth to face with maximal assistance.</p> <p>Patient will prepare shopping list for a simple breakfast using a planned menu, with minimal assist.</p> <p>Patient will complete entire morning grooming routine in 30 minutes with supervision.</p> <p>Each of these areas of consideration are important and should be kept in mind during the treatment process.</p>
--

skills and desires with the environmental context in which the client functions. The treatment program includes tasks, activities, and instruction to meet these goals. As Baum et al. says so well: “The unique contribution of occupational therapy is to maximize the fit between what the person wants and needs to do and his or her capability to do it” (1).

Well-formulated treatment goals are functional, measurable, specific, clear to the reader and reflective of the client’s priorities. Achievement of treatment objectives is easily determined when goals are written well. Goal qualifiers enhance both the specificity and the achievability of treatment goals. Goal qualifiers may include quantifiable measures such as the frequency with which a task is performed, the rate of accuracy achieved during performance, the setting in which a task is performed, or the number of rest breaks required during task performance. Table 51-3 lists several different types of goal qualifiers.

As treatment goals are achieved, the clinician in collaboration with the client sets new functional goals. New areas of occupational performance are introduced into the treatment program as the client demonstrates readiness for engagement in advanced tasks. Good communication between clinicians about goal achievement and the client’s goal priorities as the client progresses through the continuum of care facilitates progression of the treatment plan.

The clinician may employ one of several strategies to solicit client involvement in the goal setting and goal progression process. Team conferences that include clients and families provide a forum for the entire team to review progress and establish treatment priorities. A review of treatment goals by clinicians at the beginning of each treatment session gives the treatment session focus. Memory notebooks may include a section devoted to mapping treatment goals. One recent study recommended the use of a “goal notebook” to improve clinician-client discussions and to remind both the client and the clinician about active treatment goals (30).

## ADL INTERVENTION: BRINGING MEANING BACK TO LIFE

### Improving Personal Activities of Daily Living

Personal activities of daily living (PADL) include bathing, bowel and bladder management, dressing, eating, hygiene and grooming and functional mobility (23). Each person performs PADL’s in personally unique and individually customized sequences. Clients with severe brain injury frequently experience limits on their ability to perform these most basic and familiar tasks (31). Many factors contribute to deficits in self-care performance, including impaired function of the upper and lower extremities, cognitive deficits, visual-perceptual impairments, communication impairments and behavioral problems.

The comprehensive PADL treatment program provides retraining opportunities that incorporate multiple considerations associated with PADL performance. These parameters include:

1. the *context* in which the tasks are performed
2. the client’s *habits and routines* related to task performance
3. *safety* during performance of tasks
4. the efficacy of *adaptive devices and compensatory techniques*
5. *interdisciplinary team involvement*, including the caregivers
6. the client’s ability to *self-monitor and correct errors*

Knowledge of *context* related to PADL’s performance is critical. Cultural context influences the client’s choice of attire, food choices and grooming preferences. Knowledge of the physical context in which PADL’s are performed helps the clinician design strategies to overcome architectural barriers, such as inaccessible bathrooms or out-of-reach clothes closets. An awareness of context helps eliminate the imposition of the therapist’s values on the client. For example, the therapist might insist during treatment that the client place the dinner napkin in his lap during meals only to discover that the client and his family always keep napkins, as well as their elbows, on the table during meals. Treatment programs must be contextually relevant or they are ultimately of little value to the client.

PADL’s are habit-driven. *Habits* are “automatic behavior that is integrated into more complex patterns” which facilitate daily performance of self-care (23). PADL’s are so habitual that most people proceed through morning and evening self-care tasks without much conscious thought. It is helpful to the retraining program to know the client’s pre-injury habits (32). Knowledge of pre-injury habits helps the clinician formulate a treatment program that draws upon familiar patterns of behavior

that may hasten skill competence. Did the client put socks on before or after trousers? Did the client shower in the morning or evening? Was moisturizer used under makeup? Sometimes clients serve as the source of this information. However, if the client cannot provide information regarding pre-injury habits, the clinician needs to obtain this information from families. Unfortunately, because many PADLs are performed privately, families may have limited insight into the client's pre-injury habits.

The motor, cognitive, behavior and visual-perceptual sequelae common after brain injury often make performance of some PADLs risky. *Safety* is a primary concern for the clinician. Clients with dysphagia require assistance or supervision for self-feeding. Clients with balance problems may not be able to safely stand during self-dressing. Problems with incoordination, muscle weakness or visual-perceptual function can make shaving or the application of eye make-up hazardous. In addition, the unpredictability associated with impulsivity creates an environment wrought with potential safety risks. A portion of the treatment regimen must be devoted to training in the integration of safety-enhancing strategies. The therapist might advise that dressing be performed in supine in bed or that the client use an electric razor instead of a straight razor. Caregiver instruction should include training in safety concerns as well as the admonition to expect the unexpected, especially if the client has impaired self-awareness, demonstrates impulsivity, has apraxia or is confused.

*Adaptive devices* may prove helpful when motor impairments interfere with task performance. However, when memory impairments are marked, clients often forget that they have adaptive devices and thus, fail to use them. Clients who utilize elastic shoelaces may proceed to untie their shoes when undressing. Apraxia may impede the client's ability to learn to operate an adaptive device, provoking the client to abandon its use in frustration. Clients experiencing disorganization and poor sequencing may lose track of adaptive devices or fail to have them handy at the critical moment. Clinicians should consider carefully the real benefit of adaptive aids to clients with brain injury. Likewise care should be taken when devoting precious treatment time to training in the use of adaptive devices.

Clients with brain injury frequently must learn to do familiar tasks in a new ways. The use of *compensatory strategies* during PADL performance is often successful. Compensatory strategies address areas of performance breakdown. The clinician performs task analysis to identify elements critical to task performance. Task analysis involves in-depth study of the physical, cognitive and behavioral requirements of a given activity. Task analysis is applicable to any occupation, from the simplest of self-care tasks to work-related tasks. A comparison of the task requirements with the client's abilities and limitations reveals the points in task performance where

compensation or adaptation must occur to facilitate successful performance.

When teaching compensatory strategies, the clinician first structures the task, adding new elements to address the areas of breakdown. Clients unable to maintain standing need to learn to dress and bathe in a sitting or supine position. Clients with homonymous hemianopsia must learn to purposefully look to their "blind side" during feeding, grooming and dressing. Clients with severe sequencing deficits may require a written checklist to complete their morning PADL routine. A client with tonal dysfunction that worsens during strenuous activity may need a tone-reducing orthosis during ADLs. With the therapist close at hand, the client proceeds through the PADLs incorporating compensatory strategies while receiving either verbal and/or physical assistance as needed.

Once the PADLs are structured, the client practices task performance to facilitate learning. Chunking instruction in compensatory techniques may reduce the chance of overwhelming the client (32). The chunking strategy may be used, for example when addressing impairments in self-dressing with a client with hemiplegia. The therapist first teaches a compensatory technique for upper extremity dressing. The upper extremity dressing technique is practiced daily with the therapist providing assistance with lower extremity dressing. Once the client masters the upper extremity dressing technique, treatment progresses to lower extremity dressing. A compensatory strategy to facilitate independence with lower extremity dressing is taught by the therapist. Therapy focuses on practice of lower extremity dressing strategies with the therapist providing physical and verbal assistance. Once the client demonstrates competence with the two parts of dressing separately, the dressing sequence is put together and practiced until mastered.

Chaining and prompting techniques are used to facilitate learning of compensatory strategies. Because functional tasks are comprised of sequences of steps, retraining of task performance may be accomplished by forward, backward or whole-task chaining. Forward chaining involves teaching the first task step first, adding subsequent steps as the client is ready. Backward chaining entails teaching the final step task first, such as teaching a client to put on and tie his shoes first before other garments are taught. Once the last task step is mastered, the clinician works backward toward the first step of the task as the client demonstrates readiness to learn. Whole-task chaining, which proved most successful in a study by Giles, presents all task steps in their proper sequence coupled with repeated practice until competence is demonstrated (33).

Chaining allows the client to use completed steps as cues to initiate subsequent steps. Therapists either verbally assist the client through the chain of steps or provide written cue cards that outline the task sequence.

When the client is unable to move on to the next step, the therapist may query the client. Questions such as “You’ve put sugar in your coffee. What do you do next?” or “You’ve finished washing your face. What comes next?” often triggers the client’s recall of the next step or his need to reference his cue card. As the client’s competence with the task improves, fewer cueing queries from the clinician are required.

Though the area of PADL is typically the domain of the occupational therapist, the entire *interdisciplinary team* including the caregiver must be involved in the PADL treatment process. Performance of PADL’s occurs throughout the 24-hour day necessitating the participation of nurses, other therapy staff, residential staff, caregivers and family to ensure carryover of newly learned techniques, to provide consistency in cueing, to ensure safety and to promote learning thus increasing proficiency. Communication among the interdisciplinary team members regarding PADL performance must occur routinely. In-patient programs often rely on boards posted at clients’ bedsides upon which clinicians record self care performance information. Memory diaries that document PADL performance and strategies are used in in-patient programs, outpatient programs and in the community. Videos of clients performing self-care help clarify levels of performance and provide instruction for distant caregivers. Team meetings provide an opportunity to discuss self-care performance. Communication is fundamental to providing the consistency that is essential in all areas of brain injury rehabilitation.

Throughout the retraining process, the client must be taught to *monitor performance for errors* and to initiate self-correction. Feedback is one method for teaching error recognition. Feedback may involve the clinician showing a client mistakes made during task performance. While this approach works, the clinician or another individual is essential to such a feedback process.

A better technique involves guiding the client through a sequence of activity prediction, self-critique and problem solving. In activity prediction, the client estimates how he will do on a given task before the task commences. Using information from prior performances, the client identifies areas where breakdown might occur. Once the client completes the task, the client engages in self-critique, comparing actual performance with predicted performance. Activity prediction followed by self-critique improves the client’s self-awareness and improves performance (34).

Some clients repeatedly commit the same errors, at times due to an inability to approach a task in a novel, potentially more successful manner. One approach to reduce repeated errors is to help the client generate alternative approaches to a task. When a therapist notes that an error is occurring repeatedly, the therapist should work

with the client to identify areas of performance breakdown noticed during task performance. Some clients are able to identify errors spontaneously but others require the assistance of the therapist to review each step of the task. Once the pattern of error is identified, the clinician guides the client through an analysis of possible alternatives to task performance that could eliminate the repeated errors. The alternatives are then employed during task performance and analyzed by the client and therapist. Those that prove beneficial to the quality of performance are incorporated into the task routine.

### **Interventions for Deficits in Instrumental Activities of Daily Living**

Instrumental activities of daily living (IADL’s) are those activities “oriented toward interacting with the environment” and are often multifaceted in nature (23). Completion of IADL’s is usually essential to an individual’s capacity to live independently in the community. In some cases, family members may rely upon the individual to complete specific IADL’s to keep the family unit running. IADL’s include activities such as caring for other humans or pets, use of communication equipment, community-based mobility, home management, providing food for self and perhaps others and managing finances.

Because IADL’s are so complex, they are very susceptible to significant disruption after brain injury. Physical limitations such as hemiplegia, impaired balance and incoordination impact IADL’s that require bilateral extremity use to complete, such as folding laundry as well as activities that entail precision, such as dialing a cell phone or chopping vegetables for a salad. The complexity of IADL’s places a high demand on cognitive function, including memory function, executive skills, reasoning, judgment and problem-solving. Visual-perceptual-motor dysfunction such as impaired spatial skills, apraxia and hemi-inattention make accurate, independent performance of many IADL’s very difficult, if not impossible. Functional communication, money management and home management depend to some degree on language function.

Each person possesses a unique repertoire of IADL’s. Valued IADL’s are related to a person’s life roles such as parent, home maintainer, worker, student, or volunteer. Competency requirements for specific roles vary from person to person.

There is no “cook book” of interventions for treatment of dysfunction in IADL’s though treatment-oriented resources are available to the clinician (8, 22, 31, 35–39). Limited research into the effectiveness of some therapeutic approaches has been done (19, 22, 28, 36, 37, 40–44). The optimal intervention for disruption in IADL performance is personalized for each client based on the client’s preferences, willingness to adapt task performance, the

nature of the task itself and the impact of the sequelae of brain injury on task performance.

During treatment planning, the clinician should be mindful of several important points. Though the approach, strategies and techniques employed to provide intervention for IADLs vary with each patient, these considerations supply a guide for the treatment planning and implementation process.

1. the *client and family's goals* relative to previously performed IADL
2. the *setting* in which treatment for IADLs is occurring
3. facilitation of *generalization of skills* learned
4. selection of *treatment tasks*
5. utility of *technology* during task performance
6. *educational needs* of the client and family

The over-riding goal of rehabilitation is to enable the person receiving care to attain a satisfying quality of life. Disturbing data exists regarding quality of life after brain injury. In one study, at follow-up, a small proportion of patients was competitively employed. Of those studied, 12% rarely left their home because of continuing functional limitations (41). While each person defines "quality of life" differently, it is imperative that the *clients and their significant others' goals for rehabilitation and perception of quality within their own lives* form the foundation for treatment. Some families tolerate role changes within the family system better than others. While one husband is perfectly comfortable assuming all the responsibilities of home management given his wife's disability, another husband may regard his wife's ability to manage laundry, prepare meals and do housework to the extent she is able as a vital necessity to the family. Many family units need the client to be able to stay alone for a period of time during the day in order for family members to work or attend school. In such cases, the therapist must address the numerous activities essential to that client's safety and independence while home alone. In addition, clients often state a desire to resume tasks that bring special meaning to life, such as participation in religious worship or participation in the weekly bridge club. Therapists who listen carefully to their clients are able to determine the client's treatment priorities.

Once treatment priorities are identified, the therapist begins the intervention process. Clinicians must not underestimate the power of client investment on the outcome of treatment. As Pierce articulately states: "The appeal of a therapeutic activity, and thus, its treatment power, always depends on the degree to which the patient perceives it as offering desirable levels of pleasure, productivity and restoration" (45).

The *setting* in which IADL treatment naturally occurs influences the types of activities used in remediation and the nature of the treatment itself. Without question, a

familiar environment enhances performance because well-known task elements serve as prompts for the client. In fact, some researchers have concluded that treatment in an unfamiliar environment is fraught with distraction and thus is a hindrance to the client (22).

Despite shortening lengths of stay, in-patient treatment programs often begin the IADL treatment program. The in-patient therapist is challenged to provide the most realistic treatment environment possible within the hospital setting. Some in-patient rehabilitation programs feature Easy Street<sup>1</sup>, a mock naturalistic environment that includes a retail shopping area. Though not equivalent to working with the client in the "real world", mock environments like Easy Street or even the hospital gift shop and eateries enhance context. Functional tasks such as ordering from a menu, handling money, following directional signs, use of public restrooms and managing architectural barriers may be practiced in such environments. At least one paper reports a longer length of stay and less favorable FIM scores for patients who received treatment only in a clinic setting as compared to patients who had at least one session in the Easy Street environment (46). In-patient settings without benefit of the Easy Street environment may enhance contextual relevance by using the client's own recipes during cooking tasks or working on financial management using copies of the client's bills. A collection of phone directories from surrounding regions for use during phone skills retraining improves familiarity. Community outings to grocery stores, shopping centers, and restaurants formerly frequented by the client provide excellent environments for therapy. Use of more natural and contextually relevant therapeutic media within the clinical setting is recommended. The standard collection of pegs and cones can be replaced with functional task modules such as car maintenance kits, pet care supplies, a set of greeting cards to practice writing skills and coupons for sorting (36, 37). In an age where provider productivity and efficiency are mandated within the clinical setting, greater creativity is required of the clinician who desires to provide maximally relevant treatment to clients. The extra effort though is worth it when contextual relevance is improved.

Much IADL treatment occurs in outpatient, day rehabilitation and home settings as clinicians work with clients who are actively re-integrating into their naturalistic environment. Outpatient and day rehabilitation efforts may be augmented by "homework" assigned by the clinician and performed between clinical appointments. The home health therapist has the real benefit of engaging the patient in IADL retraining in the most familiar environment.

<sup>1</sup>*Product Information* Easy Street – Exclusively manufactured, sold and installed by Chamberlain West, Inc, 7300 E. Acoma Drive, Scottsdale, Arizona 85260

As the treatment program progresses, the clinician must be concerned about the client's ability to *generalize into the natural environment the skills being mastered* in the treatment session. Generalization involves the client's ability to do as well in the home setting as in the clinical setting. Cases have been reported where clients do less well when the clinician or the clinical setting are withdrawn from the context of the activity (22, 42). Neistadt emphasizes that clients with brain injury often depend on a "data-driven mode of information processing" during pursuit of IADLs. Such behavior causes inflexibility in thinking, demonstration of stimulus-bound behavior and failure to generalize (42). Techniques developed by Toglia (34, 38) and Ben-Yishay (22) create a therapeutic environment where cues and assistance are provided but gradually faded as performance progresses. Neistadt describes application of these strategies to food preparation tasks (42). Maximization of generalization is achieved by providing opportunities for practice in as many contexts as possible. Inclusion of family in the treatment session provides one alteration to task context. Practice of tasks either in a transitional apartment, while on pass or in the home between outpatient sessions provides variation in contexts. In some situations, generalization simply doesn't occur. In those situations, therapists should shift the treatment program to the practice of specific tasks in specific contexts to gain the highest level of performance competence.

When planning treatment for IADLs, the clinician should weigh the client's *choices of treatment tasks* carefully as well as the appropriate approach to treatment. All IADLs may be therapeutically graded to provide a suitable level of challenge. Grading techniques involve changing specific task parameters such as tools needed for task completion, the amount of environmental distraction, the complexity of the task and the amount of cueing offered by another person. Treatment always begins at a level where clients are challenged but not frustrated. The selection of treatment activity is guided by the client's stated goal and should be an activity in which the client has expressed interest. As performance improves, the elements of the treatment task are advanced to more greatly challenge the patient.

An occupational therapist treating a client with topographical disorientation, right-left confusion and hemi-inattention focuses the treatment plan on the client's expressed interest in meal planning. The client clips coupons to help reduce her food costs. One treatment modality employed to address the hemi-inattention and right-left confusion could be sorting coupons for food products to the left and cleaning products to the right. The OT might introduce map reading as a therapy activity. The therapist orients the patient to the map, incorporating directional terms. The complexity of the maps used increases as the client shows improved map reading

skills. Once improvements in right-left sorting and map reading tasks are noted, therapy progresses past the confines of the OT clinic into the medical facility. The OT provides written directions for a route from the OT clinic to the facility's front door. As part of the treatment session, the client uses the written directions to travel to the prescribed route. The written directions contain landmarks on the right and left that the client must note along the way. In addition to in-clinic therapy, the OT provides a homework assignment requiring the client to use written directions to find the OT clinic on the next visit, asking for assistance as needed. As treatment progresses and improvements are noted, the clinical treatment program and homework assignments are made more difficult. Advanced treatment could include having the client read directions to the person who provides transportation to OT appointments, training with the OT in the use of public transportation or the use of a state map to plan a vacation. Clinicians must make deliberate treatment modality selections based on the client's occupations and then progress the task complexity as the patient demonstrates readiness.

Ever-evolving *technology* has great potential for many clients with brain injury. Staying current with technological advances is a challenge for busy therapists and funding assistive technology is often difficult, if not impossible, for many individuals with brain injury. However, technology does provide some tremendous possibilities. Low-tech devices available at modest cost allow clients with severe motoric impairments to control their environment, such as turning on lights and using the telephone. Computers provide voice-activated options as well as adaptive peripherals which facilitate word processing for individuals without hand function (47). Electronic aids to daily living (EADLs) dial telephones, unlock doors and provide many options for environmental control.

Cognitive orthotics, sometimes called assistive technology devices (ATD's), provide "support for weakened or ineffective brain functions" (43). Such orthoses provide cues, assist with task completion, maximize self-management, allow a higher level of self-sufficiency and often promote self-esteem and self-confidence (43, 44, 48). Individuals without brain injury employ cognitive orthoses such as portable digital assistants (PDA's), portable tape recorders, watch alarms and computer-based schedulers routinely. The ISAAC cognitive prosthetic system has shown great promise in assisting clients with brain injury. A recent report (49) demonstrates the utility of this small device. Its advantages over other cognitive prosthetics include its compact size, portability, its adaptability to the individual client's needs, and its immense programming possibilities. Cognitive prosthetics have shown utility with clients with brain injury (48) and have the added advantage of being a tool used by people without disability, unlike traditional memory notebooks.

As clinicians seek technological solutions for their clients, several factors must be kept in mind. First, the client's desire to employ a technological solution must be explored. The therapist needs to determine the client's overall awareness of his deficits and how technology, when properly employed, may help. The therapist must conduct a task analysis of the client's remaining abilities and strengths that could support use of technology while also considering the intactness of client factors often essential to technological use, such as vision, language skills, ability to keep up with the device and the ability to manipulate the device (48). The cost of technology also needs to be considered. Care must be taken when introducing potentially life-changing technology to a client who lacks the financial means to purchase the device. Alternative funding sources, such as vocational rehabilitation services or even charitable organizations, are sometimes available. The motivated client can partner with a clinician to look for alternate funding. Finally, the clinician should consider the client's overall familiarity with technological devices. A client with an information technology or engineering background may more quickly learn how to use an IADL than a client who has never used a computer and who has no mechanical background. Technology has awesome potential to assist individuals with brain injury manage IADLs despite their physical or cognitive sequelae.

Throughout the IADL treatment process, clinicians must remain alert to the *educational needs of the client and family*. It is difficult for clinicians to imagine or anticipate the many issues and concerns of the caregiver, especially if the clinician has never provided personal support for a person with a brain injury. Understanding the complexity of brain injury is not easy for clients or for families. During the treatment process, families may wonder why their loved one doesn't do the things that he is perfectly capable of performing. For example, a wife may say to the therapist: "I saw my husband fix his own lunch with you. Why is it when I come home from work I discover that he hasn't gotten off the couch all day. Why doesn't he fix his own lunch at home?" Clients may wonder why they never seem to be able to finish any task they start. Education about the significant impact of impaired executive function is usually helpful for families and clients who may have received considerable instruction on performance of transfers, the administration of medications and home exercises but who have not learned sufficiently about perseveration, impaired initiation and decreased planning. As stated by McDonald et al. (50): "Impairment in executive abilities has significant implications for the day-to-day life of those who have sustained traumatic brain injury" – implications that families and clients don't always understand.

Clients and families also benefit from intense instruction in safety related to performance of IADLs. Clear advice regarding supervision needs, use of dangerous

implements such as power tools and the operation of motor vehicles must be given. Families need guidance on activities the client may safely and capably do alone, whether in the home or in the community. Discussions regarding the client's degree of self-awareness may be relevant. Lack of awareness is a common sequelae of brain injury and can lead to all manner of difficulties including resistance to rehabilitative efforts, deliberate involvement in unsafe activities and interpersonal conflict (51). As intervention is employed to improve the client's self-awareness, support and education for the caregivers may foster their ability to carry on and cope.

Families will often ask whether the client can do particular IADLs that the therapist has not yet addressed clinically. Clinicians must take care when basing judgments about a client's ability to perform tasks at home and in the community on testing of component skills or on simulated activities. For example, a therapist might state that a client is unable to stay home alone because the client performed poorly on a visual-perceptual test. While some component testing has shown encouraging relationships to IADL performance, there clearly is a disconnection between performance on a paper-pencil task related to an IADL and performance of IADL itself (22, 27). Likewise, asserting that a client is incapable of certain IADLs based on a simulated task is a stretch. Clinicians may offer predictions based on an analysis of performance components and results of simulated activities, but with caution. The best approach is to engage the client in the task in question to determine the client's actual skill level. Otherwise clinicians find themselves stating their best guess based on previous experience and the data at hand.

Clinicians do well to maintain an open door for clients and families to ask questions and receive education, not only during active treatment but also after formal treatment has ended. Improvements in as well as deterioration of IADL performance occur long after the therapy program ends. The desire and need for therapy also changes over time. One study reports that some survivors of brain injury sense a greater readiness for therapy long after the course of therapy is completed (41). Clients and families need to understand what is "expected" and "normal" after a brain injury and what constitutes a situation of concern. Referring clients and caregivers to brain injury support groups may provide a valuable resource over time.

## OCCUPATIONAL THERAPY IN BRAIN INJURY REHABILITATION

The occupational therapist functions as a part of the interdisciplinary brain injury team. Occupational therapists are trained to view clients holistically as occupational beings for whom participation in daily life is a vital part

of existence. Occupational therapists seek to improve the health of those receiving occupational therapy services while engaging clients in meaningful activity. The best occupational therapy utilizes treatment modalities that inspire and motivate the client while providing relevant experience.

Occupational therapy educational coursework includes basic sciences, anatomy, physiology, neuroanatomy, kinesiology as well as instruction in disease and disability. In addition, occupational therapy students study psychology, sociology and human development. The language of occupational therapy theory and practice is found in the *Occupational Therapy Practice Framework* that describes the domain and process of occupational therapy (23).

Occupational therapists who practice in brain injury rehabilitation programs benefit from continuing education focused on cognitive function, behavior management and intervention techniques. While the occupational therapy educational curriculum provides a basic foundation in these areas, further education sharpens the clinician's skills. The ever-evolving field of assistive technology demands that the occupational therapist continually review the literature for developments applicable to persons with brain injury.

The most significant contribution of the occupational therapist to the brain injury rehabilitation team is the therapist's understanding of and insight into the individual client's ability to participate in activities of daily living of interest and importance to the client and the family. The occupational therapist's ability to analyze task performance is critical to the team's understanding of the client's need for assistance and supervision in the community. Occupational therapists are not "ADL retrainers". Rather occupational therapists alter context during treatment in order to clarify important issues in functional task performance for the client, family and treatment team while facilitating maximal participation in activities of importance to the client.

Utilizing a collaborative approach, the physician and occupational therapist do well to mesh their understanding of the client's participation in daily life prior to the brain injury with the client's and family's stated rehabilitation goals. While a full restoration to pre-injury participation isn't always possible, the physician and OT must work with the client and family to establish reasonable, achievable expectations for improvement and performance. The physician should encourage the occupational therapy staff to be creative and innovative in treating patients. The occupational therapist and physician should work together in setting parameters on client activity, especially in the areas of driving, return to work and living situation based on the therapist's evaluation and intervention with the client in a variety of tasks and

contexts and the physician's knowledge of the client's medical condition.

## CONCLUSION

Law states (7) that "participation in the everyday occupations of life is a vital part of human development and lived experience". Brain injury can radically affect an individual's level of participation in everyday activities. Reduced participation in important life tasks affects the client's sense of competency within the environment as well as overall satisfaction with life. Therapeutic efforts directed toward improved participation in occupations must be uniquely designed to capture the client's interest as together the client and clinician work toward the client's return to quality of life and relocation of self.

## Pharmacotherapy of Neuropsychiatric Disturbances

*Jonathan M. Silver*  
*David B. Arciniegas*

### INTRODUCTION

The neuropsychiatric consequences of traumatic brain injury (TBI) are many and varied, but include problems such as depression, mania, affective lability, anxiety, apathy, psychosis, aggression, fatigue, and sleep disturbances, among others. Each of these conditions may occur as an independent problem following TBI, but often occur in combinations or partial forms that cross conventional diagnostic boundaries. These conditions most likely arise as a combination of pre-injury vulnerability factors (including pre-injury psychiatric problems, genetic issues, and psychosocial circumstances, etc.) and injury-related factors (location and/or severity of injury). Additionally, the development and persistence of such problems is often complicated by a host of post-injury factors including psychological responses, coping styles, social and economic circumstances, and medicolegal issues. The relationships between pre-injury, injury-related, and post-injury factors as they contribute to posttraumatic neuropsychiatric disturbances are complex (see Figure 52-1). Consequently, the task of understanding the development of neuropsychiatric problems in persons with TBI is necessarily a complex one. A complete review of these issues is beyond the scope of this chapter, and these problems are addressed in considerable detail elsewhere in this volume. Although we will offer some discussion of the most common posttraumatic neuropsychiatric disturbances in the

context of reviewing their pharmacologic treatments, clinicians should be mindful that these therapies should be prescribed only after a thorough and neuropsychiatrically-informed evaluation of each person for whom they are prescribed.

Regardless of the mechanisms by which they develop, the neuropsychiatric consequences of TBI complicate neurorehabilitative efforts and are a substantial source of suffering for those in who they develop. There are at present a host of therapeutic options for the neuropsychiatric consequences of TBI, including both non-pharmacologic and environmental interventions as well as pharmacotherapies. Similar to the treatment of psychiatric disorders such as depression, panic disorder, and obsessive-compulsive disorder, a combination of therapeutic interventions (e.g., medications, rehabilitative therapies, psychotherapies) administered simultaneously to the person with neuropsychiatric disturbances after TBI is often more effective than is treatment using only one of these modes of treatment. Individual, cognitive, behavioral, and family therapy, as well as environmental accommodations, may alleviate neuropsychiatric disturbances and improve recovery from and/or adjustment to TBI. Nonpharmacologic interventions are not addressed in the present chapter, but are instead reviewed in Chapter(s) elsewhere in this book. In the present chapter, we review the pharmacotherapy of these neuropsychiatric disturbances following TBI.

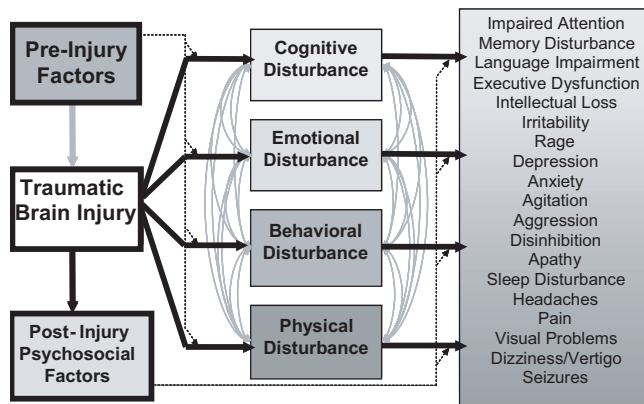

FIGURE 52-1

A schematic diagram of the complex interactions between pre-injury, injury-related, and post-injury factors that contribute to the development of neuropsychiatric disturbances following traumatic brain injury. The column on the left depicts each of the major contributing factors to neuropsychiatric outcome. Pre-injury factors such as impulsivity, risk-taking behaviour, and substance abuse may contribute to the occurrence of TBI. Depending on the location and severity of injury to the brain, cognitive, emotional, behavioral, and physical disturbances may arise from direct injury to brain structures serving each of these domains of neuropsychiatric function (middle column). Pre-injury variables such as baseline cognitive function, medical, neurological psychiatric, and/or substance use disorders may modify the effects of injury on each of these domains. After injury, symptoms in one domain may affect symptoms in one or more of the others (e.g., pain symptoms worsening attention, producing irritability, and contributing to agitation; depression worsening cognition, producing apathy, and increasing perceived severity of headache, dizziness, and other physical postconcussive symptoms; etc.). Problems in each domain of function contribute to presenting symptoms (partial list, far right). Post-injury factors such as social support, treatment and other rehabilitative interventions, socioeconomic status, and medicolegal issues may influence the expression, persistence, or remission of neuropsychiatric symptoms. Understanding the complex interactions that contribute to these symptoms informs the evaluation, diagnosis, and treatment of neuropsychiatric disturbances following TBI

### EVALUATION

For purposes of this discussion, we will assume that prior to initiating any pharmacologic treatment the treating clinician has completed a thorough psychiatric, developmental, and neurological history and examination. When considering the prescription of medications for posttraumatic neuropsychiatric symptoms, two issues require additional attention. First, the presenting complaints must be carefully assessed, defined, and operationalized, preferably through the use of objective rating scales such as the Neurobehavioral Rating Scale-revised (1, 2) or the

Neuropsychiatric Inventory (3), or more symptom-specific scales such as the Overt Aggression Scale (4) or Apathy Evaluation Scale (5). In addition to clarifying the type, frequency, and severity of symptoms prior to treatment, repeated use of such scales during treatment improves the accuracy and objectivity of monitoring treatment responses (both beneficial and adverse).

Second, the use and effectiveness of all ongoing treatments must be reevaluated, including pharmacologic and non-pharmacologic therapies, whether these are prescribed or self-administered. When reviewing the patient's current medication regimen, three key issues should be addressed: 1) the indications for all drugs prescribed, 2) whether currently prescribed medications are still necessary, and 3) the potential side effects of these medications. Patients who have had severe brain trauma may be receiving many medications that either result in or exacerbate psychiatric symptoms such as depression, mania, hallucinations, insomnia, nightmares, cognitive impairments, restlessness, paranoia, or aggression. Consultation with other treating clinicians may be required to decide whether a presently prescribed medication is necessary and/or whether a new medication might be helpful. Sometimes such treatments have not been properly applied, are predicated on misdiagnosis of the problem, or are the result of poor communication among treating professionals regarding the problem in question. In some cases, a potentially effective medication has not been beneficial because it has been prescribed in a dose that is too low and/or for a period of time that is too brief. In other instances, the most appropriate pharmacological recommendation is to eliminate some ongoing treatments. After a thorough assessment of both target symptoms and their treatments, the most useful recommendation will sometimes be to offer no medication at all and instead to use nonpharmacologic therapies.

### GENERAL PRINCIPLES OF PHARMACOLOGICAL TREATMENT OF PSYCHIATRIC SYNDROMES ASSOCIATED WITH TBI

There have been few controlled clinical trials to assess the effects of medication in persons with TBI. As suggested above, the decision regarding which medication (if any) to prescribe is based on: 1) current knowledge of the efficacy of these medications in other psychiatric disorders, 2) side effect profiles of the medications, 3) the increased sensitivity to side effects shown by patients with brain injury, 4) analogies from the brain injury symptoms to the recognized psychiatric syndromes (i.e., amotivational syndrome after TBI may be analogous to the deficit syndrome in schizophrenia), and 5) hypotheses regarding how the neurochemical changes after TBI may inform the

**TABLE 52-1**  
*General Principles of Pharmacotherapy for Patients with Traumatic Brain Injuries*

Start low, go slow	Initiate treatment at doses lower than those used in patients without brain injuries, and raise doses more slowly than in patients without brain injuries.
Adequate therapeutic trial	Although patients with brain injuries may be more sensitive to the side effects of many medications, standard doses of such medication may be needed to treat adequately the neuropsychiatric problems of these patients.
Continuous Reassessment	The need for continued treatment should be reassessed in an ongoing fashion, and dose reduction or medication discontinuation should be attempted after achieving remission of target symptoms. Spontaneous recovery occurs, and in such circumstances continued pharmacotherapy is unnecessary.
Monitor drug-drug interactions	Because patients with brain injuries are often sensitive to medication side effects and because they may require treatment with several medications, it is essential to be aware of and to monitor these patients for possible drug-drug interactions.
Augmentation	A patient experiencing a partial response to treatment with a single agent may benefit from augmentation of that treatment with a second agent with a different mechanism of action. Augmentation of partial responses is preferable to switching to an agent with the same pharmacologic profile at that producing the partial response.
Symptom Intensification	If targeted psychiatric symptoms worsen soon after initiation of pharmacotherapy, lower the dose of the medication; if symptom intensification persists, discontinue the medication entirely.

selection of medications based on current understanding of their proposed mechanisms of action.

There are several general guidelines that should be followed in the pharmacological treatment of the psychiatric syndromes that occur after TBI (see Table 52-1). In summary, these principles are:

- 1 Start low and go slow with regard to dosing.
- 2 Undertake a therapeutic trial of medications – define the target symptom, outcome, and treatment period clearly before treatment and adhere to the proposed treatment plan as much as possible.
- 3 Continuous reassessment of clinical condition, again using standardized scales to anchor that assessment wherever possible.
- 4 Identify possible drug-drug interactions prior to treatment and assess any adverse effects of treatment with this possibility in mind.
- 5 Augment partial response – if a single agent confers only incomplete relief of symptoms, consider augmenting that treatment response with an agent of different pharmacologic mechanism before discontinuing altogether a medication that is partially effective.
- 6 Discontinue or lower the dose of the most recently prescribed medication if there is a worsening of the treated symptom soon after the medication had been initiated (or increased).

Experienced clinicians often report that persons with TBI of any type are more sensitive to the side effects of

medications than are patients with similar psychiatric problems but no brain injury. Although our own experience echoes this suggestion, it is important to acknowledge that studies demonstrating increased medication sensitivity following TBI are few and that many persons with TBI appear to tolerate these medications reasonably well even at standard therapeutic doses. Nonetheless, it is prudent to raise and lower doses of psychotropic medications in relatively small increments over relatively longer time periods than might be done in general psychiatric practice (i.e., to use a “start low, go slow” approach).

When psychotropic medications are prescribed, it is important that they are given in a manner that increases the probability of benefit and minimizes the possibility of adverse reactions. It is also important that such medications be given sufficient time to impart their full effects. Thus when a decision is made to administer a medication, the patient must be offered a robust therapeutic trial of that medication, including gradual titration to maximally tolerated doses and maintenance of treatment for a period of time sufficient to fully evaluate their potential therapeutic effects. While it is important to alleviate the suffering of patients as quickly as possible, many psychotropic medications (e.g., antidepressants, anti-aggressive agents, etc.) must often be used for many weeks or longer before their benefits become fully apparent.

As noted above, continuous reassessment of neuropsychiatric symptoms during treatment is necessary to determine whether each prescribed medication is still required, particularly early after a TBI. Spontaneous recovery in the early post-injury period may change both

the need for such treatments and also their effects (beneficial and adverse) at a given dose in a dynamic fashion. Use of the aforementioned structured assessments (Neurobehavioral Rating Scale, Neuropsychiatric Inventory) may be of use in this regard, as these multidimensional scales permit both ongoing assessment of both target symptom response and also a measure with which to monitor for the development of new neuropsychiatric symptoms.

Although the literature regarding the pharmacotherapy of neuropsychiatric disturbances is evolving rapidly, few studies offer information regarding the optimal duration of these treatments and/or the issues pertaining to treatment discontinuation and relapse risk. Because spontaneous remission of some symptoms occurs over time, a previously necessary medication may at some point thereafter become unnecessary. If the patient has responded favorably to initial medication treatment for one or another neuropsychiatric problem after TBI, the clinician must use sound judgment and work together with his or her patient (and/or caregiver) in order to decide whether and/or when to taper and attempt to discontinue that treatment. In some cases, carryover effect of the medication may occur (i.e., its effects may persist after the duration of treatment), in which case a reinstatement of the medication may not be required. Extrapolating from treatment guidelines established for analogous conditions in persons without brain injury may be of some use in such medical decision-making. For example, the standard guidelines for the treatment of major depression offered by the American Psychiatric Association (2000) (6), which suggest that antidepressant treatment should be continued for 16–20 weeks following remission of depressive symptoms, may offer a reasonable framework within which to develop a treatment plan for post-traumatic neuropsychiatric disturbances.

When a new medication is initiated in combination with medications previously prescribed, the clinician must be vigilant for the development of drug-drug interactions. These interactions may include alteration of pharmacokinetics that result in increased half-lives and serum levels of medications, such as those that occur with the use of anticonvulsants or other agents that markedly affect hepatic metabolism or renal elimination. Additionally, alterations of pharmacodynamics may develop during the administration of medications with additive or synergistic clinical effects, such as increased sedation when several medications with otherwise tolerable sedative effects are administered simultaneously.

If a patient does not respond favorably to the initial medication prescribed, several alternative treatments are usually available. If there has been no response to treatment, switching to a medication with a different mechanism of action is suggested, much as is done in the treatment of patients without brain injuries. If there has

been a partial response to the initial medication, addition of another medication with a different mechanism of action may be both useful and more beneficial than abandoning entirely treatment with the partially effective agent. The selection of a supplementary (or augmenting) medication should be based on consideration of the possible complementary or contrary mechanisms of action of such agents, the individual and combined side effect profiles of the initial and secondary agents, and their potential pharmacokinetic and pharmacodynamic interactions.

While persons with TBI may experience multiple concurrent neuropsychiatric symptoms (i.e., depressed mood, irritability, poor attention, fatigue, and sleep disturbances) that seem to suggest a single “psychiatric diagnosis” such as major depression, it is not uncommon to observe persistence of some of these symptoms despite treatment of the apparent diagnosis. In other words, diagnostic parsimony should be sought but may not always be the best or most accurate diagnostic approach in this population. The neuropsychiatric approach of evaluating and monitoring individual symptoms is often the most useful one, even though it diverges from the more typical “syndromal” approach to treatment that is common in conventional psychiatric practice. In short, several medications may be required to alleviate several distinct posttraumatic neuropsychiatric symptoms. Nonetheless, it is prudent to initiate each treatment sequentially rather than concurrently in order to understand as clearly as possible both the beneficial and adverse effects of each medication prescribed.

Studies of the effects of psychotropic medications in patients with TBI are few, and rigorous double-blind placebo-controlled studies are rare (7). The recommendations contained in this chapter represent a synthesis of the available treatment literature in TBI, extensions of the known uses of these medications in phenotypically similar psychiatric populations, patients with other types of brain injury (e.g., stroke, multiple sclerosis, etc.), and the opinions of the authors based on our review of this literature. While recognizing that the pathophysiology of neuropsychiatric symptoms may differ between patients with TBI and those whose neuropsychiatric symptoms arise in the context of other neurological conditions or psychiatric disorders, and while acknowledging that generalization of response to treatment seen in the context of other forms of brain dysfunction (e.g., stroke, Alzheimer’s disease, schizophrenia) to TBI may not always be valid, the intent of this chapter is to offer clinicians guidance regarding the pharmacotherapy of posttraumatic neuropsychiatric disturbances. Where such are not available at all, we offer recommendations based on our experience in this area. Although it is our hope that such recommendations will be of use to clinicians working with persons with TBI, it is important to note that anecdotally-based recommendations must be regarded as entirely preliminary.

## PHARMACOLOGICAL TREATMENT OF SPECIFIC NEUROPSYCHIATRIC SYNDROMES

Posttraumatic neuropsychiatric symptoms are amenable to treatment with a variety of medications. In the following section, we review briefly each of the major neuropsychiatric symptoms and syndromes that may develop after TBI and discuss their most common pharmacologic treatments. This section is organized according to symptom and/or syndrome, and within each section pharmacotherapies are organized by medication class. Where such are able to be offered based on the literature, recommendations regarding the use of these medications and cautionary notes regarding their side effects are presented.

### EMOTIONAL DISTURBANCES

Emotional disturbances, including mood disorders and disorders of affect regulation, are common consequences of TBI and may be very detrimental to a patient's rehabilitation and socialization (8–12). The literature regarding treatment of these conditions after TBI is limited when compared to that for phenotypically similar primary psychiatric disorders, but is actively developing.

#### Depression

Depression after TBI is amenable to pharmacologic intervention, and may alleviate not only the mood disturbance but also reduce other postconcussive symptoms and the patient's experience of the severity of such symptoms (13). Although many factors (i.e., sleep disturbance, fatigue (anergia), difficulty concentration, anhedonia (apathy), etc.) may produce or contribute to apparent depressive symptoms, when there are sufficient symptoms to merit a diagnosis of depression – regardless of their other possible causes – antidepressant treatment should be initiated. It is, however, particularly important to distinguish between depression (a state of excessive and persistent sadness) and apathy (in which there is a loss of emotional responsiveness) before initiating treatment for depression; there is minimal overlap between the treatment of these conditions, and mistaking one of these conditions for the other may delay the delivery of the most appropriate treatments.

Somatic therapies for depression following TBI include several classes of antidepressant medications, including selective serotonin reuptake inhibitors, tricyclic and tetracyclic agents, novel antidepressants, monoamine oxidase inhibitors, and electroconvulsive therapy.

#### *Selective Serotonin Reuptake Inhibitors*

The selective serotonin reuptake inhibitors (SSRIs) include fluoxetine, sertraline, paroxetine, citalopram, escitalopram,

and fluvoxamine. Given the relatively favorable profile of the selective serotonin reuptake inhibitors (SSRIs) when compared to other presently available classes of antidepressants, these agents are suggested as the first-line treatment for depression following TBI.

Among these, the best evidence at the present time favors sertraline as a first-line treatment for depression following TBI. Fann et al. (2000) (13) describe improvement in depression secondary to mild TBI using sertraline (dose range 25–200 mg by end of study) in an 8-week, nonrandomized, single-blind, placebo run-in trial. This study included 15 patients with major depression diagnosed 3–24 months following mild traumatic brain injury. Thirteen (87%) had a decrease in Hamilton Rating Scale for Depression score of (50% (“response”), and 10 (67%) achieved a score of (7 (“remission”) by treatment week 8. Significant improvements were also observed in ratings of psychological distress, anger and aggression, functioning, and postconcussive symptoms during treatment, and only one patient discontinued treatment due to side effects. Similarly, Turner-Stokes et al. (2002) (14) performed an open-label trial of sertraline for depression following brain injuries, including TBI, in 21 adult patients. They report clinical improvement as assessed by DSM-IV criteria in all of these patients. Among the 17 patients able to complete the Beck Depression Inventory before and after treatment, significant decreases in depressive symptoms were associated with treatment in this group. Of these, 11 had failed previous treatment with a different selective serotonin reuptake inhibitor. These findings echo those of Fann et al. (2000) (13) and suggest that sertraline may be of significant benefit for depression following brain injury.

In a subsequent report, Fann et al. (2001) (15) describe sertraline treatment-related improvements in psychomotor speed, recent verbal memory, recent visual memory, and general cognitive efficiency, as well as improvements in patient perception of cognitive symptoms. Schmitt et al. (2001) (16) investigated the cognitive effects of several SSRIs on posttraumatic cognitive impairments, and their observations support and possibly inform the observation of Fann et al. (2001) (15). Schmitt et al. (2001) (16) observed significant improvements in verbal fluency among healthy middle-aged adults treated with sertraline 50–100 mg when compared to treatment with placebo. They attributed the cognitive benefits of this treatment to sertraline's modest ability to inhibit dopamine reuptake. As discussed in the chapter on the pharmacotherapy of cognitive impairment elsewhere in this volume, such increases of dopamine would be expected to improve frontally-mediated cognitive and behavioral function in this population. However, Meythaler et al. (2001) (17) performed a placebo-controlled trial of sertraline for arousal and attentional impairments in 11 subjects with severe TBI in the acute rehabilitation setting

and failed to find a statistically significant treatment effect on these cognitive functions. Although the authors of this study caution against over-interpretation of this finding in light of their small sample size, their findings suggest that neither the serotonergic or dopaminergic reuptake inhibition properties of this agent are sufficient to produce marked improvements in cognition among persons with recent, severe TBI. It is possible that in the context of milder injuries, such as were experienced by subjects included in the Fann et al. (2001) study (13, 15), treatment with sertraline may confer cognitive benefits on the basis of resolving depression alone, as a result of sertraline's modest dopaminergic augmentation of frontal lobe function, or both. Additional studies are needed to clarify the effect of sertraline on cognitive function in persons with TBI and depression.

Sertraline may also be of benefit for the treatment of irritability and aggression following TBI even when it is without specific benefit on related depressive symptoms. Kant et al. (1998) (18) describe reductions in posttraumatic irritability and aggression (as assessed using the Overt Aggression Scale-Modified for outpatients) during treatment of 13 patients with sertraline at doses of 50 mg or greater. Although some changes in depressive symptoms (as assessed using the Beck Depression Inventory) were also observed, these were not of a degree sufficient to produce statistical significance. It is possible that the relatively low-doses of sertraline used in this study were inadequate for the treatment of depression, but were sufficient to treat irritability-predominant affective lability; this suggestion is consistent with other reports describing the effects of low-dose SSRIs on such symptoms (reviewed later in this chapter).

Collectively, these reports suggest that sertraline may be of benefit in the treatment of depression following TBI, and that such treatment may reduce other affective and postconcussive symptoms as well. As with all of the SSRIs, gastrointestinal side effects during treatment with sertraline are not uncommon, although these are in many patients dose-related and/or transient (i.e., associated with treatment initiation or dose escalation). The relatively short half-life (approximately 26 hours) of this agent permits development of steady-state plasma levels within the first week of treatment in most patients; consequently, relief from intolerable side effects, when such develop, is usually afforded shortly after treatment discontinuation.

Several reports suggest that fluoxetine may be of benefit in the treatment of depression following TBI, but may be associated with a higher rate of adverse effects than is treatment with sertraline. Cassidy (1989) (19) conducted an open-label trial using fluoxetine for 8 patients with severe TBI and associated depression. They observed marked improvement in two patients and moderate improvement in three patients. Half of these patients experienced sedative side effects, and 3 out of 8 patients

reported an increase in anxiety. Wroblewski et al. (1992) (20) report a case in which fluoxetine 20 mg/day reduced depressive symptoms after treatment with desipramine alleviated depressive symptoms but precipitated post-traumatic seizures. At least one other report suggests that fluoxetine may be both useful and well-tolerated: Bessette and Peterson (1992) (21) observed a favorable response to fluoxetine 20 mg/day in a 41-year-old woman who experienced an episode of major depression after a minor brain injury.

Horsfield et al. (2002) (22) performed an eight-month open-label study of the effects of fluoxetine 20–60 mg/day in five patients with TBI and varying levels of depression in order to determine whether this medication conferred mood and/or cognitive benefits. They observed improvements in mood as well as improvement on several measures of attention, processing speed, and working memory in this small group of patients. Their findings are consistent with the observations of Fann et al. (2001) (15) with respect to an association between improvements in posttraumatic depressive and cognitive symptoms. Horsfield et al. (2002) (22) suggest that fluoxetine's ability to stimulate expression of brain derived neurotrophic factor and its specific tyrosine kinase receptor, which has in rodents been demonstrated to produce neuritic elongation and increased dendritic branching density of some hippocampal neurons, may explain the apparent benefits of this agent on posttraumatic cognitive impairments. While their suggestion is intriguing, support for it in experimental injury models is lacking. For the present, it is simpler to interpret their findings as reflecting the well-known activating effects of fluoxetine.

As with sertraline, the most common side effects of fluoxetine are gastrointestinal and these are often dose-related and/or transient. It is of note that anxiety and insomnia occur in approximately 20% of patients without brain injuries (23), which may offer some explanation for the rate of treatment-emergent anxiety associated with fluoxetine (19). Additionally, seizure during treatment with fluoxetine in a brain-injured patient has been reported (20). However, it is difficult to draw any conclusions regarding the safety (or efficacy) of this medication with respect to either seizure or any other adverse effects based upon the available literature. The authors remain circumspect with regard to the potential for fluoxetine to lower significantly the seizure threshold among persons with TBI, including those with post-traumatic epilepsy, based on our success with the use of this medication among persons with TBI. Nonetheless, the published observation of precipitation of post-traumatic seizures with this and other antidepressant medications (see below) suggests that the possibility of altering seizure threshold by their administration should not be dismissed offhandedly. At a minimum, we suggest that this possibility be discussed during the process of providing patients

with informed consent to treatment with these (or almost any) antidepressant agents.

Two case reports describe problematic drug-drug interactions with fluoxetine in persons with TBI. The first describes new-onset dysarthria and “speech blocking” when fluoxetine was added to trazodone in a man with a fall-related TBI (24). Both of these treatment-emergent symptoms resolved following discontinuation of fluoxetine. The second report describes the development of hypomania in a woman with depression following TBI who added St John’s wort and Ginkgo biloba to her ongoing regimen of fluoxetine and buspirone (25). Her hypomania remitted following discontinuation of these herbal agents. While these cases are presented in the context of fluoxetine for depression following TBI, it is important to note that these and other drug-drug interactions are possible during treatment with any of the SSRIs. As such, the reporting of such cases may or may not reflect a propensity for problematic drug-drug interactions with fluoxetine *per se*.

Despite these reports, we do not regard the rate of adverse effects during treatment with fluoxetine to be so problematic that its use in this population is precluded. In clinical practice, patients often benefit from treatment with this agent, and do so without untoward effects in the majority of cases. However, it is important to note that the average half-life of the primary and active metabolite of fluoxetine, norfluoxetine, is on average at least six days. Given that elimination of this metabolite requires 4–5 half-lives to complete, patients who develop treatment-emergent adverse effects with fluoxetine may continue to experience such effects for several weeks following treatment discontinuation. Therefore, while fluoxetine appears to be a reasonably effective treatment for depression following TBI, the possibility of prolongation of adverse effects during treatment of this agent makes it somewhat less favorable for this purpose than sertraline.

Paroxetine may be a useful treatment for depression in some patients, although there is at present only a single case report describing its use for the treatment of depression following TBI in a patient with “personality change – labile type due to traumatic brain injury” (26). The patient described might be understood as experiencing affective lability with some depressive features, and as such it is not clear that this study can be used to support the use of this medication for fully symptomatic depression following TBI. Nonetheless, paroxetine is in some cases used for this purpose and may be of benefit.

As with the other SSRIs, the most common side effects produced by paroxetine are gastrointestinal. Sedation is also a common side effect of paroxetine, occurring in almost 25% of general psychiatric patients receiving it (23). Additionally, this agent possesses more significant antimuscarinic properties than the other SSRIs (16, 27). These properties contribute to systemic anticholinergic

side effects such as dry mouth and constipation, and also pose risk for exacerbating cognitive impairments among persons with TBI. For example, Schmitt et al. (2001) (16) demonstrated that healthy middle-aged adults experienced significantly greater impairments of delayed recall in a word learning test during treatment with paroxetine 20–40 mg/day than during treatment with placebo, an effect that was attributed to paroxetine’s antimuscarinic properties. Given that TBI is associated with reduced cholinergic function in a significant number of patients (see Chapter 53), one would predict that this might place persons with TBI at risk for similar or greater degrees of cognitive impairment during treatment with this agent. Although this remains speculation at present, clinicians should remain mindful of this possibility when undertaking treatment with paroxetine in this population. As with fluoxetine, both the available literature and the potential for adverse cognitive effects of this agent suggest that paroxetine should be considered as a less favorable agent than sertraline for the treatment of depression following TBI.

At the time of this writing, the only report describing treatment with citalopram does so in combination with carbamazepine for the treatment of mood and other neurobehavioral problems following TBI (28). In an open-label fashion, subjects in this study were treated with 12 weeks of citalopram 20 mg/day and carbamazepine 600 mg/day. Clinical Global Impression ratings and Brief Psychiatric Rating Scale scores were determined before and after treatment with these agents, and were significantly improved by this combination therapy. These authors note that subjects with more remote TBI (24–36 months prior to study) improved to a lesser degree than did subjects with more recent TBI (within 6 months). It is not clear whether this observation reflects spontaneous recovery among the more recently injured subjects during the treatment period (i.e., a false-positive treatment response) or instead suggests improved treatment responsiveness in the early period following TBI. Additionally, the concurrent administration of both agents precludes attribution of the symptomatic improvements observed by the authors to either one of these agents alone.

As with the other SSRIs, common clinical experience suggests that some patients with depression following TBI will benefit from treatment with citalopram. The side effect profile, limited propensity for drug-drug interactions, and relatively short half-life of this agent make it attractive for use among persons with TBI. However, its use should be undertaken with caution pending additional data regarding its effectiveness and tolerability in this population.

At present, there are no reports regarding the use of either escitalopram or fluvoxamine for the treatment of depression following TBI. Our experience suggests that escitalopram is the more effective of these two for this

purpose and is similar to citalopram with respect to efficacy, tolerability, and drug-drug interactions. However, these agents should be used with caution pending further study of their effects and side effects among persons with depression following TBI.

### *Tricyclic and Tetracyclic Agents*

The development and use of tricyclic and tetracyclic antidepressants (TCAs) for posttraumatic depression antedates that of the SSRIs. The TCAs include imipramine, amitriptyline, trimipramine, desipramine, nortriptyline, maprotiline, doxepin, and protriptyline. Since the advent of the SSRIs, the TCAs are used less commonly as first-line agents for the treatment of depression in general as well as for depression following TBI. This may in part reflect concerns regarding the possibility of increased side effects associated with these agents, reports of more limited effectiveness of these agents among persons with TBI, waning familiarity with the use of these agents on the part of recently trained clinicians, or some combination of these factors. Regardless of the reasons for the more limited use of TCAs presently, there is less evidence to support the use of these agents for the treatment of depression following TBI than for the SSRIs. Additionally, there is evidence suggesting that these agents may not be as effective in the treatment of depression following TBI as they are for idiopathic major depressive episodes.

For example, Saran (1985) (29) conducted a crossover study of phenelzine and amitriptyline administered at therapeutic doses to ten patients with "minor brain injury" and twelve patients with major depressive symptoms but without TBI. All of the patients with idiopathic major depressive symptoms improved after 4 weeks of amitriptyline but none of the TBI patients improved. More recently, Dinan and Mobayed (1992) (30) reported 85% of patients with major depressive disorder responded to amitriptyline while only 31% of similarly depressed TBI patients responded to this treatment. In contrast to these discouraging reports, Varney et al. (1987) (31) found that 82% of 51 patients with major depressive disorder and TBI who received treatment with either TCAs or carbamazepine reported at least moderate relief of depressive symptoms. Collectively, these observations offer only modest support, at best, for the use of amitriptyline for depression following TBI. The authors do not recommend use of amitriptyline as a first-line therapy for the treatment of posttraumatic depression both as a result of its modest beneficial effects in this population and in light of the availability of newer, less problematic, and more consistently effective antidepressants.

Among the newer TCAs, nortriptyline and desipramine are used more commonly in clinical practice. However, there remains very limited evidence to guide their use and with which to assess the risks entailed by their use

in persons with TBI. Wroblewski et al. (1996) (32) performed a modified, blinded, placebo lead-in treatment study of ten patients with depression following severe TBI using desipramine and observed improvement in six of seven (86%) of patients able to complete the study. However, three patients (30%) discontinued the study, including one that developed seizures and one that developed treatment-emergent mania. An additional patient experienced a seizure during treatment with desipramine but continued treatment with this medication nonetheless. While this study suggests that desipramine may be effective for the treatment of depression in some persons with TBI, its use may also be associated with more significant adverse effects than the SSRIs. A single report offers little evidence with which to guide clinical practice, but the findings from this study should be considered by clinicians and their patients prior to undertaking treatment with desipramine as a first-line agent.

When a TCA is prescribed for depression following TBI, nortriptyline is the one used most often. This may in part reflect its more favorable side effect profile in comparison to the other TCAs as well as its established effectiveness for the treatment of depression following stroke (33). However, stroke is not pathophysiologically equivalent to TBI, and studies describing antidepressant efficacy following stroke may not be equally applicable to the treatment of depression following TBI. Both stroke and TBI may produce discrete white matter lesions that interrupt catecholaminergic or serotonergic pathways, and mood disorders following such injuries may result from dysfunction in these neurotransmitter systems. However, many persons with TBI do not suffer discrete lesions to these systems, but instead experience diffuse axonal injuries. The latter may modestly affect ascending catecholaminergic or serotonergic pathways, but also disrupts glutamatergically-dependent systems, cholinergic projections, other cortico-cortico and cortico-subcortical pathways, and cortical and subcortical structures. Additionally, TBI commonly involves bihemispheric injury, whereas as bihemispheric injury is rare following a single stroke. Therefore, the neuroanatomic and neurochemical consequences of TBI may not be equivalent to those resulting from stroke. These differences would suggest that there should be differences in both antidepressant treatment effects and also side effects in these two populations.

Based on the available evidence, we regard SSRIs as first-line treatment for depression following TBI. In the event that these agents fail and a TCA is considered subsequently, we suggest use of either nortriptyline (initial doses of 25 mg/day) or desipramine (initial doses of 25 mg tid) following careful informed consent of the patient regarding the potential side effects and complications of these treatments. Treatment should proceed slowly, with incremental dose increases no more often than weekly.

Careful monitoring of plasma levels of the parent compound and its major metabolites should be undertaken, with a goal of driving levels into the therapeutic range while assessing the clinical effects of treatment at such doses/levels (e.g., nortriptyline levels 50–100  $\mu\text{g/mL}$ ; desipramine levels greater than 125  $\mu\text{g/mL}$ ).

The most common and disabling side effects of tricyclic and tetracyclic antidepressants in patients with neurological disorders are those associated with the anticholinergic properties of these medications, which can impair attention, concentration, and memory. For example, patients with Parkinson's disease not infrequently experience increased confusion when treated with anticholinergic medications (34, 35). Experimental evidence in traumatically brain-injured rats supports this observation (36, 37), as does common clinical experience in the treatment of patients with TBI. Such observations are consistent with the observed effects of both experimental and human TBI on cortical cholinergic function. Amitriptyline, trimipramine, doxepin, protriptyline have high affinities for the muscarinic receptors. Given their strong anticholinergic properties, these medications should be prescribed only after careful consideration (and preferably empiric trials) of potentially less problematic antidepressants.

If side effects such as sedation, confusion, or symptomatic hypotension (orthostatic or otherwise) develop, dose reductions may either alleviate these effects and/or permit patients time to accommodate to them. If the patient's side effects abate following such dose reduction, gradual dose escalation may in some cases proceed without recurrence of these side effects. However, when these or other side effects limit TCA dosing to sub-therapeutic levels, either augmentation strategies or a switch to a different medication may need to be considered.

TCAs also may be associated with non-trivial rates of serious adverse events, and in particular seizures. Wroblewski et al. (1990) (38) reviewed the records of 68 patients with TBI who received antidepressant, and predominantly tricyclic antidepressant, treatment for at least 3 months. The frequency of seizures was compared for the 3 months before treatment, during treatment, and after treatment. Seizures occurred among 6 patients during the baseline period, 16 patients during antidepressant treatment, and 4 patients after treatment was discontinued. Fourteen patients (20%) had seizures shortly after the initiation of treatment. For 12 of these patients, no seizures occurred after treatment with the antidepressant was discontinued. Importantly, 7 of these patients were receiving anticonvulsant medication before and during antidepressant treatment. Also, the occurrence of seizures was related to greater severity of brain injury. Although our experience suggests that the rate of seizures during treatment with TCAs in the late period following TBI is not as high as that observed by Wroblewski et al. (1990) (38),

clinicians should be mindful of the potential for this serious adverse effect when prescribing TCAs to persons with TBI.

### *Novel Antidepressants Duloxetine*

The novel antidepressants include venlafaxine, mirtazapine, trazodone, nefazodone, and bupropion. Khouzam and Donnelly (1998) (39) report a reduction in TBI-induced compulsive behavior in response to treatment with venlafaxine. Teng et al. (2001) (40) describe the use of bupropion for treatment-resistant restlessness in a patient with severe TBI during acute rehabilitation. However, at the time of this writing neither these nor any other reports offer describe the beneficial or adverse effects associated with the use of these agents for the treatment of depression following TBI.

Common clinical experience suggests that many of these agents may be useful in the treatment of depression following TBI, but their use must be undertaken knowing that there has been no published information in this population to assist clinicians in ascertaining likelihood of benefit and the risk of adverse consequences. Due to the concern about hepatotoxicity with nefazodone, we reserve this medication for individuals who have not been responsive or tolerant to other antidepressants. Of note, bupropion is often suggested to be associated with a higher incidence of seizures in otherwise healthy psychiatric patients (41, 42). Such suggestions prompt caution prior to prescribing these agents in patients with depression following TBI. However, Johnston et al. (1991) (43), in a 102-site study of 1, 986 patients treated with bupropion for depression, report seizure rates of 0.24–0.40%. Among patients receiving bupropion 300 to 450 mg/day, the cumulative rate of seizure was 0.36%. This large data set suggests that bupropion may not be more likely to reduce seizure threshold than other antidepressants. Whether the same is true of bupropion's effects on seizure threshold following TBI is not at present clear. While it may be overly cautious to suggest avoiding use of this agent for the treatment of depression following TBI, in the absence of additional data clinicians should regard bupropion as likely to demonstrate the same dose-dependent seizure risk in persons with TBI as in the general population, and should consider the possibility that the dose at which this increased risk emerges may be lower among persons with TBI than in the general population. Pending clarification of this issue, bupropion should be considered a second-line treatment for depression following TBI.

### *Monoamine Oxidase Inhibitors*

Monoamine oxidase inhibitors (MAOIs) are not often used in persons with depression following TBI. This may reflect the high likelihood of difficulties with patient

adherence to the complex dietary restrictions required during use of these medications, and particularly among persons with significant posttraumatic cognitive impairments. Additionally, the literature offers little support for the effectiveness of these medications in the TBI population. In the studies by Saran (1985) (29) and Dinan and Mobayed (1992) (30) described above, phenelzine was not beneficial for the treatment of posttraumatic depression, including depression that had failed to respond to treatment with amitriptyline. Moclobemide, a selective, reversible MAO-A inhibitor, afforded improvement in 23 of 26 (88%) of patients with depression following TBI (44). Because moclobemide reversibly inhibits the isoenzyme MAO-A, its use does not entail the strict dietary prohibitions associated with other MAOIs. However, moclobemide is not available in the United States.

### *Other Agents*

Depressed mood due to TBI may respond to treatment with methylphenidate. Gualtieri and Evans (1988) (45) reported significant improvement on ratings of mood and cognitive performance among 15 patients with TBI following treatment with methylphenidate using a double blind, placebo-controlled crossover design study. These results were modest but suggestive of a possible role for methylphenidate in the treatment of both cognitive and mood disturbances following TBI. Although other studies offer support for the role of methylphenidate in the treatment of cognitive impairment following TBI (see Chapter 53), it is not clear if or for how long such benefits on either mood or cognition might be sustained by this treatment. Common clinical experience suggests that dextroamphetamine may be similar in its effects on mood and cognition following TBI, but no reports document a clear role for this medication in the treatment of depression following TBI.

We suggest that these medications be regarded as potential adjunctive rather than primary agents for the treatment of depression following TBI, particularly among patients with both significant depressive symptoms and also marked cognitive impairments of the sort that usually respond to treatment with stimulants (see Chapter 53).

### *Electroconvulsive Therapy*

Electroconvulsive therapy (ECT) remains a highly effective and underutilized modality for the treatment of depression in general, and it appears to be an effective treatment of depression following acute TBI (46–48). Kant et al. (1999) (49) reported on the safety and efficacy of ECT in patients with head injury in a retrospective review of 11 patients hospitalized as a result of neuropsychiatric problems after TBI. Of these subjects,

9 experienced a major depression or other mood disorder due to TBI. All of these patients responded favorably to ECT as assessed by the Montgomery-Asberg Depression Rating Scale and Global Assessment of Functioning Scale, and did so without significant adverse cognitive or physical sequelae. Functional improvement occurred irrespective of baseline cognitive functioning or severity of injury. These studies suggest that ECT may be a safe treatment for chronic and severe neuropsychiatric disorders due to TBI. When used, we recommend treatment with the lowest possible energy levels that will generate a seizure of adequate duration (greater than 20 seconds), using pulsatile currents, increased spacing of treatments (2–5 days between treatments), and fewer treatments in an entire course (four to six). If the patient also suffers from significant cognitive (especially memory) impairments due to TBI, nondominant unilateral ECT may be the preferred technique if this treatment is used.

### *Seizures and Antidepressants*

As noted above, some SSRIs, TCAs, and novel antidepressants may increase the risk for seizures during treatment of depression following TBI. This issue is raised frequently in clinical practice, but the magnitude of the risk posed by such treatments is unclear. Among patients with established epilepsy, Ojemann et al. (1987) (50) found that seizure control does not appear to worsen if psychotropic medication is introduced cautiously and if the patient is on an effective anticonvulsant regimen. There are, at present, no indications that treatment of depression in patients with posttraumatic epilepsy differs from that in patients with epilepsy of other etiologies. While we conclude that antidepressants can be used safely and effectively in patients with TBI, including patients with post-traumatic epilepsy, we recommend that these agents be prescribed with caution and that treatment with them include assiduous monitoring for change in seizure frequency.

### *Other Drug-Drug Interactions with Antidepressants*

In addition to those already noted above, there are several important drug interactions that may occur among antidepressants and other drugs commonly prescribed for neurological conditions (51). Many antiparkinsonian drugs and neuroleptics have anticholinergic effects that are additive to those of the antidepressants. Antidepressant levels are likely to be decreased—often below therapeutic range—by the anticonvulsants phenytoin, carbamazepine, and phenobarbital. Similarly, antidepressants such as fluoxetine may raise the plasma levels of the anticonvulsants phenytoin (52), valproic acid (53), and carbamazepine (54). Carbamazepine induces the metabolism of sertraline, and may therefore entail increased doses of the latter

during treatment with the former. Patients receiving treatment with medications that require therapeutic blood level monitoring should have more frequent monitoring when antidepressants are administered.

### **Mania**

Mania and bipolar disorder are less common consequences of TBI, although we believe that they are often underdiagnosed conditions in this populations. Treatment of acute manic states may include any of several pharmacologic approaches, including use of atypical antipsychotics, typical antipsychotics, anticonvulsants, and/or benzodiazepines. Prophylaxis against manic episodes is typically undertaken with lithium carbonate, carbamazepine, or valproate. There are very few reports regarding the treatment of mania following TBI (discussed below), whether that treatment is for acute manic states or for long-term prophylaxis against recurrent mania. The studies performed to-date suggest that treatment with lithium carbonate, carbamazepine, and valproate may be useful in this population as well.

Although there is emerging enthusiasm in general psychiatry for the use of other agents, including several of the newer anticonvulsants (e.g., lamotrigine, oxcarbazepine) and atypical antipsychotics (e.g., risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, etc.) for prophylactic treatment of persons with bipolar disorder, there are no reports regarding the use of these agents in persons with TBI. In light of the uncertainty regarding the efficacy and safety of these agents in this population, these agents will not be considered here in detail for this purpose. Clinicians interested in applying these agents to the treatment of persons with mania due to TBI are advised to undertake such treatments as a second-line effort following trials of the agents for which there is published data and/or after consultation with an expert in the treatment of secondary manic syndromes.

### **Lithium**

Several small cases series suggest that lithium carbonate may be useful for the treatment of mania following TBI, although partial response, relapse of symptoms, or need for a second mood stabilizer are common (55–60). Lithium appears more likely to produce nausea, tremor, ataxia, and lethargy in persons with neurological disorders than in the general psychiatric population. In addition, lithium may lower seizure threshold (61). Additionally, patients with mania after TBI may respond to treatment with lithium despite relatively low blood levels (e.g., 0.2–0.5 mEq/L). Collectively, these observations highlight the need for both a “start-low, go-slow” approach to the care of these patients and also a dosing strategy that targets symptoms rather than ostensibly “therapeutic” blood levels.

As a cautionary note, lithium has been reported to aggravate confusion in patients with brain damage (62). Consistent with that report, Hornstein and Seliger (1989) (63) reported a patient with preexisting bipolar disorder who experienced a recurrence of mania after closed head injury. This patient’s mania, before injury, was controlled with lithium carbonate without side effects. However, subsequent to brain injury, impaired attention emerged during treatment and abated when the lithium dose was lowered. Because lithium carbonate may exacerbate cognitive impairments or cause confusion, especially in combination antidepressants, anticonvulsants, and antipsychotic medications, we suggest limiting the use of lithium in patients with TBI to those with mania or recurrent depressive illness that preceded their brain damage and who previously responded well to this treatment. To minimize lithium-related side effects, we begin with low doses (300 mg/day) and titrate cautiously to beneficial effect or medication intolerance.

### **Carbamazepine**

Manic episodes occurring after TBI may also respond to carbamazepine (64, 65), although sometimes only after addition of lithium (65) or antipsychotics (57, 66). Because carbamazepine may produce or exacerbate cognitive impairments among persons with TBI (67), monitoring for this adverse effect when using this agent in patients with TBI is suggested. Additionally, brain injury appears to increase susceptibility to neurotoxicity induced by combination therapy with carbamazepine and lithium (55). For patients with mania subsequent to TBI, carbamazepine should be initiated at a dosage of 200 mg BID and in most cases adjusted to obtain plasma levels of 8–12 µg/ml. As with lithium, targeting symptoms is more important than adjusting dosing to achieve a specific blood level.

As is true for patients without histories of TBI, clinicians should be aware of the potential risks associated with carbamazepine treatment, particularly bone marrow suppression (including aplastic anemia) and hepatotoxicity. Complete blood counts and liver function tests should be regularly monitored (68). The most common signs of carbamazepine-induced neurotoxicity include lethargy, confusion, drowsiness, weakness, ataxia, nystagmus, and increased seizures. Pleak et al. (1988) (69) described the development of mania, irritability, and aggression with carbamazepine treatment. In our experience, this reaction is highly unusual and does not reflect a problem of serious concern regarding the use of carbamazepine for posttraumatic mania more generally.

### **Valproate**

Pope et al. (1988) (70) suggest that sodium valproate may be a useful mood stabilizer for patients with symptoms of

bipolar disorder following TBI, and Monji et al. (1999) (71) suggest that this benefit may extend to patients with rapid cycling mood disorders following TBI. In these retrospective report, patients with such symptoms after TBI appeared to respond more robustly than those with similar symptoms in the absence of TBI (88% vs 46%). The small sample sizes in this study do not permit extrapolation of this observation to TBI patients more generally, but are nonetheless encouraging of the use of this medication in the TBI population.

At present, we regard valproate as first-line treatment for mania following TBI. Valproate is begun at a dosage of 250 mg BID and gradually increased to obtain plasma levels of 50–100 µg/ml. As with carbamazepine, valproate may exacerbate cognitive impairments (67), although it appears less likely to do so than either carbamazepine or lithium. Nonetheless, its use should include careful and ongoing assessment of cognition. Tremor, weight gain, and diarrhea are common side effects of valproate. Although most patients tolerate valproate-induced tremor reasonably well, treatment-related weight gain is a common reason for treatment discontinuation. Hepatotoxicity is rare complication of treatment with valproate, and its occurrence is more commonly observed among children receiving concurrent treatment with multiple anticonvulsants (72).

#### *Other Anti-Manic Agents*

For mania or manic-like syndromes after TBI that do not respond to conventional mood-stabilizing therapies, relatively more novel approaches may be useful to consider. As noted earlier in this section, newer anticonvulsant agents and/or atypical antipsychotics are sometimes used in clinical practice with reasonable effect. There are no data at present with which to guide selection or inform treatment expectations, so clinicians should proceed with caution and vigilance for treatment-emergent side effects when using these agents.

Bakchine et al. (1989) (73) describe a manic-like state in a 44-year-old right-handed woman with bilateral orbitofrontal and right temporoparietal traumatic contusions that responded to clonidine after the patient's behavior failed to respond to carbamazepine and worsened with levodopa. Dubovsky et al. (1987) (74) and Levy and Janicak (2000) (75) suggest that verapamil may be a useful agent for the treatment of mania, whether this agent is used alone or in combination with other mood stabilizers. To-date, there are no studies of verapamil for the treatment of mania following TBI, but this agent might be worth considering when other conventional treatments fail or produce intolerable side effects. Clark and Davison (1987) (76) also report that ECT effected improvement in manic symptoms following non-penetrating trauma, and the authors suggest that this therapy may be valuable

to consider among persons with posttraumatic mania that fail to respond to pharmacotherapy for this condition.

#### **Affective Dysregulation (affective lability and pathologic crying/laughing)**

In contrast to mood disorders, conditions in which the baseline emotional state is pervasively disturbed over a relatively long period of time (i.e., weeks), disorders of affect denote conditions in which the more moment-to-moment variation and regulation of emotion is disturbed. The classic disorder of affective dysregulation is pathological laughing and/or crying (PLC), also known as “emotional incontinence” or “pseudobulbar affect.” Patients with this condition experience episodes of involuntary crying and/or laughing that may occur many times per day, are provoked by trivial (i.e., not sentimental) stimuli, are quite stereotyped in their presentation, uncontrollable, do not evoke a concordant subjective affective experience, and do not produce a persistent change in the prevailing mood (77). In this classic presentation, PLC appears to be a relatively infrequent (5.3%) consequence of TBI (78). Affective lability differs from PLC in that both affective expression and experience are episodically dysregulated, the inciting stimulus may be relatively minor but is often somewhat sentimental, the episodes are somewhat more amenable to voluntary control, and the paroxysms of affect are less stereotyped. As with PLC, these episodes do not produce a persistent change in mood. The prevalence of affective lability following TBI is not clear, although Jorge and Robinson (2003) (79) suggest a 1-year prevalence of approximately 12% among persons with TBI. Both PLC and affective lability are sources of significant distress and embarrassment to patients that otherwise, and quite correctly, report their mood as “fine” (euthymic). These conditions may not be understood properly by clinicians that interpret emotional disturbances only in terms of the DSM-based diagnostic system.

Although the neurobiology of mood and affect regulation overlap, the treatment of affective dysregulation in patients with brain injury overlaps with but is not identical to the treatment “uncomplicated” depression following TBI (80–84). The treatment literature overwhelmingly supports the use and effectiveness of relatively low-doses (often below typical antidepressant doses) of serotonergically and noradrenergically active antidepressants (82, 85–87), and to a lesser extent dopaminergic (88) and noradrenergic (89, 90), agents for the treatment of PLC and affective lability. Whether the lack of distinct therapies for these two disorders of affect reflects inseparable commonalities in their neurobiology or is instead an artifact of the diagnostic heterogeneity of patients included in the available treatment reports is unclear (11). It is noteworthy that the majority of treatment studies of these

problems derive from the stroke literature. Nonetheless, similar findings in multiple case series that include both persons with stroke and persons with TBI support the benefit of agents with serotonergic, dopaminergic, and noradrenergic properties for the treatment of PLC and/or affective lability following TBI.

### *Selective Serotonin Reuptake Inhibitors*

There are multiple reports of the beneficial effects of fluoxetine for “emotional incontinence” secondary to neurological disorders (81, 83) including TBI (84, 91). Brown and colleagues (1998) (92) treated 20 patients with post-stroke “emotionalism” (either PLC or affective lability) with fluoxetine in a double-blind placebo-controlled study. Those individuals receiving fluoxetine exhibited statistically and clinically significant improvement. In general, these investigators began treatment with 20 mg/day of fluoxetine, and patients often exhibited response within 5 days. The authors of this chapter have had similar success with fluoxetine both at low and also higher doses (40–80 mg/day) as well as with sertraline at doses ranging from 25–100 mg/day. A single-case report (93) and a small open label trial (94) demonstrated reductions in affective lability during treatment with paroxetine. The latter of these studies (94) also compared the effectiveness of paroxetine with citalopram for the treatment of affective lability after brain injury; while both medications effective for the treatment of affective lability, citalopram was the better tolerated medication. While only 2 of 26 patients included in the series described in this study were patients with TBI (the remainder being patients with strokes), both of these patients remained treated successfully for 1 year with paroxetine and experienced recurrent symptoms of affective lability after drug discontinuation. Andersen et al. (1999) (95) also describe improvement in episodic crying following TBI in a 6-year old child with citalopram 2.5 mg daily. As is often seen in the treatment of affective lability, treatment response occurred within 2 days of beginning treatment, a response more rapid than that usually encountered in the treatment of depressed mood/major depressive episode. Collectively, these reports suggest that the SSRIs are effective treatments for affective lability and PLC following TBI, and we recommend them as first-line agents for this purpose.

### *Tricyclic and Tetracyclic Antidepressants*

TCAs may also be effective for affective lability and PLC. Allman (1992) (96) described a marked decrease in pathological laughter in a patient treated with imipramine 150 mg/day, with improvement occurring by the second week of treatment. Common clinical practice, derived from the use of tricyclic antidepressant for PLC and affective lability following stroke (86), suggests that nortriptyline may

be of considerable benefit to patients with these conditions following TBI and may be effective at doses lower than those generally used to treat major depressive episodes (25–75 mg/day in many cases). However, we emphasize that for many patients it may be necessary to administer TCAs at standard antidepressant dosages to obtain full therapeutic effects, even when patients begin responding within days of initiating treatment at relatively low doses. Given the less favorable side effect profile of TCAs in this population, we recommend these as second-line agents for the treatment of affective lability and PLC following TBI.

### *Catecholaminergically-Active Agents*

Although psychostimulants and other medications that enhance dopamine and/or norepinephrine neurotransmission are used most often for the treatment of cognitive impairments and/or diminished motivation following TBI, they may also offer some relief from affective lability during treatment of these other problems as well. Evans et al. (1987) (90) reported reduced affective lability, as well as cognitive improvements, in a young man treated with methylphenidate or dextroamphetamine during a single-case, double-blind, placebo-controlled, dose-response study. Gualtieri et al. (1989) (97) describe sustained reduction of agitation and aggression, decreased distractibility, and improvement in affective stability among 19 of 30 TBI patients taking amantadine 50 to 400 mg/day (average dose of 290 mg/day). Udaka et al. (1984) (88) also report reductions of pathologic laughing and crying in response to amantadine or levodopa in approximately 50% of stroke or TBI patients. When patients present with affective lability or PLC in addition to cognitive and/or motivational impairments, methylphenidate, dextroamphetamine, amantadine, or levodopa may offer some relief from all of these problems.

### *Other Agents for Affective Lability*

In the event that the first-line therapies (i.e., serotonergically and/or dopaminergically active agents) do not provide adequate relief from affective lability following TBI, particularly if affective lability is comorbid with post-traumatic aggression, treatment with “mood stabilizing” (or, more appropriately in this context, “affect stabilizing”) agents may be necessary and of some benefit. Glenn et al. (1989) (98) describe an open-label trial of lithium carbonate for the treatment of affective instability and aggressive behavior in 10 patients (8 TBI and 2 stroke). The patients’ symptoms included episodic aggressive or self-destructive behavior, “mood swings,” tearfulness, and euphoria. Six of these patients demonstrated marked or moderate improvement in these target symptoms, one improved transiently, one failed to respond, and two

patients worsened with this treatment. Three patients were on concomitant neuroleptic therapy and experienced neurotoxic side effects that prompted discontinuation of the lithium. Additionally, one patient experienced decreased attentiveness and one patient experienced a seizure during this treatment. Lithium levels associated with clinical improvement ranged between 0.5–1.4 mEq/L.

Lewin and Sumners (1992) (99) describe a single case report of carbamazepine treatment of posttraumatic “episodic dyscontrol,” a term used in their report to denote uncontrolled disproportionate episodic violence, depression, and tearfulness, as well as irritability towards and intolerance of others. Treatment with carbamazepine 200 mg/day produced a good response, with no violent outbursts over the 12-month period of observation.

These reports suggest possible benefits of either lithium or carbamazepine for the treatment of some forms of affective lability following TBI, particularly in the setting of prominent episodic irritability and/or aggression. However, and as noted before, a cautious approach to dosing and continuous reassessment of benefit and adverse effects is needed in this population when using such agents.

### **Anxiety Disorders and Post-Traumatic Stress Disorder**

Anxiety disorders, including generalized anxiety disorder, panic disorder, phobias, obsessive-compulsive disorder, and/or post-traumatic stress disorder, may develop following TBI and may be a source of substantial morbidity for persons with these problems. When any of these conditions are present, clinicians should carefully assess patients for other comorbid DSM-IV Axis I or II conditions (100) that may be driving the anxiety symptoms, most notably depression, and treat these other conditions before specifically targeting anxiety symptoms. When no other comorbid neuropsychiatric condition is present, treatment should of course primarily focus on the anxiety symptoms.

Although the treatment of anxiety disorders following TBI may require medications, we generally prefer to treat complaints of anxiety in brain injury patients with supportive psychotherapy and social interventions before adding an anxiolytic medication. However, when anxiety symptoms are so severe that they require pharmacological intervention, treatment with SSRIs, benzodiazepines, or buspirone may need to be considered. There are no published reports describing the treatment of anxiety disorders following TBI. Consequently, the recommendations offered here are derived from our clinical experience and are at best preliminary.

#### *Selective Serotonin Reuptake Inhibitors*

We prefer SSRIs for the treatment of anxiety disorders following TBI given their considerable benefits on a host of

anxiety disorders in the general psychiatric population and also their relatively favorable efficacy and tolerability for other neuropsychiatric consequences of TBI. As noted earlier, the pharmacologic profiles of sertraline and escitalopram, as well as their well established efficacy in the treatment of anxiety disorders in non-brain injured persons, make these agents particularly attractive anxiolytics in this context. Since fluoxetine is associated with increased anxiety even among non-brain injured persons, it may not be the best agent with which to treat anxiety following TBI. Additionally, and as reviewed earlier in this chapter, the anticholinergic effects of paroxetine limit our enthusiasm for its use in this population despite its purported anxiolytic benefits in the general psychiatric population.

#### *Benzodiazepines*

When SSRIs fail to produce adequate and sustained anxiolysis, it may be necessary to consider treatment with a benzodiazepine or buspirone. Although benzodiazepines offer the benefit of rapid anxiolysis, their use among persons with TBI is concerning given their tendency to produce a variety of potentially problematic side effects. These agents predictably produce sedation and impair memory (101–103) even at therapeutic doses. Problems with balance, ataxia, and coordination that occur subsequent to brain injury are likely to be exacerbated by benzodiazepines. Walburga et al. (1992) (104) examined the effects of anxiolytic medications (buspirone and diazepam) on driving performance of outpatients with generalized anxiety disorder who had no neurological impairment. Each week, subjects were tested for driving ability by a 100-kilometer on-the-road driving test. Subjects who received diazepam demonstrated significantly impaired performance in the first, second, and third weeks. No impairment was detected in the subjects who received buspirone. The likelihood of similar or worse effects among TBI patients is not trivial, and poses serious concerns with respect to the effect of benzodiazepines on both everyday function and potentially risky endeavors such as driving or operating heavy machinery. Finally, in light of the fact that TBI is not uncommonly associated with pre-injury alcohol and/or drug problems, prescribing benzodiazepines for these patients may carry risks of not only dependence to these agents but also additional morbidity among those at risk for relapsing into alcohol abuse/dependence.

This constellation of adverse effects that make the use of benzodiazepines for the treatment of anxiety in patients with brain injury undesirable, and their use as first-line treatments for anxiety following TBI is not encouraged. When these agents are used, agents with moderate half-lives (lorazepam, oxazepam) are preferable to those with very short half-lives (which are highly

reinforcing and may produce rebound anxiety between doses) or very long half-lives (which may result in cumulative adverse effects with repeated administrations).

### *Buspirone*

Gualtieri (105, 106) observed “decreased anxiety, depression, irritability, somatic preoccupation, inattention, and distractibility” among four of seven patients with “post-concussion syndrome” during treatment with buspirone. As noted above, buspirone appears to carry less risk of worsening cognitive functioning in patients with TBI than benzodiazepines (104), and use of buspirone is not associated with dependency to this medication. As such, buspirone may be useful as a treatment for anxiety following TBI.

When used for this purpose, starting doses of buspirone are generally in the 5 mg BID to TID range. Gradual increases to as much as 15 mg TID are not uncommon. Side effects from buspirone include dizziness, lightheadedness, and (in rare cases) paradoxically increased anxiety. Unfortunately, buspirone’s therapeutic effects appear to require several weeks to develop. This prolonged latency of action sometimes necessitates short-term treatment with another anxiolytic, usually one of the benzodiazepines, and/or more intensive psychotherapy in order to keep the patient engaged in the use of this medication.

### **APATHY**

States of diminished motivation, or apathy, are common consequences of traumatic brain injury (18). It is important to be clear that in this context the term diminished motivation does not carry the connotation of “poor effort” or malingering that is sometimes associated with the use of this term in medicolegal contexts. Instead, the terms diminished motivation and apathy are used here to denote a neuropsychiatric syndrome in which there is a clinically significant decrease in goal-directed cognition, emotion, and/or behavior (107). Each of these three elements of the apathy syndrome may be present in varying degrees in individual patients; when present to any degree, they may interfere with rehabilitation efforts and functioning in everyday life (108). Apathetic states occur on a continuum of severity, with states of mildly diminished motivation at one end that continuum and akinetic mutism at the other end.

Although diminished motivation may be a feature of other neuropsychiatric conditions (109), and most notably depression, the syndrome of apathy also occurs independently of these conditions (110). Kant et al. (1998) (111) examined the prevalence of apathy in 83 consecutive persons with TBI seen in a neuropsychiatric clinic. Approximately 11% demonstrated apathy without depression, and an equal number were depressed

without apathy. An additional 60% of patients exhibited both apathy and depression. These authors report that younger patients, and also patients with more severe injuries, were more likely to be apathetic than older patients, among who combined symptoms of depression and apathy were more common.

Apathetic states tend to arise in the setting of significant and usually bifrontal injuries involving the anterior cingulate cortex (18), and are associated with other cognitive impairments related to frontal lobe function. Andersson and Bergedalen (2002) (112) used the Apathy Evaluation Scale (AES) (5) and a comprehensive neuropsychological assessment to ascertain the associations between cognition and apathy in 53 patients with severe TBI. They observed significant correlations between apathy score and reduced performance on tests of acquisition and memory, psychomotor speed, and executive functions. Accordingly, the treatment of these cognitive functions may improve motivation (see Chapter 53) or conversely the treatment of apathy may improve frontally-mediated cognition.

Determining whether an individual patient’s apathy is a symptom of another neuropsychiatric condition such as depression or is instead an independent syndrome is imperative prior to undertaking treatment. When apathy is a feature of depression, treatment of the underlying depression with agents like the SSRIs may relieve both mood and apathy symptoms. However, when apathy occurs as an independent problem the SSRIs are unlikely to improve this problem and may actually worsen it (113). Complicating matters, apathy not uncommonly co-occurs with behavioral dyscontrol (i.e., disinhibition, impulsivity, and aggression). This seemingly odd combination of behavioral problems may occur in the setting of injury to both the anterior cingulate-subcortical circuits (resulting in apathy) and lateral orbitofrontal-subcortical circuits (resulting in a behavioral dyscontrol syndrome). In such circumstances, patients appear apathetic at baseline and demonstrate episodic behavioral dyscontrol when an environmental or somatic stimulus produces automatic (and often aggressive or appetitive) behaviors. The development of the latter may be simplistically understood as reflecting a response to environmental or somatic stimuli sufficient to activate limbic-subcortical circuits involved in appetitive or aggressive behaviors despite a relative lack of motivation for behavioral responses more generally. This combination of apathy and behavioral dyscontrol presents substantial challenges to clinicians attempting to treat such problems, as the therapies to improve apathy may worsen behavioral dyscontrol and the therapies for behavioral dyscontrol may worsen apathy. If clinicians select apathy as the target of treatment, psychostimulants and other dopaminergically active medications are the principal pharmacotherapies (114).

### *Amantadine*

Among these pharmacotherapies for posttraumatic apathy, amantadine is most often used. Kraus and Maki (1997) (115) report on the use of amantadine among seven patients with the apathy syndrome (6 with TBI, 1 with meningitis following sinus surgery). All patients showed some degree of positive response behaviorally and cognitively during treatment, and only one experience intolerable side effects; importantly, these side effects resolved upon discontinuation of the medication. Van Reekum et al. (1995) (116) describe a single-case, double-blind, placebo-controlled study of amantadine 100 mg TID for the treatment of apathy following TBI. In that study, therapists and nurses completed inventories scoring efforts towards initiation of therapeutic activities during each session, progress in therapy, and participation in therapy during four treatment periods (two active medication, two placebo) of 2 weeks duration each. They report marked improvement in apathy, although not restoration of normal initiation, during both active treatment periods and also observed no significant treatment-emergent side effects. Amantadine also may be beneficial in the treatment of posttraumatic anergia, abulia, mutism, anhedonia, and perseveration (97, 117, 118).

Amantadine is often started at doses of 50–100 mg BID, and increased every week by 100 mg/day to either symptomatic improvement or medication intolerance. In the experience of the authors, amantadine 100 mg BID is often sufficient to impart maximal benefit without undue side effects. When higher doses are necessary, the maximum dosage of amantadine should not exceed 400 mg/day. Headache, nausea, diarrhea, constipation, anorexia, dizziness, lightheadedness, orthostatic hypotension, anxiety, irritability, depression, and hallucinations may occur during treatment with amantadine, although these latter neuropsychiatric side effects are relatively uncommon. At higher doses, psychosis and confusion may occur and may reflect the relatively robust NMDA receptor antagonism when administered at such doses. Additionally, coadministration of triamterene/hydrochlorothiazide may decrease renal excretion of amantadine, resulting in medication intolerance at otherwise therapeutic doses. These adverse reactions tend to occur more often in elderly patients than in younger patients.

Although amantadine does not possess direct anticholinergic activity *per se* at conventional therapeutic doses, it is not uncommon for patients treated with this agent to develop anticholinergic-like symptoms. Additionally, amantadine may potentiate the effects of anticholinergic agents and other psychostimulants. These observations leave open the question of amantadine on cholinergic function *in vivo*, as the direct receptor effects of this agent would not predict these effects.

It has been reported that amantadine may lower seizure threshold (97). The pharmacology of amantadine, and particularly its NMDA receptor antagonist properties, would not predict this effect. Indeed, the suggestion that amantadine reduces seizure threshold is not well supported by the literature. To the contrary, amantadine has been suggested as an augmentation strategy for the treatment of refractory epilepsy in adults (118) and children (119). In the study by Drake et al. (1991) (119), amantadine (titrated to 400 mg/day) was added to the ongoing anticonvulsant regimen of ten patients with refractory epilepsy in the setting of mental retardation. During treatment with amantadine, seizure frequency was reduced by greater than 90% in two patients, reduced by 50–90% in two patients, unchanged in three patients, and worsened in three others. In the study by Shields et al. (1985) (120), ten children with medically refractory seizures on anticonvulsant medications were treated adjunctively with amantadine. Of these, one experienced improvement in tonic seizures, one worsened, and the others remained unchanged. These reports suggest that when looked at as a group, patients with epilepsy do not invariably experience significant changes in seizure frequency during treatment with amantadine. Individual patients may experience improvements, worsening, or no change in seizure frequency during treatment with this medication. These studies suggest that patients with TBI, including those with posttraumatic seizures, may not be precluded from treatment with amantadine; however, careful monitoring for change in seizure activity or the development of new-onset seizures during treatment with this agent is recommended.

### *Bromocriptine*

Bromocriptine has also been used in the treatment of diminished motivation following TBI or subarachnoid hemorrhage (121). In this study, bromocriptine was used in an open-label fashion in six men and five women two months to five years post-injury. The authors of this study report that bromocriptine improved scores on measures of motivation and cognition, but not mood, and that improvement was maintained after bromocriptine was withdrawn in eight of the patients. The mechanism by which sustained benefit was achieved by this treatment is not clear. Eames (1989) (122) also suggested that bromocriptine and/or L-dopa/carbidopa may be useful in treating cognitive initiation problems among persons with brain injury who are at least 1 year post-injury. In a related area, Catsman-Berrevoets and Harskamp (1988) (123) observed improvements in motivation in a patient with bilateral thalamic stroke. These studies suggest that bromocriptine may be of some use in the treatment of apathy in brain-injured persons, including those with TBI.

Treatment with bromocriptine generally begins with 2.5 mg/day and is gradually titrated to the highest dose tolerated. Common side effects during treatment with bromocriptine include dizziness, drowsiness, faintness, syncope, nausea, vomiting, abdominal cramps, constipation, and diarrhea, although these are generally of mild severity. Uncontrolled hypertension and hypersensitivity to ergot alkaloids are strict contraindications to the use of bromocriptine. Although use of this agent among women who are breastfeeding their infants is contraindicated, use during pregnancy does not appear to be associated with significant increased adverse events or outcomes on fetal development. Additionally, it has been suggested that bromocriptine may possess some anticonvulsant properties (124). Although this suggestion should not be misunderstood as an endorsement of bromocriptine for the adjunctive treatment of posttraumatic epilepsy, it may offer some reassurance of its safety for use among cognitively impaired TBI survivors with this additional posttraumatic problem.

#### *L-Dopa/Carbidopa*

Lal et al. (1988) (125) reported on the use of L-dopa/carbidopa among 12 patients with brain injury, including several patients with hypoxic-ischemic brain injuries. During treatment with L-dopa/carbidopa 10/100 to 25/250 QID, patients demonstrated improvements in alertness and concentration, decreased fatigue, hypomania, and sialorrhea, and improved memory, mobility, posture, and speech. Whether fatigue in this sample is a symptomatic equivalent to apathy is not clear. DeBette et al. (2002) (126) used a levodopa/benserazide combination in five patients with cognitive, emotional, and neurobehavioral disturbances following hypoxic-ischemic brain injury. They describe variable improvements in these neuropsychiatric symptom domains during treatment, and particularly on motor dysfunction and apathy; improvements in cognition were relatively more modest. Although L-dopa/carbidopa is uncommonly used in clinical practice for the treatment of apathy, in some cases it may be an alternative to amantadine or the other catecholaminergically active agents when these have produced intolerable side effects.

#### *Methylphenidate and Dextroamphetamine*

Psychostimulants, such as methylphenidate and dextroamphetamine also may be useful for the treatment of apathy in cases in which diminished arousal, slowed speed of cognitive processing, and attentional impairments are prominent (90, 127, 128). However, these agents are not generally regarded as first-line treatments for apathy alone. This issue is discussed in more detail in Chapter 53 (Pharmacotherapy of Cognitive Impairments).

#### *Other Agents*

Cummings (2000) (129) and Levy et al. (1999) (130) suggest that the cholinesterase inhibitors (donepezil, rivastigmine, galantamine) may be of benefit for neuropsychiatric disturbances, including apathy, in persons with dementing illnesses such as Alzheimer's disease and dementia with Lewy bodies. In light of the cholinergic deficits produced by TBI and the growing use of these agents for the treatment of impaired cognition following TBI (see Chapter 53), these agents may be of similar behavioral benefit for persons with posttraumatic apathy. However, there is at present no data to support this suggestion, and the use of these agents for this purpose alone is not at present recommended.

Protriptyline, a secondary amine tricyclic agent, has been suggested to have sufficient stimulant properties to permit its use for anergia and diminished motivation in TBI patients (131). Interestingly, despite its ability to improve arousal and motivation, it does not appear to confer additional benefits on cognition. Whether this reflects the effects of this agent's anticholinergic properties or not is at present uncertain. Similarly, Reinhard and colleagues (1996) (132) administered amitriptyline (1 patient) and desipramine (2 patients) and found improvement in arousal and initiation after TBI, which they hypothesized resulted from the pro-noradrenergic effects of these agents. Although TCA's may be of some benefit for apathy following TBI, they are probably best regarded as treatments of last resort for this purpose.

#### *Psychosis*

##### *Typical Antipsychotics*

Although typical antipsychotic medications have been used to control agitation and psychosis following TBI, these are not benign treatments in this population. Stanislav (1997) (133) demonstrated improvement in cognitive performance in brain-injured patients following discontinuation of typical antipsychotic medications, the magnitude of which appeared to be greater after discontinuation with thioridazine than haloperidol. While both medications appeared to negatively affect cognitive performance, Stanislav (1997) (133) suggests that the greater improvement observed after discontinuation with thioridazine is attributable to the brain-injured patients' reduced tolerance to the anticholinergic properties of this agent. Similarly, Sandel et al. (1993) (134) observed new-onset delusions in a TBI patient receiving chlorpromazine for the treatment of agitation following TBI, an effect that may also be attributable to the significant anticholinergic properties of this agent. Antipsychotic medications have also been reported to delay neuronal recovery after brain injury (135). Consistent with this observation,

Rao et al. (1985) (136) found that patients treated with haloperidol in the acute period following TBI experienced significantly longer periods of posttraumatic amnesia than patients not treated with this medication. However, this delay in emergence from posttraumatic amnesia did not result in difference in functional outcome following acute rehabilitation.

Side effects during treatment with typical antipsychotic agents include hypotension, sedation, and confusion, and are not uncommon. Patients with brain injury are particularly subject to dystonias, akathisias, and other parkinsonian side effects — even when relatively low doses of antipsychotic medications are prescribed (138). Consistent with their greater sensitivity to medications affecting the central nervous system, patients with brain injury are more sensitive to the development of extrapyramidal symptoms during treatment with typical antipsychotic medications (137–141). Given this literature and the availability of several atypical antipsychotic medications, the authors strongly discourage the use of typical, and particularly the low-potency, typical antipsychotics among persons with TBI.

#### *Atypical Antipsychotics*

There is at present a dearth of reports to guide selection among the atypical antipsychotic agents in this population. Michals et al. (1993) (142) used clozapine (Clozaril) to treat nine brain-injured patients with psychotic symptoms or outbursts of rage and aggression that had failed to respond to other medications. Three of these patients demonstrated marked improvements in aggression and/or psychosis, three demonstrated decreased agitation and auditory hallucinations, and an adequate duration of treatment was not achieved in three patients. Two of these nine patients experienced seizures during treatment. Burke et al. (1999) (143) also report improvement in refractory psychotic symptoms after TBI during treatment with clozapine. These reports suggest that clozapine may be useful in the treatment of psychosis and aggressive behavior after brain injury. Unfortunately, this treatment carries a relatively high risk of adverse effects including seizures and agranulocytosis. Additionally, the laboratory monitoring protocol required during its use is for many clinicians and patients too cumbersome to be practical. Whether clozapine may also exacerbate cognitive impairments given its substantial anticholinergic properties is not clear, but seems likely in light of such effects produced during treatment with other low-potency antipsychotic agents.

Schreiber et al. (1998) (144) report a case in which risperidone treated delusions and sleep disturbance following TBI effectively. One of the authors (DA) has used this medication in two patients that developed psychosis (paranoid delusions, auditory hallucinations) after TBI in the acute rehabilitation setting. Each patient responded

with decreasing psychotic symptoms with risperidone 4 mg per day and without significant adverse effect. The second of these patients was treated in an A-B-A-B fashion, and psychosis recurred during each reduction of risperidone below 3 mg per day. There are, to-date, no studies reporting improvement in psychosis following TBI during treatment with olanzapine, quetiapine, or ziprasidone. Each of these medications may be of benefit in this population, but specific benefits and side effect profiles relevant to their use in TBI remain to be determined. Based on the literature and our own clinical experience in this area, we recommend either risperidone or olanzapine as first-line for the treatment of psychosis following TBI. Starting doses of risperidone are 0.5 mg Qhs or BID, and may be increased in 0.5–1 mg increments up to 4–6 mg/day. Beyond this level, additional increases in dose are associated with extrapyramidal side effects and a more “typical” antipsychotic side effect profile. Starting doses of olanzapine are 2.5–5 mg Qhs or BID, and may be increased in 2.5–5 mg increments up to 20 mg/day.

#### *Special Consideration in the Use of Antipsychotic Agents*

Neuroleptic malignant syndrome is a potentially life-threatening disorder that may emerge during the use of any antipsychotic agent. This syndrome has been reported among patients receiving haloperidol after TBI (139, 145). Patients experiencing neuroleptic malignant syndrome become severely rigid and occasionally catatonic. There is fever, elevated white blood cell count, tachycardia, abnormal blood pressure fluctuations, tachypnea, and diaphoresis. Although medications such as bromocriptine and dantrolene sodium have been suggested as treatments for neuroleptic malignant syndrome, the most important therapeutic interventions are discontinuation of antipsychotic medications, treatment of any underlying infections or other concurrent medical illnesses, and symptomatic treatment of fever and hypertension (146).

Many psychotropic medications affect seizure threshold. This is of particular concern in this population given the risk of seizures after TBI. Among all the first-generation antipsychotic drugs, molindone and fluphenazine have consistently demonstrated the lowest potential for lowering the seizure threshold (68, 147). Clozapine treatment is associated with a significant dose-related incidence of seizures (ranging from 1% to 2% of patients who receive doses below 300 mg/day, and 5% of patients who receive 600–900 mg/day) (148). The observations of Michals et al. (1993) (142) suggest that this risk may be increased in patients with TBI receiving clozapine. If this agent is prescribed at all in these patients, its use should be undertaken with extreme caution and only for the relief of refractory psychotic symptoms.

## AGGRESSION AND AGITATION

Aggressive and/or agitated behavior is a major source of disability to individuals with brain injury and a major source of stress to families of persons with this problem. Additionally, these behaviors can endanger the safety of not only patients and their families but also the professionals providing care to them. A multimodal, multidisciplinary, collaborative approach to treatment is necessary in most cases. The concurrent use of family treatments, psychopharmacologic interventions, and psychotherapeutic approaches is often required. In establishing a treatment plan for patients with agitation or aggression, the overarching principle is that diagnosis comes before treatment. It is essential to determine the mental status of the patient before the agitated or aggressive event, the nature of the precipitant, the physical and social environment in which the behavior occurs, the ways in which the event is mitigated, and the primary and secondary gains related to agitation and aggression (149, 150).

Although there is no medication that is approved by the FDA specifically for the treatment of aggression, medications are widely used (and commonly misused) in the management of patients with acute or chronic aggression. Unfortunately, there is a paucity of rigorous double-blind, placebo controlled studies (i.e. "Level I" studies) or even prospective cohort studies (i.e. "Level II") to guide clinicians in the use of pharmacologic interventions. The International Brain Injury Association has assembled a task force on reviewing the literature on this literature pertaining to the neurobehavioral consequences of TBI (in progress). At this time, we suggest utilizing the Consensus Guidelines for the Treatment of Agitation in the Elderly with Dementia as a framework for the assessment and management of agitation and aggression after TBI (151), with the caveat that the effectiveness of these medications is highly variable in persons with TBI.

Medications for posttraumatic aggression and/or agitation are generally selected with one or another hypothesis in mind regarding the neurochemistry of these problems. For example, hypothesized strategies for treatment of aggression and agitation include inhibition of excessive activity in temporolimbic areas with anticonvulsants, reduction of "hyperactive" limbic monoaminergic neurotransmission with  $\beta$ -adrenergic receptor antagonists (i.e., propranolol) or dopamine receptor antagonists (i.e., haloperidol), augmentation of orbitofrontal and/or dorsolateral prefrontal cortical activity with monoaminergic agonists (i.e., amantadine, methylphenidate, and perhaps bupirone), or modulation of limbic and frontal activity through augmentation of serotonergic activity (e.g., SSRIs). However, the neurochemistry of posttraumatic aggression is not well understood and may differ between individuals. Consequently, the pharmacologic treatment

of this problem often entails a trial-and-error approach to find a medication that is both effective and tolerable.

After appropriate assessment of possible etiologies of these behaviors, treatment is focused on the occurrence of comorbid neuropsychiatric conditions (depression, psychosis, insomnia, anxiety, delirium). When present, aggression or agitation may be a manifestation of these problems rather than an independent diagnosis. Therefore, comorbid neuropsychiatric conditions should be treated prior to developing an independent treatment approach to the patient's agitation or aggression. Additionally, it is important to consider whether the behavior is occurring in the acute (hours to days) or chronic (weeks to months) phase after TBI, and also the severity of the behavior (mild to severe). The differential diagnosis of posttraumatic aggression varies as a function of time since injury, with confusional states being more common in the early post-injury period and other neuropsychiatric problems such as psychosis being more common in the late post-injury period. The effects of these treatments may vary depending on the presence of other neuropsychiatric conditions and the time since injury. Finally, clinicians should bear in mind that patients may not respond to just one medication, but may require combination treatment, similar to the pharmacotherapeutic treatment for refractory posttraumatic depression.

### Acute Aggression

#### *Antipsychotics*

Antipsychotics are the most commonly used medications in the treatment of aggression. Although these agents are appropriate and effective when aggression arises as a result of psychosis, the use of typical antipsychotic agents to treat chronic aggression in the absence of psychosis is often ineffective and may result in serious treatment-related complications such as tardive dyskinesia. Usually, it is the sedative side effects rather than the antipsychotic properties of antipsychotics that are used (i.e., misused) to "treat" (i.e., mask) the aggression. Often, patients develop tolerance to the sedative effects of the neuroleptics and, therefore, require increasing doses. As a result, extrapyramidal and anticholinergic-related side effects occur. Paradoxically (and frequently), akathisia may result from the use of these agents and thereby worsen agitation and restlessness. As the dose of neuroleptic is increased, especially when a high-potency antipsychotic such as haloperidol is administered, these symptoms predictably worsen. Akathisia is often mistaken for increased irritability and agitation, setting in motion a cycle of increasing neuroleptics and worsening akathisia.

There is some evidence from studies of injury to motor neurons in animals that have found that haloperidol decreases recovery. This effect was only seen when animals actively participated in a behavioral task and not

when the animals were restrained after drug administration (135). It is possible that the effect on decreasing dopamine and inhibiting neuronal function, which may be the mechanism of action to treat aggression, may have other detrimental effects on recovery. As noted earlier, Rao et al. (1985) (136) found that patients treated with haloperidol in the acute period following TBI experienced significantly longer periods of posttraumatic amnesia. This finding raises important potential risk/benefit issues that must be considered before antipsychotic drugs are used to treat aggressive behavior in patients with neuronal damage.

In patients with brain injury, psychosis, and aggression, we recommend atypical antipsychotics as first-line treatments for acute agitation following TBI. Starting doses of these medications should be low (i.e., risperidone 0.5 mg) and repeated at short intervals (sometimes as frequent as every hour) until control of aggression is achieved. If after several administrations of risperidone the patient's aggressive behavior does not improve, the hourly dose may be increased until the patient is so sedated that he or she no longer exhibits agitation or violence. Once the patient is not aggressive for 48 hours, the daily dosage should be decreased gradually (i.e., by 25%/day) to ascertain whether aggressive behavior reemerges. In this case, consideration should then be made about whether it is best to increase the dose of risperidone and/or to initiate treatment with a more specific anti-aggressive medication or nonpharmacologic intervention. Other atypical antipsychotic medications such as olanzapine, quetiapine (which produces little in the way of extrapyramidal symptoms), or ziprasidone may be used, although there is no published experience with these medications in persons with TBI.

### *Benzodiazepines*

The literature regarding the effects of the benzodiazepines in the treatment of aggression is inconsistent, at best. The sedative properties of benzodiazepines are helpful in the management of acute agitation and aggression in many cases. Paradoxically, increased hostility, aggression, and the induction of rage may occur in patients treated with benzodiazepines, and particularly persons with neurological problems, although this phenomenon is rare (152). Benzodiazepines can produce amnesia, and preexisting memory dysfunction can be exacerbated by the use of benzodiazepines. Brain-injured patients may also experience increased problems with coordination and balance with benzodiazepine use. For this reason, we do not recommend the use of benzodiazepines for the treatment of acute aggression in patients with TBI.

### **Chronic Aggression**

If a patient continues to exhibit periods of agitation or aggression over weeks to months, prophylactic use of

medications may be required to decrease or prevent these behaviors. Consideration of such medications should be undertaken only after evaluation of the antecedents and consequences of these behaviors and attempts to address these issues in the service of decreasing aggression and agitation nonpharmacologically.

### *Antipsychotics*

If, after thorough clinical evaluation, it is determined that the aggressive episodes result from psychosis, such as paranoid delusions or command hallucinations, then antipsychotic medications will be the treatment of choice. There have been double-blind placebo controlled studies of risperidone showing efficacy in the treatment of agitation in elderly patients with dementia (153, 154), as well as children with autism and serious behavioral problems (155). Olanzapine appears to be more sedating, and quetiapine produces more limited extrapyramidal symptoms than does risperidone. Quetiapine appears to be the antipsychotic medication (except for clozapine) least likely to produce extrapyramidal effects in vulnerable populations, such as those with Parkinson's disease (156). Clozapine may have greater antiaggressive effects than other atypical antipsychotic medications (142), but its propensity to impair cognition and increase seizure risk, and as well as the arduous hematologic monitoring required during its use, may offset its potential benefits in this population. Based on the available evidence and our own clinical experience, we suggest that when atypical antipsychotics are used for post-traumatic aggression or agitation, risperidone, olanzapine, and quetiapine should be considered first-line before the other even newer atypical antipsychotic agents.

### *Buspirone*

Serotonin appears to be a key neurotransmitter in the modulation of aggressive behavior. In preliminary open case studies, buspirone, a 5-HT<sub>1A</sub> agonist, has been reported to be effective in the management of aggression and agitation for patients with head injury (105, 106, 157), as well as dementia, and developmental disabilities and autism (150). In rare instances, we have found that some patients become more aggressive when treated with buspirone. We recommend that buspirone be initiated at low dosages (i.e., 5 mg BID) and increased to 10 mg BID after one week. Dosages of 45–60 mg/day may be required before there is improvement in aggressive behavior, although we have sometimes observed dramatic improvement within one week of treatment initiation.

### *Benzodiazepines*

Clonazepam may be effective in the long-term management of aggression, although evidence is restricted to case

reports. Freinhar and Alvarez (1986) (159) found that clonazepam decreased agitation in three elderly patients with organic brain syndromes. Keats and Mukherjee (1988) (160) reported anti-aggressive effects of clonazepam in a patient with schizophrenia and seizures. We use clonazepam when pronounced aggression and anxiety occur together, or when aggression occurs in association with neurologically-induced tics and similarly disinhibited motor behaviors. Doses should be initiated at 0.5 mg BID and may be increased to as high as 2–4 mg BID, as tolerated. Unfortunately, sedation and ataxia are frequent side effects during treatment with this agent among persons with TBI. As noted earlier, the risk:benefit ratio of benzodiazepine use in this population should be given serious consideration prior to initiating treatment with these agents.

### *Anticonvulsants*

Carbamazepine has been shown to be effective for the treatment of idiopathic bipolar disorder and has also been advocated for the control of aggression in both epileptic and nonepileptic populations. Open-label studies have indicated that carbamazepine may be effective in decreasing aggressive behavior associated with developmental disabilities, schizophrenia, and patients with a variety of other organic brain disorders (150). Several of these studies included individuals with TBI. Chatham-Showalter (1996) (161) observed improvement in seven TBI patients treated in an open-label fashion with carbamazepine, and observed these improvements after only four days of treatment. In an open-label study of carbamazepine on assaultive behavior in eight patients with “organic brain diseases” (only two had brain injury from gunshot wounds), Patterson (1987) (162) reported that the number of episodes decreased by over 50% as documented by nursing staff. In a study by Azouvi and coworkers (1999) (163), ten patients presenting with agitation and anger outbursts after severe TBI experienced significant reduction in such behaviors as assessed using six relevant items on the Neurobehavioral Rating Scale-Revised (164) during 8 weeks of treatment with carbamazepine (mean dose of  $9.47 \pm 2.9$  mg/kg/day). However, four of the ten patients experienced significant drowsiness during the course of the study, necessitating use of lower doses than had been initially planned and that may thereby have reduced the effectiveness of this treatment. An additional patient developed a significant allergic cutaneous reaction necessitating discontinuation of carbamazepine. While the authors of this study report no significant changes in cognition during the course of this trial, their primary measure of cognition was the Mini-Mental State Examination – a measure which is widely regarded as a poor instrument for the assessment of cognition following traumatic brain injury due to its insensitivity to executive

dysfunction and to impairments of the speed and efficiency of information processing. Hence, a failure to find no change in cognition in this study must be regarded with some caution since the measure used is unlikely to be sensitive to such changes in persons with TBI.

In our experience and that of others, the anticonvulsant valproic acid may also be helpful to some patients with organically induced aggression (165–167), although there are only a few open-label case reports regarding the use of this agent among persons with aggression following TBI. Horne and Lindley (1995) (168) report a case of a 70 year-old woman whose posttraumatic emotional lability and irritability improved during treatment with valproate. Wroblewski et al. (1997) (169) observed significantly reduced posttraumatic aggression among five individuals, and report that those improvements occurred within 1–2 weeks of treatment initiation.

Gabapentin may be beneficial for the treatment of agitation in patients with dementia (170, 171). Doses have ranged from 200–2400 mg/day. However, Childers and Holland (1997) (172) report an increase in anxiety and restlessness (i.e., agitation) in two cognitively impaired TBI patients for whom gabapentin was used primarily to reduce chronic pain. Although this report is not consistent with our use of this agent among persons with TBI, it is unclear whether or to what extent gabapentin is of benefit for the treatment of posttraumatic agitation and/or aggression.

For patients with aggression and epilepsy whose seizures are being treated with anticonvulsant drugs such as phenytoin and phenobarbital, switching to carbamazepine or to valproic acid may treat both conditions and reduce adverse side effects (i.e., sedation, confusion, disinhibition) that is sometimes seen in persons treated with the older anticonvulsants such as phenobarbital. Oxcarbazepine may be an alternative to carbamazepine in light of its relative lack of hepatic autoinduction, more favorable drug-drug interaction profile, and more limited cognitive and motor effects, but there are no published reports of its use among persons with aggression following TBI at the time of this writing.

### *Lithium*

Although lithium is known to be effective in controlling aggression related to manic excitement, many studies suggest that it may also have a role in the treatment of aggression in selected, nonbipolar patient populations. These include patients with mental retardation who exhibit self-injurious or aggressive behavior, children and adolescents with behavioral disorders, prison inmates, and those with other organic brain syndromes (150). Two individuals in state psychiatric facilities with brain-injury related aggression (one patient with TBI and one with post-anoxic encephalopathy) responded to an open-label trial of

lithium (173). Glenn and colleagues (1989) (98) reported their experience using lithium in the treatment of ten "brain-injured patients with severe, unremitting, aggressive, combative, or self destructive behavior or severe affective instability." Five patients had a "dramatic response."

As noted earlier, individuals with brain injury have increased sensitivity to the neurotoxic effects of lithium (174, 175). Because of lithium's potential for neurotoxicity, we limit the use of lithium in those patients whose aggression is related to manic effects or recurrent irritability related to cyclic mood disorders.

### *Antidepressants*

The antidepressants that have been reported to control aggressive behavior include those that act preferentially (amitriptyline) or specifically (trazodone, sertraline, and fluoxetine) on serotonin. In open studies, Mysiw et al. (1988) (176) and Jackson et al. (1985) (177) reported that amitriptyline (maximum dose 150 mg/day) was effective in the treatment of twenty patients with recent severe brain injury whose agitation had not responded to behavioral techniques. Improvement was documented in 12/17 patients within the first week of treatment. Szlabowicz and Stewart (1990) (178) successfully treated a 43-year-old man with aggressive behavior subsequent to anoxic encephalopathy with amitriptyline 75 mg Qhs. Trazodone has also been reported to be effective in the treatment of aggression that occurs with organic mental disorders (150). As noted earlier in this chapter, Kant et al. (1998) (18) conducted an open-label 8-week open trial of sertraline in 13 patients with irritability and aggression after TBI. Behaviors were monitored using the Overt Aggression Scale-Modified for outpatients, and sertraline was administered up to 200 mg/day. This treatment produced a significant reduction in irritability and aggression.

Fluoxetine, a potent serotonergic antidepressant, has been reported to be effective in the treatment of aggressive behavior in a patient who suffered brain injury as well as in patients with personality disorders and depression, and adolescents with mental retardation and self-injurious behavior (150). We have used selective serotonin reuptake inhibitors with considerable success in aggressive patients with brain lesions. The dosages used are similar to those for the treatment of mood lability and depression, and should be guided by the ease-of-use considerations discussed in the preceding sections of this chapter.

### *Stimulants*

There have been several studies that have examined the role of dopaminergic medications and stimulants in the treatment of agitation and aggression. Nickels et al. (1994) (118) report improvement during treatment with amantadine in two of three subjects with post-coma

agitation, and Chandler et al. (1988) (117) report improvement during treatment with amantadine in two patients with agitation and aggression in the post-acute injury period. Mooney and Haas (1993) (179) conducted a randomized, pretest, posttest, placebo-controlled, single-blind study of the effect of methylphenidate 30 mg/day for six weeks on brain injury related anger in 38 individuals with "serious" TBI occurring six or more months prior to treatment. Patients treated with methylphenidate had a lower level of anger. Although we do not recommend these agents as first-line treatments for agitation or aggression following TBI, they should be considered in patients in who there is evidence from neuroimaging of sufficient remaining frontal cortex to permit these agents to augment function in that area and restore its ability to inhibit or modulate limbically-mediated behaviors. In the absence of remaining frontal cortex, these agents pose the risk of further increasing limbic drive and worsening agitated or aggressive behavior.

### *$\beta$ -Adrenergic Receptor Antagonists*

Since the first report of the use of  $\beta$ -adrenergic receptor antagonists (" $\beta$ -blockers") in the treatment of acute aggression in 1977, over 25 articles describing the use of  $\beta$ -blockers with over 200 patients with aggression have appeared in the neurologic and psychiatric literature (150). Most of these patients had been unsuccessfully treated with antipsychotics, minor tranquilizers, lithium, and/or anticonvulsants before treatment with  $\beta$ -blockers. The agents in this medication class that have been investigated in controlled prospective studies include propranolol (a lipid-soluble, nonselective  $\beta$ -adrenergic receptor antagonist), nadolol (a water-soluble, nonselective  $\beta$ -adrenergic receptor antagonist), and pindolol (a lipid-soluble, nonselective  $\beta$ -adrenergic receptor antagonist with partial sympathomimetic activity).

The effectiveness of propranolol in reducing agitation has been demonstrated during the initial hospitalization after TBI in a double-blind placebo-controlled study in 21 subjects with severe TBI (180). The maximum intensity of episodes and the numbers of episodes were less after propranolol than they were after placebo as assessed using the Overt Aggression Scale. Unfortunately, the authors of this study do not list the number of patients who dropped out at each time point during the study, thus diminishing the reliability of the conclusions. Greendyke and colleagues (1986) (181) performed a double-blind randomized placebo-controlled crossover study of propranolol in ten patients with aggression (mean dose 520 mg/day). Only 5 patients had TBI, and the response of these patients varied. These authors later performed a double-blind randomized placebo-controlled crossover study of pindolol (doses up to 60 mg/day) in 11 patients with behavioral problems, including aggression (182). It

appears that most of these patients also participated in their earlier propranolol study, and again only five of these were patients with TBI. Although the patients as a group demonstrated improvement in assaultiveness, hostility, and uncooperativeness, we are unable to assess whether the TBI patients responded differentially. Alpert and colleagues (1990) (183) used nadolol in chronically hospitalized patients with aggression, and observed improvements in this symptom during treatment with this agent. Unfortunately, these patients did not have TBI.

Collectively, the literature suggests that  $\beta$ -adrenergic receptor antagonists are effective agents for the treatment of aggressive and violent behaviors, particularly those related to "organic brain syndromes" such as TBI. Patients with reactive airway disease (asthma), chronic obstructive pulmonary disease, insulin-dependent diabetes mellitus, congestive heart failure, persistent angina, significant peripheral vascular disease, and hyperthyroidism are not good candidates for treatment with  $\beta$ -blockers. Among patients without cardiovascular or cardiopulmonary problems, propranolol may be initiated at doses of 60 mg/day and increased by this amount every 3 days. Among patients with hypotension or bradycardia, treatment is usually initiated with a single test-dose of 20 mg/day and treatment should not proceed if patients develop symptoms related to these problems, if severe dizziness, ataxia, or wheezing occurs, and/or if the pulse rate is reduced below 50 beats per minute or systolic blood pressure is less than 90 mmHg. When this initial test dose is tolerated, doses of propranolol are gradually increased to 12 mg/kg body weight or until aggressive behavior is under control. Doses of 800 mg or less of propranolol are usually sufficient to control aggressive behavior. Patients should be maintained on the highest tolerable dose of propranolol for at least 8 weeks before concluding that the patient is not responding to this medication.

Given the potential for drug-drug interactions with propranolol, plasma levels of all antipsychotic and anti-convulsive medications should be monitored during treatment. In particular, propranolol is associated with significant increases in plasma levels of thioridazine, and the combination of these two medications should be avoided. When a patient requires the use of a once-a-day medication because of compliance difficulties, long-acting propranolol or nadolol may be of use. When patients develop bradycardia that prevents prescribing therapeutic dosages of propranolol, pindolol can be substituted, using one-tenth the dosage of propranolol. Pindolol's intrinsic sympathomimetic activity stimulates the  $\beta$ -adrenergic receptor and may limit the development of symptomatic bradycardia.

As suggested above, the major side effects of  $\beta$ -blockers when used to treat aggression are a lowering of blood pressure and pulse rate. Because peripheral  $\beta$ -adrenergic receptors are fully blocked in doses of

300–400 mg/day, further changes in these vital signs usually do not occur even when doses are increased beyond those levels. Despite reports of depression with the use of  $\beta$ -blockers, controlled trials and our experience indicate that it is a rare occurrence.

## SLEEP

Evaluation of sleep disturbances following TBI should first include assessment of other neuropsychiatric problems (e.g., depression, mania, anxiety, delirium) that may better account for the sleep disturbance. Independent of these problems, TBI may result in significant sleep disturbances including impaired rapid-eye-movement (REM) recovery and multiple nocturnal awakenings (184). Hypersomnia that occurs after severe penetrating head injury most often resolves within the first year after injury, whereas insomnia that occurs in patients with long periods of coma and diffuse injury has a more chronic course (185). Barbiturates and long-acting benzodiazepines should probably be avoided in this population, and if they are prescribed at all then they such should be used with great caution. These drugs interfere with REM and stage 4 sleep patterns, and may contribute to persistent insomnia (186). Clinicians should warn patients of the dangers of using over-the-counter preparations for sleeping and for colds because of the prominent anticholinergic side effects of these agents.

Trazodone, a sedating antidepressant medication that is devoid of anticholinergic side effects, is the preferred agent for the treatment of insomnia following TBI. A dose of 50 mg should be administered initially. If this dose is ineffective, doses up to 150 mg may be prescribed. Nonpharmacological approaches should be used regardless of whether or not medications are used, and should include minimizing daytime naps, maintaining regular sleep onset times, and engaging in regular physical activity during the day.

## FATIGUE

Fatigue is a common symptom among persons with traumatic brain injury, and may occur independent of other posttraumatic neuropsychiatric disturbances. When treatment of other posttraumatic neuropsychiatric problems does not adequately improve fatigue, specific treatment of this problem may be required. Psychostimulants and amantadine are the most commonly used agents for the treatment of fatigue in persons with TBI, and may be of some benefit toward that end. In our experience, dosing of these agents similar that employed for the treatment of diminished arousal and attention is usually sufficient to treat posttraumatic fatigue. These medications may be

of particular benefit in patients with posttraumatic depression in whom fatigue persists despite improvement in mood during treatment with antidepressants.

Modafinil, a medication recently approved for the treatment of excessive daytime somnolence in patients with narcolepsy, also may have a role in treatment of post-TBI fatigue. Although the exact mechanism of action of modafinil is not clear, animal studies suggest that its promotion of wakefulness may result from an indirect, dose-dependent reduction of the release of GABA in the cerebral cortex, medial preoptic area, and posterior hypothalamus (187, 188), activation of hypocretin (orexin) neurons in the lateral hypothalamus (189), and dose-dependent increases in glutamate release in the ventrolateral and the ventromedial thalamus (190). Some combination of these mechanisms in humans may increase arousal via activation in regions critical to this purpose, either directly via glutamatergic thalamic activation, indirectly via reduction of GABA function, or through the secondary effects of lateral hypothalamic projections to regions involved in control of arousal and sleep-wake cycle (tubero-mammillary nucleus and the locus coeruleus) (191).

Studies of the effect of modafinil on fatigue and excessive sleepiness in patients with multiple sclerosis (192, 193) and Parkinson's disease (194) suggest benefit. Elovic (2000) (195) has suggested that modafinil may be of similar benefit in patients with TBI. Teitelman (2001) (196) described his use of modafinil among 10 outpatients with nonpenetrating traumatic brain injury and functionally significant excessive daytime sleepiness and in two patients with somnolence due to sedating psychiatric medications. The patients included in his report were between the ages of 42 to 72 years, all were outpatients, and were treated in an open-label fashion. Doses of modafinil ranged between 100 mg to 400 mg taken once each morning. Nine of these patients reported improvements in excessive daytime sleepiness, and some patients also reported subjective improvements in attention as well as other cognitive benefits. Although this medication was generally well tolerated, this report also describes treatment intolerance due to increased "emotional instability" in two women with brain injury complicated by multiple other medical conditions and receiving multiple additional medications. At the time of this writing there are no published clinical studies with which to evaluate the effectiveness or tolerability of modafinil for post-traumatic hypersomnolence or fatigue. If used in this population, dosages should start with 100 mg in the morning, and can be increased to up to 400 mg/day administered in either a single daily dose or two divided doses (i.e., 200 mg in the morning, and 200 mg in the afternoon). Higher doses (up to 600 mg/day) are sometimes used, but there is no evidence in any patient population that such doses offer benefit beyond that achieved with 400 mg/day.

## COLDNESS

Complaints of feeling cold, without actual alteration in body temperature, are occasionally seen in patients who have suffered brain injury. This feeling can be distressing to those who experience it. Patients may wear excessive amounts of clothing, and may adjust the thermostat in their homes to the point that other members of the family are made uncomfortable. While this is not a commonly reported symptom of traumatic brain injury (TBI), Hibbard et al. (1998) (197) report that in a sample of 331 individuals with traumatic brain injury, 27.9% complained of changes in body temperature, and 13% persistently felt cold. Eames (1997) (198), while conducting a study of the cognitive effects of vasopressin nasal spray in patients with TBI, reported that thirteen patients had the persistent feeling of coldness, despite normal sublingual temperature. All were treated with nasal vasopressin spray for one month. Eleven of these patients stopped complaining of feeling cold after one month of treatment, and one other patient had incomplete improvement in this symptom.

Silver and Anderson (1999) (199) performed a pilot study of the effects of intranasal vasopressin (DDAVP) twice daily for one month among six patients who complained of persisting coldness after brain injury. Five of the six patients had a dramatic response to DDAVP – some as soon as one week after initiating treatment – and no longer complained of feeling cold. This response persisted even after discontinuation of treatment. Patients denied any side effects from treatment with this agent. The authors of this study suggest that DDAVP may reverse physiologic effects of a relative deficit in vasopressin in the hypothalamus caused by injury to the vasopressin precursor producing cells in the anterior hypothalamus, and may thereby correct an internal temperature setpoint disrupted by the brain injury.

## OTHER ISSUES IN THE PHARMACOTHERAPY OF NEUROPSYCHIATRIC DISTURBANCES FOLLOWING TBI

There has been a bias held by patients, families, and some treatment centers against the use of medications for the treatment of neuropsychiatric disorders in patients with brain injury. The bias against the use of psychiatric medications may have several bases, including the stigma associated with mental illness and psychiatric treatment, and in some cases the patient's previous and often sub-optimal experience with psychotropic medications. Stigma may relate to the view that psychiatric symptoms are signs of weakness, indolence, or even moral decline. We have suggested that the neuropsychiatric paradigm – one that rejects the misleading demarcation between

“brain” and “mind” and emphasizes the neurobiological bases of all cognitive, emotional, and behavioral problems regardless of the relationship of such problems to brain injury – is the most useful response to such biases. Patients struggling to accept treatment in the face of old stigmas may benefit from an explanation of symptoms as the products of alterations in neurotransmitters, brain structures, brain networks, or some combination of these, and from the presentation of treatments as designed to alleviate or compensate for such brain dysfunctions.

Unfortunately, particularly for patients with TBI, the experience of treatment with psychotropic medications has often been a negative one and their biases against treatment with some of these medications are not entirely without merit. Antipsychotic medications, and particularly typical antipsychotics, are widely misused as a general “tranquilizer” to sedate patients agitated after TBI, with resulting impairment in alertness, cognition, and (in some cases) the production of severe extrapyramidal symptoms. For example, we evaluated in consultation one patient who had been treated with low-dose fluphenazine to control agitated behavior. One month later, the staff and family complained that she was “underaroused.” On our examination, the patient had severe cogwheel rigidity that had not been diagnosed previously. One hour after administration of benztpine 1 mg, she was “active” again.

Another fear about medication is that it will interfere with a “natural healing process” that occurs after TBI. Evidence obtained from animal models suggests that certain drugs, particularly agents that potently antagonize dopamine type-2 receptors, may interfere with recovery following neuronal injury. Feeney et al. (1982) (135) studied the effect of D-amphetamine on recovery from hemiplegia after ablation of the sensorimotor cortex in rats. They found that D-amphetamine accelerated the rate of recovery, and that this effect was blocked by haloperidol. In addition, haloperidol, when administered alone, resulted in delayed recovery. Importantly, recovery was affected only when the animal was allowed to move during drug administration. This implies that haloperidol delays the recovery process during active rehabilitation, rather than interfering with spontaneous recovery *per se*. In another model, Hovda et al. (1985) (200) found that haloperidol blocked the positive effect of D-amphetamine on recovery of depth perception after visual cortex injury.

It has been suggested that the mechanism of action of haloperidol in delaying recovery also operates through its effects as an  $\alpha$ -adrenergic antagonist (201). Clonidine, an  $\alpha$ 2-adrenergic agonist, and prazosin, an  $\alpha$ 1-adrenergic antagonist, reinstate deficits after sensorimotor cortex ablation (202), an effect not seen with propranolol (203). Other studies have demonstrated that clonidine has deleterious effects on recovery (204, 205). It should be noted that these experimental methods in animals do not produce the same neuropathological findings as contusions

or diffuse axonal injury in humans, and, therefore, may not apply fully to our understanding of the effects  $\alpha$ -adrenergic antagonism following TBI in humans.

In animal studies involving the neurotransmitter  $\gamma$ -aminobutyric acid (GABA), increased GABA function has been associated with greater neuromotor deficits and poorer recovery (206). Increased production of GABA associated with benzodiazepine administration may result in greater glutamate neurotoxicity (207). Diazepam has been found to block recovery of sensory deficits after rat neocortex ablation (208).

The studies cited above relating psychotropic use to impaired neuronal recovery after laboratory-induced brain injury have all used animal models. The study by Rao et al. (1985) (136) appears to offer support for the notion of delayed recovery following administration of haloperidol by virtue of its demonstration of increased duration of posttraumatic amnesia among patients receiving this medication. However, there have been no carefully controlled clinical trials of this important relationship in humans. Interestingly, when the medical records of recovering stroke patients were reviewed, the use of anti-hypertensive medications or haloperidol was associated with poorer recovery (209). Goldstein and Davis (1990) (205) found that when patients who had had ischemic strokes were administered phenytoin, benzodiazepines, dopamine receptor antagonists, clonidine, or prazosin, they showed poorer sensorimotor function and lower activities of daily living than stroke patients who did not receive those drugs.

Many patients are prescribed anticonvulsant drugs (ACDs) after TBI, and may still be receiving them at the time of neuropsychiatric consultation in the period following acute rehabilitation. As noted previously, it is important to ascertain whether such agents were prescribed for the treatment of active seizures, for seizure prophylaxis, or for the treatment of another neuropsychiatric problem. Treatment with anticonvulsant drugs can produce *de novo* cognitive and emotional symptoms (210–212). Phenytoin appears to adversely affect cognition more than carbamazepine (213). Dikmen et al. (1991) (214) described greater cognitive impairment during treatment with phenytoin for prophylaxis of post-traumatic seizures when compared to placebo in a study with 244 patients with TBI. Intellectual deterioration in children on chronic treatment with phenytoin or phenobarbital also has been documented (215). Dikmen et al. (2000) (216) found no adverse cognitive effects of valproate when administered for 12 months after TBI. In a double-blind placebo-controlled study of the cognitive and emotional effects of phenytoin (40 patients) and carbamazepine (42 patients) in TBI patients being treated with these medications for seizure prophylaxis, Smith et al. (1994) (217) noted that both of these medications (but particularly carbamazepine) produced significantly

more cognitive and motor slowing than did placebo. They found that both phenytoin and carbamazepine had negative effects on cognitive performance, especially those that involved motor and speed performance. Although, in the patient group as a whole, the effects were of questionable clinical significance, some patients experienced clinically significant negative cognitive effects during treatment with either of these agents. This is concordant with other observations of carbamazepine's potential to significantly impair cognition in persons with neurological conditions that confer a vulnerability to such effects (218).

However, some patients do tolerate the cognitive effects of valproate and/or carbamazepine relatively well. Minimal impairment in cognition was found with both valproate and carbamazepine in a group of patients with epilepsy (219). Although those included in this study were not TBI patients, this observation suggests that at least some neurologically vulnerable patients may not experience significant cognitive impairment during treatment with these agents. Similarly, Persinger (2000) (220) reported that 12 of 14 patients treated with carbamazepine in the late period following TBI retrospectively reported improvements in episodes of confusion and depression, increases in attention and focus, and reduction or elimination of subtle psychotic-like experiences ("aversive sensed presence"). The author of this study suggests that this finding suggests an electrical (although not epileptic) nature for such symptoms that may be amenable to treatment with carbamazepine or other anticonvulsants.

Among the newer anticonvulsant medications, topiramate, but not gabapentin or lamotrigine, has been demonstrated to adversely affect cognition in healthy young adults (221). Treatment with more than one anticonvulsant (polytherapy) has been associated with increased adverse neuropsychiatric reactions (211). Hoare (1984) (222) found that the use of multiple anticonvulsant drugs to control seizures resulted in an increase in disturbed behavior in children.

Patients who have a seizure immediately after brain injury often are placed on an anticonvulsant drug for seizure prophylaxis. Temkin et al. (1990) (223) showed that the administration of phenytoin acutely after traumatic injury had no prophylactic effect on seizures that occurred subsequent to the first week after injury. Similarly, valproate did not demonstrate any efficacy in preventing late posttraumatic seizures (223). It should be noted that there was a non-significant trend towards a higher mortality during treatment with valproate in this context. Anticonvulsant medications are not recommended after one week of injury for prevention (prophylaxis) of posttraumatic seizures (225). Any patient with TBI who is treated with anticonvulsant medication requires regular reevaluations to substantiate continued clinical necessity for such treatment.

These studies suggest that careful monitoring of cognition, motor function, and other neurobehavioral functions during treatment with any psychotropic compound in persons with TBI is warranted. In general, treatment with these medications should be reserved for patients with neuropsychiatric disturbances that are not fully amenable to treatment through nonpharmacologic means.

## CONCLUSIONS

In this chapter, we have reviewed the role of medication in the treatment of the most frequently occurring neuropsychiatric disturbances that are associated with TBI. Ideally, it would be desirable if the neuropsychiatric problems resulting from TBI could be controlled by nonpharmacologic means alone. However, posttraumatic neuropsychiatric disturbances are associated with significant distress and considerable functional disability, and some of these problems may also endanger the patient and others. In many cases, behavioral treatment and cognitive rehabilitation are of less than optimal benefit in the absence of effective psychopharmacologic treatments of neuropsychiatric disturbances. In other psychiatric conditions such as major depression, there is evidence that delay of effective treatment may result in refractoriness of the condition. For example, Post (1992) (226) reported that recurrent affective disorder becomes more difficult to treat the longer the condition persists. Thus there are theoretical reasons for prompt initiation of pharmacological treatment of neuropsychiatric disturbances in patients with TBI. When appropriately administered, medications may significantly alleviate these problems, improve rehabilitation efforts, and contribute to improved quality of life among persons with TBI.

## Pharmacotherapy of Cognitive Impairment

*David B. Arciniegas  
Jonathan M. Silver*

### INTRODUCTION

Cognitive impairments are among the most common neuropsychiatric sequelae of traumatic brain injury (TBI) at all levels of severity, and typically include impairments of arousal, speed of information processing, attention, memory, language and social communication, and executive functioning (1–5). Although each of these domains of cognitive function may be disrupted by direct injury to cortical, subcortical, or brainstem elements of the distributed cerebral networks that support them, injury to the axons connecting these elements or providing them with the neurochemical input required for their function also contributes to posttraumatic cognitive impairments (6–8). Understanding the neurochemical bases of cognition and the neurochemical consequences of TBI facilitates the development of rational approaches to the pharmacotherapy of posttraumatic cognitive impairments. Although the state of knowledge regarding these issues is at present incomplete, clinicians working with persons with cognitive impairments are well served to stay apprised of this rapidly growing body of information in order to make informed decisions regarding the use of medications in this population.

Toward that end, this chapter provides a review of the pharmacotherapy of cognitive impairment following TBI. To frame that review, definitions of the major domains of cognition most commonly affected by TBI,

their basic neuroanatomy and, where known, their neurochemistry is offered. Next, the neurochemical consequences of TBI particularly relevant to understanding the pharmacotherapy of cognitive and other neuropsychiatric consequences of TBI are reviewed. Thereafter, studies of pharmacotherapies for cognitive impairment following TBI are reviewed and recommendations for the application of those pharmacotherapies are presented.

### COGNITION: DEFINITIONS, NEUROANATOMY, AND NEUROCHEMISTRY

#### Arousal

Arousal is the most fundamental cognitive function, and is supported by a set of selective distributed reticulothalamic, thalamocortical, and reticulocortical networks (9, 10). The principal component of the reticulothalamic portion of the arousal system consists of cholinergic projections arising from the pedunculopontine and laterodorsal tegmental nuclei. These projections terminate in the body of the thalamus as well as the reticular nucleus of the thalamus, the balance of activity between which appears to modulate the degree of thalamic activity. Thalamocortical projections, which are predominantly glutamatergic, activate cortex and prepare it for information processing. The level of cortical arousal, or the readiness of cortex to engage in information processing, is modulated

by the reticulocortical portion of the arousal system. This portion of the arousal system consists of dopaminergic projections arising from the ventral tegmental area of the midbrain, noradrenergic projections arising from the locus ceruleus, serotonergic projections arising from the median and dorsal raphe nuclei, and cholinergic projections arising from the medial septal nucleus and vertical limb of the diagonal band of Broca (to medial temporal structures) and also the nucleus basalis of Meynert (to neocortical, and especially frontal, areas). These projections appear to modulate the activity of widespread areas of neocortex. Collectively, the relative balance between and reciprocal influences of the reticulothalamic and reticulocortical systems determine the individual's clinical level of arousal.

Mechanical injury to any of these elements of the arousal system may impair this most basic cognitive function (6, 8). In more severe injuries, and particularly those in which rotational forces produce shearing or frank hemorrhage in the upper brainstem (i.e., Duret's hemorrhage), arousal may be severely compromised as a result of damage to reticular structures and their reticulothalamic and reticulocortical projections (11). Mechanical injuries of the thalamus, particularly when bilateral, may also compromise cortical arousal and produce persistent vegetative or minimally conscious states (12). Unfortunately, this type of injury is frequently associated with post-TBI fatality (13). Mechanical injury to white matter fibers connecting the several portions of the arousal system (i.e., diffuse axonal injury) produces varying degrees of impaired arousal, decreased speed and efficiency of information processing, and contributes to disturbances in other aspects of cognition (14, 15). Neurochemical perturbations resulting from mechanical injury to these systems, including acute excesses of glutamate, acetylcholine, dopamine, norepinephrine, and serotonin, also contribute to acute disturbances in arousal (16–23). Chronic disturbances in arousal may be due in part to injury-induced deficits in one or more of these neurotransmitters. The role of acute and chronic neurotransmitter dysfunction in disturbances of posttraumatic arousal and other cognitive impairments is discussed in more detail in the next section of this chapter.

### Attention

Sensory gating, selective attention, and sustained attention (vigilance or concentration) are relatively basic cognitive functions. Sensory gating is a pre-attentive process that permits filtering of incoming stimuli in order to admit only a limited amount of information into attentional processing networks (7, 24–26). Selective attention refers to the direction of attentional resources to a stimulus, sustained attention refers to the maintenance of attentional processing on a stimulus, and working

memory denotes the ability to maintain attention to that stimulus in the period immediately following its absence (27).

The boundaries of attentional processes overlap with those of many other cognitive processes, including arousal, perception, recognition, memory, and executive function. Accordingly, attentional disturbances may exacerbate impairments in these other domains of cognition. For example, impairments of attention may interfere with encoding of information (new learning), and thereby produce or exacerbate memory impairments. Similarly, higher-level attentional processes may overlap substantially with executive function, both conceptually and as well as practically given the methods by which executive functions are assessed clinically.

Attentional processes are predicated on several large-scale, selective, distributed neural networks (28; see Mesulam 2000 (9) for a detailed review). These networks include those involved in arousal described above, since arousal is a prerequisite for even the most basic aspects of attention. Additionally, primary and secondary sensory cortices, heteromodal parietal cortical areas, medial temporal (i.e., hippocampal and entorhinal) areas, the striatum and pallidum, several prefrontal (i.e., cingulate, inferolateral, and dorsolateral) cortices, and the axonal connections between them are components of these distributed attentional networks (29–31).

Electrophysiological studies suggest that the neurobiological bases of sensory gating, selective attention, and sustained attention are different (26, 32). Sensory gating appears most strongly related to the function of a cholinergically-dependent hippocampal inhibitory circuit, and is a pre-requisite for the development of selective attention within sensory cortical-hippocampal-frontal networks. Sustained attention is most strongly related to the function of inferior frontal-subcortical and dorsolateral prefrontal-subcortical circuits. The function of these circuits is dependent on a complex set of interactions between the major neurotransmitter systems, including those regulating the availability and function of cortical dopamine, norepinephrine, serotonin, acetylcholine, glutamate, and gamma-aminobutyric acid.

Spatial attention and visuospatial function appear to be served by a network that includes elements of the reticular system, thalamus, superior colliculus, striatum, posterior parietal cortex, frontal eye fields, and parietal cortex (9). As with other attentional processes, most of the major neurotransmitter systems are involved in spatial attention and visuospatial function. Unlike other attentional processes, spatial attention and visuospatial function display a pattern of marked right hemispheric specialization (33, 34). Disruptions in the structure and/or functioning of these networks produce a range of clinical symptoms, although the classic attentional disturbances arising from these right hemisphere attentional

networks include acute confusional states (delirium) and left hemi-inattention (neglect).

As with arousal, acute and chronic neurochemical dysfunction within the networks serving these attentional functions most likely contributes to posttraumatic attentional impairments (24, 35, 36). Impairments in attention may also contribute to problems with the speed of information processing, although the latter is a complex cognitive process predicated not only on attention but also the efficiency and connectivity of the various networks involved in attentional processing and the executive control of attention.

### Memory

Memory is a multifaceted cognitive function that includes both new learning (encoding) and recall (retrieval) of both declarative and non-declarative (implicit and/or procedural) information (37–39). Declarative memory refers to encoding and retrieval of both semantic (or fact) and episodic (or event) information; in other words, declarative memory serves learning and recall of information regarding “who,” “what,” “when,” and “where.” The process of declarative learning, whether verbal or non-verbal, is a hippocampally-dependent process (40, 41). Highly processed multimodal sensory information is transmitted from the inferior parietal (heteromodal) association cortices to the entorhinal-hippocampal complex. When that information produces a sufficiently robust signal in the hippocampus (a process that is, at least in part, predicated on assignment of motivational, emotional, or other “survival-related” significance by amygdala-hippocampal interactions), the process of long-term potentiation is initiated and that information is encoded for later recall. After declarative information is consolidated by this hippocampally-dependent process, retrieving declarative information requires frontal structures to activate the selective distributed networks in which that information was originally encoded. Declarative memory is also therefore highly associative, meaning that memories may be retrieved by reactivation of nearly any part of the network involved in the original encoding of that information or by activation of other networks whose constituent elements are shared by the network involved in the original encoding of that information.

Declarative memory disturbances are relatively frequent consequences of TBI, and may result from injury to the cortical, subcortical, and white matter elements of the networks that serve the various aspects of memory. From a neurochemical perspective, acute excesses of glutamate produce a series of excitotoxic events (i.e., increases in intracellular calcium and activation of second messenger systems) that damage entorhinal and hippocampal areas involved in the development of memory. Damage to these areas results in chronic impairments declarative

memory (42–46). Persistent neurochemical dysfunction in these and other structures required for declarative memory, including alterations in glutamatergic function (43–46) and cholinergic function (7, 24, 47–50), may contribute to posttraumatic impairments in new learning. Injury to the frontal-subcortical elements of this system appears to result in difficulties with efficient retrieval of previously learned information. Information retrieval may be affected by structural and/or neurochemical damage to the frontal-subcortical circuits that subserve this function. In particular, deficits in the availability of dopamine, norepinephrine, and acetylcholine to these circuits appear to contribute to impairments in memory retrieval (51–54).

Procedural memory involves the learning of information of non-declarative nature, and for our purposes is best understood as memory for “how” to perform certain tasks. Procedural memory is predicated on the development and fine-tuning of the sensorimotor-subcortical-cerebellar networks that required for learning and efficiently retrieving complex sensorimotor programs. As such, procedural memory is not hippocampally-dependent and its function and dysfunction are dissociable from declarative memory. Additionally, procedural memory is not associative, but is instead dedicated: it is inflexibly limited to the context (i.e., the specific sensorimotor processes) involved in procedural learning.

Ward et al. (2002) (55) note that procedural memory appears to be less affected by traumatic brain injury than is declarative memory. Recognition of the dissociation between posttraumatic procedural and declarative memory deficits may be relevant to the design of rehabilitation strategies to improve functional memory performance in this population (56). Although procedural memory may be distinguished from declarative memory on anatomical grounds, normal performance in this cognitive domain is dependent on many of the same neurotransmitters required by the frontal-subcortical circuits involved in retrieval of declarative information (57).

### Language

Language refers to the symbolic (both verbal and written) means of communicating thought, and is generally a function of the dominant cerebral hemisphere. The principal domains of language include fluency, comprehension, repetition, and naming, each of which is associated with a selective distributed network specialized to serving its respective language domains (see Damasio and Damasio (2000) (58) for review). Fluency is predicated on a network of frontal structures involving at least dorsolateral, prefrontal motor association, and anterior insular cortices, white matter and subcortical structures through which these areas are connected, and the frontal opercular (Broca’s) area. Output from this network of structures

requires that primary motor cortex and the physical structures needed to communicate verbally or by writing are intact, although communication impairments related to disturbances in elementary motor function are generally distinguishable from true language disturbances (aphasias).

Comprehension of language is predicated on a network of temporoparietal structures, including at least the superior temporal language association cortex (Wernicke's area), inferior parietal heteromodal association cortex, and the white matter structures connecting them. Input to these areas requires that the sensory structures, their connections to primary sensory cortices, and the connection of these areas to sensory association systems are intact. Communication disturbances due to impairments in sensory structures and primary sensory cortices are also generally distinguishable from true language impairments.

The neural networks serving fluency and comprehension are distinct and dissociable, resulting in the production of aphasias referable to dysfunction in their respective networks. Disturbances in the networks subserving fluency produce the "anterior" aphasias, including Broca's and transcortical motor aphasias. The hallmark feature of these aphasias is impaired language syntax (i.e., agrammatisms), reduced phrase length, and undue word finding pauses. Disturbances in the networks subserving comprehension produce the "posterior" aphasias, including Wernicke's and transcortical sensory aphasias. The hallmark feature of these aphasias is impaired language semantics, including impaired understanding of word or phrase meaning and ineffective monitoring of language output (e.g., substitutions, phonemic paraphasias, neologisms, etc.).

Repetition is served by a distinct network comprised of Wernicke's area, a phonological output area at the anterior border of Wernicke's area, Broca's area, and the arcuate fasciculus which connects the posterior and anterior language areas. Disruption of any of these areas produces deficits in repetition. Disruption of the phonological output area or arcuate fasciculus may produce an isolated disruption of repetition, a problem referred to clinically as conduction aphasia. The neural networks subserving naming are widely distributed, and overlap substantially with those upon which fluency, comprehension, and repetition are predicated. Consequently, impairments of naming are commonly associated with any disruption sufficient to produce impairments in these other areas of language.

Disturbances of language and functional communication are not uncommon among persons with TBI (59–64), and may negatively affect functional outcome after TBI (65). Frank aphasias are generally associated with direct injury to cortical language areas or their subcortical white matter connections, and are relatively less common after TBI than are more subtle functional

communication impairments. These subtle language disturbances, such as mild word-finding and naming problems, are common consequences of TBI across the spectrum of injury severity, and tend to be more strongly associated with anterior (i.e., frontal and temporopolar) rather than posterior (temporoparietal) lesions (63).

The neurochemistry of posttraumatic language impairments is less clearly understood than is the neurochemistry of posttraumatic impairments of arousal, attention, and memory. Several reports of the pharmacotherapy of aphasia suggest a role for augmentation of dopamine (66–72) and acetylcholine (73) in the treatment of language disturbances in persons with stroke and TBI, although findings from such studies are not universally positive (74). While inferential reasoning of the neurochemistry of language from pharmacotherapeutic interventions should be undertaken with caution, these reports suggest that dopaminergic and/or cholinergic systems may be reasonable targets for the treatment of posttraumatic language disturbances.

### Prosody

Prosody refers to the affective import and kinesics of language (75, 76). Disturbances of prosody, or the aprosodias, demonstrate a pattern of non-dominant hemispheric specialization. The nondominant hemisphere structures and networks serving prosody are simplistically understood as homologous with those in the dominant hemisphere serving the syntax and semantics of language. Impaired function of the nondominant frontal structures involved in language may produce disturbances in the affective and kinesic aspects of language production, resulting in flat or monotonous expression that fails to communicate effectively the emotional relevance and subtlety of the information expressed. Impaired function of the non-dominant temporoparietal structures involved in language may produce disturbances in the appreciation of the affective and kinesic aspects of the communications of others.

At present, little is known about the frequency of either the posttraumatic aprosodias or their neurochemistry. It has been suggested that dopaminergic dysfunction may influence prosody (77). However, Raymer et al. (2001) (66) observed no improvements in prosody despite improvements in fluent language in a patient with a post-stroke aphasia treated with bromocriptine. Although the neurochemistry and pharmacotherapy of the aprosodias is poorly understood, clinicians should be mindful of such language disturbances as they may mask affective or mood disturbances experienced by persons with TBI and may impair the ability of these individuals to engage in effective social communication despite otherwise intact language.

## Praxis

Praxis refers to the on-demand integration of task understanding and execution, and impairments of this ability are referred to as apraxias (78, 79). Ideomotor apraxia denotes a condition in which an individual is unable to perform on demand a relatively simple (ostensibly “single-step”) task such as brushing one’s hair or teeth, pointing to objects, or pantomiming simple actions. Ideational apraxia denotes a condition in which the sequential linking of several ideomotor tasks is impaired.

Praxis displays a pattern of dominant hemisphere specialization, and the neural networks subserving this domain of cognition appear to overlap substantially with those serving language (10, 80). Consequently, the apraxias tend to be associated with the aphasias, and particularly with the nonfluent aphasias. The neurochemistry of praxis is not well understood, although it has been suggested that striatal dopamine deficits may contribute to the development of apraxia (81). As such, interventions targeting the aphasias, when effective, may be expected to improve concurrent disturbances of praxis. However, Raymer et al. (2001) (66) observed no improvement in limb apraxia despite improvement in nonfluent aphasia in a patient with post-stroke aphasia treated with bromocriptine. The specific neurochemistry of apraxia therefore remains uncertain, as does the neurochemical basis for pharmacotherapy of posttraumatic impairments in praxis.

## Complex Cognition

Complex cognitive functions, including comportment (“social intelligence”), motivation, and executive function are also frequently impaired after TBI (82–86). Comportment describes the manner in which one interacts with others, and involves the integration of emotional (i.e., limbic and paralimbic) information with an understanding of the rules of social interaction. As such, we have described this function as the foundation of “social intelligence” (87). This term refers to the ability to understand and integrate self-assessment with social cueing, and deficits in social intelligence may result in socially inappropriate and maladaptive behavior. This cognitive function is most often ascribed to the lateral orbitofrontal-subcortical circuit (88), given the role of this cortical area in the integration of limbic-paralimbic information with other socially or environmentally relevant information.

Motivation refers to the process of generating, directing, and sustaining goal-directed cognition, emotion, and behavior. Dysfunction of this process results in apathy: a reduction in goal-directed motor, emotional, and cognitive activity (89). Motivation is most often ascribed to the anterior cingulate-subcortical circuit (88–90).

Although the occurrence and treatment of both comportmental and motivational impairments overlap substantially with those of impaired cognition, these impairments typically are more commonly regarded as behavioral rather than cognitive disturbances *per se*. As such, treatment of these problems is discussed in the chapter describing pharmacotherapies of neuropsychiatric disturbances elsewhere in this volume.

Executive function refers to a collection of abilities including: categorization and abstraction; systematic memory searching and information retrieval; problem solving; self-direction; planning and organization of cognition and behavior; independence from external environmental contingencies; maintenance of and fluent shifting between information or behavior sets; and use of language to guide behavior. These are the functions that are most immediately regarded as “intelligence” by patients, their families, and their care providers.

Executive function is most often ascribed to the dorsolateral prefrontal-subcortical circuit, and in particular its ability to integrate the processing and interaction of more “basic” cognitive processes carried on elsewhere in the brain. Executive dysfunction is a relatively common consequence of TBI, and may arise as a direct effect of injury to the dorsolateral prefrontal cortex, the subcortical elements connect to this cortical area, or the axonal connections between them (82). The function of the dorsolateral prefrontal-subcortical circuit serving executive function is dependent on a host of neurotransmitters including glutamate (serving as the primary excitatory neurotransmitter), acetylcholine, dopamine, norepinephrine, serotonin, (serving various modulatory functions), and gamma-aminobutyric acid (GABA, serving as the primary inhibitory neurotransmitter), among others (87, 88, 91). Consequently, posttraumatic disturbances in the function of any of these neurotransmitters may contribute to executive function impairments. By extension, pharmacotherapies that improve the function of posttraumatic impairments in these neurotransmitter systems would be expected to produce improvements in executive function.

## Summary of the Neuroanatomic and Neurochemical Bases of Cognition

In this section we reviewed the basic neuroanatomy and neurochemistry of several cognitive domains in which posttraumatic impairments are common. Although normal cognition ultimately depends on a complex set of neurotransmitter, neuroactive peptides, neurohormones, second messenger system, and genetically-regulated neurochemical processes and interactions, several simple themes relevant to currently available pharmacotherapies are apparent. Glutamate-mediated neuronal damage and/or long-term glutamatergic dysfunction (either excess or deficit) may adversely affect a host of cognitive functions,

including arousal, attention, memory, and executive function. Catecholamine (i.e., dopamine and norepinephrine) dysfunction appears particularly important to cortical aspects of arousal attention, speed of processing, language, executive function, and perhaps also memory retrieval. The role of serotonin in cognition is uncertain; augmentation of serotonin via nonselective serotonin reuptake inhibitors does not appear to be of direct benefit to cognition, but may indirectly affect cognition via improvement of comorbid disorders such as depression (92). Whether more limited alteration of serotonergic activity (e.g., alteration of action at 5HT-3 receptors) improves cognition directly or indirectly through modulation of other neurotransmitter systems is a matter of present investigation (see Buhot et al. 2000 (93) for review). Cholinergic function appears important to both subcortical and cortical aspects of arousal, attention, and memory, and may also play an important role in language and executive function. In the next section of this chapter, we will review the evidence for neurotransmitter dysfunction following TBI in order to frame the neurochemical basis of pharmacotherapies for posttraumatic cognitive impairments.

### THE NEUROBIOLOGICAL BASES OF COGNITIVE IMPAIRMENT FOLLOWING TBI

Cognitive deficits arising from penetrating and/or focal trauma are often understandable given the functions known to be subserved by the site of injury; for example, executive impairments following severe bifrontal contusion and/or white matter injury, impaired anterograde memory following bilateral entorhinal-hippocampal injury, and so on (94). However, the etiology of cognitive impairments following non-penetrating (or “non-focal”) injuries is relatively less well understood. Cytotoxic processes such as calcium and magnesium dysregulation, free radical injury, neurotransmitter (especially glutamate and cholinergic) excitotoxicity, and diffuse axonal injury due to straining and shearing biomechanical forces result from non-penetrating, non-contusional injuries (see McIntosh et al. (1999) (95) and Halliday (1999) (96) for review). These processes functionally and structurally disrupt the neural networks subserving neuropsychiatric function (i.e., cognition, emotion, and behavior). Studies of neurochemical changes subsequent to TBI suggest that alterations in neurotransmitter production and/or delivery occur within these networks both acutely and chronically, and therefore play a role in the development of cognitive impairments following TBI. As discussed in the following sections of this chapter, all of the major neurotransmitter systems, including glutamate, dopamine, norepinephrine, serotonin, and acetylcholine, are elevated in the acute period following TBI, a process that we

suggest may be simplistically understood as an acute traumatically-induced “neurotransmitter storm.” However, the timing and/or eventual recollection of these neurotransmitter elevations influences the relevance of each of these systems to acute and/or chronic posttraumatic cognitive impairments.

### Glutamate

TBI-induced glutamatergic disturbances are almost certainly important in the genesis of injury to areas critical to neuropsychiatric function (see Obrenovitch and Urenjak (1997) (19) for a detailed review). Excessive release of the amino acid neurotransmitters glutamate and aspartate appears to be at least in part responsible for traumatically-induced neuronal injury, particularly to areas in which these neurotransmitters play key roles (i.e., hippocampus and frontal cortices) (97–99). The degree of elevation of these excitatory amino acid neurotransmitters appears to be associated with the severity of injury and post-injury survival (100–102). The principal neurotoxic effects of glutamate are generally attributed to its action at N-methyl-D-aspartate (NMDA) receptors. When glutamate activates an NMDA receptor, it opens a channel in the cell membrane that permits influx of calcium. When excessive amounts of calcium enter the cell, oxidative processes and activation of proteolytic enzymes ensue, and the axonal terminus of the neuron is injured or destroyed. Even where such excesses are not directly excitotoxic, they tend to “drive” glucose utilization, which may exceed the capacity of the brain for oxidative metabolism, thereby producing toxic accumulations of lactate (103).

Cerebral glutamate levels are elevated within hours following TBI and appear to remain elevated for at least the first week following TBI in humans (104–107). The rate of return to normal levels of glutamate may be adversely affected by concurrent hypoxia (108). With or without such complicating factors, the rate at which glutamate levels return to pre-injury baseline – if they do indeed completely normalize after TBI – is uncertain. The rate of decline of glutamate levels observed in studies performed to-date suggests a trend towards normalization of cerebral glutamate in the weeks following TBI. However, early elevations of glutamate may permanently damage cortical areas (109) and thereby contribute to persistent posttraumatic cognitive impairments.

Animal models suggest that antagonism of glutamate receptors may attenuate the severity of neuronal injury following either focal ischemia (110) or trauma (98, 99). Additionally, glutamate-mediated excitotoxicity may be attenuated by therapeutically induced, but not spontaneous, cerebral hypothermia delivered in the acute post-injury period (111). Unfortunately, there are at present no widely available pharmacotherapies that effectively

limit the destructive effects of acute excesses of glutamate or that ameliorate cognitive or other neuropsychiatric problems predicated on glutamate-induced neuronal damage (112).

Memantine and amantadine, two moderate-affinity uncompetitive NMDA receptor antagonists, are of theoretical interest to both the prevention of glutamate-mediated neurotoxicity in TBI and also the remediation of posttraumatic cognitive impairments predicated on glutamatergic dysfunction. Although there is evidence that memantine confers neuroprotection from glutamate-mediated excitotoxicity when administered shortly after experimental TBI in animals (113), there are at present no studies demonstrating neuroprotection from either amantadine or memantine in human TBI. Memantine and amantadine appear to indirectly increase striatal, prefrontal cortical, and nucleus accumbens dopamine function through their actions at glutamate receptors on midbrain dopaminergic neurons (114–117) or other yet undetermined mechanisms (118). The effects of these medications on both glutamate function and dopaminergic function may account for the purported benefit of memantine among persons with cognitive impairments due to Alzheimer's disease (119–122), cerebrovascular disease (120–123), and Wernicke-Korsakoff syndrome (124). As discussed in the next section, amantadine has been observed to improve arousal, attention, motivation, and other frontally-mediated functions in persons with TBI (125–129). Although encouraging of the potential application of this medication and other uncompetitive NMDA receptor antagonists to the treatment of posttraumatic cognitive impairments, the role of the glutamatergic properties of these agents towards that end is at present uncertain.

### Catecholamines

Discrete lesions to ascending monoaminergic projections may interfere with the cognitive function served by the networks dependent upon them (130). Monoaminergic afferents course from the brain stem anteriorly, curving around the hypothalamus, the basal ganglia, and the frontal cortex, placing them in anatomical areas that are especially vulnerable to strain and shear forces that occur during TBI. Catecholamines alter the signal-to-noise ratio in the circuits that process information (131–133). In the setting of optimal catecholamine levels, the processing of contextually relevant cognitive, emotional, or behavioral information (signal) is enhanced and processing of background information (noise) is inhibited. As such, catecholamines serve as key modulators of information processing circuits in the brain. Because dopamine and norepinephrine exhibit an inverted U-shaped dose-response curve with respect to their effects on cortical information processing (9), either deficient or excessive dopamine may interfere with this process.

Two studies found markedly elevated plasma catecholamine levels after acute head injury in humans (22, 134). Acute elevations of these neurotransmitters are predictive of poor recovery from TBI (17, 22, 23). Whether such elevations are themselves sufficiently injurious to contribute to poor recovery after TBI or are instead simply a proxy for injury severity is not clear.

Also unclear is the role of catecholaminergic dysfunction in the development of persistent posttraumatic cognitive impairments. Tang et al. (1997) (18) suggested that striatal hyperdopaminergia contributes to post-TBI memory deficits in recently injured animals, antagonism of which improved visual memory performance. This finding appears to contradict the inference of reduced dopamine function drawn from observations of cognitive benefits following augmentation of dopaminergic function (using methylphenidate, for example) among persons with TBI in the days to weeks following injury (135, 136) and the observation that robust dopamine antagonism delays recovery from posttraumatic amnesia (137). However, it is consistent with the suggestion that either hyper- or hypodopaminergia may interfere with cognition following TBI. Very few other experimental-injury studies (20, 138) offer support for the hypothesis that cerebral catecholamine levels are chronically altered by TBI, and only one human study offers indirect evidence of relationship markers of dopaminergic or noradrenergic function and long-term cognitive deficits in traumatically brain-injured humans. Konrad et al. (2003) (35) studied 26 children with TBI, 31 children with attention deficit hyperactivity disorder (ADHD), and 26 healthy comparison children. Subjects with TBI and ADHD excreted significantly more urinary normetanephrine in resting situations and less urinary epinephrine after cognitive stress, and showed a decreased blink rate (an indirect measure of dopamine function) compared to normal controls. Children with TBI also demonstrated a higher excretion of metanephrine in the resting situation in comparison to children with ADHD and controls. Children with ADHD showed a higher tonic activity of the noradrenergic system and a less adaptive epinephrine excretion in response to cognitive stress, and children with TBI were impaired in their tonic epinephrine excretion. These observations suggest the possibility of long-term alterations in systemic monoaminergic function following TBI, but they offer only indirect evidence of posttraumatic dysfunction in cerebral monoaminergic systems.

Although evidence of direct, persistent, and statistically significant injury to catecholaminergic afferents following TBI is at present lacking (139), genetically-determined individual differences in the metabolism of these neurotransmitters by catechol-O-methyltransferase (COMT) may contribute to posttraumatic cognitive impairments. Substitutions in the gene sequence for COMT at codon 158 (Val/Met) result in expression of

an enzyme with either high activity (COMT-val) or low activity (COMT-met) (140). Persons homozygous for the COMT-val isoform appear to metabolize catecholamines more efficiently than persons homozygous for the COMT-met isoform, and heterozygotes (i.e., COMT-val/met) metabolize catecholamines with an intermediate level of efficiency. In a study of 123 persons with TBI and posttraumatic executive dysfunction, Lipsky et al. (2002) (141) observed the highest levels of executive dysfunction on the Wisconsin Card Sorting Task (generally regarded as a measure of executive function) among subjects homozygous for the fast-acting COMT enzyme, intermediate levels of impairment among heterozygotes, and the lowest levels of impairment among subjects homozygous for the slow-acting COMT enzyme. This finding suggests that even if TBI produces only modest injury to reticulocortical catecholaminergic projections, individual differences in the metabolism of these neurotransmitters might in some persons (i.e., those with the fast-acting COMT enzyme) transform modest structural injury into substantial functional impairments in catecholamine-dependent cognitive functions.

In summary, while the extent of dopaminergic and noradrenergic dysfunction in the late period following TBI remains uncertain, pre-injury genetic differences in the metabolism of these neurotransmitters may contribute to posttraumatic cognitive impairments. The implications of such finding with respect to long-term neuropsychiatric disturbances require further study.

### Serotonin

Serotonergic projections to frontal cortical areas are susceptible to biomechanical injury, and both diffuse axonal injury and contusions may produce dysfunction in this neurotransmitter system. Secondary neurotoxicity that is caused by excitotoxins and lipid peroxidation may also damage serotonergic projections (142). Pappius (1989) (21) demonstrated widespread increases in hemispheric serotonin levels following experimentally induced brain injury in rats, and noted that increases in serotonin appeared to produce decreases in cerebral glucose utilization. Busto et al. (1997) (143) observed a prompt increase in the extracellular levels of serotonin in cortical regions adjacent to the impact site in an experimental injury study in rats. Tsuiki et al. (1995) (144) demonstrated in an experimental injury paradigm that serotonin synthesis was significantly increased in cortical areas throughout the injured hemisphere, particularly in the dorsal hippocampus and hippocampal area CA3, in the medial geniculate nucleus, and in the dorsal raphe nucleus. These authors observed depression in cortical glucose use in areas with increased serotonin synthesis. Eghwurdjakpor et al. (1997) (20) demonstrated a rapid increase in hemispheric concentrations of serotonin,

dopamine, and norepinephrine shortly after trauma experimentally induced traumatic brain injury in rats, with continued increases to three to four times control levels by 24 to 48 hours postinjury. These authors also report significant regional differences in serotonin levels after experimental TBI, with increases in the cerebral hemispheres but decreases in the spinal cord.

Findings regarding posttraumatic cerebral serotonin levels are discrepant, but such discrepancies may be attributable to between-study differences in the sites from which CSF samples are obtained. For example, Vecht et al. (1975) (145) and Bareggi et al. (1975) (146) found that lumbar cerebrospinal fluid (CSF) 5-hydroxyindoleacetic acid (5-HIAA) was below normal in conscious patients and normal in patients who were unconscious. Decreased CSF levels of serotonin are reported by Karakucuk et al. (1997) (142) in 45 adults undergoing minor surgery with spinal anesthesia within 24 hours of TBI. However, Porta et al. (1975) (147) demonstrated elevated ventricular CSF 5-HIAA levels in patients within days of severe TBI. These findings suggest that ventricular sampling in humans may more accurately reflect alterations in cerebral serotonin levels after TBI than lumbar cerebrospinal fluid sampling. Additionally, focal and diffuse lesions may result in differences with respect to monoaminergic alterations after TBI. For example, Van Woerkom et al. (1977) (148) investigated patients with frontotemporal contusions and those with diffuse contusions. They documented decreased levels of 5-HIAA in patients with frontotemporal contusions, but increased 5-HIAA levels in those with more diffuse contusions.

The evidence in both animal and human studies suggests that TBI results in acute increases in hemispheric serotonin levels and also that such increases are associated with decreased cerebral glucose utilization. As a result of decreasing cortical metabolism, acute elevations of serotonin may in part contribute to posttraumatic cognitive impairments during the acute injury period. It stands to reason that augmentation of serotonergic function in the acute injury period would be of little benefit cognitively. Consistent with that reasoning, Meythaler et al. (2001) (149), in a placebo-controlled trial of sertraline for arousal and attentional impairments in 11 subjects with severe TBI in the acute rehabilitation setting, failed to find a statistically significant treatment effect on these cognitive functions. Although their small sample size precludes generalization of their findings, they suggest that augmentation of serotonergic function alone is insufficient to produce marked improvements in cognition among persons with recent severe TBI. Similarly, Wilson and Hamm (2002) (150) observed no improvement in memory function in experimentally-injured rats treated with fluoxetine. These findings suggest that selective serotonin reuptake inhibitors (SSRIs) such as these should not at the present time be regarded as agents with direct

cognitive-enhancing properties in the setting of acute severe TBI.

Whether the SSRIs are without such effects in the late period follow TBI is uncertain. Schmitt et al. (2001) (151) investigated the cognitive effects of several SSRIs and demonstrated significant improvements in verbal fluency among healthy middle-aged adults treated with sertraline 50–100 mg when compared to treatment with placebo. The authors of this study attributed that effect to sertraline's modest ability to inhibit dopamine reuptake. Fann et al. (2001) (92) describe improvements in psychomotor speed, recent verbal memory, recent visual memory, general cognitive efficiency, and patient-reported perception of cognitive symptoms during treatment of post-TBI depression with sertraline. It is possible that treatment with sertraline may confer cognitive benefits on the basis of resolving depression alone, as a function of augmenting either frontal serotonergic or dopaminergic function, or by both these and other mechanisms.

Similarly, Horsfield et al. (2002) (152) performed an eight-month open-label study of the effects of fluoxetine 20–60 mg/day in five patients with TBI and varying levels of depression in order to determine whether this medication conferred mood and/or cognitive benefits. They observed improvements in mood among persons with such symptoms, and demonstrated improvement on several measures of attention, processing speed, and working memory in this small group of patients. Their findings are consistent with the observations of Fann et al. (2001) (92) with respect to improved cognition in association with reduced depressive symptoms, but extend that finding to suggest a possible benefit of this serotonergic augmentation on cognition more generally. The authors of this study also note fluoxetine's ability to stimulate expression of brain-derived neurotrophic factor and its specific tyrosine kinase receptor. Such effects have been demonstrated to produce neuritic elongation and increased dendritic branching density of some hippocampal neurons in rodents. Although it is possible that similar mechanisms may be operative in humans, the sample size and findings of the Horsfield et al. (2002) (152) study do not support this interpretation at present. Instead, interpreting their findings as reflecting the activating effects of fluoxetine (which may operate through a variety of neurochemical mechanisms) is both simpler and more likely to be correct.

At present, it appears that serotonergic augmentation using SSRIs may be of benefit in the treatment of depression following TBI, and that alleviation of depression is associated with improvement in cognition. It is not clear that these agents, which are non-selective with respect to their effects at a receptor level, confer any direct benefit on cognition alone. Receptor-specific modulation of serotonergic function (i.e., agonism of 5-HT<sub>2A</sub>, 5-HT<sub>2C</sub> or 5-HT<sub>4</sub> receptor, or antagonism of 5-HT<sub>1A</sub> or 5-HT<sub>3</sub>

and 5-HT<sub>1B</sub> receptors) may afford cognitive benefits (93). Consistent with that suggestion, Kline et al. (2001) (153) demonstrated improvement in spatial memory in experimentally-injured rats treated with the 5HT<sub>1A</sub> receptor antagonist repinotan. Additional studies are needed to clarify the cognitive effects of agents that modify receptor specific serotonergic activity among persons with TBI.

### Acetylcholine

Findings from both basic and clinical studies suggest that TBI produces acute elevations and long-term deficits in cortical cholinergic function. Multiple studies (48, 154–160) demonstrate this pattern of cholinergic dysfunction following experimentally-induced TBI in rodents, as well as a robust relationship between chronic post-traumatic cholinergic deficits and spatial memory impairments. One of the most compelling demonstrations of relatively selective cholinergic injury following TBI is the report of Schmidt and Grady (1995) (139). They induced a fluid-percussion head injury sufficient to cause a 13- to 14-minute loss of righting reflex in rats anesthetized with halothane. Rats with experimentally induced midline injury suffered significant bilateral reductions in cholinergic neurons, including reductions in area Ch1 (medial septal nucleus; 36%), Ch2 (nucleus of the diagonal band of Broca; 44%), and Ch4 (nucleus basalis of Meynert; 41%). Among animals with lateralized injuries, similarly severe losses of cholinergic neurons were observed ipsilateral to the injury site and lesser but nontrivial (11–28%) losses were observed contralaterally. The authors note that these losses did not extend to brainstem cholinergic nuclei (Ch5 and Ch6), and there were no observable effects on forebrain dopaminergic or noradrenergic innervation. These findings suggest that cholinergic deficits may be the most prominent type of chronic posttraumatic neurotransmitter disturbance.

TBI in humans produces the same pattern of cholinergic dysfunction as is reported in the experimental injury literature, with acute elevations of cerebral acetylcholine followed by chronic cholinergic deficits. Grossman et al. (1975) (161) demonstrated that patients with TBI had elevated acetylcholine levels in fluid obtained from either intraventricular catheters or lumbar puncture in the acute period following TBI. Dewar and Graham (1996) (162), Murdoch et al. (16, 163) demonstrated loss of cortical cholinergic afferents with concurrent preservation of post-synaptic muscarinic and nicotinic receptors several weeks after severe and fatal TBI. Arciniegas et al. (7, 25, 26), using the hippocampally-mediated cholinergically-dependent P50 evoked waveform response to paired auditory stimuli as a marker of cholinergic function, demonstrated electrophysiologic abnormalities in patients with chronic symptoms of impaired auditory gating,

attention, and memory in the late (>1 year) period following TBI. In a subsequent study, Arciniegas et al. (2003) (24) demonstrated that this electrophysiologic abnormality is present in the majority of persons with persistent attention and memory complaints in the late period following TBI. Collectively, these findings support the hypothesis that cholinergic function is chronically deficient among many persons with TBI and that cholinergic deficit may be a significant contributor to posttraumatic cognitive impairments.

Given the role of acetylcholine in arousal and attention (9, 10), memory (164, 165), and executive function (166), and the evidence suggesting that cholinergic deficits contribute to posttraumatic cognitive impairments, pharmacotherapies that augment cholinergic function may improve posttraumatic cognitive impairments. These therapies are discussed in more detail in the next section of this chapter.

### Summary of Post-Traumatic Neurochemical Disturbances

Animal and human studies suggest that most of the major neurotransmitter systems are acutely activated by mechanical brain injury. These excesses appear to result in a complex set of cerebral, and hence cognitive, dysfunctions. Neurotransmitter disturbances appear to be not only consequences of TBI but also contributors to brain injury. Excesses of glutamate are excitotoxic and may permanently damage areas with dense glutamatergic innervation, including frontal, striatal, and medial temporal (i.e., hippocampal) areas. There is, at present, no evidence to support chronic reductions in glutamatergic function after TBI. However, it is conceivable that improving the efficiency of glutamatergic neurotransmission with agents like memantine, amantadine, or neramexaane (another uncompetitive NMDA receptor antagonist presently under study in humans) may improve cognitive and other neurobehavioral functions in persons with TBI.

Acute catecholaminergic excesses after TBI appear predict poor outcome following TBI; when present, such increases may simply be a marker of injury severity in the studies in which they were assessed. Although evidence of chronic reductions in catecholaminergic function after TBI and/or a relationship of such to posttraumatic cognitive impairments in humans is lacking, more modest reductions in these neurotransmitters may in some genetically vulnerable persons (i.e., those with a fast-acting COMT enzyme) contribute to posttraumatic impairments in catecholamine-dependent cognitive functions. Alternatively, persons with traumatic lesions to catecholamine projections would be expected to develop cognitive impairments in the areas to which the lesioned fibers project. The cognitive functions served by the cerebral

(i.e., frontal) areas to which these catecholaminergic fibers project are at greatest risk for disruption, including arousal, attention, speed and efficiency of information processing, executive function, and perhaps also language.

At present, there is also a dearth of evidence to support a relationship between posttraumatic dysfunction in serotonergic systems and cognitive impairment. Acute serotonergic excesses are associated with decreased cortical metabolism in the areas in which such excesses occur. In the acute post-injury period, serotonin-induced cerebral hypometabolism may contribute to cognitive dysfunction. It is not clear whether such excesses normalize, persist, or transition to posttraumatic deficits in serotonergic function. There is some evidence that treatment with the sertraline (92) or fluoxetine (152) may facilitate cognitive improvements in persons with depression following TBI. However, it does not appear that these agents facilitate cognitive improvements alone, at least not among persons with severe TBI (149). Consequently, the contribution of serotonergic dysfunction to posttraumatic cognitive impairments in the absence of comorbid posttraumatic depression is uncertain.

There is considerable animal and human evidence of acute posttraumatic excesses of acetylcholine and chronic posttraumatic reductions in cholinergic function. Because acetylcholine is a major contributor to the function of brain systems involved in arousal, attention, memory, language, and executive function, cholinergic deficits would be expected to contribute posttraumatic cognitive impairments.

The pharmacotherapy of TBI should be considered in the context of these findings. As will become clear in the next section of this chapter, the pharmacotherapeutic studies performed to-date appear to support most strongly the suggestion that augmentation of catecholaminergic and cholinergic function, and perhaps also glutamatergic function, are useful neurochemical targets for pharmacologic intervention among persons with posttraumatic cognitive impairments.

### PHARMACOTHERAPY OF POST-TRAUMATIC COGNITIVE IMPAIRMENTS

As with any pharmacotherapy for the neuropsychiatric (i.e., cognitive, emotional, or behavioral) sequelae of TBI, the basic principles of pharmacotherapy (see Chapter 52, "Pharmacotherapy of Neuropsychiatric Disturbances") in this population should be followed. For purposes of this discussion, we will assume that prior to initiating any pharmacologic treatment for posttraumatic cognitive impairments the treating clinician has first completed a thorough psychiatric, developmental, and neurological evaluation. When subsequently considering pharmacotherapy of cognition, two issues require additional

attention. First, the presenting cognitive complaints must be carefully assessed, defined, and operationalized, preferably through the use of objective measures of cognition. These measures may include “bedside” tests such as the Mini-Mental State Examination (167), any of several versions of the Clock Drawing Test, the Frontal Assessment Battery (168) or other similar measures of frontally-mediated cognition, but are better assessed through formal neuropsychological testing. Measures that are sensitive to both global cognitive impairment as well as impairments of speed of information processing, attention, memory, language, and executive function should be included in any pre-treatment cognitive assessment.

Second, the use and effectiveness of all ongoing treatments must be reevaluated, including both pharmacologic and non-pharmacologic therapies (whether prescribed and/or self-administered). Several classes of medications are of particular concern. Anticonvulsants such as phenytoin and carbamazepine may exacerbate cognitive impairments among persons with TBI. In a double-blind placebo-controlled study of phenytoin (40 patients) and carbamazepine (42 patients) in TBI patients being treated with these medications for seizure prophylaxis, Smith et al. (1994) (169) report that both of these medications (but particularly carbamazepine) produced significantly more cognitive and motor slowing than did placebo. Dikmen et al. (1991) (170) also observed greater cognitive impairment during treatment with phenytoin for prophylaxis of posttraumatic seizures when compared to placebo in a study with 244 patients with TBI. Additionally, phenytoin conferred no benefit against the development of post-traumatic seizures when used after the first week post-TBI. Both studies suggest that careful monitoring of cognition during treatment with anticonvulsants in brain-injured patients is warranted, and that such treatment should be reserved for patients with clearly established posttraumatic seizure disorders. Typical antipsychotic medications (e.g., haloperidol, fluphenazine, thioridazine, chlorpromazine) may exacerbate cognitive impairments among persons with TBI (171) and may prolong the period of posttraumatic amnesia (137). Benzodiazepines are known to impair memory and other aspects of cognition even among individuals without brain injuries (172), and there is some evidence supporting the common clinical belief that these agents impair cognitive performance among persons with TBI (173). It is concerning that prescription of anticonvulsants, typical antipsychotics, and benzodiazepines remains common in this population. It is sometimes the case that such treatments have not been properly applied, are predicated on misdiagnosis of the problem, or are the result of poor communication among treating professionals regarding the problem in question. When treating posttraumatic cognitive impairments, the most appropriate first pharmacological recommendation is to eliminate

these medications. If after eliminating these medications there remain cognitive, emotional, or behavioral problems that require treatment, nonpharmacologic therapies should be offered. When these interventions fail to afford improvement in posttraumatic cognitive performance, then medications may be required.

As noted in the previous sections of this chapter, advances in our understanding of the neurochemistry of TBI have been used to develop *a priori* hypotheses to guide the selection of pharmacotherapeutic agents in some treatment studies. While these studies are few in number, continued development of the pharmacotherapeutic literature in this area should be predicated on such *a priori* hypothesis rather than on the basis of extrapolation from the treatment of other neuropsychiatric disorders. At present, our understanding of the neurochemical consequences of TBI yields three principal themes in the pharmacotherapy of posttraumatic cognitive impairments: modulation of glutamatergic function, augmentation of catecholaminergic function, and enhancement of cholinergic function.

There are at present no proven therapies with which to limit the effects of glutamate-mediated excitotoxic injury among traumatically brain-injured persons. It is also not clear whether or to what extent acute alterations or long-term dysfunction of glutamate function contribute to posttraumatic cognitive impairments. This is likely to be an area of increasing research in the field of TBI, and clinicians should be aware of the possibility that agents affecting glutamatergic function may find applications in the pharmacotherapy of posttraumatic cognitive impairments. However, given the lack of data regarding this approach we will not consider further this issue.

The majority of the pharmacotherapeutic literature in this field focuses on augmentation of catecholaminergic function, cholinergic function, or both. As discussed above, chronic cholinergic and/or catecholaminergic dysfunction contribute to cognitive impairments following TBI. While the experimental and human literature offers stronger evidence of chronic posttraumatic cholinergic dysfunction, clinical evidence suggests a potentially useful role for augmentation of either or both of these neurotransmitter systems in persons with posttraumatic cognitive impairments. However, the interindividual response to such agents is not uniform (136). Some patients respond to psychostimulants, some to cholinesterase inhibitors, some require medications from both classes, and some respond to neither class of medication. Selecting an appropriate treatment for a given patient might be made easier if clinical markers of dysfunction in these systems were available. However, simple, inexpensive, and widely available markers of *in vivo* neurotransmitter function are at present lacking.

In the absence of widely available markers of neurotransmitter dysfunction, pharmacotherapeutic studies performed to-date generally employ agents observed to

be effective for the treatment of cognitive impairments among persons with phenotypically similar but etiologically distinct neuropsychiatric disorders. For example, the attention deficits of persistently impaired TBI survivors sometimes superficially resemble those of patients with attention-deficit hyperactivity disorder (ADHD). Given this similarity, psychostimulants (e.g., methylphenidate, dextroamphetamine) and dopaminergically active medications (amantadine, bromocriptine, L-dopa/carbidopa, etc.) have been used with some success for the treatment of posttraumatic impairments of arousal, processing speed, attention, and executive function. Because posttraumatic memory disturbances may in some respects resemble those observed among persons with Alzheimer's disease, agents used for the treatment of cognitive impairments in Alzheimer's disease have been studied in persons with similar problems following TBI. Although there are some differences in the relative predominance of encoding and retrieval deficits between these conditions, the cholinesterase inhibitors have been used with some success among patients with posttraumatic memory impairments.

Complicating the matter of selecting the agent most likely to improve posttraumatic cognitive impairment in an individual patient is the relative paucity of rigorously conducted clinical studies upon which to base treatment decisions. Although the pharmacotherapy of posttraumatic cognitive impairments is the most extensively studied area of neuropsychiatric treatment in this population to-date, the limited number and methodological problems of these studies limit their generalizability to everyday clinical practice.

In this section, studies of pharmacotherapies for posttraumatic cognitive impairments are organized according to medication class. Included in the discussion of the agents are the types of cognitive impairments they appear to improve. These studies include some double-blind placebo-controlled studies, uncontrolled open-label studies, and also case series or single-case reports. The strength of the evidence they provide for the use of these agents in clinical practice is a matter of considerable debate, and most offer evidence sufficient to support the use of these agents only as treatment options for posttraumatic cognitive impairments. Guided by the published literature and our own clinical experience, we offer preliminary recommendations regarding the pharmacotherapy of posttraumatic cognitive impairments. However, we encourage clinicians to consider the application of these agents to the treatment of in an individual patient a matter of empiric trial, and we suggest that clinicians consider reviewing the articles referenced herein prior to using these agents in their clinical practice.

### **Psychostimulants**

The effects of psychostimulants such as methylphenidate and dextroamphetamine on central monoaminergic systems

are complex. Methylphenidate and dextroamphetamine increase the release of dopamine and norepinephrine and, at higher doses, block the reuptake of these monoamines. These agents also appear to inhibit monoamine oxidase, which in combination with their other effects increases the effectiveness of monoaminergic neurotransmission. The effect of increased catecholaminergic activity in the ascending reticular activating system, the striatum, and the several cortical-subcortical circuits appears to be an increase in arousal, speed of processing, and attention. Such agents may afford such benefits in both the acute inpatient rehabilitation and post-acute outpatient settings, and there are theoretical reasons to suggest that stimulants may also facilitate neuronal recovery after brain injury by a variety of dopaminergically-mediated mechanisms (174).

#### *Methylphenidate*

Evans et al. (1987) (175) performed a single-case controlled study of methylphenidate (.15 mg/kg BID and .3 mg/kg BID) in a 21-year old male with a remote severe TBI. They observed improvements on measures of sustained attention, processing speed, motor speed, memory, and also mood. Subsequently, Gualtieri and Evans (1988) (176) performed a double-blind placebo-controlled crossover design study of methylphenidate among 15 adult patients with severe TBI. Subjects were 5–12 months post-injury, and were treated with methylphenidate .15 mg/kg BID and .3 mg/kg BID. They report treatment-related mood and behavioral, but not cognitive, improvements. In a similarly designed study, Speech et al. (1993) (177) treated 12 adult subjects with moderate to severe TBI with methylphenidate .3 mg/kg BID one year or more after their injuries. They observed a nonsignificant trend towards improvement in mood and performance on measures of vigilance and distractibility. They observed no improvements in memory, processing speed, or social interaction.

Plenger et al. (1996) (178) demonstrated a significant effect of methylphenidate on attention, Disability Rating Scale scores, and motor performance during subacute recovery from TBI in a randomized, double-blind, placebo-controlled study during which 23 subjects were treated for 30 days. They found that attention and functional performance were significantly improved by treatment with methylphenidate at day 30, but were not different from placebo treatment at day 90. In this study, methylphenidate treatment did not affect the ultimate level of recovery on these measures but appeared to improve the rate of recovery. However, analysis of data from this study is complicated by subject dropouts: only 12 subjects remained in the study at 30 days and only 9 subjects remained at 90 days. Consequently, it is difficult to fully evaluate the effects of methylphenidate in this

cohort. Whyte et al. (2002) (136) suggest that random variations in initial injury severity of these subjects might either account for or potentially mask true drug effects. In a similar study, Kaelin et al. (1996) (179) describe the effect of methylphenidate 15 mg twice daily on the course of recovery in 11 patients with TBI during acute inpatient rehabilitation setting. Using an A-A-B-A design, they demonstrated that methylphenidate significantly improved attention as measured by performance on digit span and symbol search tasks and was associated with improved Disability Rating Scale scores. Although one subject was withdrawn from the study due to tachycardia, methylphenidate was generally well tolerated. Although these studies are not without methodological problems and their findings are modest, they suggest that methylphenidate may improve cognitive function and the rate of recovery following TBI.

More recently, Whyte et al. (1997) (135) performed a randomized, double-blind, placebo-controlled, repeated crossover design to assess the effect of methylphenidate on attention in 19 subjects with nonpenetrating TBI recruited from either inpatient or outpatient settings. Referral for study participation was based on attending physician's recommendation of this treatment for clinically apparent problems with attention. Subjects were excluded if they had a history of prior TBI or other neurological disease, major mental illness, learning disability, attention deficit disorder, or if they were taking any psychoactive medication other than carbamazepine (which two subjects were taking at the time of study). Eleven of these patients participated in a task assessing distractibility and phasic arousal and 19 participated in an assessment of behavioral inattention. Patients were on average 31 years old (median age 27), had an average of 12 years of education, and were in general in the post-acute period following TBI (mean interval since injury = 514 days, median interval since injury = 145 days). Subjects underwent six serial assessments, typically separated by 1–3 days. Task administration was randomly assigned to methylphenidate or placebo in pairs over the course of the study in order to facilitate interpretation of individual subject performance patterns and to distinguish practice from treatment effects. Methylphenidate was administered at a dose of 0.25 mg/kg (rounded to the nearest 2.5 mg) BID, and assessments were performed approximately 90 minutes after administration of methylphenidate or placebo. The study tasks created 22 performance variables for analysis. Methylphenidate significantly improved arousal and speed of processing, but did not improve most aspects of vigilance (sustained attention), distraction, or motor speed.

Placed in the context of other studies of methylphenidate in adults with posttraumatic cognitive impairments, the findings of Whyte et al. (135) suggest that principal benefit of this agent is on processing speed and to a lesser extent on subjective ratings of behavior and

mood. This finding stands in contrast to the more common clinical use of methylphenidate for impairments of vigilance and distractibility. They note that there is, at present, little data to support the use of methylphenidate for posttraumatic memory impairments. It stands to reason that improvements in attention might secondarily benefit memory, although the studies performed to-date offer little support for this suggestion. Whether methylphenidate has benefits on aspects of attention other than processing speed remains uncertain, but common clinical experience suggests that at least some persons with attentional impairments benefit from treatment with this agent.

Two studies (180, 181) describe the use of methylphenidate in the treatment of children and adolescents with posttraumatic cognitive impairments. In the study by Mahalick et al. (1998) (180), methylphenidate .3 mg/kg BID was administered in a crossover design study of 14 subjects (age 5–14 years) approximately 1.2 years after mild-to-moderate TBI. They observed statistically significant improvements in vigilance, processing speed, and distractibility. In a similarly designed study, Williams et al. (1998) (181) examined the effects of methylphenidate 5–10 mg BID (adjusted for subject weight) in 10 subjects (age 5–16 years) who were on average 2 years post-injury (of unspecified severity). They observed no significant effects of this treatment on cognition, although there was suggestion in their data of improved accuracy on a continuous performance task. They report a trend towards behavioral improvements as assessed by teachers using the Conners Rating Scale (a scale commonly used in the assessment of children with attention deficit disorder), but parents ratings on this scale did not support teacher ratings. Considered together, these studies leave uncertain the possible benefits of methylphenidate in children and adolescents with posttraumatic cognitive impairments.

### *Dextroamphetamine*

Dextroamphetamine is frequently used in the treatment of attention and memory impairment following TBI, and is thought to have additional beneficial effects on depression, anergia, and impaired motivation. However, there are only three reports to support its use in this population. Evans and Gualtieri (1987) (176) assessed cognition, mood, and behavior during treatment with dextroamphetamine .1 mg/kg BID and .2 mg/kg BID. They describe treatment-related improvement in measures of vigilance (sustained attention), processing speed, motor speed, memory, and mood during treatment with dextroamphetamine. Bleiberg et al. (1993) (173) conducted a double-blind, crossover study of the effects of dextroamphetamine, lorazepam, and placebo on measures of processing efficiency and speed in a 55-year old male who suffered a complicated mild TBI (5 minutes loss of consciousness and left subdural hematoma) approximately

5 years prior to study. They observed improvements in cognitive speed and stability of performance (correct responses per unit of time) during treatment with dextroamphetamine but not placebo, and also observed decrements in cognitive function during treatment with lorazepam. Hornstein et al. (1996) (182) reviewed the use of dextroamphetamine in the treatment of individuals during acute rehabilitation after TBI in the context of a larger review of this subject. Of the 27 patients so treated, 15 appeared to benefit from treatment with dextroamphetamine as measured by Glasgow Outcome Scale.

### *Methylphenidate and Dextroamphetamine in Clinical Practice*

Although psychostimulants would be predicted to improve catecholaminergically-dependent cognitive functions among persons with TBI, the literature is variable with respect to their beneficial effects. In light of the relative lack of *in vivo* evidence of long-term dopaminergic or noradrenergic dysfunction following TBI presented earlier in this chapter, the variability of benefit in the published reports is not surprising. Additionally, methodological issues (e.g., small sample sizes, study design, assessment measures, study period, interval since injury, etc.) in the studies performed to-date make interpretation of the cognitive and neurobehavioral benefits of psychostimulants in persons with TBI difficult, at best. Nonetheless, common clinical experience suggests that some patients do experience cognitive improvements during treatment with psychostimulants. To the extent that an individual's posttraumatic cognitive impairments are related to catecholaminergic dysfunction, whether from injury to afferent projections, synaptic catecholamine metabolism (i.e., COMT enzymatic activity) that exceeds catecholamine availability, or some combination of these factors, methylphenidate and related psychostimulants may afford some degree of cognitive improvement among persons with TBI, and may in particular be useful for the treatment of posttraumatic impairments in arousal, speed of processing, and possibly attention.

In clinical practice, careful assessment of arousal, speed of processing, and attention should be undertaken before and during treatment with these agents. Although such assessments may be difficult to undertake in some clinical practices (183), they are important to perform in order to determine whether these medications impart sufficient benefit to merit their continued use in a given patient. Assessment with appropriate neuropsychological tests (for example, continuous performance tests or other standardized tests of reaction time or processing speed) may be particularly helpful in this regard. In the absence of improvement on such measures during treatment with these agents, reports of subjective improvement in cognition or daily function during treatment with these

agents are frequently used as a measure of treatment response. While such reports may be used to justify continued use of these agents, the observation of subjective improvement but lack of improvement on objective measures should prompt reconsideration of the etiology of the impairments reported. Since psychostimulants may improve mood, increase motivation, or lessen fatigue, subjective improvements without evidence of demonstrable cognitive improvements may suggest that the primary problem lies in posttraumatic depression, apathy, fatigue, or some combination of these non-cognitive problems.

Unlike many other medications used to treat neuropsychiatric conditions, stimulants generally take effect quickly (within 0.5–1 hour following administration) and also lose effect after only a few hours. Therefore, the first issue in the administration of these agents is determining the optimally effective dosage and dosing frequency required to sustain that effect. Methylphenidate and dextroamphetamine are generally administered twice daily, typically at breakfast and again at midday. Initial dosing with either agent generally begins at 5 mg BID and is gradually increased in increments of 5 mg BID until either beneficial effect or medication intolerance is achieved. Most studies suggest that optimal doses of either methylphenidate or dextroamphetamine are in the range of 10–20 mg BID, although some clinicians use of considerably higher doses (i.e., 40 mg or more BID). Some individuals may require relatively frequent dosing (i.e., readministration every 3–4 hours) of methylphenidate or dextroamphetamine in order to sustain cognitive benefits from them throughout the course of the day. Multiple longer-acting methylphenidate or dextroamphetamine preparations are available. Individuals requiring relatively high and frequent doses of methylphenidate or dextroamphetamine may benefit from use of longer-acting preparations of these medications.

Adverse reactions to these medications are most often related to increases in cerebral dopamine, and to a lesser extent cerebral norepinephrine, activity. Dextroamphetamine and methylphenidate have the potential to produce paranoia, dysphoria, anxiety, agitation, and irritability, although these adverse effects are in practice very uncommon at doses typically used to treat posttraumatic cognitive impairments. Psychosis is a relatively rare consequence of administration of these medications. Even among persons with posttraumatic psychosis, these agents may be of benefit for cognitive impairments and without untoward effects on psychotic symptoms when used in combination with an atypical antipsychotic medication. However, combined therapy with psychostimulants and antipsychotics is not recommended unless the patient is under the care of a neuropsychiatrist with expertise in the use of this medication combination. Mild increases in heart rate and/or blood pressure may occur

during treatment with psychostimulants, although these tend to occur relatively infrequently in patients without other cardiac or vascular problems and are only rarely of sufficient magnitude to merit discontinuation of these agents. Use of these agents during pregnancy is discouraged, and their use is contraindicated among patients receiving monoamine oxidase inhibitors (MAOIs) and women who are breastfeeding. Clinicians are advised to avoid use of these agents among persons with comorbid Tourette's syndrome and other tics, glaucoma, untreated hypertension or cardiovascular problems, and symptomatic hyperthyroidism. These agents may potentiate the effects of phenobarbital and phenytoin by delaying gastrointestinal absorption, increase the noradrenergic effects of tricyclic antidepressants, increase the dopaminergic effects of antiparkinsonian agents, and potentiate the analgesic properties of meperidine. Because depressed mood and increased fatigue may develop following abrupt discontinuation of psychostimulants, these medications should be discontinued gradually among patients receiving them chronically.

Clinicians are sometimes reluctant to make use of psychostimulants out of concern that they might lower seizure threshold in patients with TBI. Wroblewski et al. (1992) (184) examined changes in seizure frequency after initiation of methylphenidate among 30 patients with both severe brain injury and posttraumatic seizures. The frequency of seizures was monitored for 3 months before treatment with methylphenidate, 3 months during treatment, and 3 months after treatment was discontinued. They found that only 4 patients experienced more seizures during methylphenidate treatment, and 26 had either fewer or the same number of seizures during treatment. Although many patients in this study were treated concurrently with anticonvulsant medications, 13 of these experienced fewer seizures when treated with methylphenidate. While this finding should not be misunderstood as suggesting an anticonvulsant effect of methylphenidate, it does suggest that methylphenidate does not substantially increase seizure risk among persons with TBI, including those with posttraumatic epilepsy.

Similarly, in a double-blind placebo-controlled study of the effects of methylphenidate (0.3 mg/kg body weight bid) in 10 children with well-controlled seizures and attention-deficit disorder, no seizures occurred during the 4 weeks of treatment with either active drug or placebo (185). Although this observation was not made among persons with TBI, it supports the thesis that methylphenidate itself does not appear to increase the risk of seizure even among patients with established epilepsy. Interestingly, dextroamphetamine has been used adjunctively in the treatment of refractory seizures (186). While most clinicians would not regard this agent as an adjunctive therapy for seizures, this report echoes other observations of a relative lack of adverse effect of stimulants

on seizure frequency. It appears that this class of medications is generally well tolerated with respect to its effects on seizure frequency, and that even established epilepsy should not preclude treatment with this agent when a clinician deems it to be of potential benefit to an individual patient.

### **Bromocriptine**

Bromocriptine appears to act directly on postsynaptic dopamine receptors – particularly dopamine type 2 (D2) receptors – and serves as an agonist in dopaminergically-mediated cerebral systems. At low doses, bromocriptine acts as a pre-synaptic D2 agonist, and thereby reduces dopaminergic release and function in dopaminergically-mediated systems. Its net effect at mid-range doses appears to be augmentation of cerebral dopaminergic systems (187). Accordingly, Eames (1989) (188) suggest that bromocriptine may be useful in treating “cognitive initiation” problems of brain injury patients who are at least 1 year post-injury. McDowell et al. (1998) (189) studied 24 subjects using a counterbalanced, double-blind, placebo-controlled crossover design. Bromocriptine improved performance on some frontally-mediated tasks, such as executive function and dual-task performance, but did not improve working memory. No other effects of bromocriptine on posttraumatic cognitive dysfunction were observed.

Others report benefits on nonfluent aphasia (71), akinetic mutism (190), and apathy (191) during treatment with this bromocriptine among patients with such problems following stroke. These effects have been attributed to dopaminergic augmentation of frontal function (192). Unlike the psychostimulants, bromocriptine has not been demonstrated to have a consistent effect on affective lability or mood disorders due to TBI, stroke, or other neurological conditions.

Treatment with this agent generally begins with 2.5 mg/day and is gradually titrated to the highest dose tolerated. Common side effects during treatment with bromocriptine include dizziness, drowsiness, faintness, syncope, nausea, vomiting, abdominal cramps, constipation, and diarrhea, although these are generally of mild severity. Uncontrolled hypertension and hypersensitivity to ergot alkaloids are strict contraindications to the use of bromocriptine. Although use of this agent among women who are breastfeeding their infants is contraindicated, use during pregnancy does not appear to be associated with significant increased adverse events among pregnant patients or on fetal development. It has been suggested that bromocriptine may possess some anticonvulsant properties (193). Although this suggestion should not be misunderstood as an endorsement of bromocriptine for the adjunctive treatment of posttraumatic epilepsy, it may offer some reassurance of its safety

for use among cognitively impaired TBI survivors with this problem.

### Amantadine

The effects of amantadine on dopaminergic function are not entirely clear, but include increasing dopamine release, decreasing presynaptic dopamine reuptake, stimulation of dopamine receptors, and/or enhancement of postsynaptic dopamine receptor sensitivity. As such, amantadine is generally regarded as an agent whose principal effects on posttraumatic cognitive and neurobehavioral disturbances are mediated through indirect augmentation of dopaminergic function. As noted previously, amantadine is an uncompetitive antagonist at NMDA receptors (194). The clinical effects of amantadine's NMDA receptor antagonist properties are uncertain, although it is possible that it may contribute to stabilization and/or augmentation of glutamatergic function. Additionally, amantadine also appears to stimulate striatal acetylcholine release indirectly via its effects on NMDA receptors in this brain region. To the extent that improved striatal cholinergic function contributes to improvements in cognition dependent on frontostriatal circuits, amantadine might also be of benefit via this mechanism of action. However, the relative contributions of NMDA receptor antagonism and/or indirect striatal pro-cholinergic effects to the clinical effects produced by amantadine are at present a matter of speculation.

Kraus and Maki (1997) (125) administered amantadine 400 mg/day to six patients with TBI and observed improvements in motivation, attention and alertness, and executive function. They also observed treatment-related improvements in impulsivity and emotional (affective) lability. It has also been suggested that amantadine improve posttraumatic anergia, abulia, mutism, anhedonia, perseveration, and/or agitation (126–129).

Amantadine is often started at a dose of 50 mg BID, and is usually increased every week by 100 mg/day to either symptomatic improvement or medication intolerance. In the experience of the authors, amantadine may be of use in the treatment of hypoarousal and/or fatigue following TBI. Amantadine 100 mg BID is often sufficient to impart improvement in these symptoms without undue side effects. When higher doses are necessary, the maximum dosage of amantadine should not exceed a total daily dose of 400 mg. When used at higher doses, treatment-emergent adverse effects may be more common.

Headache, nausea, diarrhea, constipation, anorexia, dizziness, lightheadedness, orthostatic hypotension may occur during treatment with amantadine. Anxiety, irritability, depression, and hallucinations may also develop during treatment with this agent, but are relatively uncommon. At higher doses, psychosis and confusion may occur. These treatment-emergent symptoms may be

the result of excessively strong NMDA receptor antagonism, dopaminergic excess, or some combination of these effects. Abrupt withdrawal has been associated (rarely) with neuroleptic malignant syndrome. Adverse reactions to amantadine appear to occur more often in elderly patients than in younger patients. Additionally, coadministration of triamterene/hydrochlorothiazide may decrease renal excretion of amantadine, resulting in medication intolerance at doses that would ordinarily be regarded as within the usual therapeutic range.

Although amantadine does not possess direct anticholinergic activity *per se* at conventional therapeutic doses, it is not uncommon for patients treated with this agent to develop anticholinergic-like symptoms. Additionally, amantadine may potentiate the effects of anticholinergic agents and other psychostimulants. These observations leave open the question of amantadine on cholinergic function *in vivo*, as the basic science studies of the neurotransmitter effects of this agent would not predict these effects.

It has been reported that amantadine may lower seizure threshold (128). However, this suggestion is contentious. Two studies (195, 196) investigated amantadine as an adjunctive anticonvulsant therapy among persons with refractory epilepsy. These studies report improved seizure control in about 30%, no change in seizure frequency in 30–40%, and worsened seizures in 20–30% among patients treated with amantadine. These findings suggest that amantadine does not invariably precipitate or worsens seizure frequency, even among persons with refractory epilepsy. Nonetheless, it is prudent to be vigilant for the development or worsening of seizures when amantadine is used among persons with TBI.

### Carbidopa/L-Dopa

L-dopa (levodopa) is a dopamine precursor. When coupled with carbidopa to decrease the extent of its metabolism in the periphery, L-dopa increases dopamine levels in the central nervous system. Although this medication is uncommonly used in clinical practice for these purposes, it may be an alternative to the traditional psychostimulants for the treatment of cognitive impairments and other neurobehavioral disturbances following TBI.

Lal et al. (1988) (197) describe the use of carbidopa/L-dopa among 12 patients with brain injury (including several patients with hypoxic-ischemic brain injuries). During treatment with L-dopa/carbidopa 10/100 to 25/250 QID, patients demonstrated improvements in alertness and concentration, decreased fatigue, hypomania, and sialorrhea, as well as improved memory, mobility, posture, and speech.

Treatment with carbidopa/L-dopa should begin with low doses (10/100 BID) and may be gradually increased to doses of 25/250 QID. Consultation with a neurologist or neuropsychiatrist experienced in the use of this

agent in this population is suggested when clinicians unfamiliar with carbidopa/L-dopa elect to use this agent in this population. Common side effects are predominantly related to its central dopaminergic effects, and may include dyskinesias, anxiety, hallucinations (especially visual), paranoia or overt psychosis. Nausea may be a treatment-limiting side effect in some patients, and is more common during treatment with preparations with relatively lower doses of carbidopa (i.e., 10/100 vs. 25/100). Other less frequent side effects include palpitations, orthostatic hypotension, anorexia, vomiting, and dizziness. Rare but serious adverse effects include gastrointestinal hemorrhaging, duodenal ulcer, hypertension, phlebitis, leukopenia, agranulocytosis, thrombocytopenia, and hemolytic or nonhemolytic anemia. Carbidopa/L-dopa does not appear to reduce seizure threshold clinically, but there is insufficient data with which to assess the risk of seizures during treatment with this agent among persons with TBI.

### Modafinil

Modafinil, a medication recently approved for the treatment of excessive daytime somnolence in patients with narcolepsy, may have a role in treatment of post-TBI fatigue and cognitive impairment. Although the exact mechanism of action of modafinil is not fully understood, animal studies suggest that its promotion of wakefulness may be attributable to activation of hypocretin (orexin) neurons in the lateral hypothalamus (198), indirect, dose-dependent reduction GABA release in the cerebral cortex, medial preoptic area, and posterior hypothalamus (199, 200), and dose-dependent increases in glutamate release in the ventrolateral and the ventromedial thalamus (201). Some combination of these mechanisms in humans may increase arousal via activation of neurons of the arousal system, either directly via glutamatergic thalamic activation, indirectly via reduction of GABA function, or through the secondary effects of lateral hypothalamic projections to regions involved in control of arousal and sleep-wake cycle (tubero-mammillary nucleus and the locus coeruleus) (202).

Studies of the effect of modafinil on fatigue and excessive sleepiness in patients with multiple sclerosis (203, 204) and Parkinson's disease (205) suggest that the beneficial effects of this agent are not exclusive to narcolepsy. Elovic (2000) (206) has suggested that modafinil may be of similar benefit in patients with TBI. Teitelman (2001) (207) described his use of modafinil among 10 outpatients with nonpenetrating traumatic brain injury and functionally significant excessive daytime sleepiness and in two patients with somnolence due to sedating psychiatric medications. The patients included in his report were between the ages of 42 to 72 years, all were outpatients, and were treated in an open-label fashion.

Doses of modafinil ranged between 100 mg to 400 mg daily. Nine patients reported marked improvements in excessive daytime sleepiness and three reported moderate improvements. Some of these patients reported subjective improvements in attention as other cognitive functions. Although this medication was generally well tolerated, Teitelman (2001) (207) observed treatment intolerance due to increased "emotional instability" in two women with brain injury complicated by multiple other medical conditions who were receiving multiple additional medications.

At the time of this writing there are no published formal clinical trials with which to evaluate the effectiveness or tolerability of modafinil for post-traumatic hypoarousal, hypersomnolence, fatigue, or other cognitive impairments. We have used this agent in the acute inpatient rehabilitation setting in persons with moderate-to-severe TBI in the lower Rancho Los Amigos stages (III-IV) for the treatment of hypoarousal or excessive daytime sleepiness with some success and without serious adverse effects; however, anecdotal reports such as this must be regarded with caution pending further study of this agent for this purpose.

If used in this population, modafinil should be started at 100 mg QAM, and can be increased to up to 400 mg/day administered in either a single daily dose or two divided doses (i.e., 200 mg in the morning, and 200 mg in the early afternoon). Higher doses (up to 600 mg daily) are sometimes used, but there is no evidence in any patient population that such doses offer benefit beyond that achieved with 400 mg daily.

### Other Stimulant-like Medications

In general, prescription of tricyclic antidepressants should be avoided where possible among persons with significant posttraumatic cognitive impairments. The significant anticholinergic and antihistaminergic effects of these agents would be expected to further impair cognition in this population; such adverse effects of tricyclic antidepressants have been reported among persons with TBI and other neurologically-impaired populations (208, 209). Protriptyline, a secondary amine tricyclic agent, may be an exception in this regard. This agent has been suggested to have sufficient stimulant properties to permit its use for anergia and diminished motivation in TBI patients (210). However, this agent does not appear to confer any benefit on cognition beyond that afforded by improved arousal and motivation alone. Protriptyline should be considered as a treatment for posttraumatic hypoarousal, anergia, and apathy only when other standard psychostimulants have not proven effective or have produced intolerable side effects. Similarly, Reinhard and colleagues (1996) (211) administered amitriptyline (1 patient) and desipramine (2 patients) and found improvement in arousal and initiation after TBI. They

hypothesized that the cognitive-enhancing effects of these agents resulted from the pro-noradrenergic effects of these agents. Again, these agents may be of some benefit on posttraumatic impairments in arousal but are probably best regarded as treatments of last resort when other stimulants have proven ineffective or intolerable. The side effects and drug-drug interactions of these agents are discussed in more detail in Chapter 52 (Pharmacotherapy of Neuropsychiatric Disturbances).

Showalter and Kimmel (2000) (212) report better-than-expected improvements in level of arousal in 9 of 13 severe (Rancho Los Amigos Scale I-III) TBI patients taking lamotrigine during the post-acute recovery period (up to 10 months). They suggested that this agent may permit more rapid emergence from deeper stages of diminished arousal (i.e., coma) following TBI than might occur spontaneously. Pachet et al. (2003) (213) also report improvements in cognition and other neurobehavioral functions (as assessed by the Functional Independence Measure) in a single case study of this agent in a 40 year-old man with severe TBI treated with lamotrigine for approximately four months in the late (1–1.5 years) period following his injury. The mechanism by which lamotrigine confers such benefits is unclear. Showalter and Kimmel (2000) (212) suggest that lamotrigine's ability to block of sodium channels and inhibit glutamate release may either prevent excitotoxic injury and/or facilitate recovery from injury. Additional studies are needed to ascertain the validity of this suggestion.

### Cholinesterase Inhibitors

As described earlier in this chapter, posttraumatic cognitive impairments may, at least in part, result from chronic deficiencies of cerebral cholinergic function (7, 214). The common clinical observation of the susceptibility of TBI patients to exacerbation of cognitive impairments during treatment with anticholinergic medications, as well as animal studies echoing this observation (155, 159, 215), suggests that TBI results in reduced reserves of cerebral acetylcholine. As such, augmentation of cholinergic function may be an effective strategy by which to improve posttraumatic cognitive impairments.

Administration of the acetylcholine precursors, lecithin and choline, do not appear to reliably increase cerebral cholinergic function or confer cognitive benefits among persons with other neurological illnesses in which cholinergic deficits figure prominently (e.g., Alzheimer's disease) (216). Additionally, centrally-selective nicotinic or muscarinic receptor agonists are not presently available for use in this context.

At present, the principal pharmacologic means by which central cholinergic function may be augmented is cholinesterase inhibitors, of which there are several available for use in humans. These include physostigmine,

tacrine, donepezil, rivastigmine, and galantamine. Although these agents differ in their central (i.e., cerebral) selectivity and additional mechanisms of action – for example, prominent butyrylcholinesterase inhibition by rivastigmine (217), and allosteric nicotinic modulation by galantamine and physostigmine (218) – all of these agents principally exert their clinical benefits via inhibition of synaptic acetylcholinesterase. This enzyme is the predominant synaptically-active cholinesterase, and is the principal mechanism by which acetylcholine is metabolized in cerebral synapses. Inhibition of synaptic acetylcholinesterase increases the availability of acetylcholine to both pre- and post-synaptic nicotinic and muscarinic receptors, and may thereby improve cholinergically-dependent cognitive functions such as arousal, attention, memory, language, and executive function.

Although there is considerable interest in the possible use of the cholinesterase inhibitors for the treatment of posttraumatic cognitive impairments, at the time of this writing there is published data for only physostigmine and donepezil. It is possible that the secondary mechanisms of action of both rivastigmine and galantamine may confer either greater or additional benefits on cognitive and neurobehavioral function among persons with TBI; however, reports describing both their effects and tolerability are needed before offering any formal recommendations regarding their use in this population.

### *Physostigmine*

Physostigmine inhibits acetylcholinesterase both centrally and peripherally. Although it exerts its principal effects through inhibition of synaptic acetylcholinesterase, it also appears to allosterically modulate nicotinic receptors in a fashion similar to galantamine (218). Several reports describe cognitive improvements following administration of physostigmine, both in the acute (219) and post-acute (220, 221) injury period. Levin et al. (1986) (222) performed a double-blind, placebo-controlled study of combined oral physostigmine and lecithin in 16 patients with cognitive impairment following moderate to severe TBI. Sustained attention on the continuous performance test was more efficient under physostigmine than placebo, and lecithin did not appear to increase this effect. Cardenas et al. (1994) (223), in a double-blind, placebo-controlled, crossover design study of physostigmine, placebo, and scopolamine (a muscarinic receptor antagonist) in 36 males with memory impairment of at least 3 months duration following TBI, demonstrated improved memory scores on the long-term storage component of the Selective Reminding Test in 44% of subjects during treatment with oral physostigmine but not placebo or scopolamine.

Physostigmine is available in oral and intravenous preparations. Its absorption after oral administration is unpredictable, and its duration of action ranges from

30 minutes to 5 hours. Consequently, its use entails frequent dosing. Although physostigmine may be of benefit to cognitively impaired TBI survivors, both its lack of central selectivity and frequent administration produce systemic toxicity that limits its acceptability as a treatment for posttraumatic cognitive impairments (224). Given the availability of newer and generally better-tolerated cholinesterase inhibitors, we do not recommend routine use of physostigmine among persons with TBI. However, the benefits afforded by this agent do support the suggestion that cholinesterase inhibition may improve posttraumatic cognitive impairments in some patients, and may be used to support the use of the newer cholinesterase inhibitors in this population.

### *Donepezil*

Donepezil is a cholinesterase inhibitor that exhibits relative central selectivity. Although it modestly inhibits butyrylcholinesterase (225), its predominant mechanism of action is believed to be inhibition of synaptic acetylcholinesterase (226). Taverni et al. (1998) (227) describe improvements in refractory memory impairments on the Rivermead Behavioral Memory Test and Ross Immediate Processing Assessment in the late (>3 years) post-injury period in two patients with severe TBI. These benefits were apparent after approximately three weeks of treatment with donepezil 5 mg per day. In a similarly small case series, Masanic et al. (2001) (228) treated four patients with persistent posttraumatic cognitive and neurobehavioral impairments with donepezil 5 mg per day for eight weeks followed by treatment with donepezil 10 mg per day for an additional four weeks. Patients were assessed pre- and post-treatment using the Rey Auditory Verbal Learning Test (RAVLT) and the Complex Figure Test (CFT). Items from the Rivermead Behavioral Learning Test (RBMT) and a test of semantic fluency were also administered. The Neuropsychiatric Inventory (NPI) was used to assess other neurobehavioral changes during treatment, and overall function was assessed using a clinician-based rating scale and the Functional Independence Measure (FIM). The authors reported modest but significant improvements in learning and short- and long-term recall on the RAVLT and more substantial improvements in short- and long-term recall on the CFT. Trends toward improvements were observed on the RBMT and the NPI. Given the small sample sizes, remoteness of injury, and the relatively severe injuries of the subjects in both studies, the observation of improvement in is encouraging of the possible benefits of donepezil for the treatment of posttraumatic memory impairments. However, the small sample sizes and uncontrolled nature of both studies limits the validity and generalizability of these treatment effects.

Kaye et al. (2003) (229) performed an 8-week open-label study of 10 persons with remote (1–5 years,

mean = 1.2 years) TBI in an outpatient setting using a forced titration protocol (5 mg per day for 4 weeks followed by 10 mg per day for 4 weeks). Subjects ranged in age from 26–60 years (mean age = 41 years), and included six with mild, one with moderate, and 3 with severe TBI. All subjects underwent pre- and post-treatment neuropsychiatric evaluations, including assessment of cognition using the Global Memory Scale (GMS) of the Memory Assessment Scale and two-independent clinician ratings of overall improvement using the Clinical Global Improvement scale (CGI). Eight subjects completed the study; one subject was dropped from the study due to treatment noncompliance, and one subject discontinued treatment due to intolerable gastrointestinal side effects. Among those completing the study, CGI ratings improved, although not necessarily as a function of improvements in memory. In fact, the authors observed no improvement on the GMS. Instead, the authors report that CGI improvements instead appeared to reflect the subject reports of improvements in “focus, attention, and clarity of thought.” They note that several subjects reported being better able “to keep multiple ideas in mind simultaneously,” and that subjects’ family members frequently described “improved socialization.” The authors note the limitations of the cognitive assessment used as a primary outcome measure in this study, and suggest that other measures better suited to assess cognitive flexibility, non-verbal abstract reasoning, learning from mistakes, and incidental visual memory might be more appropriate outcome measures in subsequent studies of this kind. They acknowledge that controlling for other variables such as age, severity of injury, time since injury, and baseline cognitive function, as well as the use of placebo control, is necessary to more rigorously assess the benefits of donepezil in the treatment of posttraumatic cognitive impairments. In spite of these limitations, they conclude their report by noting that seven of the eight subjects completing the study elected to continue treatment with donepezil given the subjective improvements they experienced during its use in this study. The eighth subject also reported such benefits, but elected not to continue treatment due to the development of treatment-emergent nausea.

Morey et al. (2003) (230) studied the effectiveness of donepezil for the treatment of chronic memory impairments in a group of seven patients with TBI. Subjects were on average 33 months post-injury (range = 20–65 months) and mean age was 31 years (range = 19–51). All subjects were without other medical, psychiatric, or physical problems that might interfere with ability to participate in neuropsychological assessment, and none were taking medications with anticholinergic properties. Measures of cognitive function included the Brief Visual Memory Test – Revised, Hopkins Verbal Learning Test, Digit Span and Letter-Number Sequence subtests of the Weschler Adult Intelligence Scale – Revised, Controlled Oral Word

Association Test, and the Memory Functioning Questionnaire, all of which were administered pre- and post-treatment during the two treatment phases of the study. These phases included donepezil 5 mg daily one month followed by donepezil 10 mg daily for an additional five months; following a six-week washout period, patients were treated for an additional six months with donepezil 5 mg daily. Treatment-emergent side effects (lethargy and somnolence) were observed in two subjects, prompting their discontinuation from the study. It is not clear in this report whether the final subject group in who cognitive testing was performed included seven or five subjects. Regardless, there were very few other complaints of side effects at either dose of donepezil. Improvements in immediate and delayed memory as assessed by the Brief Visual Memory Test – Revised were reported as a function of treatment with donepezil 10 mg per day but not 5 mg per day. No other significant effects on cognition were observed during treatment with this agent at either dose. Although this report suggests the possibility of benefit on visual memory during treatment with donepezil at 10 mg per day, lack of subject characterization data (i.e., severity of injury, presence of focal contusions vs. diffuse injury) and small sample size limit the generalizability of both positive and negative findings of this study.

Whelan et al. (2000) (231) performed an open-label study of donepezil in 53 outpatients and subsequent cognitive impairment who were receiving treatment for neuropsychiatric problems following TBI. All patients were assessed pre- and post-treatment using a clinician-based rating scale. Twenty-two of these patients were also assessed pre- and post-treatment using the Wechsler Adult Intelligence Scale-Revised (WAIS-R) and the Hooper Visual Organization Test. All of the patients were treated adjunctively with donepezil 5–10 mg daily for an average of 12 months. The authors reported improvements in full-scale IQ in the subset of patients in who cognitive assessments were performed, and improvements in clinician-based ratings in the sample as a whole. Although these improvements occurred well after the period during which spontaneous recovery and “practice effects” might offer better explanations for them, details regarding injury severity, specific neuropsychiatric comorbidities, other concurrent treatments, and changes in those treatments during the period of study are not fully described in that report, making interpretation of the reported findings challenging. Additionally, the cognitive assessment measures used are unusual in treatment studies of this kind. It is possible that modest improvements across the range of cognitive functions assessed by the WAIS-R contributed to the observed improvements while improvements in subscale scores were insufficient to rise to statistically significant levels. Alternatively, the sample size may have been inadequate to provide the statistical power needed to demonstrate a significant effect of

donepezil on the WAIS-R subscales. Given these considerations, this study is probably best interpreted as offering only a suggestion of a possible benefit of donepezil as an adjunctive treatment for persistent cognitive impairments among persons with other chronic neuropsychiatric disturbances following TBI.

More recently, Zhang et al. (2004) (232) reported findings from a 24-week, randomized, placebo-controlled, double-blind crossover trial of donepezil 10 mg daily in 18 subjects with TBI seen in two University-based hospitals. Patients were enrolled on the basis of a documented history of TBI (regardless of severity) 2–24 ( $4.6 \pm .7$ ) months prior to the study. Approximately two-thirds of the patients were male, ranged in age from 19–49 years, and had 10–17 years of education. Mean GCS scores at 24–48 hours post-injury were approximately  $9 \pm 1$ . All subjects demonstrated persistent attention as measured by the Paced Auditory Serial Addition Test (PASAT) and/or short-term memory impairment as measured by the Auditory Immediate Index (AII) or Visual Immediate Index (VII) of the Weschler Memory Scale-III. Subjects were excluded if they had cardiac arrhythmias on electrocardiogram (regardless of etiology), a history of cardiac contusion, uncontrolled posttraumatic seizures, uncorrected electrolyte imbalance, endocrine dysregulation, infection, or gastrointestinal bleeding. Subjects with severe cognitive and behavioral disturbances (i.e., Rancho Los Amigos functioning at level V or below), other neurologic or psychiatric problems (e.g., stroke, epilepsy, major depression, or neurodegenerative disorders), taking other psychotropic medications (e.g., antidepressants, anticonvulsants, antipsychotics, psychostimulants), or communication impairments (aphasia, dysarthria) that would interfere with neuropsychologic testing were excluded. Glasgow Outcome Scale scores were 4 or 5, and Rancho Los Amigos scores ranged from 7 to 8. In other words, the majority of subjects were functioned at an independent or a modified independent level but required some guidance and supervision from family members for daily activities.

Subjects were randomly assigned to two study groups consisting of 10 subjects each. The first group received donepezil 5 mg daily for two weeks followed by donepezil 10 mg daily for an additional 8 weeks; after a 4 week washout period, patients received placebo for 10 weeks. The second group received these preparations in the opposite order. Subjects were assessed using the PASAT, AII, and VII at baseline, and again at treatment weeks 10 and 24. Both study groups demonstrated significantly improved performance on these measures at treatment week 10 compared with baseline, and both groups demonstrated improvements at treatment week 10 compared to placebo week 10. The group treated with donepezil prior to placebo also demonstrated cognitive improvements at the end of the placebo phase when compared to baseline,

suggesting a possible carry-over effect of donepezil on cognitive performance in this study population.

Although this is the most carefully performed study of donepezil for attention and memory impairments following TBI to-date, it suffers from several limitations. First, subjects were studied during the period in which spontaneous recovery may occur; while the placebo-controlled crossover design of the study offers some control over this confound, it cannot be entirely discounted as a contributor to the improvements observed in these subjects. Second, subjects with either mild injuries or more severe cognitive impairments were excluded from the study, limiting the generalizability of the study findings. Similarly, patients with common medical and neuropsychiatric comorbidities were excluded, as were patients taking other neuroactive medications prescribed commonly in this population. Both of these exclusions also limit the generalizability of the study findings. Nonetheless, this study offers reasonably strong evidence that donepezil improves attention and memory impairments in the post-acute injury period.

### *Cholinesterase Inhibitors in Clinical Practice*

Collectively, these studies suggest that cholinesterase inhibitors may be of benefit for the treatment of post-traumatic cognitive impairments, and particularly post-traumatic attention and memory impairments. However, findings from the limited number of published studies are mixed with respect to the beneficial effects of these agents in this population. Given the ubiquitous role of acetylcholine in cognition and behavior, the cholinesterase inhibitors might be expected to improve a variety of cognitive impairments (e.g., hypoarousal, inattention, memory impairment, aphasia, executive dysfunction) and other neurobehavioral disturbances (e.g., apathy) in which cholinergic dysfunction is implicated.

The extent to which this type of treatment will be useful in an individual patient most likely depends on the extent to which cholinergic dysfunction in that patient contributes to his or her cognitive and behavioral impairments. Not all persons with TBI demonstrate post-mortem (16, 162, 163) or *in vivo* electrophysiologic (24) evidence of posttraumatic cholinergic dysfunction. Consequently, it is unlikely that augmentation of cerebral cholinergic function will benefit all persons with post-traumatic cognitive impairments. However, findings from the published studies of cholinesterase inhibitor therapy among persons with TBI suggest that at least a portion of this population will benefit from such treatments. Multicenter, double-blind, placebo-controlled trials are needed to define both the types of benefits afforded by such treatments and the clinical profile of TBI patients most likely to experience such benefits.

For the present, cholinesterase inhibitors are among the pharmacotherapeutic options available to clinicians

treating persons with posttraumatic cognitive impairments. Among these, donepezil is prescribed most commonly, although rivastigmine and galantamine are also sometimes used. When donepezil is prescribed, treatment begins with 5 mg daily. The relatively long half-life of donepezil makes it suitable for once-daily dosing (226). It is not clear whether increases to donepezil 10 mg daily affords additional benefits over 5 mg daily. When higher-dose donepezil is used, titration is generally undertaken at intervals of 2–4 weeks. Slower dose titration may limit the development of treatment-emergent side effects (usually gastrointestinal). Rivastigmine and galantamine have shorter half-lives, and require twice daily dosing. Rivastigmine is generally started at 1.5 mg BID and increased in 1.5 mg BID increments every four weeks until maximal benefits are attained or treatment intolerance develops. Galantamine is generally started at 4 mg BID and increased in 4 mg BID increments until maximal benefits are attained or treatment intolerance develops.

Although all of these agents may produce side effects such as headache, nausea, diarrhea, vomiting, fatigue, insomnia, muscle cramping, pain, and abnormal dreams, these side effects are generally related to overly rapid dose-escalation. Even in this context, such effects are usually transient. When intolerable side effects develop and/or persist during treatment with any of these agents, dose reduction is prudent. Such reductions may reduce adverse effects and permit patients to continue treatment. Use of these agents should be avoided in women who are pregnant or who are breast feeding their children. Cardiac conduction abnormalities (first-degree A-V block) and symptomatic bradycardia are relative contraindications to the use of these medications. Concurrent administration of agents that inhibit hepatic metabolism via CYP450, 3A4, and 2D6 enzymatic pathways (e.g., ketoconazole and quinidine) may increase blood levels of donepezil. Inducers of hepatic metabolism (phenobarbital, phenytoin, carbamazepine, dexamethasone, rifampin) may decrease donepezil blood levels. To-date, there are no reports suggesting that the use of these agents in persons with traumatic brain injury is associated with a change (positive or negative) in seizure frequency.

### **CDP-Choline**

Cytidine 5'-diphosphocholine (CDP-choline or citicoline) is an essential intermediate in the biosynthetic pathway of phospholipids incorporated into cell membranes. Orally ingested CDP-choline is metabolized into its two principal components, cytidine and choline. CDP-choline appears to activate the biosynthesis of structural phospholipids in neuronal membranes, increase cerebral metabolism, and enhance activity of dopamine, norepinephrine, and acetylcholine (157, 233). In light of these

properties, CDP-choline might be expected to improve posttraumatic cognitive impairments.

Calatayud et al. (1991) (234) performed a single-blind randomized study of 216 patients with severe or moderate TBI during the acute post-injury period. They observed improvements in motor, cognitive, and psychiatric function during treatment with CDP-choline, and use of this agent was associated with decreased length of stay in the hospital. Levin (1991) (235) performed a double blind placebo-controlled study of 14 patients to evaluate the efficacy of CDP-choline for treating post-concussional symptoms in the first month after mild to moderate TBI. Oral CDP-choline (1 g daily) and placebo control groups were matched for age, education and severity of initial injury (as assessed by impairment of consciousness). CDP-choline reduced the severity of post-concussional symptoms and improved recognition memory for designs. Other aspects of neuropsychological performance were not significantly influenced by this treatment.

CDP-choline is available in the United States only as an over-the-counter nutritional supplement, and is most commonly formulated in 250 mg capsules. The content and purity of CDP-choline formulations may vary considerably, both within and between manufacturers. Patients electing to undertake treatment with CDP-choline should be cautioned about these problems and monitored carefully for both beneficial and adverse reactions during its use. A metaanalysis of studies using CDP-choline in elderly patients suggests that its use is associated with fewer adverse effects than placebo (236), and there are no reports of serious adverse events related to treatment with this agent among persons with TBI. At present, the limited scope of the relevant literature and the lack of rigorous FDA scrutiny of the safety, tolerability, and efficacy of this agent preclude recommending routine use of CDP-choline in this population. However, for patients unwilling or unable to take other prescribed medications, CDP-choline may be a "nutritional supplement" that some patients may find acceptable and of modest benefit.

## SUMMARY

Pharmacotherapy is one of several potentially useful strategies for the treatment of posttraumatic cognitive impairments. Prior to initiating any such treatment, following the basic principles of pharmacotherapy is imperative. Other neuropsychiatric conditions and other ongoing treatments should be evaluated in order to determine whether such may be contributing to an individual's apparent cognitive problems. The use of agents that are known to interfere with cognition in this population, including typical antipsychotics, anticonvulsants, and benzodiazepines, should be discontinued where possible.

If treatment with such medications is needed, those least likely to impair cognition should be used whenever possible. When pharmacotherapy of posttraumatic cognitive impairments is considered, the period over which an empiric trial of such medications will be undertaken should be defined prior to starting treatment. Specific target symptoms should be defined, and assessment of cognition using standardized bedside or formal neuropsychological measures before and during treatment should be performed. When treatment is initiated, using a start-low, go-slow approach that includes careful monitoring of adverse and drug-drug effects is recommended.

Our present understanding of the neurochemistry of cognition and the neurochemical consequences of TBI suggest that catecholaminergic and cholinergic function are likely to be the most useful neurochemical targets for pharmacologic intervention among persons with typical posttraumatic cognitive impairments such as hypoarousal, inattention, slowed processing speed, memory impairments, language disturbances, and executive dysfunction. It is possible that as more effective and tolerable NMDA receptor antagonists are developed, glutamatergic dysfunction in the acute, post-acute, and late post-injury periods may become a reasonable target for pharmacologic intervention as well.

Although there is less evidence of persistent catecholaminergic deficits among persons with TBI as a group, interindividual differences in the integrity of cerebral catecholaminergic systems post-injury and/or the metabolism of catecholamine neurotransmitters may offer some explanation for the apparent cognitive benefits afforded by catecholaminergically-active agents in this population. Although there is better evidence for persistent cerebral cholinergic dysfunction in association with cognitive impairments following TBI, the number of studies investigating cholinergic augmentation strategies and the strength of the evidence they provide are at present limited. Consequently, only preliminary treatment recommendations regarding the use of medications that increase cerebral cholinergic function can be offered.

In general, patients whose most troubling cognitive impairments include arousal, impaired speed of processing, and inattention may benefit from treatment with a psychostimulant such as methylphenidate. These agents may also improve posttraumatic language, praxis, and executive function impairments, and most of these agents appear to modestly improve some neurobehavioral functions such as apathy, agitation, and perseveration. The present evidence suggests that methylphenidate should be regarded as first-line therapy when an agent from this medication class is used. If methylphenidate proves ineffective or produces intolerable side effects, dextroamphetamine, amantadine, or bromocriptine may be useful alternative stimulant medications. In cases where none of these are effective, clinicians might consider use of

modafanil, carbidopa/L-dopa, or other non-standard agents with stimulating properties such as protryptline or lamotrigine.

Use of psychostimulants in the acute rehabilitation setting may facilitate engagement in rehabilitation therapies, and it is possible that such treatment may hasten the recovery process (functionally, if not also neurobiologically). If used during the post-acute injury period (during which spontaneous recovery may occur), periodically decreasing the dose of these agents after maximal cognitive benefit has been achieved is recommended in order to determine if continued prescription of a psychostimulant is still necessary. When used in the late post-injury period, common clinical experience suggests that these medications maintain their effectiveness over the long-term and that abuse of and/or dependence on these agents is rare.

Among patients whose principal posttraumatic cognitive impairment is in the domain of memory (encoding, retrieval, or both), cholinesterase inhibitors may be of some benefit. Cholinergic augmentation would be predicted to have additional benefits on posttraumatic impairments in arousal, attention, language, executive function, and frontally-mediated behaviors, but the evidence in support of this prediction is at present preliminary. Among the cholinesterase inhibitors, donepezil is used most commonly and is for the present the agent with the most published evidence with which to support and guide its use. When patients respond to treatment with this agent, these benefits appear to be sustained during continued treatment over relatively long periods of time (i.e., months to years). It is not clear whether the other commonly used cholinesterase inhibitors (i.e., rivastigmine, galantamine) afford similar benefits, but there are theoretical reasons to expect comparable effects during treatment with these agents. Although the majority of reports describing the use of cholinesterase inhibitors in this population focus on the treatment of persons in the late post-injury period, these agents may be of use in the acute rehabilitation setting as well (237). If used during the period in which spontaneous recovery is likely to occur, periodic dose reduction and/or discontinuation of these agents is prudent in order to determine whether their use is still needed. In our experience, cognitive impairments that emerge following such dose reductions and/or medication discontinuations remain responsive to treatment once it is reinstated.

In the absence of cost-effective and widely available *in vivo* markers of neurotransmitter function with which to guide the selection of a class of medication, pharmacologic treatment of posttraumatic cognitive impairments in an individual patient remains a matter of clinical judgment and empiric trial. Some patients respond robustly to catecholaminergic agents, others to cholinesterase inhibitors, some require treatment with some combination of these

agents, and others respond poorly to all presently available medications. Additional studies are needed to clarify which agents are most effective for which types of post-traumatic cognitive impairments and better methods are needed to facilitate the identification of patients most likely to respond to such pharmacotherapies.

## Neuropharmacology: A Rehabilitation Perspective

*Jay M. Meythaler*  
*Ross D. Zafonte*  
*Lisa Lombard*  
*Cara Camiolo Reddy*

### INTRODUCTION: REHABILITATION PHILOSOPHY

Traumatic Brain Injury (TBI) is not a homogenous entity. Rather it encompasses a series of mechanisms that may each have a preferential effect on different regions of the brain and/or effect preferentially specific types of neuronal populations (1). One needs to consider the mechanism of TBI whether it is blunt trauma to the outer cortex, diffuse axonal injury (DAI), induced intracerebral hemorrhage (as well as the type of hemorrhage), and complicating factors such as anoxia and secondary ischemia when considering injury, prognosis and treatment (1–4). Consequently, it is unrealistic that one approach will fit persons with TBI. This is likely the case on both a mechanical as well as person specific (gender, genetic) plane. What is most important to stress is that there is no “silver bullet” that will treat each area of the brain and its specific cell types with equal efficacy. TBI and its subsequent recovery are a continuum of events that are spread out over several months or years.

A second principle that has become quite evident is that what may be useful early in TBI will not be useful later in the recovery stage and may be detrimental. The very time course of injury cascades suggests that some mechanisms that enhance injury in the acute period encourage recovery in the post-acute period. This fact leads to some of the clinical controversies that shape the

rehabilitation perspective of neuropharmacology. Furthermore, what may be neuroprotective or enhance recovery of one cell type may not have any effect on another type of neuronal cell population or even may be detrimental to that cell population (1). There is a complex interaction between the various neuronal populations and their associated glial cells that we are only just beginning to understand.

Despite the fact that TBI is the number one cause of disability in the U.S and comprises 12% of all hospital admissions in the United States (5–13). The current state of research funding in TBI has traditionally been abysmal especially for postacute TBI. This fact is compounded by professional perceptions. Thus much opportunity exists to understand the role of rehabilitation neuropharmacology in the recovery process and how pharmacology can interact with recovery programs.

However, there have been some advances in our understanding of the mechanisms of injury and processes that follow in TBI. This has resulted in some general principles that have evolved regarding the mechanism of injury, the location of injury, the cell types involved and the various neurotransmitters that may be affected following TBI. All of this leads one to considerable trepidation when utilizing medications that may affect the neurotransmitter systems of the brain following TBI. This chapter will serve to outline some theoretical principles of rehabilitation neuropharmacology; these principles of

injury and neurotransmitter function will be high lighted by their role in the acute injury and recovery process. We also will focus on the controversy they raise that help to shape the clinician perspective of neuropharmacology. This is not an all-inclusive discussion as it is beyond the scope of a chapter but should aid in the readers' understanding of the various other chapters in this book.

**MEDICATION PRINCIPLES**

**Early vs. Late Effects**

Acute TBI is really a series of mechanical events that effects the physical structure of the brain followed by a series of physiological and biochemical responses. When mechanical energy is applied to a substance it is deformed as defined by its mechanical property interrelations (elastic, viscous, or plastic response). The deformation response is time dependent, and dependent on the amplitude of the impact energy wave. When some of the energy is transmitted from the deformed structure to the structures it contacts, there are forces deforming these structures as well (1). If the elastic limit of a structure, such as the cell membrane, the neural filaments and other intraaxonal organelles, is exceeded then there will be a permanent physical deformation to these

structures (1). These factors are often referred to as the primary injury and reflect clinical process such as contusion, intra and extra axial lesions.

This is followed by a series biochemical of events. After the initial period of injury there is a prolonged progression of secondary events that may ultimately result in neuronal and or glial cell death. Maxwell et al recently summarized this theorized sequence of events (14). After injury, there is a depolarization followed by a focal loss of axonal transport as a result of disruption of the cellular organelles. One of the consequences of DAI is direct intracellular injury from direct mechanical displacement of the cytoskeleton and cytoplasm (15). The cascade of biochemical events that leads to further neuronal cell injury and axonotmesis probably exacerbates cellular injury and death. This injury process may involve the neuron cell body and even the glial cells. The sequence of events involves the depletion of adenosine 5'-triphosphate (ATP), intracellular calcium overload, and the production of strong oxidants resulting in oxidative stress (1, 16). The energy failure mechanism is key to the injury process. Clearly, injury to the mitochondria results in a decrease in the local production of ATP within the cell (17). Without ATP, the ion pumps that maintain Na<sup>+</sup>, K<sup>+</sup> and Ca<sup>++</sup> homeostasis within the axon begin to fail (1, 18) (Figure 54-1).

FIGURE 54-1

Axonal injury. (From *Archives of Physical Medicine & Rehabilitation*, V82. Copyright © 2001 American Congress of Rehabilitation Medicine and the American Academy of Physical Medicine and Rehabilitation. Reprinted with permission.)

Neuronal cell death as a result of neuronal and glial cell injury is in part mediated by the secondary release of glutamate activating NMDA channels and alpha-amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA) receptors on the neuronal cell body (1, 18, 19). After neuronal cells start to die and their membrane integrity is breached, more glutamate, free radicals and strong oxidants are released and the cycle repeats itself (1, 15). The influx of calcium through voltage-gated calcium channels may cause further cellular death and the release of more glutamate and inflammatory substances resulting in the activation of more n-methyl-d-aspartate (NMDA) receptors (1, 18).

Except for the secondary ischemia and anoxia complications, it appears this whole process is much more prolonged series of events than noted to occur in stroke. Animal and basic science data indicates that hours after acute TBI as much as 50%–60% of the neurons affected could potentially be saved via intervention. This is very different than that noted with ischemic stroke where perhaps only 15% of the neurons might be salvageable after 4 hours or more after the event. This fact raises potential clinical concerns regarding early activation and intervention. The reason is that the penumbra of secondary biochemical affects that can cause cellular death is quite large in trauma versus that noted in ischemic stroke (1). These principles are well established when one compares a stroke due to an intracerebral hemorrhage versus a stroke due to ischemia (1–4).

The trimming of various interventions may be key. As an example of what one uses early may be detrimental later, it is clear that seizure prophylaxis with phenytoin during the first week following injury may help prevent seizures, but that treatment prophylaxis for up to six months may slow recovery (20). It has been suggested that phenytoin may actually be neuroprotective and prevent further damage as it acts as a sodium channel blocker (21). This is the oldest example of a medication that is useful early after injury and is detrimental during the later stages of recovery following TBI. It resulted in the early practice guidelines to originating from the Brain Trauma Foundation and American Academy of PM&R (20, 22).

### Neuroprotective Agents

Recently there has been considerable focus on agents that may block excitatory neurotransmitters that can cause cellular death in already injured and susceptible neurons (23). Drugs that block NMDA channels, AMPA channels as well as the cytokines that are increased after TBI have been the focus of much research (14). Over the first few hours following TBI, there is compaction of the neurofilaments and collapse of their side arms as well as a loss of axonal microtubules (24, 25). The changes in the neurofilaments correspond with an influx of extracellular

calcium resulting from the altered membrane pump Ca-ATPase and ecto-Ca-ATPase activity (25). High levels of calcium also activate several lipases, which results in the production of arachidonic acid leading to inflammatory eicosanoids that promote neutrophil, macrophage invasion and the production of more strong oxidants (26–28). In other words, those cells that have been injured, but have enough metabolic capability to “hold on,” are pushed over the edge to cell death by secondary factors that increase calcium influx into the cell. The cycle repeats itself as the calcium/sodium influx reaches a critical level in the adjacent cells; there is more cellular necrosis and apoptosis (29). The prolonged period of elevated intracellular Ca<sup>++</sup> activates the calcium-dependent neutral cysteine proteases such as caspase-3 and calpains, which hydrolyze proteins resulting in more cellular necrosis and apoptosis (16, 30, 31). The slow progression of neuronal injury may suggest that apoptosis may be occurring with this type of injury due to the oxidative stress that accompanies reduced-glutathione depletion (32).

Secondary biochemical pathways, particularly those focused on the reduction of sodium and calcium influx into neuronal cells following TBI, which eventually activate the apoptotic pathways have also been the focus of considerable scrutiny (1, 2). Glutamate is often mentioned as the mediator of the final common pathway (1–4).

However, it is also clear that glutamate and other excitatory neurotransmitters are required if one is to learn adapt and take advantage of the neuroplasticity that is present in all of our brains (1). Without a release of glutamate we cannot learn. Thus long-term glutamate suppression is not optimal for during the rehabilitation process. The ability to learn as indicated by ones educational level is the most profound predictor of recovery in CNS injury. If we block these pathways with medications we may thus block the recovery process. This may be most important in the first months following TBI. Thus a fundamental controversy is when the injury cascade slows down and the process of recovery begins.

### Enhancing Neuroplasticity

On the other hand it may be just as detrimental to utilize those drugs or treatments that may enhance neuroplasticity too early in the recovery process. This includes medications that enhance excitatory neurotransmitters as well as therapy interventions that may increase these same processes. It has been recently established in animal models that rehabilitative physical or cognitive therapy started too early after neuronal injury may increase damage (33). Furthermore, over stimulating the neuronal process to fatigue may also cause cell death. Understanding this process further has important implications for rehabilitation.

**NEUROTRANSMITTER SYSTEMS**

**Cholinergic System**

As an example let's take a look at the critical cholinergic systems in the brain. The cholinergic system is intimately involved in the pathways associated with memory as well as in patterned motor movements. A lack of cholinergic neurons has been implicated in Alzheimer's disease. Over activity of the cholinergic system with regard to a balanced affect from the dopaminergic system has also been implicated in the development of tardive dyskinesia, and other associated movement disorders (34–36).

The hippocampal pathways have been considerably implicated in the development of antegrade memory loss associated with TBI. This is particularly true of DAI, which may be a factor in over 1/2 of all TBI. Secondly, it is well established that anoxia preferentially affects these areas. This region is rich in cholinergic contribution. Within 10–13 minutes of induced anoxia there is calcium influx into the neurons of the hippocampus and is followed by cellular loss (37). Antegrade posttraumatic amnesia (PTA) is one of the most profound developments of TBI. Preserving and subsequently enhancing these pathways may be of paramount importance.

Acetylcholine receptors are classified as either nicotinic, muscarinic or activate alpha-Latrotoxin. Acetylcholine receptors are ligand-gated cation units composed of several different polypeptide groups (38). The activation of acetylcholine receptors leads to an influx of Na+ and an efflux of K+ thus resulting in cellular depolarization. Naturally occurring or synthetic compounds effect cholinergic neurons either positively or negatively. Muscarinic receptors employ a G-protein activation system while nicotinic receptors do not, there effector mechanism is shown in figure 54-2 (39). Cholinergic neurons can be facilitated by the administration of cholinesterase inhibitors. Cholinesterase inhibitors have also been employed as nerve gases and have a clinical role in the treatment of myasthenia gravis. Several antagonists of acetylcholine receptors exist and may be clinically useful in the acute care period after brain injury. Atropine blocks acetylcholine receptors at muscarinic receptors only while botulinum toxin inhibits the release of acetylcholine (40).

*Acute Injury*

In the first week following injury it has been postulated agents that can protect these neurons may be quite useful. Cannabinoids, naturally occurring (marijuana), endogenous or synthetic (dexamabinol) have been theorized to be useful in TBI where this region is susceptible to injury (41). Studies with the synthetic cannabinoid dronaxinabol have improved TBI patient outcomes as measured by the Galveston Orientation and amnesia test (GOAT). However, they did not improve other outcome measures that may be more dependent on other neuronal cell types. A recent multi center trial sponsored by Pharmos was reported a negative for the primary outcome measure (40).

*Recovery*

On the other hand the neuroscience literature is replete with examples of medications and substances that block these cholinergic pathways and accelerate the processes noted with memory loss or inhibit the recovery of memory (42, 43). This needs to be kept in mind when treating patients following TBI. Profound and long-term blockade of the muscarinic system can worsen the Alzheimer's pathology associated with Parkinson's disease (42–44). Furthermore, long-term use of cannabinoids can be detrimental to memory pathways in otherwise healthy individuals (42).

These drugs and substances should be evaluated in the recovering person with TBI. At the very least they likely will impede recovery in a TBI patient. On the other hand donepezil, an acetylcholinesterase inhibitor has been suggested to improve memory disorders following traumatic brain injury (45–48)

*Controversy*

The level of evidence to support the use of cholimemetic agents after TBI is less than robust. The use of citicoline (a phosphosphingolipid) has been preported to have both neuroprotective and neurofacilitatory properties (49, 50). The acetylcholinesterase inhibitors have been studied in a limited fashion in the brain injury population (51, 52). The effects of cholinergic augmentation with donepezil on short-term memory and sustained attention have been

examined in one randomized, double-blind, placebo-controlled trial Zhang studied twenty patients with TBI who were randomized from two postacute rehabilitation clinics; 18 completed the trial. During the donepezil phase, the drug was administered at 5 mg/day for the first two weeks and 10 mg/day for the remaining eight weeks of the trial. Group analysis showed significant benefits of donepezil on neuropsychological functioning (52). Benefits of donepezil were sustained after the washout period. An early case series found that this medication did help in self-reported improvement of memory in two persons with acute TBI, yet this series was problematic in its design and control (48). An open label trial of 10 subjects with TBI treated with donepezil, patients noted a clinical global improvement (46). These agents have not yet been shown to assist in emergence from posttraumatic amnesia.

**Dopamine Pathways**

The dopamine neurons are generally located in the mid-brain the periventricular areas of lateral ventricles including the very well known substantia nigra pathways. The most important dopaminergic pathways are the nigrostriatal, tuberoinfundibular, mesolimbic and mesocortical pathways (53, 54). Dopamine receptors exist as families of receptors with their designation in part being determined by their ability to activate adenylyl cyclase (D1, D2, D3, D4, D5) see figure 54-3 (54). The D1 and D5 family of receptors activate adenylyl cyclase while the D2, 3 and 4 family of receptors inhibit adenylyl cyclase. These receptors all employ G proteins to inhibit or active processes (54). Dopamine is associated with motor movement and probably arousal. The pathways project to the hypothalamus and are associated with autonomic functions and hormonal levels.

In acute injury, a vast excitotoxic cascade occurs. It has been well established the increases in dopamine are correlated with increased cell death in the regions where dopamine acts as a neurotransmitter (55). Furthermore medications that block dopamine release or receptors have been implicated in slowing neuronal recovery (36, 56–58), these agents may affect hormonal levels through their affects on the hippocampal releasing hormones, and cause dysautonomia. Deficits associated with decreased

**FIGURE 54-2**

Dopamine receptor

dopamine such as movement disorders, and neuroleptic malignant syndrome is associated with blockade of the dopamine pathways as well (36).

**Recovery**

Patients who have had profound disruption of the dopamine pathways as noted in DAI and anoxic injury may forever be very susceptible to the side effects of medications that block the D1-D5 pathways (35, 36). For this reason these medications need to be judiciously utilized with preference to medications that block as few of these pathways as possible. For this reason medications that block the dopamine pathways are generally restricted in the early recovery stages of TBI due to their potential clinical effect.

**Controversy**

Typical antipsychotics and atypical antipsychotics carry varying degrees of dopamine blockade. Typical antipsychotics exist along a spectrum carrying various degrees of dopamine blockade (mostly D2) and anticholinergic activity (59). Atypical antipsychotics have activity not only via dopamine blockade but also on the serotonin system (59).

Typical antipsychotics have been used for the immediate control of aggression or agitation in TBI (60). These agents have the potential concern of lowered seizure threshold and clouded sensorium. As with other patient groups, neuroleptic malignant syndrome has been reported

**TABLE 54-3**  
**Dopamine**

RECEPTOR	G-PROTEIN	EFFECTOR MECHANISM
D1, D5	Gs	↑adenylyl cyclase; ↑cAMP
D2, D3, D4	Gi, Go	↓adenylyl cyclase; ↓cAMP; Ca <sup>2+</sup> /K <sup>+</sup> channels

with the administration of typical and atypical antipsychotic agents. Presenting symptoms can include fever, leukocytosis, and muscle stiffness; this entity carries a potential mortality of 10% (61). The source of these adverse events appears to be the typical antipsychotic medications particular affinity for the D2 dopamine receptor. Atypical antipsychotic agents have less D2 activity and more 5HT<sub>2a</sub> activating thus theoretically reducing some of the undesirable effects and adrenergic blockade (59). Recently clinical concerns with cardiac dysfunction have been raised in the dementia population with the use of atypical and typical antipsychotic agents (62).

While numerous studies have been done in animal models there is a lack of clarity in optimal timing and in human data. Animal models of recovery after TBI consistently demonstrate a negative impact of dopamine blockers on recovery in the postacute period (57, 63). Yet not all animal models are clear on this issue. In an animal study evaluating the effects of antipsychotics on cognitive function after TBI, haloperidol was demonstrated to be harmful while olanzapine was not (64). Recent work has demonstrated a negative impact of chronic risperidone use (65). Perhaps these differences are explained by the relatively strong D2 receptor activity of risperidone (65).

While most rehabilitation clinicians treating those with TBI would attempt to avoid dopamine blockade the actual human evidence for this is rather weak. Rao et al studied the impact of haloperidol in a rehabilitation setting and noted no change in outcome but a longer length of posttraumatic amnesia in the haloperidol group (66). Maryinak et al demonstrated the successful use of the older antipsychotic methotrimeprazine in persons with TBI admitted to a rehabilitation unit (67). These authors noted that while those treated with the antipsychotic had a longer length of posttraumatic amnesia is likely reflected a greater injury severity (67). Other authors have noted that weaning antipsychotics in the chronic setting results in improved neuropsychological test scores (68). Of interest however is a recent study suggesting a benefit to the use of haloperidol in the ICU setting. Milbrandt and colleagues examined a total of 989 persons with ICU stays and mechanical ventilation of greater than 48 hours (69). Haloperidol use was associated with lower hospital mortality. While this retrospective study has limitations, this data appeared to remain consistent for those with trauma and neurological dysfunction. The authors postulated that at least acutely haloperidol inhibits the secretion of proinflammatory cytokines.

Medications that may increase dopamine have been postulated to enhance recovery from TBI (70, 71). The most studied of these medications is amantadine, which also may have effects on various neuronal growth factors. Other medications such as bromocriptine that demonstrate specific D1-D2 receptor pathway activity have also been useful (71).

The disruption of the dopaminergic pathways has also been implicated in the development of psychiatric disorders following TBI (35, 36). Delusions, hallucinations, and various behavioral dyscontrol syndromes have been implicated with TBI.

The role of dopamine enhancing medications in the potential recovery of persons with TBI remains an issue of great interest. These agents have been employed for aphasia, hemineglect, arousal, agitation and dysautonomic syndromes. Dixon and Klein have demonstrated the role of amantadine in the treatment of a laboratory model of chronic TBI (72). Bromocriptine has also been shown to improve lipid peroxidation after TBI (73). Other agents such as selegiline have shown promise in the laboratory (74). Clearly, clinical trials are lacking and little level I evidence exists to guide clinicians in the use of these medications. Potential side effects of these medications include: dyskinesia, hypotension, lowered seizure threshold, hallucinations and behavioral dysfunction.

While many clinicians use neurostimulant medications for the treatment of hypoarousal in persons with TBI, unfortunately the literature to support their use is sparse (40). Amantadine has both pre and post dopaminergic activity as well as functioning as a NMDA antagonist (71). In a case report by Zafonte and colleagues, a male patient in a minimally conscious state regained full consciousness when placed on the dopaminergic agent amantadine but subsequently experienced a significant decline when the medication was withdrawn (76). A double blind placebo cross over study by Meythaler and colleagues, showed significant improvements in DRS scores and FIM-cognitive scores in groups taking amantadine were found, regardless of when it was started (71). Additionally, amantadine has shown promising results when given in the acute phase of TBI. Saniova et al. found decreased mortality rates and improved GCS scores in a small group of persons admitted to an ICU after severe TBI who were given a three-day course of amantadine (77). This agent is presently under evaluation in a multicenter trial to evaluate its impact on arousal. McDowell tested a group of 24 subjects with TBI using a double blind, placebo-controlled crossover trial (78). Bromocriptine was found to improve performance on some tasks served by prefrontal function, but not others. Dobkin had previously shown improvement in antegrade amnesia in a women with TBI (79). Substantial work still remains to identify the specific syndromes and characteristics of persons who respond to these medications.

### Serotonergic Pathways

The serotonin pathways are found predominately in the midbrain and brain stem but are distributed diffusely throughout the CNS. They have profound projections throughout the brain including to the frontal lobes and

the hippocampus (80, 81). It has been theorized that these pathways are most disrupted by DAI. Serotonin (5-hydroxytryptamine or 5-HT) is likely the most phylogenetically ancient of currently known neurotransmitter molecules. Serotonergic neuronal cell bodies are organized in two distinct groups (81); caudal (in the medulla oblongata and the caudal half of the pons) and rostral (in the midbrain and rostral pons) (81). The rostral 5-HT neuron axons ascend toward the forebrain, while those from the caudal group descend to brainstem structures and the spinal cord. Numerous serotonin receptor types have been identified (82, 83) (Figure 54-4). The current classification system takes into account drug related properties, as well as information about amino acid sequencing of the receptor. It is the receptor interaction with the G protein that permits the particular receptor to modulate the activity of different effector systems such as ion channels, substances like adenylyl cyclase. The 5HT1 family and 5HT2 family represent the major classes of serotonin receptors this family also includes the 5HT4, 5HT6 and 5HT7 all of whom are G protein dependent (83, 84). The 5HT3 receptor system is a gated ion channel dependent system and represents a separate functional family of receptors. These receptor differences create opportunity and hazards in drug development and clinical utility.

These widely distributed serotonergic pathways are involved in diverse cognitive functions. Data suggest that serotonergic neurotransmission plays a major role in stabilizing and modulating brain function (84, 85). The rostral part of the serotonergic raphe system consists of the caudal linear nucleus (in the midbrain), the dorsal raphe nucleus (extending from the caudal midbrain to rostral pontine levels), and the median raphe nucleus (superior central raphe nucleus found in the rostral pons) (80, 81). In the caudal division there are descending serotonergic neuronal projections found in the raphe magnus nucleus, raphe pallidus nucleus, and raphe obscurus nucleus. In addition there are serotonergic neuronal cell bodies present in the medullary reticular formation (involved in alertness and wakefulness) and other non-raphe regions such as the hippocampus (involved in memory functions) and the substantia nigra (involved with motor control) (80, 81) (see table 54-4).

### Acute Injury

Very little work has been performed on the affects of acute serotonin disruption following TBI. However, increasing the levels in the first week following injury is hypothesized to have the same affect of causing increased neuronal cell death as with other excitatory neurotransmitters.

Unfortunately, projections of the serotonin system, including to the forebrain, limbic areas, and hippocampus,

**TABLE 54-4**

5-HT5	Unknown	Poorly Characterized

are prime sites of direct or secondary injury resulting from TBI. There is ample evidence that TBI impacts levels of serotonin in the central nervous system (CNS), but whether there is an elevation or depletion of serotonin is a matter of some debate. Several studies have documented elevations of serotonin in the CNS during the hours immediately after CNS injury, possibly extending for several days (85–88). Markianos, et al. found a significant negative correlation between CNS level of serotonin and the Glasgow Coma Scale score obtained at the time of assay, as well as an association of high serotonin levels with subsequent death (89). Under these conditions, serotonin has been suspected of worsening edema and contributing to vascular spasm (85–88). On the other hand, there are also studies that indicate diminished CNS serotonin levels within the first 24 hours after TBI (88–91), even in cases of mild injury (92). The decrease in serotonin level has been documented up to 60 days following TBI (60), suggesting a chronic down-regulation of the serotonergic system. In addition, there is evidence that serotonin may assist in controlling edema and serotonin receptor agonists may diminish the excitotoxic effects of glutamate release, or secondary inflammatory factors after neurotrauma (93, 94). Disruption of normal serotonin functioning has been documented on a chronic basis after even milder injury, based on a diminished prolactin response to buspirone, which activates serotonin receptors under normal conditions and results in prolactin release (90). Animal models also suggest that neuronal synthesis of serotonin may be inhibited even though extracellular levels of the substance may be high (95).

### Recovery

Damaged serotonergic neurons can survive an injury and in time re-energize target regions, reestablishing

synaptic and neurotransmitter function and restoring behavior (1, 95–97). Mature adult neural circuitry can be remodeled and affected by the use of neurotrophic or neurotoxic factors (96). Serotonin facilitation may be involved in controlled neurogenesis. Pharmacological manipulation of neurotransmitter levels, including serotonin, may aid in the repair and reestablishment of useful neural pathways. Serotonin also plays a key role in sleep initiation.

### *Controversy*

Animal data has suggested that 5HT agonist medications may be both helpful and harmful. Repinotan hydrochloride (repinotan) is a highly potent and selective 5-HT(1A) full receptor agonist. This agent has shown rapid uptake and a broad spectrum of neuroprotection in stroke and TBI (97). Kline has reported that 5-HT1A-receptor agonist 8-hydroxy-2-(di-n-propylamino)tetralin (8-OH-DPAT) attenuated traumatic brain injury (TBI)-induced cognitive deficits and histopathology (96). However Wilson studied the selective serotonin 5HT1a receptor agent fluoxetine that in a chronic administration did not impact motor or cognitive recovery (98). Boyeson's team observed that high doses of the phenylpiperazine agents trazodone induced deficits in an animal model of TBI (99, 100).

Thus, there may be a period of time when introduction of serotonin agonist agents might be beneficial to recovery of the normal serotonin response. Selective serotonin reuptake inhibitors are among the most utilized medications in North America. These agents have been employed to enhance arousal, improve behavior, and treat depression and emotional lability. An initial phase I study (101) examining the potential beneficial impact of serotonin agonists on recovery after TBI indicated that sertraline was safe, although the study may have been limited by a small subject pool and a short duration of treatment with an SSRI (2 weeks).

It has been theorized that disruption of these pathways is one of the causes of increased depression following TBI (102, 103). A single blind placebo run in trial by Fann et al demonstrated the potential utility of the SSRI Zoloft in the treatment of depression following mild TBI. These pathways have also been implicated in the development of the emotional lability and emotional incontinence noted to follow TBI (102). The use of SSRI antidepressants has become common during the rehabilitation phase following brain injury due to either stroke or TBI. In two studies, antidepressants were shown to aid in the management of behavioral disturbance. Kant and colleagues gave sertraline for eight weeks to 13 patients with TBI, resulting in decreased outbursts and irritability yet this study failed to clarify this issue (104). Bupropion was reported to

improve psychomotor agitation and participation in therapies in a 20-year-old woman with TBI who had failed treatment with several other medications (105).

Trazodone, a triazolopyridine antidepressant, is a selective 5-HT reuptake inhibitor and 5-HT<sub>2</sub> receptor antagonist and has been frequently used for its sedating effects. Used as an antidepressant, doses of up to 500mg/d are commonly required, however, at lower doses its sedative properties likely result from its antagonistic effect of the 5-HT<sub>2</sub> receptors (106, 107). The effects of trazodone on sleep have been shown to occur after the first dose (107, 108). It has been found to closely mimic the natural sleep cycle by increasing the amount of total sleep, increasing the percentage of deep sleep (stages 3 and 4) and decreasing the number of intermittent awakenings (106, 108–114). Trazodone in one dose of 50 to 100 mg nightly to patients showed improvements in early sleep waking, lack of sound sleep, and difficulty in initiating sleep at two weeks and six weeks with significant increases in total sleep time (111).

Mirtazapine is an alpha<sub>2</sub>-adrenoceptor antagonist as well as an indirect 5-HT agonist, increasing both synaptic norepinephrine and serotonin. Mirtazapine has been found to improve sleep continuity and increase latency to REM sleep, which may in part be due to its antihistamine properties (115). Yet concern exists regarding rapid weight gain have been noted. Further studies evaluating the role of mirtazapine in sleep disorders in the TBI population are warranted in order to evaluate potential cognitive sequelae.

These studies need to be expanded upon and several are underway at the current time. Whether increases in serotonin will improve the functional status following TBI, beyond that associated with affective disorders is not well understood. Just as important is a clearer understanding of the risks of these agents and their effectiveness in this population.

### **Norepinephrine Pathways**

The excitatory norepinephrine pathways are widely distributed in the brain. However, they are most predominant in the neocortex. From a small cluster of neurons in the locus coeruleus axons are projected to vast areas diffusely throughout the central nervous system including the spinal cord, cerebellum, thalamus and cerebral cortex (116). These pathways have profound effects on behavior, affect, motor function and attention to name just a few of the wide effects of NE. As an example of the critical interactions between neurotransmitters a reduction of NE in the frontal cortex has been associated with attention deficits related to new learning (117). Hence, memory deficits may be related to reduced attention without deficits in the acetylcholine pathways.

**TABEL 54-5**  
**Norepinephrine**

RECEPTOR	G-PROTEIN	EFFECTOR MECHANISM
$\alpha$ 1A, $\alpha$ 1B, $\alpha$ 1D	Gq	$\uparrow$ PLC, $\uparrow$ phosphoinositide hydrolysis; $\uparrow$ IP3; $\uparrow$ [Ca <sup>2+</sup> ] <sub>i</sub>
$\alpha$ 2A, $\alpha$ 2B, $\alpha$ 2C	Gi, Go	$\downarrow$ adenylyl cyclase; $\downarrow$ cAMP; $\downarrow$ Ca <sup>2+</sup> influx/ $\uparrow$ K <sup>+</sup> efflux
$\beta$ 1, $\beta$ 2, $\beta$ 3	Gs	$\uparrow$ adenylyl cyclase; $\uparrow$ cAMP

### Acute Injury

Increases of NE are discouraged in the first minutes, hours and days following TBI as the increase alone has been linked to increased neuronal cell death (118, 119). These increases play into the secondary injury cascade and appear to exacerbate other pathways. Indeed, blockade of some NE adrenergic pathways has been hypothesized to be useful in the first few days after injury (120–122).

### Recovery

Long term reductions have been associated with an acquired attention deficit syndrome in TBI. This chronic decrement in response has been demonstrated in animal models (123, 124). Consequently, there has been research on the use of agents to increase NE in the weeks following TBI (125, 126).

### Controversy

D-amphetamine enhances NE release and has been demonstrated to show benefits in dorsal frontal injury. Kline has demonstrated that chronic methylphenidate treatment enhances water maze performance in animal models of TBI (124).

The most commonly utilized medication is methylphenidate (125–127). Methylphenidate is believed to impact its action at least in part by activity at the dopamine transporter (DAT)(128). One group of investigators has conducted two randomized, double blind, placebo-controlled trials using crossover designs to evaluate the effects of methylphenidate on various aspects of attention after TBI (125). Methylphenidate's potential utility was demonstrated in a study of 34 adults with TBI and persistent deficits in attention (125). Significant benefits of methylphenidate were seen on speed of information processing, but not on divided attention, sustained attention or susceptibility to distraction. This well-designed study suggests the potential beneficial effects of methylphenidate on specific aspects of attention after TBI. While it's

role in arousing patients is not clear methylphenidate does appear to improve attention and processing speed. In a study of ICU persons with TBI, early use of methylphenidate was associated with reductions in ICU and hospital length of stay by 23% in severely TBI patients (128). Although concerns in using early methylphenidate therapy exist such as: increasing the excitability cascade and the proper timing of such therapies. Medications indicated for attention deficit, both on label and off label, have been frequently utilized in TBI patients to improve attention and processing speed in those patients with documented deficits. Since attention is related to so many neurocognitive function, there is a significant need to perform further research in this area. Further evaluation of the population specific benefits is also needed.

### GABA Pathways

$\gamma$ -Aminobutyric acid (GABA) is among the most prevalent neurotransmitter in the CNS. It invariably acts as an inhibitory pathway on excitatory neurotransmitters such as acetylcholine, dopamine, glutamate and norepinephrine. GABA pathways are distributed throughout the brain (116, 129).

GABA receptors have been classified into subtypes A, B and more recently C. The GABA<sub>A</sub> receptor is the best understood and has three distinct subunits (116, 129, 130). GABA has been implicated in the inhibition of dopamine, norepinephrine, and cholinergic pathways in the brain. It also modulates the excitotoxicity of Glutamate (116). More recently, GABA has been implicated in the release of serotonin (131). As such GABA is the most widespread neurotransmitter and is invariably inhibitory (116).

### Acute Injury

Because of GABA's effects via the G1 protein at Glutamate activated channels it has been considered to be a potentially neuroprotective agent in the first minutes, hours and days following TBI (116). Unfortunately, GABA is completely hydrophilic and does not cross membranes. This leads us to consider medications that indirectly increase its release.

**TABEL 54-6**  
 **$\gamma$ -Aminobutyric acid (GABA)**

RECEPTOR	G-PROTEIN	EFFECTOR MECHANISM
GABA <sub>A</sub> GABA <sub>C</sub>	NA	Cl <sup>-</sup> channel
GABA <sub>B</sub>	Gi, Go	$\downarrow$ adenylyl cyclase; $\downarrow$ cAMP; $\downarrow$ Ca <sup>2+</sup> influx/ $\uparrow$ K <sup>+</sup> efflux

One potential mechanism linked to the neuroprotective effects acute ETOH exposure following CNS injury is the blocking effects at Glutamate activated NMDA channels (132). However, chronic use of ETOH may actually down regulate the receptors thereby reducing the brain's ability to self protect itself from excitatory neurotransmitters (133–137).

### Recovery

Use of GABA agonists has been implicated to reduce the rate of recovery following brain injury (138). This includes medications such as benzodiazepines and baclofen (139). The benzodiazepines are termed sedative hypnotics, they make you forget and/or they put you to sleep (138, 139). Both conditions are not conducive to recovery. It is felt that the first six months after injury from TBI are most critical to recovery. This means that these medications, often utilized for seizure prophylaxis, spasticity management and behavioral control should be restricted as much as possible.

### Controversy

Benzodiazepines, antiepileptic medications (AED's) and antispasticity agents act via GABA yet their longterm impact of these agents is not well understood (138). Benzodiazepines are the oldest family of medications used for spasticity. Diazepam, the most commonly used agent, acts near the GABA<sub>A</sub> receptor to hyperpolarize the cellular membrane, and thus increases presynaptic inhibition (140, 141). Work on the use of diazepam in spinal cord injury, cerebral palsy and multiple sclerosis demonstrated its efficacy in the treatment of spasticity over placebo (142–143). Diazepam has not shown functional improvement. Diazepam's major limitation is in its rather significant side effect profile is sedation it has limited tolerance of diazepam and thus limit its use in the TBI population (138, 140). Baclofen is active at the GABA b receptor both pre and postsynaptically. It has been employed for the treatment of spasticity in persons with SCI, cerebral palsy, multiple sclerosis, stroke and brain injury (138). Enteral baclofen therapy may be warranted for those with severe spasticity of cerebral origin who cannot tolerate dantrolene sodium and face the risk of severe contracture or loss of range of motion (140).

Baclofen has been noted to produce sedation, especially among those with cerebral disorders. Concerns with the use of this medication include: asthenia, depression, hallucinations, nausea, dizziness and paresthesias. Attention and memory induced deficits have been raised in animal models and observed with humans. GABA facilitatory agents may impair recovery (145). Memory dysfunction has been associated with baclofen therapy in both animals and humans (145, 146). Additional concerns with

baclofen include lowered seizure threshold, and withdrawal syndrome (146). Rapid withdrawal from baclofen therapy should be avoided and can induce seizures, altered mental status, hallucinations, hyperthermia and rigidity (138). Therefore concerns are raised regarding potential negative impact on neurorecovery. One implication of this concept is the long-term use of AED's, particularly those that may function via GABA, are discouraged in the long-term prophylaxis of seizures following TBI. There is considerable evidence they may impede recovery. Finally, inhibiting the effects of excitatory neurotransmitters such as glutamate via GABA invariably affects our ability to learn and adapt. Glutamate is necessary for neuroplasticity and learning and blockade invariably has the potential to reduce the rate and end-point of recovery. The timing of dosing of GABA agonists (early may be better than late) and amount of blockade by the various drugs may be critical.

### CONCLUSION

While this is a brief discussion regarding some of the principles of neuropharmacology following TBI, there is much more to follow in the later chapters of the book. The primary purpose of this chapter is to give one a general outline of some of the major neurotransmitter systems that may affect the outcome from TBI. What has not been explored are therapeutic thresholds and toxicity levels for medications.

More research needs to be performed on the use of medications that modulate transmitter systems and the pharmacogenetics involved in treating such persons. When utilizing medications, thought should be given to their profound effects, often beyond the intended results. Randomized placebo controlled trials are needed to further define the potential benefits and risks of such therapy. In addition, a broad understanding of the "window of opportunity" for such medications is needed. As one reads further chapters in the textbook consider the untoward side effects presented as well as the beneficial uses of medications that may affect the CNS.

# 55

## Nutraceuticals

*Jeffrey S. Hecht*

**I**n surveys of various patient populations, it has been found that nutritional supplements not prescribed by (or known to) the attending physician are being used (1). Increasingly, physicians are being urged to ask about use of these non-traditional medications and become aware of the common and uncommon interactions with prescribed drugs. A huge and growing business exists for those purveyors of “health foods” and “health supplements”—with large sections of traditional pharmacies carrying them. The German government has long established a bureau to assure standard doses of these supplements, but the US has no such regulation at the present. However, in recent years the federal government, through the National Institute of Health, has established the National Center for Complementary and Alternative Medicine (NCCAM). The NCCAM has sponsored trials with nutritional supplements for dementia, but so far not in the area of traumatic brain injury.

The growing interest in nutritional supplements has led to a growth of research in this area (2), a 1997 survey estimated that 12.1 percent of adults in the United States had used an herbal medicine in the previous 12 months (as compared with 2.5 percent in 1990), resulting in out-of-pocket payments of \$5.1 billion, but little is specifically in the area of traumatic brain injury. Yet, some of the studies are relevant to problems experienced by the brain injured. These include the psychostimulants ginkgo and ephedra,

and the antidepressant St John’s Wort (1, 3). One literature survey of particular value is that by Fugh-Berman and Cott in *Psychosomatic Medicine* (4).

### **NUTRITIONAL SUPPLEMENTS USED TO IMPROVE COGNITION**

*Choline* Choline is an important component of the neurotransmitter acetylcholine. There is evidence that high doses of choline may improve memory in adults. (Doses up to 2500 mg po bid are used.) Choline is one of the B complex vitamins, and occurs in foods such as eggs, meat, fish, nuts, legumes, and soy.

*Phosphatidylcholine* Phosphatidylcholine is the most active ingredient found in soy lecithin. Every cell membrane in the body requires phosphatidylcholine (PC). Nerve and brain cells in particular need large quantities of PC for repair and maintenance. PC also aids in the metabolism of fats, regulates blood cholesterol, and is a component of myelin. PC is a major source of the neurotransmitter acetylcholine. Most of the choline normally present in our diet is in the form of lecithin where it occurs in seed oils and in unrefined foods containing oil.

Supplemental PC increases the amount of acetylcholine available for memory and thought processes. Increasing acetylcholine levels has been shown to improve

performance by humans in a variety of intelligence and memory tests. Acetylcholine also is extremely important in maintaining brain cell structure.

**CDP-Choline, Citidine, Citicoline, cytidine-5-diphosphate-choline, tidinediphosphocholine, Somazina, cytidine 5'-diphosphate choline**

A medication that has been studied over 25 years with demonstrated efficacy in a variety of conditions including traumatic brain injury (TBI) is CDP-Choline. The drug is made of cytidine and choline moieties connected by a pyrophosphate bridge. Cytidine is incorporated into nucleic acids while choline ultimately "is in part converted into betaine, which in turn acts as methyl donor to homocysteine, yielding [14C]methionine, subsequently incorporated into proteins" (5).

Studies in animal models first suggested possible benefit of this drug. One study suggested inhibition of phospholipid breakdown by inhibition of an enzyme that is released following brain injury—phospholipase A2 (6).

Another study noted the strong polar nature of this drug, which prevents it from effectively crossing the blood-brain barrier (BBB). They studied a way to better cross the BBB by trapping citicoline in liposomes with the goal of improving its therapeutic effectiveness. The real therapeutic effectiveness of these citicoline liposome formulations was evaluated by biological assay with levels compared to the survival rate of ischemic reperfused male Wistar rats. Conjugated diene levels in the rat brains were measured, since this is an index of lipid peroxidation in rat cerebral cortex during post-ischemic reperfusion. The best mixture produced a reduction in diene levels of 60% and an increase in rat survival rate of about 24% and compared to the free drug (7). Other studies indicated that CDP-choline decreases edema formation and blood-brain barrier disruption following traumatic brain injury (TBI). One study of controlled cortical impact (CCI)-induced TBI in adult Wistar rats involved administration of the drug immediately post injury and once 6 hours post injury. The animals were sacrificed and the number of hippocampal neurons counted on the seventh post injury day. Treatment with CDP-choline significantly prevented TBI-induced neuronal loss in the hippocampus, decreased cortical contusion volume, and improved neurological recovery (8).

In another study, the authors examined the effect of CDP-Choline on brain edema and breakdown of the blood-brain barrier after TBI. Like the prior study, TBI was created using a CCI device. Half of the Sprague-Dawley rats received intraperitoneal injections of CDP-Choline twice following TBI. No significant benefit was noted at a low dose, but the higher doses (100 and 400 mg/kg) significantly decreased brain edema and BBB breakdown. Neuroprotective effects were demonstrated in the hippocampus as well as the directly injured cortex (9).

A Turkish study demonstrated significant neuroprotective effect of the drug and mortality reduction in rats following experimental cerebral ischemia (10).

A study from the department of neurosurgery at the University of Pittsburgh explored the role of CDP-choline in attenuating deficits in posttraumatic motor and spatial memory performance caused by direct trauma using a CCI model. They also explored whether CDP-choline increases acetylcholine (ACh) release in the dorsal hippocampus and neocortex.

The drug was first administered one day post injury and continued for 18 days. In the behavioral study, traumatic brain injury (TBI) was produced by lateral controlled cortical impact (2-mm deformation/6 m/sec) and administered CDP-choline (100 mg/kg) or saline daily for 18 days beginning 1-day post injury. Between 14–18 days post injury, CDP-choline-treated rats had significantly less cognitive (Morris water maze performance) deficits than injured saline-treated rats. CDP-choline treatment also attenuated the TBI-induced increased sensitivity to the memory-disrupting effects of scopolamine, a muscarinic antagonist. Microdialysis studies demonstrated a significant increase in extracellular levels of ACh in the dorsal hippocampus and neocortex in normal, awake, freely moving rats. The authors opined that this provides additional evidence that spatial memory performance deficits are, at least partially, associated with deficits in central cholinergic neurotransmission and that treatments that enhance ACh release in the chronic phase after TBI may attenuate cholinergic-dependent neurobehavioral deficits (11).

Clinical use of CDP-Choline in neurosurgery was first reported in the Japanese literature (12). Ogashiwa's article first reported both on the whole-body distribution of the drug in Wistar rats. It then went on to describe administration of CDP-choline to seven patients by intrathecal route to bypass the BBB. His second study reported benefit from 39 infusions given to 15 patients (13). Use of the drug in 60 cases of severe head injuries (wide-spread cerebral contusions and/or severe concussion) was reported by Cohadon and others in the French literature. They postulated that a shortening of the comatose period and an acceleration of neurological deficits recovery noted in the treated group was due to reduction of cerebral edema (14).

The authors of a Spanish single blind randomized study of 216 patients with moderate or severe brain injury study found "a trend towards a greater improvement in motor, cognitive and psychic alterations in the patients treated with CDP-choline, as well as a shortening of the stay in the hospital ward in the patients receiving this drug that initially presented with severe head injuries" (15).

By 2001, use of CDP-choline had apparently become part of standard neuro traumatology practice in Japan (16). The authors observed, "There appear to be two obvious differences in selection of pharmacological

therapies among neurosurgeons in Japan and those in other countries; neurosurgeons in Japan prefer glycerol to mannitol for osmotic control of intracranial pressure, and barbiturate to morphine as sedatives. Two drugs are currently available in Japan for promoting the recovery from disturbance of consciousness after head trauma: cytidine diphosphate choline (CDP)-choline (Nicholin, Takeda Chemical Industries, Ltd., Osaka) and protirelin tartrate (Hirtonin; thyrotropin-releasing hormone (TRH) analogue, Takeda). Another TRH analogue, NS-3 (montirelin hydrate), is currently submitted to the Ministry of Health and Welfare for approval.

CDP-Choline has been the subject of double-blind placebo-controlled trials in humans in Japan with another type of brain insult—ischemic stroke—where it was found to be efficacious. Significant improvements in level of consciousness (Tazaki) and hemiplegia (Hazama) were noted in the studies (17, 18). In Spain, it has been reported to be effective in clinical trials of patients with Parkinson's Disease (19, 20) and Alzheimer's disease (21). CDP-Choline has been used late after brain injury as well as in the early stages. Harvey Levin, at the University of Texas in Galveston, reported it to be effective in a double-blind placebo-controlled trial of 14 patients with mild to moderate closed head injury who had postconcussional symptoms persisting for one month (22). Leon-Carrion and others, in Spain, reported that CDP-Choline improved cerebral blood flow of seven patients (by reversing brain injury-induced hypoperfusion) in the inferior left temporo-basal region. Additionally, they noted an improved response to neuropsychological rehabilitation—specifically observing that the domains of “memory, learning processes and verbal fluency . . . improved significantly after treatment” (23). One case report suggesting positive effects on recovery was particularly interesting as it is autobiographical (24).

A review of the use of CDP-choline as well as other cholinomimetic agents is helpful. Their primary observation is that “preliminary data in traumatic brain injury suggest acetylcholine esterase inhibitors may play a significant role in the treatment of this patient population as well.” (25)

Most published studies in animals (26, 27) and humans (28, 29) indicate that CDP-choline is safe. No side effects were observed in the studies on rats and dogs. One of the human tolerance studies of 2817 patients with neurological diseases on the medication for therapeutic reasons observed side effects in 5.01% of the patients: “the most frequently seen were digestive troubles, observed in 3.6% of the cases”. The mean dose in that study was 6 ml/day. The other study of 12 adult healthy volunteers noted, “transient headaches were the only untoward events recorded”, but the frequency was 33% in the “low dose” (600 mg/day) group and 42% in the “high dose” (1000 mg/day) group.

*Ginkgo biloba.* Ginkgo has been used to improve memory and attention. Ginkgo biloba extract is the most commonly prescribed plant remedy in the world. For thousands of years, Ginkgo has been part of the armamentarium of traditional Chinese herbal medicine. In Indian Aryeurvedic medicine, it is part of the elixir called Soma.

Modern studies have also demonstrated the effectiveness of this medication. A randomized, double-blind, placebo-controlled trial of 309 patients with Alzheimer's or multiinfarct dementia concluded that Ginkgo was beneficial in the treatment of dementia (30). The authors concluded that Ginkgo biloba “was safe and appears capable of stabilizing and, in a substantial number of cases, improving the cognitive performance and the social functioning of demented patients for six months to one year.” Benefits were equivalent to Tacrine or Aricept—medications commonly prescribed to slow the progression of dementia. LeBars et al. found Ginkgo biloba extract effective, but with a side effect profile equivalent to placebo. This well-designed multicenter study showed significantly less decline in cognitive function among patients with dementia receiving ginkgo. They found the dose of 240 mg/day more effective than 120mg (31). They noted, “in contrast to narrow memory tests, broad cognitive assessments were more likely to detect the treatment effect.” Beaubrun and Gray reviewed 40 controlled trials of ginkgo extracts in the treatment of dementia and found that 39 of 40 studies demonstrated clinically significant improvement in memory loss, concentration, fatigue, anxiety, and depressed mood (32). Wong and others found good evidence for the efficacy of ginkgo in the treatment of memory impairment caused by dementia (33). Other studies have also demonstrated significant benefit (34–36).

Side effects of ginkgo biloba are minimal. In a German post-marketing surveillance study of 10,815 patients treated with LI 1370 (another brand of standardized ginkgo), only 183 reported side effects. These side effects included nausea, headache, stomach problems, diarrhea, allergy, anxiety or restlessness, sleep disturbances, and in rare cases, serious bleeding problems. There have been five reports of bleeding associated with ginkgo treatment. These include two subdural hematomas, one with a documented increase in bleeding time, one intracerebral hemorrhage, and one subarachnoid hemorrhage. In most cases, patients were receiving concurrent anticoagulant drugs. Ginkgo reduces platelet aggregation by inhibiting platelet activation factor. Concurrent use of anticoagulants and ginkgo extracts should probably be avoided. It should also be avoided in patients with clotting problems. One case study reported ventricular arrhythmias with Ginkgo (37).

Cochrane reviews conclude there is “promising evidence of improvement in cognition and function associated with Ginkgo”, but recommends larger controlled trials (38). Two randomized, placebo controlled and double blind

trials of ginkgo biloba have been sponsored by the National Center for Complementary and Alternative Medicine (NCCAM). The Ginkgo Biloba Prevention Trial in Older Individuals was a stage III trial set up to determine the effect of 240mg/day Ginkgo biloba in decreasing the incidence of dementia and specifically Alzheimer's disease (AD), slowing cognitive decline and functional disability, reducing incidence of cardiovascular disease, and decreasing total mortality over five years. All subjects were 75 or older and without serious comorbidities. The study is now closed.

The other study, Preventing Cognitive Decline with Alternative Therapies, focuses on the oldest old who are at a particularly high risk for developing mild cognitive impairment (MCI), a precursor to dementia. The effect of standardized ginkgo biloba extract (GBE) on preventing or delaying cognitive decline in people age 85 years or older is studied over 42 months. Not yet closed, they plan to enroll 200 elderly cognitively healthy subjects and follow them for detection of conversion to MCI. The study hopes to definitively examine whether GBE has a disease modifying effect on the brain—distinct from a symptomatic effect. The magnitude of biological effect of the treatments will also be assessed with volumetric quantitative MRI, a complementary means of confirming whether there is a brain modifying effect (measured as a decrease in brain volume loss with treatment). Peripheral markers of oxidation status will measure possible anti-oxidant effects of GBE. The Principal Investigator is Dr. Jeffrey Kaye at the Oregon Health Sciences University in Portland.

*Pyritinol* Pyritinol is used by some to enhance neuronal metabolic function. The pyritinol molecule is structurally similar to vitamin B<sub>6</sub>, but functions in the brain in a different way. The dose of pyritinol used in most of the human clinical studies is one 200-mg capsule taken three times a day.

Fischhoff, et al. reported on a 12-week, double-blind clinical trial that was performed to investigate the benefit of pyritinol in the treatment of several forms of senile dementia (39). A total of 156 patients were allocated to either of two groups: the "senile dementia of the Alzheimer's type" group, or the "multi-infarct dementia (stroke)" group. The investigators noted, "The therapeutic efficacy of pyritinol was clearly demonstrated by confirmatory analysis as the drug was statistically significantly superior to placebo in all three target variables (of cognitive function). The EEG mapping demonstrated significant differences between placebo and pyritinol . . . it can be accepted that the therapeutic effect of pyritinol is superior to placebo in patients with mild to moderate dementia of both degenerative (Alzheimer's) and vascular (stroke) etiology."

A double-blind, placebo-controlled trial was carried out on 40 patients suffering from moderately advanced

dementia. The patients were allocated randomly either pyritinol (800 mg daily) or identical placebo for three months. Assessments using a modified Crichton Geriatric Behavioral Rating Scale were made pre-treatment and monthly up to three months, and then at follow-up at six months. Patients on pyritinol showed significantly higher levels of improvement than did those on placebo. Laboratory tests conducted throughout remained within normal limits for both groups (40).

Another study, reported 26 patients with Alzheimer's disease who were randomly assigned in a double-blind trial of pyritinol versus placebo. The patients had a mild to moderate degree of dementia. The results of the study showed that "pyritinol was associated with a significant improvement in cognitive performance. Regional cerebral blood-flow data showed that treatment with pyritinol normalized the pattern of blood flow increase during activation and improved the score on the test used for activation (41). In the German journal *Pharmacopsychiatry*, the effects of pyritinol were investigated in a placebo-controlled, randomized, double-blind study in geriatric patients suffering from cerebral functional disorders, with a moderate to severe degree of chronic brain syndrome. In a previous study, a rise in the vigilance (wakefulness, alertness) level was demonstrated in patients undergoing pyritinol treatment. Data from 107 patients were included in the statistical analysis, 54 on pyritinol and 53 on placebo. No notable adverse drug reactions were observed. They noted "Statistically significant results were found in favor of pyritinol, compared with placebo, in both the level of clinical symptomatology and the performance level. Particularly impressive was the superiority of pyritinol in the factor 'social behavior'"(42).

One of the few studies that specifically used nutritional supplements in the brain-injured was carried out in the late 1970s by Kitamura in Tokyo. Two hundred and seventy patients suffering from the sequelae of different forms of brain injury were treated orally with pyritinol, 200 mg three times a day, for a period of six weeks. Compared with placebo therapy, pyritinol produced statistically significant improvements in the clinical and psycho neurological manifestations. It was concluded that pyritinol is a drug of therapeutic benefit in the treatment of the sequelae of cerebral trauma (43).

*Piracetam (also nootropil) and Levirpiracetam (the S-enantiomer)* Piracetam has been the subject of multiple animal and human studies. It has been described as a "nootropic" drug due to its putative neuroprotective effects in rat models of brain injury. It has been reported as helpful in cognitive enhancement (44). It has been described as the "number one worldwide cognitive enhancer" on one web site that served to facilitate its procurement (the site has now been closed by federal agents.) A nonblinded polish study was reported in 1998 where

the drug was administered IV or orally to patients with acute brain injury (45). Their conclusion that “the use of piracetam is recommended” is not supported by the study. Ricci reported on its use in acute ischemic stroke and found no demonstration of effectiveness, but a trend of increased mortality in the treatment group (46). Oosterveld reported on benefit in vestibular disorders following brain injury (47). Kessler and others reported in Stroke in 2000 that piracetam facilitates rehabilitation of post stroke aphasic patients (48). Yet, Greener and others, reporting in their Cochrane database review of use of piracetam for aphasia, found a trend toward increased mortality in the treatment group of Kessler’s Study (49). Gualtieri and others questioned study design as the reason for some studies failing to demonstrate effectiveness of piracetam (50). Piracetam is available through foreign pharmacies and/or state side compounding pharmacies.

*Acetyl-L-Carnitine and Vinpocetine* Some nutrients with intriguing findings in human studies and possible value in humans, (44) but which need further study include vinpocetine (51, 52, 53, 54) and acetyl-L-carnitine.

**Vinpocetine, Cavinton, vinpocetine-ethyl-apovincaminat, 14-ethoxycarbonyl-(3alpha,16alpha-ethyl)-14, 15-eburnamine, Apovincaminic acid**

Another biological product with a variety of reputed CNS effects is vinpocetine. Originally synthesized in the late 1960s from an extract of the leaf of the lesser periwinkle plant (*Vinca minor*), vinpocetine was first commercially available in 1978. Marketed as Cavinton by the company Gedeon Richter Ltd in Budapest, the drug has been used widely in Eastern Europe. In fact, most of the literature is in Russian and other Slavic languages.

Vinpocetine is reported to have diverse effects. A Hungarian study noted:

Early experiments with vinpocetine indicated five main pharmacological and biochemical actions: (1) selective enhancement of the brain circulation and oxygen utilization without significant alteration in parameters of systemic circulation, (2) increased tolerance of the brain toward hypoxia and ischemia, (3) anticonvulsant activity, (4) inhibitory effect on phosphodiesterase (PDE) enzyme and (5) improvement of rheological properties of the blood and inhibition of aggregation of thrombocytes. Later studies in various laboratories confirmed the above effects and clearly demonstrated that vinpocetine offers significant and direct neuroprotection both under *in vitro* and *in vivo* conditions (55).

Regarding mechanism, Nicholson summarizes a review of the literature with reference to vinpocetine that

“This compound attenuates cognitive deficits, reduces ischaemia-induced hippocampal cell loss and increases cerebral blood flow and glucose utilisation. These effects may be induced by modulation of cyclic nucleotide levels and adenosine re-uptake inhibition” (Nicholson, CD)(56).

Research published by the manufacturer reported that “vinpocetine is a potent inhibitor of the voltage-dependent Na(+) channels and a selective inhibitor of the Ca(2+)/calmoduline-dependent phosphodiesterase 1.” Their positron emission tomography (PET) scan studies in monkeys and healthy humans using intravenously administered [11C]-labeled vinpocetine showed “the distribution pattern of vinpocetine in the brain was heterogeneous, with the highest uptake in the thalamus, basal ganglia and visual cortex.”(57)

Is there a neuroprotective effect? A British study in normal subjects demonstrated a protective effect against memory impairments caused by exposure to benzodiazepines (58). A study of brain preservation in a rat model of ischemia showing a 42% reduction of infarct volume (59). The drug was even used in 162 victims of the accident at the Chernobyl Atomic Electric Power Station diagnosed with “dyscirculatory encephalopathy” (60). Hadjiev argues it is protective against cerebrovascular insufficiency in humans (61).

Does the drug really work in demented humans? A 2003 review article in Nutrition concluded that it is effective (62). A review of nontraditional medicines by Kidd observed that vinpocetine “is an excellent vasodilator and cerebral metabolic enhancer with proven benefits for vascular-based cognitive dysfunction.”(63) One double-blind placebo controlled trial of the drug over nine months in 84 patients diagnosed with vascular dementia demonstrated the treatment group performed consistently “better in all evaluations of the effectiveness of treatment including measurements on the Clinical Global Impression (CGI) scale, the Sandoz Clinical Assessment-Geriatric (SCAG) scale, and the Mini-Mental Status Questionnaire (MMSQ)”(64). Yet, a yearlong Veterans Administration (VA) study of Alzheimer’s patients found no benefit of vinpocetine at a variety of dosages (65).

A Cochrane database review in 2003 found three trials with a total of 583 people with degenerative or vascular dementia treated with vinpocetine (30–60 mg/day) or placebo (66). The number of patients treated for 6 months or more was small and only one study extended treatment to one year. They noted, “the evidence for beneficial effect of vinpocetine on patients with dementia is inconclusive and does not support clinical use.” The conclusion was the same in a 2000 Cochrane review of its use in acute stroke (65).

The literature supporting the use of vinpocetine in traumatic brain injury (TBI) is even more sparse. One Russian study primarily reporting that diabetics do worse

than others following TBI observed “inclusion of vasoactive agents Cavinton and Complamin into the scheme of complex therapy accelerates regression of the neurological symptomatology” (68). In an experimental study involving animals, Romodanov found that these vasoactive agents “promote regression of the changed cerebral blood flow” following TBI.

In summary, vinpocetine is of equivocal benefit, but there is little evidence of toxicity. Due to research suggesting effectiveness in some groups, further double-blind placebo-controlled studies of its use in specific patient populations is warranted.

#### **DMAE (dimethylamino ethanol), Pantothenic acid, Lucidril, and Citicoline**

Other nutrients are recommended on web sites with little evidence on effectiveness in humans. Based on animal studies (mostly Russian and Japanese from over twenty years ago), these include DMAE (dimethylamino ethanol), pantothenic acid, lucidril, and citicoline.

#### **FOR BEHAVIORAL DISTURBANCES**

*Kava (Piper methysticum)* Kava is widely used in Polynesia and Micronesia as a tranquilizing ceremonial beverage. Kava is one of the few herbs for which active constituents are well delineated. Some are centrally acting skeletal muscle relaxants and anticonvulsants. Their effects seem to be due to inhibition of sodium and calcium channels as well as effects on glutamate systems. Some are potent inhibitors of norepinephrine uptake (4).

A psychoactive member of the pepper family, kava is used to relieve anxiety and insomnia in Europe and the United States. It is formally approved in Germany for anxiety, tension, and agitation. In a randomized, double-blind, placebo-controlled trial, 58 patients with “anxiety and neurotic disorders” were randomly assigned to receive 70 mg of kava lactones or placebo three times daily for 4 weeks. Compared with the placebo group, the kava group demonstrated a significant reduction in anxiety (assessed by HAM-A) by the end of the first week; differences between the two groups increased during the course of the study. Side effects were minimal (69).

In a randomized, double-blind, placebo-controlled multicenter study, 101 outpatients with anxiety disorders (agoraphobia, specific phobia, generalized anxiety disorder, or adjustment disorder with anxiety) were treated with a kava extract for 24 weeks. Results showed significant reductions in HAM-A scores in the kava group beginning in the eighth week and increasing throughout the trial. Improvements were also seen in secondary outcome variables, which included Hamilton subscale scores for somatic and psychic anxiety, the Clinical Global Impression scale,

Self-Report Symptom Inventory, and the Adjective Mood scale (70). Side effects were greater in the placebo group than the kava group. Treatment with kava did not lead to tolerance. Several other controlled double-blind trials on kava extracts or the isolated compound DL-kawain have been published in the German literature (4).

Kava is reported to have potential adverse effects and interactions. Therapeutic doses may result in mild gastrointestinal complaints or allergic skin reactions (incidence, 1.5%) (4). Chronic use of kava up to 100 times the therapeutic dose results in an ichthyosiform eruption known as kava dermatopathy, which is often accompanied by eye irritation. Abstaining from kava results in complete resolution of symptoms. Kava may potentiate the sedative affect of anesthetics (72).

*Picamilon* Picamilon is a vitamin-like compound consisting of a niacin analogue (n-nicotinyl) uniquely bonded to GABA (gamma aminobutyric acid). When niacin is bound to GABA, it readily penetrates the blood-brain barrier and enhances cerebral and peripheral circulation. Picamilon has reportedly been studied and used in Russia or its “tranquilizing influence on negative emotions”. The effects of picamilon have been characterized as “a tranquilizing effect, without a sedative component but with elements of stimulant action.” Doses are reported as 20–50 mg bid or tid. Picamilon has been reported to decrease cerebral blood-vessel tone and “increases intracranial circulation rate”. Picamilon reportedly reduces anxiety and hyperesthesia (whereby normal touch creates pain) without sedative effects, and yet improved sleep. Studies in English are few.

*Ginseng (Panax ginseng and others)* Ginseng is a popular “tonic” herb that some take regularly for a “cumulative strengthening effect”. There are several varieties of ginseng commonly used in herbal medicine: *P. ginseng*, grown in northeastern China and Korea; *P. quinquefolius*, grown in the United States and Canada; and *P. notoginseng*, grown in southwest China. Ginseng reportedly has many interesting effects, but its place in the treatment of psychiatric conditions or improving quality of life has not been demonstrated in clinical trials.

An 8-week, placebo-controlled study of a commercial ginseng among 60 patients admitted to the geriatric unit of a hospital found no differences between the treatment and control groups in length of stay, activities of daily living, cognitive function, or somatic symptoms (73, 80). Yet, a double-blind study of a multivitamin complex supplemented with ginseng vs. a multivitamin complex without ginseng in 625 patients complaining of stress or fatigue found significant improvement in the quality of life index at 4 months in those receiving ginseng (74). Hypoglycemia as well as bleeding complications have been reported with ginseng (72, 75).

*Passionflower (Passiflora incarnata)* Passionflower is used as a mild sedative. No clinical trials of its use as a single agent have been conducted. The German Commission E recommends 4 to 8 g of dried herb per day for “nervous unrest.”

Passionflower contains flavonoids: a flavonoid derived from *Passiflora coerulea*, is a partial agonist of benzodiazepine receptors and has anxiolytic activity in mice without inducing sedation or muscle relaxation and could account for the activity of the plant (4).

In a double-blind trial in 182 patients with adjustment disorder with anxious mood, patients received a preparation containing six extracts (*Passiflora*, *Crataegus*, *Ballota*, *Valeriana*, *Cola*, and *Paullinia*) or placebo. HAM-A scores were improved in patients who took the herbal mixture compared with those who received a placebo (76).

*Valerian (Valeriana officinalis)* Valerian is a botanical medicine used for its mild sedative and tranquilizing properties. Valerian is an odoriferous plant that is a popular sleep remedy. In one study enrolling 166 subjects with various sleep difficulties, two different formulations of valerian were compared to placebo. Each person received three of each capsule, which were taken in random order on non-consecutive nights. Only 128 patients completed the study, but only one patient withdrew because of side effects. Both valerian preparations improved sleep quality and reduced sleep latency scores. Night awakenings and dream recall were not affected by valerian, nor did valerian cause any somnolence the next morning (77). Beaubrun, in a review of the herbal medication literature, noted that: “Valerian has been shown to decrease sleep latency and nocturnal awakenings and improve subjective sleep quality, but placebo effects were marked in some studies, and in some cases the beneficial effects were not seen until two to four weeks of therapy” (Beaubrun G)(78).

Another study found efficacy of both valerian and melatonin (79). Dosing recommendations vary, but the German Commission E recommends 2 to 3 g of the dried root one or more times a day for “restlessness and nervous disturbance of sleep” (80).

A valerian withdrawal syndrome has been described. Garges reported a withdrawal reaction of delirium, and high output cardiac failure in a 58-year-old man hospitalized for congestive heart failure who received general anesthesia. After extubation, the patient developed sinus tachycardia, high output cardiac failure, oliguria, tremor, and signs of delirium. It was later discovered the patient had been taking valerian up to 2 g five times per day for years. A benzodiazepine was helpful in resolving many of his symptoms (81). Also, Valerian may potentiate the sedative effects of anesthetics (72).

Another problem with valerian is its unpleasant odor—one foul enough to be used as the aversive stimulus

in a study of brain activation (71). This interferes with patient tolerance as well as the ability to do double-blinded trials.

*Folic Acid, Vitamin B<sub>12</sub>, S-adenosylmethionine (SAM or SAME) and Mood* Folic acid deficiency is one of the most common nutritional deficiencies in the world and has often been associated with neuropsychiatric disorders (82). Deficiencies of vitamin B<sub>12</sub> and folate both cause similar neurological and psychiatric disturbances, including depression, dementia, and psychosis. Folate deficiency appears most tightly connected with depressive disorders, and cobalamin deficiency with psychosis (83). Contrary to intuition, vitamin deficiencies appear to occur infrequently with eating disorders. Hutto notes: “Clinicians should remain vigilant to the possibility of deficiencies of folate and cobalamin in diverse psychiatric populations” (Hutto)(83).

Normal hematological indices do not rule out B<sub>12</sub> and folate deficiencies. This deficiency may be an overlooked and understudied risk factor for depression. Godfrey in London found that 41 (33%) of 123 patients with acute psychiatric disorders (DSM III diagnosis of major depression or schizophrenia) had borderline or definite folate deficiency (red-cell folate below 200 micrograms/l). These patients took part in a double-blind, placebo-controlled trial of methyl folate, 15 mg daily, for 6 months in addition to standard psychotropic treatment. Among both depressed and schizophrenic patients methyl folate significantly improved clinical and social recovery. The differences in outcome scores between methyl folate and placebo groups became greater with time. The authors wrote: “these findings add to the evidence implicating disturbances of methylation in the nervous system in the biology of some forms of mental illness” (Godfrey)(84).

Several studies have found that up to 35% of depressed patients are folate deficient (84). In elderly patients, the incidence of deficiency may even be higher.

Fava and others examined the relationships between levels of folate, vitamin B<sub>12</sub>, and homocysteine and response to fluoxetine (20 mg/d for 8 weeks) treatment as measured by the 17-item HAM-D in 213 outpatients with major depressive disorder. Subjects with low folate levels were more likely to have melancholic depression and were significantly less likely to respond to fluoxetine (85).

Folate and vitamin B<sub>12</sub> are required for the methylation of homocysteine to methionine and for the synthesis of S-adenosylmethionine. S-adenosylmethionine is involved in numerous methylation reactions involving proteins, phospholipids, DNA, and neurotransmitter metabolism. S-adenosylmethionine (SAM) has antidepressant properties. The commonest neuropsychiatric complication of severe folate deficiency is depression (86). Methylation in the nervous system may underlie the expression of mood and related processes and may be

implicated in some affective disorders. Folate deficiency may specifically affect central monoamine metabolism and aggravate depressive disorders. The folate derivative necessary for the synthesis of serotonin and dopamine, tetrahydrobiopterin, has also been reported to have antidepressant activity (87). Folic acid may be helpful in bipolar disorders.

In a double-blind comparing a daily supplement of 200 mcg folic acid placebo in a group of 75 patients on lithium therapy, folate was shown to enhance the efficacy of lithium. During the trial the patients with the highest plasma folate concentrations showed a significant reduction in their affective morbidity. Patients who had their plasma folate increased to 13 µg/ml or above had a 40% reduction in their affective morbidity. The authors suggested that a daily supplement of 300–400 micrograms folic acid would be useful in long-term lithium prophylaxis (88).

Also called SAME, S-adenosylmethionine is a methyl donor closely linked with folate and vitamin B<sub>12</sub> (cyanocobalamin) metabolism. SAME is required in numerous transmethylation reactions involving nucleic acids, proteins, phospholipids, monoamines, and other neurotransmitters. Bottiglieri at Baylor in Dallas wrote that deficiencies of either folate or B<sub>12</sub> have been found to reduce the synthesis of SAME (and thus its levels) in the central nervous system. They noted: "SAME has antidepressant properties, and preliminary studies indicate that it may improve cognitive function in patients with dementia. Treatment with methyl donors (betaine, methionine and SAME) is associated with remyelination in patients with inborn errors of folate and C-1 (one-carbon) metabolism" (Bottiglieri)(89).

Some feel this is relevant to brain injury rehabilitation. The administration of SAME has antidepressant properties (91, 92). However, there are potential side effects of folic acid and same supplementation. In a randomized, double-blind, placebo-controlled trial of 15 inpatients with major depression, oral SAME induced mania in one patient with no prior history of mania (90). In another study of SAM-treated patients with depression, 89% of bipolar patients switched from depression into an elevated mood state (hypomania, mania and euphoria) and the rest did not respond. Just over half of the endogenous unipolar patients improved and five did not (92). Anecdotally, methionine supplementation has been reported to aggravate schizophrenia. SAME has been reported to cause mild and transient insomnia, nervousness, and lack of appetite, constipation, headaches, heart palpitations, nausea, dry mouth, sweating, and dizziness (93).

Folate has been reported to reduce the effectiveness of several anticonvulsants, potentially leading to seizures (94).

**Tryptophan and 5-HTP** The amino acid, tryptophan, is a precursor of serotonin and has been used increase

brain levels of serotonin. Tryptophan depletion can increase depressive symptoms in patients with major depression and seasonal affective disorder. Studies have shown tryptophan supplementation has positive effects in some depressed patients—particularly those with a relative tryptophan depletion (95). In most cases, tryptophan by itself may be insufficient to boost serotonin levels (96). Thus, SSRI antidepressants are much more efficacious overall. On the other hand, using tryptophan to supplement standard antidepressants has been more successful. Walinder found that 24 depressed patients started on clomipramine improved more rapidly in the symptoms of depressed mood, suicidal intent, depressive thought content, and anxiety with tryptophan supplementation (97). 5-HTP is an intermediate metabolite of the amino acid L-tryptophan in the serotonin pathway. Like tryptophan, 5-HTP is used for depression—in efforts to achieve a higher level in the CNS (98). Tryptophan is converted into 5-HTP by the enzyme tryptophan hydroxylase. This is the rate-limiting step in serotonin synthesis. 5-HTP is commercially produced by extraction from the seeds of an African plant, *Griffonia simplicifolia*—an extract available in the United States. However, there are significant concerns with tryptophan and 5-HTP supplementation. The severe complication of eosinophilic myositis (EMS) has occurred with contaminated tryptophan. It causes muscle pain and weakness (99). While contaminated L-tryptophan has been definitively associated with EMS, 5-HTP has been linked with several unusual cases of EMS-like symptoms. One study suggested that contamination may be difficult to avoid with L-tryptophan and 5-HTP preparations.

## AGGRESSION AND DEPRESSION

**Omega-3 Fatty Acids** Neuronal membranes contain high concentrations of the essential fatty acids arachidonic acid and DHA, which are crucial components of the phospholipid bilayer (each comprises approximately 25% of the phospholipid content).

It has been suggested that depletion of omega-3 polyunsaturated fatty acids, particularly DHA, impairs membrane function and may be of etiological importance in depression, aggression, schizophrenia, and other mental and neurological disorders. Hibbeln writes: "we propose that excessive phospholipase-A2 (PLA2) activity disrupts membrane fluidity, composition, and therefore, the activity, of membrane-dependent proteins. Similar disruptions in these proteins are documented in depressed patients and can be accounted for by excessive PLA2 activity" (Hibbeln)(100, 101).

The number of authors supporting this premise is limited. Yet, lipids and the membranes they inhabit may be very important. There are reports that rapid lowering

of blood lipids by hydroxymethylglutaryl coenzyme A reductase inhibitors is associated with a large number of psychiatric disorders. In a national Norwegian database, 15% of psychiatric drug reactions were attributed to statins (102). Reactions included aggression, nervousness, depression, anxiety, and sleeping disorders. Cholesterol-lowering therapies and low cholesterol levels have been thought to increase the risk of suicide—possibly by lowering serotonin turnover. Therefore, some recommend omega-3 fatty acid supplementation as possibly helpful in brain disorders.

*St John's Wort (Hypericum)* St John's Wort (SJW), also called Hypericum, is one of the most widely-used supplements. In 1998, Wong reported that there was good evidence for the efficacy of St John's wort for the treatment of depression(33) There is data to suggest that St John's wort is more effective than placebo in the treatment of mild to moderate depression. The absolute increased response rate with the use of St John's wort ranged from 23% to 55% higher than with placebo, but ranged from 6% to 18% lower compared with tricyclic antidepressants (103). In 2000, Beaubrun and Gray reported on their review of herbal medicines for psychiatric disorders. They found nine controlled and standardized trials of St. John's wort. Of these, five showed the herb's superiority to placebo, and four found no differences in effectiveness when compared with antidepressant drugs (78). One author reported extensively on its neuropharmacology (3, 104).

Combination therapy may be helpful in combined anxiety and depression. Muller's open labeled study with SJW and valerian concluded that symptoms associated with anxiety that severely afflict patients can be clearly improved more quickly with a combination therapy of St John's wort extract and valerian extract than with St John's wort monotherapy (105). The combination therapy was well tolerated, no significant side-effects occurred. St. John's Wort is metabolized by the P450 system and thus has been reported to interact with several medications.

### NUTRITIONAL SUPPLEMENTS FOR THE TREATMENT OF HEADACHE

Melatonin has been recommended for cluster headaches. In a double-blind, placebo-controlled clinical study of 20 patients, melatonin was reported to effectively reduce cluster headache in 50% of treated patients. In the paper's discussion, melatonin's biological functions are reviewed in relation to the putative mechanisms that cause cluster headache (106). In a more recent review of cluster headaches, Dodrick reported that melatonin may be a useful adjunctive therapy (112).

### Petadolex, *Petasites hybridus*, Butterbur root (a naturopathic agent)

Another agent used for headache is Petadolex (*Petasites hybridus*, an extract of Butterbur root). *Petasites hybridus* (PH) is much more commonly referenced for respiratory problems such as asthma than for headache (107). It is also used to reduce gastrointestinal and urogenital tract spasms. Reportedly, its active components are the petasines which inhibit the synthesis of leukotrienes (anti-inflammatory) and decrease the intracellular concentration of calcium (spasmolytic).

Still controversial, it has been recommended for migraine prophylaxis, but only one blinded study could be identified. A German group reported twice on the same randomized, group-parallel, placebo-controlled, double-blind clinical study of 60 patients. A "special CO<sub>2</sub> extract from the rhizome of *Petasites hybridus*" was administered at a dose of 50 mg b.i.d. for 12 weeks. Although no significant decrement in intensity and duration was observed, a significant 60% reduction in the frequency of migraine attacks was seen. No adverse events were reported (108, 109). Another unaffiliated group reanalyzed the data from that study (110). They looked at the data differently, but still noted a significant reduction in attack frequency—from 3.4 at baseline to 1.8 after three months. They concluded, "This small trial indicates that butterbur may be effective in the prophylaxis of migraine."

A German-language review article observed that toxicity is reportedly infrequent since the development of "extraction with supercritical CO<sub>2</sub> . . . (which reduced) the concentrations of the potentially hepatotoxic and carcinogenic pyrrolizidine alkaloids (to) below the detection limits"(111). Four cases of reversible cholestatic hepatitis have been associated with long-term administration of butterbur. Further side effects involve the gastrointestinal tract and are usually mild.

Other relatively unsupported recommendations for headache include green tea (which contains caffeine)(113) megadose vitamins C, (114, 115) and vitamin E, (116) lipoic acid, and Coenzyme Q at 150 mg/day (117). Gingko biloba has been anecdotally reported to be helpful for those patients suffering from migraine headaches. Another study found it helpful in preventing headache symptoms of acute mountain sickness (118). Oral magnesium is a complementary therapy for headache (119) that has documented efficacy in migraine prophylaxis for children (9mg/kg/day) (120). Recent studies using functional MRI suggest a drop in magnesium concentration may play a role in severe types of headaches (121, 122). In a Brooklyn, NY study, six of nine children with non-traumatic headaches had a deficiency in serum ionized magnesium, (123) but total magnesium levels were normal. The National Institute of Neurological Disorders and Stroke (NINDS) is sponsoring a phase III study of magnesium sulfate given within

eight hours of a moderate or severe traumatic brain injury to look at the effect on survival, seizures, and outcome. <http://www.edc.gsph.pitt.edu/neurotrauma/> .

### NUTRITIONAL SUPPLEMENTS FOR VESTIBULAR DYSFUNCTION

*Gingko biloba* In an open label study of vertigo, ginkgo biloba given over three months improved symptoms of dizziness and also, on neuro-otologic testing, improved several parameter. Improvements were noted in saccadic velocities and smooth pursuit gain, nystagmus, vestibulo-ocular reflex and the visuovestibular-ocular reflex (124).

*Pyritinol* A reference in the French journal *Ouest Med* (29/1 1976), reports that pyritinol was tested on sixty patients who suffered from vertigo. They report “a cure rate of 83%, accompanied by an improvement in the patients’ mental and social state. The drug was tolerated well by patients of all ages.” The dose was 200 mg three times a day (125).

*Piracetam* A 1999 literature review of piracetam recommended doses of 2.4–4.8 gm daily for vertigo of central origin such as after brain injury (47).

*Coenzyme Q10 (ubiquinone)* Much of the extent of neurological impairment following brain injury depends upon secondary brain damage, with delayed neuronal death. Some stroke research suggests that secondary brain damage follows from secondary mitochondrial (and bioenergetic) failure after blood flow resumes.

Recent evidence points to programmed cell death as a major factor in delayed neuronal death. While this programmed cellular suicide normally disposes of aged cells, stroke may trigger it prematurely. Mitochondrial injury following ischemia leads to calcium overload, excitotoxicity, oxidative stress, and opening of the mitochondrial mega channels.

Medications that support normal cellular energy production and antioxidant defense could protect against this excitotoxic damage and subsequent programmed cell death. Some studies suggest CoQ10 may provide this protective effect (126–129).

*Creatine* Of all the nutritional supplements currently available, creatine appears to be the most effective for maintaining the ability of mitochondria to produce high-energy compounds such as adenosine triphosphate (ATP) and thus reduce “oxidative stress.”

When ATP loses a phosphate molecule and becomes ADP, it must be converted back to ATP to once again be able to release energy. Creatine is stored in the human body as creatine phosphate (CP). Then ATP is depleted,

it can be “recharged” by CP. CP donates a phosphate molecule to ADP allowing it to form a high-energy bond and reform ATP. An increased pool of CP means faster recharging of ATP, which means more work can be performed.

Creatine may protect the brain from neurotoxic agents, certain forms of injury and other insults. Neurons exposed to either glutamate, beta-amyloid (both highly toxic to neurons) are involved, (130) N-methyl-D-aspartate (NMDA) and malonate(131) (Another study found that feeding rats creatine helped protect them against tetrahydropyridine (MPTP), which produces parkinsonism in animals through impaired energy production (132). Another study found creatine protected neurons from ischemic damage (133).

### NEUROPROTECTIVE ROLE OF CURCUMIN FROM CURCUMA LONGA ON ETHANOL-INDUCED BRAIN DAMAGE

*Curcumin* A widely used spice and coloring agent in food, curcumin has been shown to possess potent antioxidant, antitumor promoting and anti-inflammatory properties in vitro and in vivo. Curcumin is a small-molecular-weight compound that is isolated from the commonly used spice turmeric. In an animal study, curcumin was screened for neuroprotective activity using ethanol as a model of brain injury. Oral administration of curcumin to rats caused a significant reversal in lipid peroxidation of brain lipids and produced enhancement of glutathione, an antioxidant (134).

### VITAMIN SUPPLEMENTATION TO FACILITATE NEUROLOGICAL RECOVERY

Vitamin (MVI) supplementation is controversial. Certainly the minimum daily requirement of MVI is needed for normal enzyme function. Earlier in this paper, effects of folic acid and vitamin B<sub>12</sub> deficiencies and supplementation were discussed. However, some physicians feel that megavitamin supplementation of water-soluble vitamins is a waste – producing “only an expensive urine”. Yet, the true need may vary between individuals and in disease states. High doses of Vitamin B<sub>6</sub> (50–200 mg) are commonly used in carpal tunnel syndrome. By analogy, some physicians feel it is helpful in other types of nerve injury. Yet, in the example of Vitamin B<sub>6</sub>, megadose (2000 mg<sup>+</sup>) can itself be neurotoxic (135).

Suggested supplements from physicians who prescribe for neural recovery following brain injury include vitamin B<sub>1</sub> (100 mg), vitamin B<sub>6</sub> (100 mg), vitamin B<sub>12</sub> (1 mg), folic acid (1 mg) and vitamin C (500 mg). Also recommendations for myelin repair are octacosanol (2000–400 mg/day) with zinc, vitamin C and B<sub>6</sub>. (Internet communication from

William Walsh, PhD re: study at Schwab Rehab Hospital—reportedly facilitating recovery after plateau in severe brain injury).

### NUTRITIONAL SUPPLEMENT TO RETARD MUSCLE ATROPHY

In the setting of hypoglycemia, glutamine is the primary gluconeogenic amino acid. Aggressive glutamine supplementation is recommended to help maintain muscle mass for those critically ill or immobilized with severe brain injury.

However, extra caution is recommended in diabetics due to abnormal glutamine metabolism. Adding taurine may be beneficial.

### WEB SITES OF INTEREST

Several studies looking at internet web sites for information about a variety of topics have determined that most offer limited and biased information of poor quality with most claiming to prevent, diagnose, treat, or cure specific diseases despite federal regulations prohibiting statements of this type (136, 137). Nevertheless, some sites have been determined to be particularly helpful in the investigation of dietary supplements. In a study conducted by the College of Pharmacy at the University of Michigan, the best electronic databases for providing information on herbal and dietary supplements were felt to be “Micro Medex” and the “Natural Medicine Comprehensive Database” (138). The best internet site was determined to be “The Natural Pharmacist”. Another fine site is a review article on natural medications in *Psychosomatic Medicine*: <http://www.psychosomaticmedicine.org/cgi/content/full/61/5/712>

The interest in and use of nutritional supplements by the public has grown faster than the definitive medical knowledge of these drugs. Yet there is fairly extensive bench and some clinical research for many of them. Few studies have been done using these medications in patients with traumatic or anoxic brain injury. Yet much of what is known may be relevant to these populations. Desperate patients and families will look to their physicians for direction on optimal treatment. Greater physician knowledge of the benefits and results of the nutritional supplements will lead to better care.

## Traditional Chinese Medicine Theory in the Mechanism and Treatment of TBI

Gary G. Wang

### INTRODUCTION

The theory of traditional Chinese medicine (TCM) is completely different from that of western medicine. The formation and development of TCM theory was greatly influenced by ancient Chinese philosophy. It is necessary to explain some basic TCM theories that developed over the past 3000 years before going into its specific applications in traumatic brain injury (TBI) management.

The theories of “*Yin-Yang*” and “The Five Elements” were two approaches to the study of nature in ancient China. Every object or phenomenon in the universe was thought to consist of two opposite yet interdependent parts known as *yin* and *yang*. The theory of the five elements on the other hand, held that wood, fire, earth, metal, and water constituted the physical world. Like *yin-yang*, the five elements were interdependent and inter-resistant. Both theories described the world in a state of constant change between balance and imbalance. Ancient Chinese physicians believed in the integration of the natural world with the bodies of human beings. Diseases were believed to be caused by imbalance among *yin-yang* and the five elements.

As with natural phenomena, ancient Chinese physicians classified human organs and emotions as belonging to one of the five elements. The laws pertaining to

the inter-promoting, interacting, over-acting and counter-acting of the five elements were used to interpret the relationship between the physiology and pathology of the human body. “*Zang-fu*” refers to the gross anatomical entities of the internal organs. However, its meaning is different from that of modern anatomy. The term *zang-fu* is a generalization of the physiological functions of the human body. The heart, liver, spleen, lung, kidney and pericardium are known as the six *zang* organs. They are related to *yin*. Their main physiological functions are to manufacture and store essential substances including vital essence, *qi* (vital energy, pronounced “Chee”), blood, and body fluid. The small intestine, gall bladder, stomach, large intestine, urinary bladder, and *Sanjiao* are known collectively as the six *fu* organs. They are related to *yang*. *Sanjiao* is the name of a function without body shape structure. The main functions of *fu* organs are to receive and digest food, absorb nutrients, and transmit and excrete wastes.

The brain and uterus are two extraordinary *fu* organs. They are closely related to the other regular organs. According to TCM theory, the essence of the kidney produces the marrow that forms the brain as “a sea of marrow.” The brain performs thinking and memorization functions. The heart is the main organ that dominates the mental activity of the brain. The heart, protected by pericardium, governs mental activities and

generally handles the physiological function of the brain as it “houses the mind.” Meanwhile the liver is also related to mental activities by regulating the unrestraint and patency of vital functions. The lung and spleen interfere with mental activity indirectly. The lung promotes the diffusion of *qi*, blood and body fluid into every portion of the body. The spleen supplies nourishment essential to heart and lung, keeps the blood circulating inside the vessels. Dysfunction of *zang* and *fu* will prevent the proper functioning of the brain. Conversely, disorders of the brain will also interfere with the function of *zang* and *fu*.

The channel doctrine is also essential for TCM theory. Meridian channels and the collaterals (Jing and Luo) are the pathways of *qi*, blood and fluid circulation. Meridian channels are the main routes while collaterals are the branches of the channels that connect internal organs as well as limbs to make the whole body into an entity. Each meridian channel comes from different *zang* or *fu* organs and distributes in the trunk and limbs. Channels and *zang fu* viscera are shown on the superficial human body at specific acupuncture points. Through these points, *qi* may be infused into the channels to promote balance in the body. The points are also the places where disease evils can easily pass through. This explains why acupuncture points are always selected as therapeutic locations. Acupuncture is a TCM therapy method to remove obstructions in the meridian channels and to regulate blood and *qi* by stimulating the points with needles. According to the philosophy of TCM, medications and treatment procedures facilitate the rebalance of the human body by altering its constituents.

Ancient Chinese physicians recognized and classified medications (most of these herbs) mainly by observing the effects of their clinical application. By performing numerous experiments, each medical herb was classified to either *yin* or *yang* and was characterized as belonging to one of the five elements with the ability to target different organs. The characteristics and functions of Chinese herbs were described in the book *Compendium of Materia Medica*, which was written by Li Shi-Zhen (1518–1593 A.D.). The process of prescribing the appropriate herbal prescription is a systematic technique developed over thousands of years starting with the analysis of clinical information collected from the patient by observation, auscultation, interrogation, and palpation of the pulse. A TCM physician will diagnose the location and nature of the major unbalanced elements and then prescribe an appropriate formula (combination) of herbs. There are several medical herbs in each formula and each of them may have a different function. Certain combinations of herbs work efficiently to target certain disease conditions and fulfill pharmacology functions. The effect of each formula has been documented through clinical verification and may be adjusted accordingly. A special name is given to each established formula. Thousands of

years of successful clinical treatment applications have produced many herb formulas that are still in use today.

Following, is an introduction to the classification of brain injury and TCM disease elements by organ system which includes prescription formulas available in China as pills widely used in the management of disorders related to TBI. The precise makeup of these prescriptions is too vast to include here, but can be researched using the name. Acupuncture management for traumatic brain injury will also be briefly discussed.

### Acute Severe TBI: Consciousness and Qi Disturbance

TCM physicians differentiate and classify TBI patients into different syndromes according to their clinical symptoms. TCM physicians believe that traumatic injury will rupture the integrity of the natural protection system, permitting the invasion of evil factors, leaking essential *qi*, blood and fluids and inducing blood extravasation. All of these will directly disturb normal *qi* and blood circulation and induce pain. The brain is considered the cleanest organ. It is polluted by trauma, which facilitates the invasion of external pathogenic factors. After severe head trauma, evil factors will attack *zang-fu* organs, blocking the *qi* aperture of the heart and hurting the *qi* that acts as the primary motive force for life activities. TCM physicians usually differentiate and classify acute severe TBI patients into two syndrome-specific groups according to the patient's clinical symptoms, named *qibi* (blockage of *qi*) and *qituo* (exhaustion of *qi*). Because such cases are critical, the modern TCM physicians will usually suggest combined management with modern western medical methods.

*Blockage of Qi* *Qibi* symptoms include unresponsiveness, severe confusion, agitation, delirium, restlessness, flushed face, twitching, and tachypnea. A yellowish sticky film coats the tongue. The pulse is rapid and deep. The focus of treatment of *qibi* is to remove the pathogenic factors blocking the aperture of the heart. Some patients may have fever, flushed faces and be agitated. TCM believes that fever is caused by hot evil *qi* that blocks the function of the brain. An-Gong-Niu-Huang-Wan (安宫牛黄丸), Zi-Xiu-Dan (紫雪丹), and Zi-Bao-Dan (至宝丹) are the medications usually applied. These medications are also used for coma or severe agitation due to other etiologies such as stroke, high fever, meningitis, or encephalitis. An-Gong-Niu-Huang-Wan, is the pill most commonly prescribed. Its extracts for intravenous injection, named Xing-Nao-Jing (醒脑静), are available in China. Several preliminary controlled studies have shown the effectiveness of the intravenous application of Xing-Nao-Jing to treat the comatose state (1–3). As like other TCM medications, the chemical contents of An-Gong-Niu-Huang-Wan are

**TABLE 56-1**  
**TMC Diagnosis and Treatment of Acute Severe TBI**

DIAGNOSIS	MANIFESTATION	TMC TREATMENT
Blockage of Qi	unresponsiveness, severe confusion, agitation, delirium, restlessness, flushed face, fever, yellowish tongue with sticky coat, rapid and deep pulse	<i>Decoction</i> An-Gong-Niu-Huang-Wan Zi-Xiu-Dan Zi-Bao-Dan <i>Acupuncture methods</i> Stimulating the points of the GV Channel on head combined with points on limbs, slightly bleeding the points on terminal digits.
Exhaustion of Qi	deep coma, loss of jaw control, lost bladder control, heavy perspiration, cooling distal limbs, whitish coat of tongue, weak pulse	<i>Decoction</i> Shen-Fu-Tang adding San-Qi  <i>Acupuncture methods</i> Applying moxibustion and/or retaining needles to points of the Ren Channel adding stimulating at CV4, CV6, CV8.

complicated. The exact mechanisms of their effects on acute brain injury are not clear from Western biomedical views. However, recent scientific studies have provided some clues. For example, Niu-Huang (Bos Calculus), one of the major contents of An-Gong-Niu-Huang-Wan is bovine gallstone, a mixture of bilirubin metabolites and endogenous bile acids. After traumatic brain injury and stroke, massive bleeding could produce significant iron-mediated oxidative stress, programmed cell death (apoptosis), and neurodegeneration. Bilirubin metabolites were found to be potent endogenous antioxidants with neuroprotective effects (4–6). One of the major endogenous bile acids, tauroursodeoxycholic acid, was found to have the ability to modulate cell death by interrupting classic pathways of apoptosis and has wide-ranging neuroprotective effects after brain injury (7). However, because the formulation contains small amounts of arsine and mercury, the authors do not recommend the prolonged use of An-Gong-Niu-Huang-Wan.

The acupuncture methods for treating the syndrome of *qi* blockage promote resuscitation by stimulating the points of the Governor Vessel Meridian (GV Channel). Renzhong (GV 26) and Baihui (GV 20) are the two points most often selected. Usually, Yongquan (KI 1) is the point added to “conduct the evil factors down.” The points at the distal fingers including Shaoshang (LU 11), Shaochong (HT 9), Shaoze (SI 1), Zhongchong (PC 9), Shangyang (LI 1), Guanchong (TE 1) are often selected for slight bleeding. In addition, Taichong (LR 3), Fenglong (ST 40), Laogong (PC 8) are sometimes stimulated.

*Exhaustion of Qi Qituo* by severe traumatic brain injury is a very serious and critical condition. The major

symptoms include deep coma with unresponsiveness, loss of jaw control with spontaneous mouth opening, heavy perspiration, lost of bladder control, and distal limb cooling. The tongue coat becomes whitish. The pulse is weak. Management of *qituo* is aimed at consolidating vital energy. TMC physicians prepare a formula by combining Shen-Fu-Tang (参附汤, a decoction of Ginseng and prepared Aconite) with powder of San-Qi (Radix Notoginseng). Acupuncture is also applied frequently for exhaustion of *Qi* to recapture *yang* and avert the collapsing status. Applying moxibustion to points of the Ren Channel is the traditional way. Guanyuan (CV 4), Qihai (CV6) and Shenjue (CV8) are the points for emergency measures to restore vital function. Continuous indirect moxibustion with salt and/or retaining needles for 30 minutes at these points is the traditional method.

### Subacute TBI management with TCM

In TCM, diagnosis and treatment is based on clinical symptoms. Different diseases with similar clinical pictures usually are treated in similar ways. Meanwhile, the same disease with different clinical symptoms may be treated in different ways. Because of the clinical similarity, the management of TBI is quite similar to the treatment of stroke. After the crisis acute stage, in cases of prolonged comatose status, An-Gong-Niu-Huang-Wan and Su-He-Xiang-Wan (苏合香丸, Storax Pill) are often used for resuscitation. Acupuncture methods for coma cases are similar to that for *qi* blockage and additional appropriate points are added according to clinical symptoms present. TCM physicians will apply acupuncture by combining the local and distal points according to the courses of the

channels. For example, because the Large Intestine Channel and Stomach Channel traverse the cheek, Jiache (ST 6), Xiaguan (ST 7) and Hegu (LI 4) are the points to be stimulated for those coma patients with clenched jaw. According to TCM theory, functionally the tongue is related to the heart. Aphasia is a symptom of heart function disorder. Ren-Shen-Zai-Zao-Wan (人参再造丸, Ginseng Restorative Bolus) is the often used to benefit heart *qi*, blood circulation, and promote recovery of aphasia. Yamen (GV15) and Lianquan (CV 23) are local and adjacent points of the tongue. Tongli (HT 5) is the Luo (connecting) point of the Heart Channel. These points are often selected to relieve stiffness of the tongue and treat aphasia and dysarthria. A small control study on TBI aphasia patients showed the functional recovery of the acupuncture treatment group was much better than that of the control group (8).

TCM believes that paresis is a mobility function deficit due to obstruction of *qi* and blood circulation in Channels. Huo-Luo-Dan (活络丹) is one of the popular TCM pills used in hemiplegia cases to remove obstruction and readjust *qi* and blood circulation. Acupuncture is widely used in China to promote the recovery of hemiplegia. The *Yang* Channels of the affected side are the main points to puncture. Points of the healthy side may be added also. Usually, TCM practitioners puncture the healthy side first and then the affected side. Moxibustion may be applied as a supplement. Baihau (GV 20), Fengfu (GV16), and Tongtian (BL 7) are commonly used for all paralysis cases. Jianyu (LI 15) Quchi (LI 11), Shousanli (LI 10), Waiguan (TE 5), and Hegu (LI 4) are usually selected for upper extremity affected cases. Huantiao (GB 30), Yanglingquan (GB 34), Zusanli (ST 36), Jiexi (ST 41), and Kunlun (BL 60) are used for lower limb paresis. Yifeng (CV 17), Dicang (ST 4), Jiache (ST 6), Yangbai (GB 14),

Hegu (LI 4), Quanliao (SI 18), and Xiaguan, (ST 7) are usually added for cases of facial paralysis.

Prescription of traditional Chinese medications is usually made according to a TCM diagnosis based on clinical symptoms. Following are the TCM diagnostic syndromes, most often seen in the subacute TBI cases. The prescriptions will be briefly introduced accordingly.

**Stasis of Blood** Stasis of blood is one of the key etiologies in the TCM brain injury model. TCM theory dictates that the heart houses the mind. Traumatic brain injury may disturb the blood and *qi* circulation and interfere with heart function. Injury may directly induce the stasis of blood. The invasion of external pathogenic factors due to trauma may also interfere with blood circulation and induce stasis. Stasis of blood will interfere with *qi* movement. Pain usually comes from insufficiency or blockage of local *qi* circulation. As “the heart houses the mind”, blood stasis results in a decreased level of consciousness. Consequently, these cases usually have headache and cognitive deficiency. Many TBI cases with symptoms of migraine-like headache are due to blood stasis. Usually, the patient complains of persistent pricking or stabbing headache in a fixed location. A purple tongue or purple spots on the tongue may be seen. The pulse is stringy and hesitant. Promoting blood flow to remove blood stasis is the focus of treatment. Xue-Fu-Zhu-Yu Tang (血府逐瘀汤) and Shu-Jing-Huo-Xie Tang (疏经活血汤) are among the most widely prescribed TCM formulas for those cases of blood stasis with headache and/or other neuralgia. Recent research has confirmed the beneficial effects of these groups of Chinese medicines on neural regeneration. It was reported that after the extracts of Shu-Jing-Huo-Xie Tang were added in a culture medium of neural cells, the neurite outgrowth induced by nerve growth factor (NGF)

increased approximately 30-fold compared to NGF alone (9). Ci-Wu-Jia (Radix Acanthopanax Sceticosi) is one of the herbs prescribed for this type of patient either individually or combined with other TCM medications. Animal studies have demonstrated the strong anti-inflammatory and antinociceptive activities of Acanthopanax Radix extract (10) and its effects as an agent in the prevention of multiple organ dysfunction (11). Acanthopanax Radix is also known to have healing and protective effects on stress-induced disturbances of mental status. Animal studies have suggested that Acanthopanax Radix may act by regulating noradrenaline (NA) and dopamine (DA) levels in specific brain regions related to the stress response (12).

*Deficiency of Qi and Stagnancy of Blood* According to TCM theory, the brain is an organ belonging to *yin* and collecting clean *qi* of *yang*. The function of the brain depends on momentum of *yang-qi*. Some subacute TBI patients show weakness of *qi* as their major clinical phenomena. Deficiency of *qi* can induce stagnancy of blood. Fatigue and headache are the major complaints. The patients look tired with low voices. They have a dull headache, aggravated by fatigue, accompanied by lassitude, lack of strength, anorexia, palpitations, shortness of breath, and sometimes aversion to cold with cool limbs. The tongue shows a thin white coat. The pulses are “thready” and weak. Most TBI cases with hypopituitarism would be classified in this syndrome group. Promoting blood circulation by invigorating *qi* is the method of treatment. Bu-Yang-Huan-Wu-Tang (补阳还五汤), Yi-Qi-Hua-Yu-Tang (益气还五汤) and Taohong Siwu Tang (桃红四物汤, Decoction of Four Ingredients with Peach Seed and Safflower) are among the classic decoctions prescribed to TBI patients for promoting blood circulation by invigorating *qi*. A large-scale clinical case report on the management of subacute or chronic subdural hemorrhage patients with Yi-Qi-Hua-Yu-Tang showed significant therapeutic effects (13). It was reported that Bu-Yang-Huan-Wu showed beneficial effects on disturbance of the hypothalamus-pituitary-thyroid axis after brain ischemic injury (14). Animal studies found that Bu-Yang-Huan-Wu may protect brain neurons from apoptosis after cerebral ischemia. The mechanism may be related to its effects on the improvement of cerebral energy metabolism, regulation of nitric oxide synthesis and antagonism of toxic excitatory amino acids (15). The Taohong Siwu Decoction is effective in hydroxyl radical scavenging and is effective in inhibiting lipid peroxidation (16).

Astragalus root, Chinese angelica root, Ligusticum chuanxiong rhizome, and safflower are the common ingredients among these decoctions. Astragalus, Chinese Angelica, and Ligusticum Chuanxiong have demonstrated a wide range of immunopotentiating and immunomodulating effects (17–19). Angelica Sinensis,

Ligusticum Chuanxiong, and safflower have also showed anti-inflammatory and antioxidizing effects. They could improve brain microcirculation through inhibiting thrombus formation and platelet aggregation as well as blood viscosity active components (20–22). Laboratory studies have also suggested that chaunxiong and safflower have brain neuroprotective effects (23–25).

*Kidney Insufficiency* Insufficiency of the kidney is a contributing factor in some of the post brain injury syndrome cases, especially among the geriatric population. Kidney insufficient patients usually complain of a constant dull headache, with a feeling of emptiness often worsening with exercise. Common accompanying symptoms include lassitude, debility, aching, weakness of the lower back and legs, forgetfulness, decreased intelligence and impotence. The patient often has a reddened tongue with little or no film. The pulses are deep, thready, and weak. There are two kinds of kidney insufficiency, *yin* and *yang*. Cases of the kidney *yin* insufficiency are usually accompanied by dizziness, tinnitus, dry mouth, flushed cheeks, and a hot sensation in the palms and soles. Liu-Wei-Di-Huang-Wan (六味地黄丸, Six Flavor Tea, Rehmannia Pill, LWDH) and Jin-Gui-Shen-Qi-Wan (金匮肾气丸) are the TCM decoctions given most widely. Insufficiency of the kidney-*yang*, is usually accompanied by aversion to cold, cold limbs, nocturia, and pale complexion. The tongue is pale and corpulent with a thick whitish coating. In these cases the TCM physician will usually prescribe kidney *yang* reinforcing medications such as You-Gui-Wan (右归丸) and Shen-Qi-Wan (肾气丸). The contents of LWDH are the main components for the formulas of all the kidney insufficiency prescriptions. LWDH has been widely studied. Recent animal studies have shown that LWDH possesses anti-amnesia effects and memory enhancing properties (26). It was suggested that LWDH corrects the abnormal expressions of hippocampal genes in dementia animals (27). Traditionally, kidney tonic Chinese medications containing LWDH are used widely for general health condition improvement. Those medications are able to enhance non-specific immunology activities (28). LWDH is able to improve immune function by regulating the ratio of T and B cells and control over-expression of cytokine genes from activated mononuclear cells (29–32). In addition, the compounds in LWDH may also protect tissues and organs from cytotoxic attack by noxious reagents (33–34). Dihuang (Radix Rehmanniae), one of the major ingredients of the kidney tonic formulas is also reported to have effects on intelligence enhancement (35).

*Liver Dysfunction* The liver dominates unrestrained *qi* and maintains the patency of *qi* flow. Acute or subacute brain injury may alter liver function by changing the balance of liver-*yang* and of endogenous wind in the liver. Exuberance of liver-*yang* results in a headache characterized by cramping pain in the temple and vertex and is

**TABLE 56-3**  
**Subacute TBI TMC Differential Diagnosis and Decoctions Used Often**

DIAGNOSIS	MANIFESTATIONS	DECOCTION
Stasis of blood	migraine-like headache and cognitive deficiency, purple or purple spots on the tongue, stringy and hesitant pulse	Xue-Fu-Zhu-Yu Tang Shu-Jing-Huo-Xie Tang
Deficiency of qi and stagnancy of blood	fatigue, dull headache, low voices, lassitude, anorexia, palpitations, shortness of breath, aversion to cold, cool limbs, thin whitish coated tongue, thready weak pulse	Bu-Yang-Huan-Wu-Tang Yi-Qi-Hua-Yu-Tang Taohong Siwu Tang
<i>Kidney Insufficiency</i>	constant dull headache with a feeling of emptiness, lassitude, debility, aching and weakness of the lower back and legs, forgetfulness, decreased intelligence	<i>kidney yin insufficiency</i> dizziness, tinnitus, dry mouth, flushed cheeks, and a hot sensation in the palms and soles, reddened tongue with little or no coat, deep and weak pulse
		<i>kidney-yang insufficiency</i> aversion to cold, cold limbs, listlessness, impotence, nocturia, pale complexion, spontaneous perspiration, pale and corpulent tongue with thick whitish coat, weak pulse
<i>Liver Dysfunction</i>	cramping headache in temple and vertex aggravated by anger. faintness, giddiness, insomnia, bitterness in mouth, decreased self-control, irritability, restlessness, insomnia, tremors, twisting of the body, and localized or generalized convulsions, thin yellow coated tongue, a stringy rapid pulse	Tianma Gouteng Yin

aggravated by anger. The headache is often accompanied by faintness, giddiness, dizziness, insomnia, and bitterness in the mouth. Alterations of endogenous wind in the liver cause disturbances of emotions and body movements. Wind is always moving and changing reflecting the patient's symptoms of decreased self-control, irritability, restlessness, and insomnia. The patient may have abnormal body movements such as tremors, twisting of the body, and localized or generalized convulsions. Patients have a thin yellow tongue coating and a stringy rapid pulse. TMC management is oriented at subduing the exuberant *yang* of the liver in turn calming the internal wind. Tianma Gouteng Yin (天麻钩藤, Decoction of Gastrodia and Uncaria) is the formula most commonly prescribed for these patients. Tianma (*Gastrodia elata* Bl.) and Gouteng (*Uncaria rhynchophylla* Jack) are traditional Chinese herbs that are used to treat convulsive disorders such as epilepsy. Synergistic anticonvulsive effects were observed in animal studies (36). Gastrodia is widely used by TCM physicians to manage headache, dizziness, vertigo, dementia, and convulsions (37). Pharmacological studies have shown that the anticonvulsive properties and brain neuronal protective effects of the constituents of Gastrodia are related to their free radical scavenging activities and modulator effects on neurotransmission

(36, 38–41). The cognitive beneficial effects of *Castrodia* and its ability to improve learning and memory have been confirmed by animal studies (42–44). Interestingly, animal studies have also shown that motion sickness can be treated with *Gastrodia* (45).

### Chronic Post-TBI Syndrome:

Patients suffering from brain concussion, brain contusion, and traumatic intracranial hemorrhage may have residual symptoms of post brain injury syndrome such as headache and dizziness. TCM physicians divide cases of post brain injury syndrome into several types according to the accompanying symptoms. The treatment methods may be the same for different diseases that share similar clinical pictures.

*Qi*, blood and body fluids are fundamental substances in the human body. They sustain normal vital activities. Their existence and function are generally manifest in the functional activities of various tissues and organs. Blood and *qi* are closely related. The formation and circulation of blood depends upon *qi*, while the formation and distribution of *qi* is intimately absorbed in blood. TCM physicians believe, as a result of endogenous injury, the chronic post brain injury syndrome is due to

the unbalance of *qi*, blood, and body fluid. Trauma and prolonged morbid status would excessively consume *qi*, blood, and fluid essence and induce *qi* deficiency. Patients with *qi* deficiency will complain of a dull headache, which is aggravated by fatigue, accompanied by lassitude, lack of strength, anorexia, palpitations, and shortness of breath. A thin white tongue coating and thready weak pulse is usually found. Buzhong Yiqi Wan (补中益气丸) is the formula of choice to replenish *qi*. Post-brain injury patients with general blood deficiency usually have headache, dizziness, palpitations, insomnia, dreamful sleep, blurred vision, numbness of the limbs, pale tongue, and “thready” pulse. Siwu Tang (四物汤, Decoction of Four Ingredients) is the basic formula used to nourish the blood. Siwu Tang plus Flos Chrysanthemi (chrysanthemum flower) and Fructus Viticis (chastetree fruit) is a treatment for blood deficiency patients with headache as their major complaint. Those patients with symptoms of both *qi* and blood deficiency receive Renshen Yangyin Wan (人参养阴丸, Geinseng Nutrition Pill) and Shiquan Dabu Wan (十全大补丸, Bolus of Ten Powerful Tonics). Excessively consuming essence fluid of the kidney will induce kidney *yin* deficiency. For those post brain injury cases with *yin* deficient phenomena as described previously, Qi Ju Dihuang Wan (杞菊地黄丸, LWDH with Wolfberry and Chrysanthemum) is often prescribed.

Some cases with poor general health may also show symptoms similar to liver *yang* disturbance. Liver *yang* hyperactivity may be secondary to a relative *yin* deficiency. Nourishing *yin* and calming down *yang* is the strategy for treatment with Liu-Wei-Di-Huang-Wan and Zhengan Xifeng Wan (镇肝熄风丸). TCM physicians believe the liver aids the spleen and stomach in digestion and absorption. Trauma may disturb liver *qi* leading to digestive disorders manifested as nausea, anorexia, abdominal distention, acid regurgitation, loose stool, etc. Female patients may have irregular menstruation. For cases accompanied by liver-*yang* hyperactive symptoms described previously, Longdan Xiegan Wan (龙胆泻肝丸) is administered. Post-TBI patients with deficiency of the liver-*qi*, usually have a coexisting deficiency of blood in the liver. This manifests as pallor of the face and lips, lassitude, tinnitus, deafness, and liability to panic. Dan Zhi Xiaoyao Wan (丹栀逍遥丸) is a medication often given (Table 56-4).

The acupuncture management strategies of post-TBI syndromes are also formulated according to clinical complaints and symptoms. Among the various post-TBI clinical symptoms, headache is one of the most common complaints. We hereby discuss headache as an example to introduce the basic acupuncture treatment methods of post-TBI symptoms. TMC theory relates that the head is the place where all the *yang* channels of the upper and

**TABLE 56-4**  
*Chronic Post-TBI Syndrome TCM Differentiation and Treatment*

TYPES	MANIFESTATION	DECOCTION SUGGESTED
<i>Qi</i> deficiency	dull headache, aggravated by fatigue; lassitude, anorexia, palpitations, shortness of breath, thin white coated tongue, thready and weak pulse	Buzhong Yiqi Wan
Blood deficiency	headache, dizziness, palpitations, insomnia, dreamful sleep, blurred vision, numbness of the limbs, pale tongue, thready pulse	Siwu Tang
Both <i>qi</i> and blood deficiency	as above combined	Renshen Yangyin Wan Shiquan Dabu Wan
Kidney <i>yin</i> deficiency	lumbago, lassitude, dizziness, tinnitus, nocturnal emission, premature ejaculation, dry mouth, sore throat, flushed cheeks, hot sensation in palm and sole, reddened tongue with little or no coating, thread and rapid pulse	Qi Ju Dihuang Wan
Liver <i>yang</i> hyperactivity	cramping headache over temple and vertex, intermittent dizziness, giddiness, restlessness, irritability, insomnia, bitter taste, taut pulse	Liu-Wei-Di-Huang-Wan and Zhengan Xifeng Wan
Disturb liver <i>qi</i>	nausea, anorexia, abdominal distention, acid regurgitation, loose stool, irregular menstruation	Longdan Xiegan Wan
Deficiency of the liver- <i>qi</i> ,	pallor of the face and lips, lassitude, tinnitus, deafness, liability to panic	Dan Zhi Xiaoyao Wan

**TABLE 56-5**  
*Acupuncture Point Selection for Chronic Post-TBI Headache*

REGION OF HEADACHE	CHANNEL OF DISTAL POINT SELECTED	PRESCRIPTION EXAMPLE
Occipital	Urinary Bladder Channel of Foot – Taiyang	GB 20, BL 10, BL 60
Forehead and supraorbital	Stomach Channel of foot-Yangming.	ST 8, GV 24.5, LI 4, ST 44
Temporal	Gall bladder Channel of foot-Shaoyang.	GB 8, TE 5, GB 41
Parietal	Liver Channel of foot-Yueyin.	CV 20, SI 3, BL 67, LR 3

lower limbs meet. Attacks by trauma and other endogenous or exogenous factors may cause derangement of *qi* and blood in the head and retardation of circulation of *qi* in the channels that traverse the head. In such cases, headaches occur. Usually, the headache is differentiated according to its locality and its supplying channels (Table 56-5). The selection of acupuncture points is based on the combination of local points around the symptomatic area and distal points according to the channels affected. Pain at the occipital region and nape of the neck is believed to be Urinary Bladder Channel of Foot – Taiyang related. Fengchi (GB 20) and Tianzhu (BL 10) are the local points punctured. Kunlun (BL 60) is one of the distal points selected often. Pain at the forehead and supraorbital region is related to the Stomach Channel of foot-Yangming. Puncturing the local points of Touwei (ST 8) and Yintang (GV 24.5) combined with distal points Hegu (LI 4), Neiting (ST 44) is one of the popular methods. Headaches at the temporal region bilaterally or only one side are related to the Gall bladder Channel of foot-Shaoyang. Shauigu (GB 8), Waiguan (TE 5), and Zulinqi (GB 41) are the points to be punctured. Parietal region headache is related to the Liver Channel of foot-Yueyin. The points often selected include Baihui (CV 20), Houxi (SI 3), Zhiyin (BL 67), and Taichong (LR 3). For those with exuberance of liver-*yang*, add Xingjian. (LR 2) and Yanglingquan (GB 34). In cases of deficiency of *qi* and blood Qihai (CV 6) and Zusanli (ST 36) would be punctured also.

Post TBI cases are differentiated to Shi (solid) and Xu (insufficiency) types. Cases with symptoms of stasis of blood and exuberance of liver-*yang* belong to Shi types, while those with symptoms of insufficiency of *qi*, blood and kidney are grouped as Xu types. The acupuncture points are selected accordingly. For example, Laogong, (PC 8) and Yongquan (KI 1) are the points to be stimulated for Shi cases with syncope and dizziness. However, combining puncture and moxibustion at Baihui (GV 20),

Qihai (CV 6), and Zusanli (ST 36) is the treatment for those Xu cases with similar symptoms.

More and more evidence supports that acupuncture is able to stimulate the central nervous system to release chemicals, which influence the body's self-regulating systems and promote natural healing abilities. Most acupuncture points are located in the trunk and limbs. However, the points over the head play an important place in traditional TBI management with acupuncture. Scalp acupuncture is a newly developed promising method to treat severe TBI and its related symptoms (46–48). Future research may be aimed at scalp acupuncture and its effects on the release of neurotransmitters and neurohormones.

## Discussion

Unlike the development of Western medicine, which is mainly based on the progress of biomedical sciences, the development of Traditional Chinese Medicine is based on the experience of numerous clinical applications of natural products and acupuncture. TCM has been used for at least 3,000 years and has accumulated rich clinical application experience. The chemical ingredients of natural products are complicated. The chemical contents of a TCM formula, made up of a combination of natural medicines, are even more complicated. Pharmacological research is needed to bring TCM from an experiential and historical level to current biopharmaceutical standards level. This is not to say that the chemical elements of TCM formulas should be extracted and purified into a single compound for administration in isolation.

Although there are increasing numbers of patients and physicians in western countries accepting TCM as an alternative form of medical treatment, there have been no large-scale, well-controlled studies done evaluating TCM management of TBI. Some “natural” ingredients may be harmful to humans. The issues of toxicity may be even more relevant following TBI when blood brain barrier permeability may be adversely impacted. Considering the complex contents of TCM medicines, it is certainly possible that some of them may interfere with the effects of prescribed pharmaceutical drugs. Most of the TCM medications mentioned in this chapter are available in the West as “natural food products”. The authors recommend that patients who wish to use TCM medications for TBI related problems consult their physicians, and if such treatment is pursued, patients should ideally be under the guidance of TCM trained practitioners.

Acupuncture seems to have no obvious side effects; however, there are no large-scale controlled studies done yet on acupuncture management of TBI related problems. Clearly, this is an area of research that can meld TCM with Western medicine in an attempt to best optimize patient outcome following TBI.

How ultimately TCM will be integrated into the rehabilitative management of persons with traumatic brain injury is yet to be seen. Practitioners should remain open to treatment strategies such as TCM that potentially assist their patients' recovery and/or function and commensurately advocate for these areas of intervention to be more critically assessed through high quality controlled research studies.

## ACKNOWLEDGEMENTS

We would like to thank Qu Yun, O.M.D. at Department of Rehabilitation Medicine, School of Medicine, Sichuan University in China for his help, suggestions and comments.

## Complementary and Alternative Medicine

*Jacinta McElligott, Alan M. Davis,  
Jeffrey S. Hecht, Sunil Kothari,  
John A. Muenz, Jr., Gary G. Wang*

**I**n the mid-1800's, medical and health care in the United States included a rich mixture of many different health care practices and philosophies from various cultures around the world. The introduction of the research control trial (RCT) and development of the scientific methodology and rigor which allowed for the proof of the efficiency of an intervention resulted in an explosion of effective medical treatments in the latter part of the nineteenth century. This successful biomedical approach continues to dominate the practice of medicine in western societies today. Traditional practices, although based on thousands of years of human experience, are now considered “complementary” or “alternative” therapies. Despite the predominance of the modern biomedical approach to medical practices the use of complementary and alternative medical practitioners in the United States and other Western societies continues to grow. Patients with brain injury may be particularly likely to seek treatment through CAM practitioners especially when there is a lack of effective treatment for many chronic impairments and symptoms associated with brain injury. The development of the research infrastructure, including centers of study and evidence-based scientific exploration has resulted in a growing body of literature related to the practices of CAM.

The purpose of this chapter is to explore the evolution of the modern biomedical approach to medicine from

traditional to the scientific. We discuss the application and implications of the growing consumer use of CAM as it pertains to our current medical and rehabilitation management of patients with brain injury. We contend that CAM interventions can be most appropriately and successfully integrated into rehabilitation management of brain injury with the development of the scientific evidence to support such practices. We also discuss CAM interventions which may be of special interest to patients with brain injury along with the availability and accessible research literature relative to the integration of CAM into evidence-based practice.

Complementary and alternative therapy (CAM) is defined as the use and practice of therapies or diagnostic techniques that are not part of the current Western health care system. It was not until the latter part of the nineteenth century that the scientific research and rigor which forms the foundation of the modern biomedical approach to medical practice was introduced. With the success and preferential development and emphasis on the biomedical approach, traditional practices, often based on thousands of years of human experience may have been inadvertently left behind. Consider for example Ayurveda, practiced throughout the Indian subcontinent for more than 7000 years. Ayurveda promotes (1) an integrated approach to the prevention and treatment of disease with a healthy lifestyle of diet, herbs, exercise and yoga. Another of Asia's contributions to alternative medicine

is Bencao Gangmu which was published during the Ming dynasty in China (1552–1558) (1). This text, by Li Shi-Zhen, lists 1,892 medical substances and contains more than 1,000 illustrations and 10,000 detailed descriptions. Chinese knowledge of botanic medicine dates back to 3,000 years B.C. with the discovery of Ma Huang, used as a stimulant and for respiratory afflictions. The active ingredient in Ma Huang was subsequently identified as ephedrine (1).

The modern biomedical approach to medical practice is based on an understanding of the pathophysiology of disease and scientific proof of the efficacy of an intervention. Some believe that this approach to medicine was established in the 2nd century AD by Galen, a Greek physician (1). Galen published a guide to the evaluation and treatment of patients which focused on anatomical knowledge and the use of visual and physical objectivity (1). In the 1800's, scholars in China also sought to move away from speculation and root their studies in "hard facts" (2) by practicing "Kaozhang" translated "practicing evidential research."

A landmark in the evolution of evidential research was the development of the randomized controlled trial. When James Lind (1716–1794) (3) was appointed as a ship's surgeon in Britain, scurvy was a crippling and prevalent disease among sailors. In his meticulous observations Lind included a simple account of what may have been the first prospective randomized controlled trial (RCT) ever undertaken in humans. With their full cooperation, Lind randomized sailors afflicted with scurvy into separate groups, each group receiving a different mode of treatment thought efficacious at that time. The results of the experiment were simply stated, "of the two men who had received 2 oranges and 1 lemon daily, one was fit for duty at the end of 6 days and one recovered to the point of attending the rest of the sick patients in the other groups". With this one concise clinical experiment Lind established the clear superiority of citrus fruits above all other supposed antiscorbotic remedies. Lind's work ultimately led to a government ordinance requiring the provision of citrus fruits to all sailors which in turn led to virtual eradication of this disease. Subsequently the continued systematic development of the scientific rigor which was so successful in proving the efficacy of interventions resulted in an explosion of effective preventative, diagnostic and therapeutic interventions. In medical education a report by Abraham Flexner early in the 20th century ultimately led to the disproportionate funding and development of medical schools which trained their students in the biomedical approach.

Despite the success and preferential development of the biomedical approach, patients in the United States and other Western societies are seeking treatment from traditional and alternative medical practitioners in growing numbers. Eisenberg et al. (4) performed a survey which

documented the expanding use of CAM interventions by American Families. This survey identified an increase in the use of CAM from 33.8% of families in 1990 to 42.1% in 1997 (4). Extrapolating from the survey results the author's suggested a 47.3% increase in visits to alternative medicine practitioners, 427 million in 1990 to 629 million visits in 1997. Visits to alternative practitioners exceeded total visits to all U.S. primary care physicians with estimated expenditures for alternative medicine services in at \$21.2 billion. CAM therapies were sought both for the maintenance of health and the prevention and treatment of illness. For conditions most pertinent to brain injury CAM interventions were sought for headache, neck problems, insomnia, depression and anxiety. An estimated 15 million adults in 1997 took prescription medications concurrently with herbal remedies and high dose megavitamins and less than 40% of patients disclosed this to their physicians (4).

Physicians attitude towards CAM was evaluated in a survey in 1997 by Sikand et al. (5). This survey was mailed to the fellows of the Michigan Chapter of the American Academy of Pediatrics (5). The majority of pediatricians responding believed a small percentage of their patients were seeking alternatives to conventional medicine. In addition, half of the physicians responding would consider referring patients for CAM, and most were interested in continuing medical education on CAM (5). In 1999 Spencer et al. reported that 63 US medical schools were offering courses and electives in CAM(6) however CAM therapies remained largely outside of most conventional medical school curriculums. The increasing use of CAM led to an awareness of the need for further research into CAM and may have prompted Congress to establish the Office of Alternative Medicine (OAM) at the National Institute of Health (6). Funds were appropriated to establish 11 centers of study and with the development of these centers the literature devoted to CAM has expanded and the number of research CAM databases has grown (6). Subsequently the World Health Organization designated the OAM as a collaborating center for traditional medicine (6).

There are inherent differences in the biomedical and CAM approach to medical practice. CAM interventions are often based on a philosophy and a holistic approach and often rely on verbal reports to evaluate effectiveness. Recognizing these fundamental differences Katz et al. (7) proposed a method of evidence mapping to evaluate the strength of the evidence in CAM. Evidence mapping systematically organizes the evidence available pertaining to a broad topic such as CAM. The breadth, depth, methodology and overall quality of pertinent evidence are characterized. Evidence mapping seeks to be broadly inclusive, performs abstractions and detailed assessments including systematic reviews and meta-analysis. The study objectives included, mapping the evidence underlying

CAM, identifying high priority areas of deficient evidence and conducting pilot studies in the areas where evidence is sparse. With this method of evidence mapping Katz et al. identified over 4,000 papers distributed to over 207 priority health care areas. Of conditions most pertinent to BI Katz et al. identified 7 RCT's relating to the use of CAM interventions in headache and 15 for the use of CAM in neck pain. Depression was considered one of the top 25 priority health care areas and 11 RCT were devoted to the study of relaxation and depression. There were a total of 112 studies in the use of vitamins and depression of which 41 were RCT. Fatigue was also included in the top 25 priority health care areas and 2 RCT were identified in the use of herbs for fatigue.

In a method similar to evidence mapping, consensus conferences draw from a broad body of experts to evaluate the evidence of therapeutic interventions, for example the NIH and the OAM sponsored a consensus conference evaluating the quality of research assessing the efficacy of acupuncture, unfortunately this conference concluded that generally the quality of the evidence was low with few well-designed studies assessing efficacy of acupuncture (8).

The development of research centers and internet access to electronic research databases set the stage for Gordan Guyatt at McMaster University in Canada to propose a paradigm shift in health care called evidence based medicine (EBM) (9). EBM is defined as the integration of best research evidence with clinical expertise and patient values. The agency for health care policy research (AHCPR) has sponsored several programs closely identified with evidence-based medicine in the United States (10). The Medical Treatment Effectiveness Program funds research on the efficacy, cost effectiveness, and appropriateness of clinical interventions. The AHCPR supports 12 Evidence Based Practice Centers, which include a mixture of academic centers and private organizations with national and international reputations for their work on systematic reviews, meta-analyses, and technology assessments. Several centers are devoted to complementary and alternative medicine including the following: Center for Alternative Medicine Research in Asthma and Immunology at the University of California at Davis; Center for Addiction and Alternative Medicine Research at the University of Minnesota; Complementary and Alternative medicine program in aging at Stanford University (10).

The Cochrane collaboration uses an evidence based approach including a registry of randomized control trials and systematic reviews. Systematic reviews critically appraise the qualitative aspects of the research literature and the strength of the evidence to support a particular intervention. Within the Cochrane database there is a complementary therapy research section. The Database of Abstracts of Reviews of Effectiveness (DARE) (11) published, in 2003, a systematic review of randomized

control trials of complementary/alternative therapies in the treatment of tension-type and cervicogenic headache. Two reviewers used an 18-item quality protocol for adult headache sufferers. The participants in most studies were patients with tension type headache. A minority of patients suffered from cervicogenic or post-traumatic headache. Of the studies, which received a high quality, 1 RCT on the use of homeotherapy in 98 patients found no difference in efficacy of the treatments provided. One Research controlled trial (RCT) including 57 subjects found that Tiger Balm and paracetamol produced significantly greater pain relief for one episode of headache.

EBM has now been incorporated throughout health care curriculums and for clinicians trained in the biomedical approach, evidence based medicine is the safest and most effective means of incorporating the research available in complementary and alternative medicine into conventional clinical practice. EBM stresses the need for the clinician to examine the available information, or lack of information, from clinical research and to critically analyze the literature and incorporate the results of such analysis into clinical practice including the use of CAM. The expansion in the availability of health sciences electronic databases and libraries has supported the access and availability of pertinent research on CAM in real time to clinicians. The OAM, the creation of specialized centers and databases of systematic reviews of best evidence allows clinicians rapid access to concise summaries and evaluations of the evidence to support the therapeutic and diagnostic practices of CAM. See (Table 57-1) for electronic databases which contain literature applicable to CAM.

In the following sections of this chapter we explore some of the CAM techniques in common use in the US from a historical and traditional perspective, as well as the available research evidence to support the CAM practice especially as applicable to patients with brain injury.

## HOMEOPATHY AND NATUROPATHY

Homeopathy is a 200-year-old therapeutic system that uses small doses of various substances to stimulate self-regulating and self-healing processes (12). Of the nearly 2.5 million patients using CAM in the United States in 1997 approximately 3.4% of patients used homeopathy and 0.7 % used naturopathy (13). Homeopathy remains one of the most controversial CAM's. *Similia similibus curentur* or, treating "like with like" is the basis of homeopathy. Homeopaths believe that patients complaining of particular symptoms can be cured with substances that can produce the same symptoms in healthy individuals. In addition to matching the symptoms of the disease, a homeopathist will select remedies based on the constitutional factors of the individual patient such as the patients' psychological state, environmental reactions, and habitus. Of the large number

of homeopathic medicines which have been described, approximately 200 are in regular use (14) and about 60% of plant origin. Animal products, minerals, chemical salts, and disease products also may be used. Homeopaths believe that remedies retain biological activity if they are serially diluted and agitated between each dilution. The dilution most frequently used is designated “6c”, which is a  $10^{-12}$  dilution of the original “mother tincture”. It is likely that a 6c dilution will contain a few molecules of the initial substance. These dilutions are said to produce effects even when diluted beyond Avogadro’s number in which no original molecules of the starting substance remain. Many scientists believe that homeopathy violates natural laws and thus any effect must be a placebo effect (15). However, because of the high dilution, homeopathy appears to be very safe, which is an important motivating factor amongst its patients. The public’s belief in the effectiveness of homeopathy is widespread (16). In the United States, patients who seek homeopathic care are more affluent and younger (17). As with other diseases and syndromes, the effectiveness of homeopathy for brain injury (BI) is quite questionable and controversial. A small pilot research study suggested that homeopathy is efficacious for certain symptoms related to brain injury such as headache (18, 19). Actually, there is insufficient evidence to show that homeopathy is clearly efficacious for any single clinical condition. Reviews on homeopathic clinical trials have found that the majority of available studies have

reported some positive results but the evidence is not convincing (20, 21).

There is no concise history of naturopathic medicine since the development of naturopathy has been strongly influenced by various cultures and religions and is therefore not a single discipline. Naturopathy and conventional medicine hold certain principles in common. Both emphasize disease prevention, patient education, seeking and treating the causes of disease, and both employ the therapeutic potential of the doctor-patient relationship. The basic principle of naturopathy dictates that nature acts powerfully through healing mechanisms in the body and mind to maintain and restore health. Naturopaths work to restore and support these inherent healing systems using non-invasive treatments believed to be in harmony with natural processes such as lifestyle modifications, nutrition, dietetics, herbs, education, and hydrotherapy. In addition, naturopaths may elect to use a variety of healing modalities including acupuncture, botanicals, homeopathy, massage, oriental medicine, and minor surgery (22). In general, naturopaths function as primary care providers with emphasis on prevention, education, and health maintenance (23, 24). It is vital that naturopathy be incorporated into conventional medical practices where treatment which has been proven to be effective is available, for example if a BI patient develops progressive hydrocephalus, a neurosurgical procedure may be appropriate to prevent further neural damage and facilitate

functional recovery. It would not be appropriate to over-emphasize natural healing and natural treatment modalities in such situations.

Most of the modalities applied by naturopathy are relatively safe, however, they are not without any risks (25, 26). Naturopathy recommends administering vitamins and herbal medicines widely, even though more clinical trials are necessary to obtain evidence supporting their efficacy. For example, vitamins A, C, and E are considered necessary for protecting tissue free radical damage and are commonly used by naturopaths, however, there is not enough scientific data supporting their necessity in addition to what is consumed in a normal diet (27). Only a small fraction of the thousands of medicinal plants used worldwide have been tested rigorously in randomized controlled trials (28). Several clinical trials have shown that some herbal or natural medicines may have efficacy in BI related symptoms, for instance, use of hypericum perforatum (St. John's wort) for depression and Ginkgo biloba for dementia is supported by a significant amount of evidence (29–31). Results of randomized controlled trials also support the use of kava for anxiety and valerian for insomnia (32, 33). Although evidence for the use of vitamins and amino acids as sole agents for BI related neuropsychological symptoms is not strong, there is intriguing preliminary evidence for the use of folate, tryptophan, and phenylalanine as adjuncts to enhance the effectiveness of conventional antidepressants. Another product S-denosylmethionine seems to have some antidepressant effects, while omega-3 polyunsaturated fatty acids, particularly docosahexaenoic acid, may have mood-stabilizing effects (34). It is important to note that scientific evidence is still lacking to support that the natural methods serve any therapeutic purpose better than conventional management. The scientific evidence is also lacking regarding what kind of natural foods the body can use for "reconstruction". Rehabilitation physicians should ask their BI patients about the "natural products" they take and discuss their use in a frank and nonjudgmental manner. The potential side effects and drug-drug interactions should also be considered when initiating naturopathy (35, 36). Patients who seek alternative medical management may do so because the available standard pharmacological treatments are not effective for their symptoms however the evidence on the effectiveness of homeopathy for post BI patient is scant. Some of the natural herbs may have effects to relieve some BI related symptoms; however, there is inadequate evidence to support the natural methods as serving the therapeutic purposes better than conventional. Natural herbs also have potential side effects and may induce drug-herb reactions. Rehabilitation physicians should maintain open communication with their patients to help them understand the potential, sometimes adverse drug-herb interactions and to ensure patients are informed of effective therapies for

serious diseases when the evidence for effective conventional therapy exists.

## AROMATHERAPY

Aromatherapy is the therapeutic use of aroma-producing oils (essential oils) extracted from organic materials (flowers, leaves, stalks, bark, rind or roots), and utilized as a form of relaxation therapy. The oils are mixed with another substance such as an alcohol, oil, or a lotion, and are then applied to the skin, sprayed in the air, or inhaled. The oils can also be poured into a soaking bath to derive the therapeutic effect. Originating in Europe in the early 1900's, the philosophy behind aroma therapy is that specific plant oils produce aromas and fragrances that stimulate or relax the body, by acting on certain areas within the brain. Fragrances stimulate nasal nerves which then send impulses to the areas of the brain controlling memory and emotion. The oils themselves are thought to interact with the body's own naturally occurring hormones and enzymes to cause changes within autonomically-mediated reflexes, including the blood pressure and pulse. Theory suggests a fragrance stimulates glands to produce analgesic substances, perhaps prostaglandin stimulating substances, effecting relaxation pain relief. Practitioners utilize essential oils to treat physical conditions including inflammation and infection. Aroma therapy is used to treat mental health conditions, including anxiety, depression, and insomnia. Individuals with asthma, respiratory allergies, chronic lung disease, or certain skin allergies should use care participating in aromatherapy. Aromatherapy should be avoided in children under the age of five as their immune systems are not yet competent.

## RELAXATION THERAPIES

Meditation is a relaxation therapy where one's attention is directed toward altering one's own state of consciousness. Meditation is a complex mental process involving changes in cognition, sensory perception, affect, hormones, and autonomic activity (37). The health benefits of meditation have been recognized in eastern philosophies for thousands of years with meditation now widely practiced in the west. There are two meditation techniques most commonly used: concentrative and mindful. In concentrative meditation, one focuses on a single image, sound, mantra (words spoken or sung in a pattern), or one's own breathing. Mindful meditation does not focus on a single purpose; rather, one is aware of all thoughts, feelings, sounds or images that pass through one's mind. Meditation usually involves slow regular breathing and quiet sitting, usually for durations of fifteen to twenty minutes. Meditation is used to help treat

a wide range of physical and mental problems, including addictive behaviors; immune system diseases; anxiety, stress, depression; high cholesterol and high blood pressure; and, pain. There are believed to be no negative side effects or medical complications of meditation when combined with conventional medical treatment. Meditation alone is not considered appropriate or safe for acute or life-threatening situations.

Transcendental meditation (TM) is unique and fundamentally different from any other type of meditation. It was founded by the Maharishi Mahesh Yogi in 1957. TM is reportedly a very simple technique to learn and is simple to practice. Over 5 million people around the world, almost 200,000 in the United Kingdom, have learned the technique since it was founded in 1957. People learn TM for many reasons, including reducing stress, improving health, and increasing personal effectiveness. The first scientific research on TM was published in 1970, and now there are hundreds of published studies documenting the benefits for mind-body relationships and the environment. TM is neither mind control nor mental discipline. It is not concentration, eastern philosophy, or a way of life, and it does not exert control over breathing or muscles. Hypnosis is a state of focused concentration during which time a person becomes less aware of their immediate surroundings. The use of hypnosis and hypnotherapy have been recognized by the American Medical Association as a valid medical treatment since 1958. Hypnotherapy has been used to treat many physical or psychological conditions, and can be led by a therapist, or it can be taught to individuals, for self-hypnosis. It is thought that during hypnosis, a trancelike state, individuals have a heightened ability to accept suggestions. By suggesting changes in an individual's actions or behavior, an improved physical or mental condition is created. The hypnotherapist's goal is not to control a person, or give the person answers, but rather to help the person solve his or her own problems. Hypnosis does not work for everyone, as a person must be willing to directly focus his or her attention and follow the suggestions of the therapist. Hypnosis is covered in greater detail in another section of this chapter; but it is mentioned here as it is considered a powerful relaxation and self-improvement therapy (38).

Guided Imagery is a relaxation technique where a series of thoughts or suggestions direct a person's imagination toward a relaxed and focused state. An instructor, in person or on recorded media, guides the individual through the process of imagery. Guided imagery is based on the concept that one's mind and body share a unique connection. Using the special senses, one's body seems to respond as though what one is imagining is, indeed, occurring. A relaxed state may be achieved when it is imagined, in full detail. This relaxed state can then aid learning, healing, and performing. Guided imagery can

have one feeling in control of one's emotions and thought processes, which then improves one's attitudes, health, and well-being. Guided imagery is especially useful in promoting relaxation. This relaxed state can lower blood pressure; reduce other stress-related problems, and enables one to reach other goals. Guided imagery is helpful in preparing for athletic events and for performance enhancement, including learning, weight loss, smoking cessation, and pain management. Guided imagery is safe, with no known associated risks, and it can be performed in any circumstance where improved performance is desired.

Autogenic training is a relaxation technique that teaches your body to respond to your own verbal commands. Using certain commands, a practitioner of autogenic training is able to tell their own body to relax, thus controlling breathing, blood pressure, heart rate and temperature. Autogenic training consists of six standard exercises that enable the body to feel relaxed, heavy, and warm. Each exercise has the individual assuming a simple posture, concentrating without goal, and then using visual imagery and verbal cluing to promote relaxation of the body in a specific way. The ultimate goal of autogenic training is to allow the individual to achieve a deep relaxation and stress reduction. Autogenic training is an effective treatment for chronic stress, as well as for other mental and emotional health issues. The mechanism of action is not fully understood, but the effects on the body are measurable. Experts believe that autogenic training works similarly to hypnosis, or self-hypnosis, or biofeedback. Helpful, with problems like generalized anxiety, fatigue, and irritability, some use autogenic training to manage pain, reduce sleep disorders, or increase their resistance to stress. Autogenic training has shown effectiveness in addressing: hyperventilation, asthma, gastrointestinal disorders, cardiovascular irregularities, autonomic dysfunction, headaches, and endocrine disorders. Some individuals have noticed a sharp change in their blood pressure when practicing autogenic training exercises; therefore, it is recommended that individuals with hypotension or hypertension have their individual physician's approval prior to participating in autogenic training. Autogenic training is not recommended for children under the age of five or in individuals with severe mental or emotional disorders (39).

Humor therapy, occasionally known as therapeutic humor, is a relaxation method that uses the power of smiles and laughter to help heal. Therapeutic humor, or humor therapy, simply means finding ways to make others, or yourself, smile and laugh more often. Laughter appears to actually change the brain chemistry, demonstrated on P.E.T. scans, and it may also boost the immune system, as well. Humor allows people to feel in greater control of their situations, can provide special perspective on problems, can allow the release of fear and anger, and it can eliminate stress that can create harm. Commonly,

humor is used in the treatment of long-term and chronic diseases, especially those worsened by stress. Humor therapy is valuable as well as a preventative measure aiding the care-partners of people with chronic illness or disease, including stroke, heart attack and brain injury, as they are at high risk of becoming ill themselves.

Music therapy is a relaxation therapy used to promote physical and emotional healing and wellness. Generally, a trained and certified music therapist is able to offer therapy in school, healthcare facility, hospice mental health facility, and private practice setting. Sessions of therapy can involve passive listening, active music making, or both. Research is currently revealing how music works therapeutically on both body and mind. The rhythm and tone of music can stimulate or sedate; has positive effects on heart rate, oxygen saturation, blood pressure, and cognitive ability; and is a healthy, non-verbal mode of self-expression. It is socially connective and expressive; and it enhances verbal expression, fluency, and communication with self and with other individuals. Music therapy calms the body and mind, and with its rhythm, order and function, it organizes the mind. Sometimes, music therapy, combined with movement therapy, such as dance, is utilized as a combined therapy. Long-term and medium term memories appear stimulated with music therapy and it has been shown that newborn premature infants, in intensive care units, are better able to tolerate painful procedures when exposed to music therapy. There are no known risks to music therapy and more information can be obtained by visiting the American Music Therapy Association website at [www.musictherapy.org](http://www.musictherapy.org) (40).

Biofeedback is a relaxation therapy where an individual, utilizing physical and mental exercises, consciously seeks to control a bodily function in a manner normally autonomically regulated. The bodily function (under control) is measured and displayed on monitors, concurrent with the treatment, demonstrating the individual's self-control. Once an individual achieves the desired functional change, monitors flash lights or sound audible signals. Biofeedback is of two types. One device uses electromyography (EMG) as the principal device for measuring relaxation; the other device uses peripheral limb temperature for feedback. Learning biofeedback routinely requires multiple instructor-led sessions to achieve competence. Beyond relaxation, electroencephalographic (EEG) biofeedback has become a widely used alternative treatment for a variety of neurologic and non-neurologic conditions.

## ELECTROENCEPHALOGRAPHIC BIOFEEDBACK

EEG biofeedback (also known as neurofeedback or neurotherapy) is a widely used alternative treatment for variety of neurologic and in-neurologic and non-neurologic conditions. Based on the same principles as conventional

(somatic) biofeedback. EEG biofeedback teaches individuals to modify, through the use of computerized feedback, the electrical activity of their own brains (41). As in other biofeedback modalities, the goal is to make normally unconscious or involuntary bodily processes perceptible so that they can be manipulated consciously. In conventional biofeedback, targets include such somatic processes as muscle tension, heart rate, and skin temperature. In EEG biofeedback, on the other hand, the target processes are certain characteristics of the patient's own EEG, such as frequency, amplitude, or cerebral localization.

During a typical EEG biofeedback session, the patient's brainwaves are recorded through scalp electrodes placed according to the "10-20" system used in traditional EEG recordings. The raw signal is amplified, filtered, and analyzed by specialized software which determines by how much the patient's EEG pattern deviates from target values that are determined ahead of time by the treating clinician. This information, in simplified form, is then communicated to the patient ("feedback"). Usually, the patient is only informed as to whether or not they are reaching their targets. This feedback can be delivered by something as simple as a light or sound that turns on only when patients are in the target range. Newer systems are characterized by more sophisticated and engaging modes of delivering feedback. For instance, one system utilizes a "Pacman" style video game: the "Pacman" character only moves (and thus scores points) when the EEG pattern is in target range. The costs of an EEG biofeedback session can range from \$50 to \$150 per session and most practitioners recommend an average of 40 (range 20-60) sessions for TBI, resulting in a total average cost of approximately four thousand dollars for a full course of treatment.

There are few, if any, dangerous side effects reported, although practitioners express concern about the possibility of triggering a seizure in patients with a known seizure disorder (this despite the fact that EEG biofeedback is considered a treatment for epilepsy). In general, the reported side effects already assume that EEG biofeedback is efficacious. For instance, practitioners will report concerns about "overshooting" and agitating a person with reduced initiation. Or, conversely, causing someone who is restless and anxious to become too sedated. Obviously, whether or not these side effects actually occur depends on whether EEG biofeedback can actually modify neurological or psychological symptoms.

The proposed mechanism of action of EEG biofeedback rests on two assumptions. First, it is assumed that EEG patterns are correlated with neurological or psychological states. For instance, the EEG of someone with anxiety disorder is thought to differ in predictable ways from the EEG of someone with depression. There is a fair degree of empirical support for this claim (42-44). There is also evidence for the second assumption, namely that

individuals can be trained to modify features of their own EEG (45). Thus, one proposed explanation of how EEG biofeedback works is that patients are learning to “normalize” abnormal EEG patterns and that, as these patterns are normalized, the patient’s symptoms improve or even resolve completely. Despite the empirical support for the assumptions that underlie this explanation, there is only limited evidence for the efficacy of EEG biofeedback in ameliorating clinical symptoms.

The FDA does not regulate either EEG biofeedback as a treatment modality or the equipment used (except generically as general biofeedback equipment). In addition, there are no local or national standards regulating the training or qualifications of those who provide this treatment. There are two national competency certifications offered by the Biofeedback Certification Institute of America as well as the Neurotherapy and Biofeedback Certification Board; however, these are strictly voluntary. Although anyone can provide these treatments, most providers tend to be professionals licensed in the fields of psychology, medicine, counseling, etc. It is estimated that approximately 3000 clinicians are currently providing EEG biofeedback treatment in the U.S. (46).

In fact, EEG biofeedback has been used for approximately 30 years to treat a variety of psychological conditions (including attention deficit disorders, depression, substance abuse, etc.) (47–52). There is a professional society entirely devoted to EEG biofeedback (International Society for Neuronal Regulation, with approximately 400 members) as well as an EEG Biofeedback Section (with approximately 600 members) in the well established Association for Applied Psychophysiology and Biofeedback. There are textbooks (53, 54) and a professional journal (*Journal of Neurotherapy*) devoted to the field. In addition, there are a growing number of dissertations being written on the topic. Finally, EEG biofeedback has become increasingly visible amongst consumers with TBI and their families. Recently, the Brain Injury Association of America published an article that discussed the modality in their national magazine (55). In addition, the state of Texas passed a law in 2001 mandating that commercial insurers must cover EEG biofeedback services for individuals with TBI (56).

The earliest and strongest evidence for the efficacy of EEG biofeedback is in the treatment of epilepsy. The intuition behind this research was the recognition that epilepsy was, by definition, a condition characterized by disordered electrophysiology. The goal was to teach individuals to modify those aspects of their EEG that most strongly correlated with seizure risk. Since 1972, there have been over 20 articles in peer-reviewed journals reporting on the use of EEG biofeedback to reduce seizure frequency in epilepsy; these have been recently summarized (57). Several of these articles reported the results of trials (including blinded, placebo controlled trials). The results were almost

uniformly positive and supported the efficacy of EEG biofeedback in reducing seizure frequency. Indeed, even a recent review article that was skeptical of EEG biofeedback acknowledged its potential role in epilepsy (58).

Unfortunately, as noted by the same reviewer, the evidence of efficacy in the treatment of other neurological or psychological conditions is much more limited. Much of it has been in the form of case reports and case series (59) which have been systematically reviewed in several recent articles (60–65). Recently, however, several trials evaluating the efficacy of EEG biofeedback for attention deficit disorder (66–69), learning disabilities (70, 71), anxiety disorders (72–74), substance abuse (75), and fibromyalgia (76) have been published and all of them supported the efficacy of EEG biofeedback. Unfortunately, these studies all had significant methodological weaknesses that limit the conclusions that can be drawn from them. These weaknesses include: high risk of Type I error due to multiple outcomes and multiple statistical comparisons, small sample sizes, lack of blinded assessments, and lack of adequate controls (including the lack of blinded control groups) (77, 78). Recognizing these methodological flaws the two primary organizations in the field recently assembled a task force on “Methodology and Empirically Supported Treatments” which discussed some of the methodological problems unique to the field of EEG biofeedback (in contrast, for instance, to pharmaceutical research). These authors published a set of standards (79). These recommendations have been echoed by others (80).

With regards to TBI, the published literature is even more sparse. Here, too, all of the published accounts reported positive results. However, the number of articles in the peer-reviewed literature is very small and consists primarily of case reports (81) and case series (82–85) although two prospective trials (86, 87) have recently been published. Moreover, the published reports have almost exclusively involved individuals with mild TBI (88). There have been no published reports on individuals with primarily moderate or severe TBI.

The best designed prospective trial in TBI (89) still shares many of the methodological weaknesses of the studies discussed earlier. In this NIH funded study, 12 subjects with chronic, symptomatic, predominantly mild TBI were randomized into either an active treatment group or a wait-list control group. The treatment consisted of 25 sessions of neurotherapy over 8 weeks. Outcome measures, comprised of symptom rating scales and neuropsychological tests, were administered at baseline, post-treatment, and at three-month follow-up. Once the initial active treatment group finished treatment, the wait-list control underwent the same treatment protocol. At the conclusion of the study, two different types of statistical analyses were performed.

First, the results for the two different groups (active vs control) were compared in a “between-groups”

analysis. Subsequently, the results of all subjects were pooled and their pre- and post-treatment outcomes were compared in a “within-groups” analysis. The analyses revealed that subjects experienced improvement in a variety of different domains (8 out of 26 measures in the between-groups analysis and 18 out of 26 measures in the within-groups analysis). The authors concluded that “taken as a whole, the findings of this study are strong enough to identify Flexyx Neurotherapy System as a promising new treatment for TBI, which merits further evaluation” (89).

Despite the promising results, there are several limitations of this study. These include a very small sample size ( $n=12$ ), heterogeneous sample composition (9 mild and 3 moderate TBI), no mention of issues of subject retention/drop out, lack of a placebo control group, unblinded outcome assessments, no correction for practice effects seen in the neuropsychological measures, and multiple outcomes/statistical testing. The authors of the study recognized many of these weaknesses and correctly point out that many of them are inherent in the exploratory nature of the study. However, they are all issues that any future study must address.

In summary, there is insufficient evidence currently to support the use of EEG biofeedback in the treatment of TBI. However, the evidence of efficacy in other conditions is promising and more studies are clearly warranted. In the meantime, clinicians may choose to discuss this option with their patients, especially when there seem to be no further conventional treatments for relevant applicable symptoms. The relatively low risk and costs associated with EEG biofeedback make EEG biofeedback one of the more attractive options in alternative medicine. However, the clinician should stress the lack of research evidence supporting its use in TBI.

## ENERGY-BASED THERAPIES

Bi-Aura therapy is an energy-based therapy which works to seek out, and remove, energy blockages from within the body and from within the body’s energy field (aura or bio-field). Eastern medicine has long recognized the known energy and energy flow from the body, also known as Ch’I, Qi, and Prana. Bi-Aura therapy is a therapy in which a practitioner mostly through non-touch Bi-Aura techniques removes imbalances in the body’s energy field. These imbalances can occur from trauma, physical and emotional distress, and from physical illness. Bi-Aura therapy seeks to locate energy imbalances, address them, and allow the body to return to health. Bi-Aura therapy can also function to help balance the mental and emotional state of the individual by clearing these bio-field blockages and restoring health. Light therapy, known also as phototherapy, involves the exposure to bright, non-full spectrum light. White light is considered optimal over

narrow band wavelengths or ultraviolet light, both of which have been demonstrated to be toxic to skin and internal organs. It is believed that light therapy has an anti-depressant affect, that it may help balance certain brain chemicals, and that it may help reset proper circadian rhythms within the brain. Light therapy of 2,500 to 10,000 lux is generally considered safe and is considered one of the first lines of therapy for seasonal affective depression (SAD), a transient affective disorder affecting many during the cold and shortened daylight periods found in more northern latitudes, in the winter. The side effects of light therapy include visual disturbances with eyestrain, headaches, or skin irritation being the most common (90–92).

Healing touch therapy is an energy-based therapeutic approach to healing. Healing touch influences the energy system that is life itself. By assessing and treating the energy system, the practitioner helps the patient to self heal. Healing touch begins with the thought that people are naturally healthy, and that physical and emotional stress disturbs the natural energy, thereby causing illness. The goal in Healing touch is to restore wholeness through harmony and balance, through the “centered heart”. It is non-invasive and economical (93). Healing touch is not considered appropriate or safe for acute life-threatening situations.

Reflexology is a type of energy-based therapy that predates the discovery of the new world. Reflexology presumes that there are specific areas in the hands and the feet, reflex points, that correlate to analogous organ systems in the body. Manipulation of these reflex points is believed to promote mental and physical relaxation-relaxation that then promotes healing. Reflexology is used to treat one of nine principle systems, each representing a major organ system, thereby aligning the harmony of the body. The results of reflexology have reportedly been most impressive in treating musculoskeletal disorders. Reiki is an ancient healing method that uses a hands-on approach to manipulate energy flows throughout the body. Reiki means “universal life energy and practitioners believe that there is an energy force in and around one’s body, flowing between the person performing Reiki and the receiver of the treatment. It is thought that Reiki releases your own energy flow and allows your body’s own natural healing ability to work. It is completely non-invasive, and the Reiki practitioner will put his or her hands over the body of the recipient at one of the main energy centers, called chakras. Reiki is occasionally utilized to assist sufferers with chronic pain. Some health professionals believe it may be useful in helping to acutely reduce stress and anxiety, which in effect may help to facilitate the natural healing process.

Massage therapy has a long history with many different types developed over centuries. These vary from light touch to very deep massage. Some forms focus on

specific points or body areas. The many types and subtypes are beyond the scope of this chapter. Like other consumers of massage therapy, individuals with brain injury seek relief of pain and musculoskeletal symptoms using massage. Massage therapy has been successfully used in a number of post-traumatic pain syndromes as well as chronic pain syndromes for patients both with and without brain injury. Massage therapy forms part of most physical therapy interventions for myofascial pain syndrome in conjunction with trigger point injections and stretching (94). Gam et al. (1998) (95) studied the long term effectiveness of massage, exercise, and ultrasound treatments for myofascial pain syndrome using a randomized controlled trial of 67 individuals. They found that exercise and massage, but not ultrasound, resulted in a decreased pain measured by visual analog scale and improved trigger point index scores when followed up six months later. In a survey of individuals with neck or back pain 54% used a complementary health care provider compared to 37% using a conventional provider. Of the 14% choosing massage, 65% found it "very helpful" compared to 27% receiving conventional care (96) (Wolsko 2003). Massage therapy has been shown to be effective in 2 randomized clinical trials as a treatment for chronic low back pain (97). Hernandez-Reif et al. (2001) (98) compared the effectiveness of relaxation therapy to massage therapy in 24 adults with nociceptive back pain of at least 6 months duration or longer. Patients were randomized to either relaxation therapy or 30 minutes of massage twice weekly for 5 weeks. Those individuals receiving massage had less pain, better sleep and higher dopamine and serotonin levels. A meta-analysis of randomized or quasi-randomized research trials for individuals with chronic or subacute low back pain suggests that massage may be effective for pain relief especially when exercise and education are also included in the treatment plan (99). Massage has been applied to temporomandibular joint dysfunction (TMD). In a survey of complementary and alternative therapy (CAM) use by individuals with TMD, CAM with massage was the most frequently used, the most satisfactory and the most helpful (100).

The literature specific to traumatic brain injury is less substantial. Post-traumatic headache has been shown to respond to cervical massage better than cold packs in one prospective clinically controlled study (101). A case report successfully used massage therapy for hypersexuality after traumatic brain injury (102). In other patient populations massage produces relaxation, decreases anxiety and decreases pain (103). Massage was rated highly in survey of spinal cord injury patients for pain control (104). One mechanism of action that could account for better pain control, decreased anxiety, and the induction of relaxation could be increased parasympathetic activity. Parasympathetic activity can be assessed by analysis of heart rate variability. The respiratory sinus arrhythmia

(the mild acceleration and deceleration of heart rate associated with breathing) has a parasympathetic component that can be isolated through analysis of heart rate variability. In a randomized controlled trial evaluating the short term autonomic effects of massage to the back, neck and shoulders on 30 healthy individuals, (105) noted significantly decreased systolic blood pressure and increased parasympathetic activity. Other possible mechanisms producing these effects could be soft tissue mobilization with passive stretching, stimulation of circulation to remove accumulated metabolic products in chronically tense muscles, and the effect of touch itself. In summary, the general literature supports the use of massage to reduce pain and anxiety in patients with post-traumatic pain syndromes such as neck and back pain, temporomandibular dysfunction, and myofascial pain syndrome. There is a smaller quantity of literature supporting its usefulness in other neurologic conditions such as spinal cord injury and stroke. Massage also forms an adjunct to other therapeutic interventions provided by physical therapists, occupational therapists, massage therapists and non-conventional body workers. The literature specific to brain injury is sparse, but for musculoskeletal post-traumatic pain syndromes may be generalized to brain injured individuals.

## CRANIOSACRAL MANIPULATION

William Garner Sutherland, DO, devised craniosacral manipulation, also known as osteopathy in the cranial field, starting in 1939. Craniosacral osteopathy is used by osteopathic physicians (DO), allopathic medical doctors (MD), and dentists who attend research conferences and clinical courses presented by the Sutherland Cranial Teaching Foundation and the Cranial Academy. An extensive research bibliography is available from the Cranial Academy (106). A derivation called CranioSacral Therapy has been developed by John Upledger, DO, for massage therapists and other allied professionals who train at the Upledger Institute. Most CST practitioners are exposed to only a simplified version of the method, and chiropractors practice another variation called SacroOccipital Therapy.

After observing a disarticulated skull, Sutherland noted that bone and suture relationships were "beveled like the gills of a fish, indicating respiration" (107). Because this inherent pulsatile movement begins with embryonic development, well before the neonate's first breath of air, he called this phenomenon the Primary Respiratory Mechanism (PRM). The PRM provides the midline organization of structural and functional development. This impulse can be traced from the embryonic plate to the notochord, continuing in the adult as the oscillations between the lamina terminalis in the skull and the phylum terminale at the base of the spinal cord. In the

same way that one can take a pulse to assess heart rate and count breaths to determine respiratory rate, one can learn to palpate subtle motions of the skull that correlate clinically with central nervous system motility. Research has only recently corroborated the millimeter-scale movements of the cranial vault that Sutherland identified with his hands (108). Even a cadaver's cranial bones move when typical craniosacral pressure is applied (109). Normal physiologic movements of the cranial vault are described as cycles of flexion and extension, occurring approximately six to fourteen cycles per minute. Sutherland called this the Cranial Rhythmic Impulse (CRI). Restrictions and alternations of the CRI include patterns of torsion, strain, and compression involving the craniofacial bones, membranes, and fluids and extending to the sacrum and the rest of the body. Sutherland stated five principles:

- Inherent motility of the brain and spinal cord
- Rhythmic fluctuation of the cerebrospinal fluid
- Motion of dural membranes
- Articular mobility of the cranial bones
- Articular mobility of the sacrum between the pelvic ilia.

Practitioners palpate subtle movements of the cranial vault and other structures to assess the cranial rhythmic impulse and to prompt its balancing. From the standpoint of osteopathic philosophy, return of wholeness to the person is the ultimate goal of this therapy. The physiologic effects of this therapy have yet to be clearly elucidated in the medical literature.

Individuals using craniosacral therapy typically seek relief from pain and functional problems such as balance deficits. There is very limited medical literature on craniosacral therapy and only one study of craniosacral therapy for brain injury. Most of the studies look at inter-rater reliability and reproducibility as well as documenting an abnormal cranial rhythm (110). Greenman et al. (1995) studied the cranial rhythmic impulse in 55 patients with traumatic brain injury as part of their assessment and treatment within an outpatient rehabilitation program. The author notes that cranial osteopathy has been empirically shown to be effective in the treatment of patients with traumatic brain injury. The study documents the cranial impulse slower than average with typically encountered cranial strain patterns noted in 97% of the patients. Three of the patients (5%) seized during treatment. Other unlikely adverse reactions reported include mild headache, exacerbation of vertigo, and visceral symptoms. Due to this seizure risk and adverse reactions, consideration of the practitioner and setting where craniosacral manipulation is performed should include preparedness for these events. Both the positive outcomes and adverse side effects suggest that cranial osteopathy affects the autonomic nervous system. Patients who have participated in

this treatment commonly report profound relaxation suggesting a parasympathetic activation. This was evaluated by Robbins (1996) (111) in a randomized controlled study of 6 normal individuals. Each subject underwent four interventions. The active treatments were cranial osteopathy on the head and cranial osteopathy on the sacrum. The control treatments were no touch and light touch to a different area of the body. The order of treatment and controls was randomized and each subject underwent the whole protocol twice with washout periods between interventions. Cranial therapy at the head, as opposed to treatment at the sacrum, produced significantly higher parasympathetic activity than no touch or light touch. In conclusion, despite patient reports of osteopathic cranial therapy and its variations having effectiveness in post traumatic headache, anxiety, and balance deficits, the paucity and quality of research on craniosacral therapy as reviewed by (112) Green (1999) do not support its effectiveness.

## SPIRITUAL HEALING

Many individuals respond to illness and impairment by turning to prayer and requests for spiritual healing. Rehabilitation by its very nature seeks to motivate the patient and family members to produce the best possible functional outcome. Traumatic brain injury often occurs at a young age leaving people and their social support network with many years of living within a void replacing their previously functional lives. Maintaining hope in spite of this challenges the best of people. Prayer has been a traditional means of keeping a positive, constructive outlook in the face of despair. Prayer has an extensive literature that was reviewed in Larry Dossey's book *Healing Words* (113). In this book the author demonstrates the positive effect of prayerful intention on health across a number of clinical conditions. He notes that prayer is both non-local and not bound by time. Effective prayer may cross great distances or incredible boundaries. The time of prayer may be unrelated to the time of its need by the individual receiving prayer.

Harold Koenig wrote about spirituality and religion as a practical part of patient care (114). In this excellent book he addresses issues that arise when considering discussing patients' spirituality including boundaries, means to begin the discussion, and possible outcomes based on a review of medical literature. Three simple questionnaires discussed and in use today are the FICA spiritual assessment tool (115), the HOPE questionnaire (116), and the ACP Spiritual History (117). These tools can be used as part of the psychosocial history during patient interviews. Collecting this information serves as a means to let the patient know that their beliefs are valued and may strengthen the therapeutic relationship between the

clinician and the patient. If the patient desires, the information is used to refer the patient to the hospital chaplain, a pastoral counselor, a clergy, or another person within their spiritual or religious community. Patients use religion and beliefs to cope with illness. In a review of more than 1200 articles from the 20th century evaluating the association between religion and health, Harold Koenig found that the vast majority of them showed a positive association (118). Medical literature suggests that patients do want to discuss how their spirituality and beliefs play a role in the recovery from illness and relief from impairment (119).

The shaman or community medicine man probably represents the oldest spiritual healing tradition dating back to pre-historic times. Historically the shaman represents a cross-cultural approach to the diagnosis and treatment of illness. This has traditionally been a culturally bound practice. Western contemporary shamanic practitioners may practice without a culturally bound approach. From the practitioner's perspective, the patient with traumatic brain injury who reports an abrupt personality change, a sense of loss or void, and depression suggests a profoundly spiritual component of illness. The practitioner may suggest that the patient had partial soul loss. During the traumatic event, the part of the person's soul fled as a survival mechanism. This would be described as dissociation in psychological terms. Another complaint of depression, loss of personal drive, lack of interest in life, and overall misfortune may be the result of spiritual power loss. The practitioner would approach these spiritual illnesses by attempting to retrieve them and reinstating them to the patient. Individuals with BI who have attempted these spiritual healing approaches have reported return of previous personality, relief of depression, increased sense of life's worth and improved energy level. Herbert Benson (120) proposes that spiritual healing could be a magnification of the placebo effect whereby, because the individual thinks that something will work, it is effective. This may be an appropriate mechanism for those interventions when a person knows something was done to them or for them. It doesn't explain non-local anonymous healing through prayer. Specific spiritual healing techniques besides prayer have little or no voice in the medical literature at present. Spiritual healing addresses the transpersonal element of returning to wellness. Individuals with brain injury commonly express a void in their life. This profound disconnection with the world is addressed through spiritual healing by re-connection to a whole greater than themselves. This affects individuals on a level responding to the questions of what happened to me; why did this happen to me; and does my life have any meaning anymore? By supporting the patient's spiritual and religious beliefs the physician expresses caring and compassion for the patient. In doing so the physician strengthens their relationship to the

patient, opens the door to more effectively motivate the patient and their support system, and allows for healing outside of the medical model.

## ELECTRICAL AND MAGNETIC THERAPIES

The relevance of magnetism to health care is only recently being explored in a scientific manner as demonstrated by the expansion of magnetic resonance imaging technology over the last twenty years. The history of magnetic and electrical therapy dates back into early recorded medical history. Dr. Frank Krusen, in his classic *Physical Medicine and Rehabilitation* (121) notes the medical reference to electrical therapy dated to about 2000 years ago:

Electrotherapy was inaugurated in the reign of the Roman Emperor, Tiberius (14 to 37 CE). Anthero, a freedman, during a walk at the seashore, stepped on a torpedo (an electrified fish) and was thus "freed of gout."

About 50 CE, the physician Scribonius Largus recommended repeated applications of the electric-ray fish for the treatment of headache and neuralgia. In 78 CE, Pedanius Dioscorides recommended shocks from the torpedo fish for intractable headache, a procedure echoed by Galen in 200 CE. Moving away from the fish itself, Aetius in 450 CE recommended that a patient with gout hold a magnet as a treatment. Paracelsus (before 1541 CE) observed that the magnet has "power over the matter of all diseases." It was William Gilbert however who became the father of magnetic therapy, Gilbert published "De Magnete" (Of the Magnet) in 1600 CE and was appointed "chief physician in personal attendance on Queen Elizabeth" the next year. Gilbert also coined the term "electric", derived from the Greek name for amber. Magnets have been used in shoes and wristbands purportedly to help pain. Electromagnetic fields are commonly used to facilitate bone healing in the setting of a non-union, particularly of the tibia or spine. There is also limited research behind advocating magnets for various other medical conditions including wound healing, pain in the limbs, and muscle recovery after exercise (122). Unfortunately numerous claims in the lay literature that magnetism promotes healing are not supported in the available scientific literature to date.

Transcranial magnetic stimulation (TMS) is a widely available, painless and safe technique with a good sensitivity for both corticospinal and corticobulbar tract abnormalities. Owing to the low sensitivity of clinical signs in assessing upper motor neuron (UMN) disorders, there is a need for investigative tools capable of detecting abnormal function of the pyramidal tract. In TMS, an electromagnetic coil is placed on the scalp, high intensity

electrical current is rapidly turned on and off in the coil, through the discharge of capacitors, with the stimulation produced by this discharge of electromagnetic capacitors then causing either an increase or a decrease in the excitability of the affected brain structures. TMS may contribute to the diagnosis of motor neuron disorders by reflecting a UMN dysfunction that is not clinically detectable (123–128).

Electrical stimulation was and is still used on the brain by psychiatrists (Electroconvulsive Therapy, ECT) to treat intractable depression. It has been speculated that the pathophysiology of depression may include synaptic hypoactivity of the left prefrontal cortex (129). Recently, transcranial magnetic stimulation (TMS) has been used to treat depression. TMS has been shown to be effective in double-blind, placebo-controlled trial (130, 131) and it was as effective as ECT in another controlled trial (132).

In 2001, a meta-analysis was performed on 12 published and unpublished sham-controlled studies of left or right prefrontal cortical repetitive transcranial magnetic stimulation (rTMS) in the treatment of depression (133). The study compared the decrease in Hamilton Depression Rating Scale (HDRS) achieved with rTMS and sham stimulation. The authors reported that rTMS was statistically superior to sham stimulation in the treatment of depression, showing a moderate to large effect size. However, the clinical significance of these results was modest and the differences in response to rTMS across studies was not clearly explained (134). A study by Triggs and others at the Human Motor Physiology Laboratory of the University of Florida Health Science Center at Gainesville looked for possible cognitive side effects associated with left prefrontal magnetic stimulation. They measured the effects of left prefrontal rapid TMS on mood, cognition, and motor evoked potential threshold in 10 patients with medication-resistant major depression. In a 2-week open trial of left prefrontal rapid TMS off antidepressant medications, scores on the Hamilton Rating Scale for Depression and the Beck Depression Inventory decreased by 41% and 40%, respectively. After resuming pre-TMS antidepressant medication, improvement in mood was still significant at 1 and 3 months later. In their study, TMS had no adverse effects on neuropsychological performance. Interestingly, TMS treatments were associated with significant decreases in motor evoked potential threshold in the 9 of 10 patients who remained off psychotropic medications during the 2-week treatment period (135).

In addition to its reported effect on mood, TMS has been studied in various types of motor pathology. From Italy, Cantello reported a use of TMS in movement disorders. Diseases for which TMS has been studied include Parkinson's disease, corticobasal degeneration, multiple system atrophy, progressive supranuclear palsy, essential tremor, dystonia, Huntington's chorea, myoclonus, the

ataxias, Tourette's syndrome, restless legs syndrome, Wilson's disease, Rett syndrome, and stiff-person (stiff man) syndrome (136). In a controlled study from Spain, Gironell reported that TMS over the cerebellum is helpful in the treatment of essential tremor (137). From his Neuro Communication Research laboratory in Danbury, Connecticut, Sandyk has used TMS extensively in Parkinson's disease (138). Various aspects of Parkinson's disease were studied with TMS in a series of experiments conducted by Sandyk. All of Sandyk's studies were reported in the journal he established, the *International Journal of Neuroscience*. Sandyk reported improvements with weak electromagnetic fields using TMS in PD patients with speech impairments (139–144). Some would argue that his studies are quite controversial because of their publication in non-refereed journals, the weakness of the employed magnetic fields (in picotesla), generalization from case studies of just one subject or a limited number of subjects, and the lack of any attempt at blinding the patient and observer.

Heldmann reported in 2000 that repetitive Peripheral Magnetic Stimulation (RPMS) is useful in the treatment of sensory/right parietal lobe deficits by helping to overcome tactile extinction (145). Reporting from the Technical University of Munich, Germany, they studied 14 patients with lesions in the right-hemisphere and tactile extinction. Patients were randomly allocated to an experimental or a control group. The experimental group received one single RPMS treatment of the left forearm as well as a condition of attentional cueing known to improve visual extinction. The control group, with comparable tactile extinction scores, neither received RPMS nor verbal cueing. In the experimental group RPMS led to a significant reduction of left-sided extinctions in the recognition of different tactual surfaces, but had no effect on ipsilateral errors. They felt that these results showed that sensory inflow is an important modulatory factor in tactile extinction. Moser and others at the University of Iowa found improvements in cognition—reporting that rTMS improved executive functioning (146). In their study, the cognitive effects of active and sham repetitive transcranial magnetic stimulation (rTMS) were examined in 19 middle-aged and elderly patients with refractory depression. Patients received either active ( $n = 9$ ) or sham ( $n = 10$ ) rTMS targeted at the anterior portion of the left middle frontal gyrus. Patients in the active rTMS group improved significantly on a test of cognitive flexibility and conceptual tracking (Trail Making Test-B). Roth et al. studied rTMS on knowledge acquisition in 20 normal subjects and found no significant difference in a group of normal subjects treated with 25 minutes of high-frequency left dorsolateral prefrontal rTMS compared to a sham untreated group for any memory acquisition. In the area of motor functioning, Fraser et al. at the University Department of Gastroenterology in Salford, United Kingdom, reported

that TMS can improve motor recovery following brain injury and speculated that the mechanism is improved plasticity of the motor cortex (147). They studied a group of acutely dysphagic stroke patients. TMS was used with varying patterns of input. They found that a specific pattern of magnetic stimulation induced the strongest cortical activation (and thus enhanced brain excitability) as measured by functional Magnetic Resonance Imaging (fMRI). This pattern was 5 Hz at 75% of the maximal tolerated intensity for 10 minutes. When this specific pattern of frequency, intensity, and duration of the magnetic stimulus was applied, a greater improvement in swallowing function was seen. This enhanced corticobulbar excitability was increased mainly in the undamaged hemisphere and correlated with recovery.

Others have likewise speculated upon and studied the mechanism of TMS. Conforto reported that TMS speeds central motor conduction time (148). As noted above, one study found that TMS treatments were associated with significant decreases in motor evoked potential threshold (149). Fraser and others wrote that TMS enhances plasticity of the motor cortex (150).

From the Max Planck Institute of Psychiatry in Munich, Keck and others reported that rTMS increases the release of dopamine in the mesolimbic and mesostriatal systems. These authors speculated that this increase in dopaminergic neurotransmission may contribute to the beneficial effects of rTMS in the treatment of affective disorders and Parkinson's disease. From the Montreal Neurological Institute at McGill University, Strafella and others reported that rTMS of the dorsolateral prefrontal cortex, but not the left occipital cortex, in healthy human subjects induces dopamine release in the ipsilateral caudate nucleus (151). They used [(11)C]raclopride and positron emission tomography to measure changes in extracellular dopamine concentration in vivo after repetitive transcranial magnetic stimulation (rTMS). In this study, there were no dopaminergic changes in the putamen, nucleus accumbens, or right caudate.

There is great controversy over the necessary intensity of the magnetic field for clinical effects to be seen. Sandyk uses electromagnetic fields that are so weak that some have questioned their efficacy. For cognitive deficits, he described using two successive transcranial applications, each of 20 minutes duration, with AC pulsed electromagnetic fields of 7.5 picoTesla flux density and frequencies of 5Hz and 7Hz respectively (152). For perceptual deficits, he describes using "AC pulsed electromagnetic fields (EMFs) in the picotesla flux density applied transcranially" (153, 154). For word-fluency deficits, he describes five patients in which he used "electromagnetic fields (EMF) of extremely low intensity (in the picotesla range) and frequency (5–8Hz)" (155). Also using a relatively weak magnetic field, Baker-Price and others studied four subjects with a history of persistent or frequently intermittent

refractory depression following a closed head injury. They applied a "weak" field that was actually 100 times the strength of that used by Sandyk:  $10^{-6}$  vs  $10^{-8}$  to the head of each (156). A one microTesla complex, burst-firing magnetic field was applied to the temporoparietal regions of the head for five 30-minute sessions over five weeks. Their results showed that significant improvement of Beck depression scores, while other emotional and physical parameters did not change. They note that their results "support converging theoretical and empirical evidence that very weak, applied complex magnetic fields whose wave structure and pulse patterns are congruent with groups of neurons within specific regions of brain volume can improve neurocognitive function in human beings." (157) On the other hand, most authors recommend magnetic fields of higher intensity. In most cases, the magnetic field is quite powerful and is in the range of 1–2 Teslas or 10,000 to 20,000 Gauss. This was originally used for brain mapping to test the domains of brain function in the range of 2–3 cycles per second (Hz). More recent machines have used increased frequencies at ranges up to 50 Hz (158). Fraser's study improving dysphagia used 75% maximal tolerated intensity at 5 Hz for 10 min (159).

Since the general technology for magnetic stimulation may not be patented, several companies exist that fabricate the devices. Each has their own patents on their particular coils. Two of the largest include; *Neuronetics*, *magstim.com*, *www.neuronetics.com*, *www.magtim.com* Richards and others noted "there are EM effects on biology that are potentially both harmful and beneficial." (160) Certainly this is true, yet there have been few reported complications with TMS. A literature review revealed one study which reported one case of a "pseudoabsence seizure" (161). As mentioned above, one study specifically looking for complications found TMS had no adverse effects on neuropsychological performance (162). Regarding strength of the electromagnetic field, the FDA had ruled that a limit of 80% of the level, which would cause neuron depolarization, was the maximum levels considered safe for application. It has been suggested that the frequency and variation of the field is more important than its strength. This is an issue that needs to be addressed with further research.

TMS is a new frontier in brain injury and the efficacy remains controversial even in psychiatry (163) and Parkinson's disease—where it has most frequently been studied. Yet reports of its possible effectiveness with low morbidity are encouraging. Patients with brain injury certainly have many of the problems for which TMS has been purported to work: depression, movement disorders, tremor, and parietal lobe syndrome. Nevertheless the high power magnets are expensive and the procedure is a not yet a covered Medicare service, also the technology is not yet widely available. It remains to be seen whether what

appears to be promising technology will be proven to be useful in brain injury.

Functional electrical stimulation (FES), sometimes referred to as functional neuromuscular stimulation (FNS) or neuromuscular stimulation (NMS), has both therapeutic and functional purposes, but excludes use in sensory systems. FES is used to stimulate nerves which innervate specific muscle groups to produce an effect similar to muscles in voluntary exercise. The clinical applications of FES in rehabilitation include muscle strengthening, improved range of motion, facilitation and re-education of voluntary motor function in orthotic training, and, inhibition of spasticity. It is believed that there are no absolute contraindications for FES though relative contraindications include individuals with cardiac arrhythmias, pregnancy, wounds that are healing (as stimulating muscle directly under healing tissues may be contraindicated), electrode sensitivity, or congestive heart failure. Occasionally these devices are implanted in the body to provide long-lasting effects, usually with electrodes at, or near, the spinal cord itself. FES is known to benefit paralysis of spasticity (UMN disorders) and is known to improve de-conditioned cardiovascular patients, and can function to facilitate improved limb movement. Neurogenic bowel and bladder have been shown to benefit from FES, as has sexual dysfunction, resulting from spinal cord injury, stroke, MS or closed head injury.

Transcutaneous electrical nerve stimulation (TENS) is a therapy that utilizes electrical current, usually direct current, delivered through electrodes which have been placed on the skin. TENS is used for pain relief, electrical stimulation of the nerves has been shown to encourage the body to produce endorphins, which function to block the perception of pain, both centrally and peripherally. TENS is performed with a battery powered device, attached to two or four electrodes by small gauge insulated wires, that then conduct the electrical current from the TENS unit to the area of pain. The placement is frequently in a rectangle, surrounding the painful area and the current generated by the device creates a circuit of electrical impulses that, travel along the nerve fibers, reducing pain. The machine can be set for various wavelengths, and frequencies. The individual's physical therapist or physician usually determines the settings. Used most often to treat muscle, joint and bone problems occurring with neuromuscular or musculoskeletal problems, TENS is often utilized for acute or chronic pain including low back pain, neck pain, tendonitis, or bursitis. Though considered generally safe, the machine could cause harm if misused, so TENS use is currently restricted to application only after physician prescription.

Cranial electrical stimulation (CES) is an experimental and an investigational therapy used for the treatment of neuropsychological disorders. CES uses microcurrent, pulsed high frequency carrier waves (15,000 Hz) in

a modulating action at low current levels to re-establish optimal neurotransmitter levels and functioning within the injured brain. The foundation of CES therapy is conversion of amino acids to neurotransmitters, improving the quality of neurotransmission (164). Its particular mode of functioning is as a corrective measure for brain dysrhythmia. After placement of electrode clips on each earlobe, the microcurrent pulses are thought to reach the brain via a perineuronal or vascular pathway, coursing via the auditory meatus to the thalamus, the primary center of activity. This cell membrane interaction occurs in a manner which then produces modifications in information transduction (physical energy conversion into nervous signal energy), as is associated with classical second messenger pathways, calcium channels and cyclic AMP (cAMP). Depression and anxiety have been shown to improve with CES use, as have hypertension and headaches. CES works in potentiating the effects of centrally-mediated analgesic drugs like fentanyl, morphine, and dextromoramide, thus aiding in chronic and cancer pain therapy. Neuroepileptic medication use in individuals with BI is decreased with CES therapies and the effects of general brain dysfunction and mood change subsequent to closed head injury appear responsive to CES (165). CES treatments are applied in the early hours, after awakening from sleep, avoiding use within three hours of scheduled sleep, to avoid a stimulative effect. Generally, CES is well tolerated, with no negative effects or major contraindications found for the use of CES, either in the US or in Europe. Rare paradoxical events occur, such as hyperexcitement, though this is unusual.

Electro-crystal therapy is a form of electrical therapy which involves the pulsing of electrical signals, through mineral crystals, in order to greatly amplify the crystals' inherent power. Crystal therapy works with the energy of specific crystals to clear blockages, both in the physical and auric bodies. This therapy uses resonance (one vibrating substance affecting the vibration in another vibrating substance) to re-establish balance in the ill or injured body, thus allowing the body the optimum opportunity of self-healing. Reportedly, after a crystal therapy session by a qualified crystal therapist, a great sense of relaxation and well-being is produced. A session alleviates tension and stress, bringing relief on the mental, emotional and physical plane. A tube of special crystals is placed over the area to be treated; then, the healing qualities of the specific crystals are magnified thousands of times by electrical signals passing through them. Electro-crystal therapy is believed to be beneficial in the treatment of stress and anxiety, headaches, musculoskeletal pain, spine pain, and chronic fatigue syndrome. There are no reported contraindications for the use of electro-crystal therapy and no reported adverse side effects are known.

Electro-homeopathy works according to the belief that there are two vital fluids present in the human body,

the lymph system and the blood system. Practitioners believe that any blockages in either of those two systems causes disease and illness. It is believed then that electro-homeopathic medicines can regulate this lymph and blood problem, thereby assisting healing.

### ALTERNATIVE MOVEMENT THERAPIES

The Alexander technique and Feldenkrais method are two popular contemporary alternative movement therapies used by individuals with BI. Both techniques are active treatment programs usually learned from a certified practitioner and performed by the patient. Both focus on awareness of movement and the person's inner emotional state associated with it. Frederic Matthias Alexander was a 19<sup>th</sup> century actor who lost his voice and developed his technique in response to observing how his uncoordinated movements and posture led to his voice loss. Alexander therapy consists of evaluating how common functional activities such as sitting, standing, and walking have muscular tension associated with them and then learning how to avoid triggering the muscular tension with the old pattern of movement. Attention initially focuses the individual's inner sense of movement and then progresses to shifting that sense to discover the release of tension with awareness of proper posture. By inhibiting those postural elements leading to tension the participant is able to recover greater fluidity of movement. No references were identified in a review of the medical literature specific to the application of Alexander technique to brain injury survivors. A randomized controlled clinical trial compared the Alexander technique, massage and no intervention on disability, depression, and attitude toward self, for patients with Parkinson's disease (166). The study showed statistically significant improvement in all three categories only in those patients treated with the Alexander technique.

Moshe Feldenkrais, a physicist, initially developed the Feldenkrais method based on his personal experience with severe knee injury. The therapy has evolved to a series of mat exercises and some touch-guided movement that together raise the awareness of the patient to their own movement patterns. Unlike traditional physical therapy techniques that desire a specific movement pattern as the outcome and train the patient toward the desired pattern, Feldenkrais's method seeks to support change through the deepest inner sense of the client's actual movement. A review of the medical literature did not provide any references specific to the application of the Feldenkrais method to brain injury survivors. The Feldenkrais method was compared to sham intervention for patients with multiple sclerosis using a crossover study design (167). Hand dexterity, anxiety, depression, self-efficacy, multiple sclerosis symptoms, performance, and

perceived stress were measured. The Feldenkrais method significantly decreased perceived stress and anxiety, but did not improve self reported function or dexterity. Both the Alexander technique and the Feldenkrais method use awareness based learning rather than repetitive physical exercise. They seek to produce more fluid movement and more choices in movement with greater conscious awareness of the potential outcomes for chosen movement patterns. Traumatic brain injury patients using these therapies report a greater sense of comfort during activity, more solidity in their standing and walking, and fewer complaints related to their neurologic compromise such as vestibular hyper-reactivity and paresis. Based on the types of interventions and exercises applied, the mechanism could be postulated to result from greater body awareness of posture and movement. Through this awareness the individual may inhibit muscular tension, poor posture, and gait disturbances. A review of the medical literature provides no documented effectiveness in brain injury, but a limited literature shows some success in application to other neurologic conditions

### HYPERBARIC OXYGEN THERAPY

Hyperbaric oxygen therapy (HBOT) is an established medical therapy for certain conditions and is increasingly being advocated for the treatment of neurological disorders such as cerebral palsy, multiple sclerosis, stroke, and traumatic brain injury (168). HBOT delivers 100% oxygen under pressure, which increases the amount of oxygen dissolved in the blood, thereby increasing the oxygen delivered to the body's tissues. HBOT may also enhance the formation of new blood vessels, decrease inflammation, and increase the volume of blood flow (168, 169).

Treatment sessions occur inside a sealed, pressurized space known as a hyperbaric chamber. The oxygen is delivered either by mask or directly into the chamber. The pressures used are expressed in units of atmospheric pressure and commonly range from 1.5 to 3 atmospheres. The sessions, often referred to as "dives", usually last from 30 to 90 minutes. Many practitioners recommend an average of 100 sessions (range 80–150) for the treatment of chronic, severe BI (168). Because the cost ranges from approximately \$200- \$400 a session, the total estimated cost of a full course of treatment is approximately twenty five thousand dollars. This amount is never covered by Medicare and rarely by commercial insurance. More the treatment of TBI is not recognized as an conceptual indication for HBOT.

Adverse events can be significant and are related to either the increased pressure or the high concentration of oxygen and include the possibility of seizures, pulmonary injury, and otic trauma. The incidence of seizures is thought to be about 1–2% in the non-neurological

population and is related to the duration of treatment as well as the pressures utilized (170). Pulmonary injury includes aspiration, infiltrates, or direct barotrauma and has a reported incidence of 10% to 30% (170). Otic complications such as pain or rupture of the tympanic membrane have an incidence of 5% to 10% (170) but may be prevented by temporary myringotomies. Additionally there is concern that a prolonged course of HBOT may result in subtle, long-term neurological deficits, although this has not been established (170).

Although the FDA regulates the hyperbaric chambers themselves as medical devices, there are no mandated national or local standards for the staffing or training of personnel. Even less regulation governs free-standing facilities because they are not covered under the regulations for hospitals. These issues are partially being addressed by a recent program of voluntary accreditation administered through the Undersea and Hyperbaric Medical Society. Treatment with HBOT requires a prescription from a physician. However, prescribing HBOT for the treatment of BI would be considered an "off-label" use, since BI, stroke, multiple sclerosis, and cerebral palsy are not FDA approved indications for HBOT. In fact, there are only thirteen FDA approved indications for HBOT among them carbon monoxide poisoning, air embolism, selected wounds, and decompression sickness.

Although many of these conditions are seen treated as HBOT for over 50 years, the use of HBOT has recently become even more common. There are over 500 HBOT centers currently operating in the United States. In addition, there is a major professional organization devoted to HBOT is the Undersea and Hyperbaric Medicine Society, which also publishes "Undersea and Hyperbaric Medicine". This organization, founded in 1967, now has over 2500 members. Board certification is offered by passing a subspecialty examination offered by the American Board of Preventive Medicine. Finally, there are two main textbooks in the field (168, 169). However, these organizations and publications focus almost exclusively on the accepted indications for HBOT and infrequently address the use of HBOT in the treatment of neurological conditions such as brain injury (BI).

The evidence for the efficacy of HBOT in the treatment of TBI, strokes, and cerebral palsy was extensively reviewed recently by the Agency for Healthcare Research and Quality (AHRQ) (170). The most authors of this report also published a separate review specifically addressing the evidence in TBI (171). The conclusions of these reviews were endorsed by the Undersea and Hyperbaric Medicine Society which also conducted their own review of the role of HBOT in the treatment of multiple sclerosis (172). In addition, a review of HBOT as a treatment for BI and stroke was also separately completed by an agency of the government of British Columbia (180). Finally, the Cochrane Database of Systematic Reviews

recently published their own reviews of the HBOT in TBI (174). All together, these reviews evaluated over one hundred papers that met their inclusion criteria.

In general, all of these reviews found that there was little evidence for the efficacy of HBOT for the conditions reviewed. In addition to TBI, the AHRQ report reviewed the role of HBOT in both stroke and cerebral palsy. For both these conditions, there were observational and uncontrolled studies that reported a significant benefit from HBOT. However, there were very few controlled trials (four in stroke and one in cerebral palsy) and none of them were rated better than "fair" by the AHRQ (on a scale of poor, fair, and good). Moreover, none of these trials demonstrated any benefit of HBOT treatment. Despite this, given the methodological limitations of the trials, the report concluded only that there was currently insufficient evidence of efficacy in these conditions (as opposed to evidence of lack of efficacy). The report by the agency of the provincial government of British Columbia reached a similar conclusion. The situation in multiple sclerosis is different to the extent that there have been many more controlled trials in this population (ten) and, with one exception, none demonstrated a benefit for HBOT treatment. Given the weight of the evidence, the review by the Undersea and Hyperbaric Society concluded that HBOT did not appear to be an effective treatment for multiple sclerosis (although they acknowledged that there may be subsets of patients who might benefit, especially with longer treatment periods).

In TBI, there has been only one controlled study in the past twenty five years (175). This trial was in the acute care setting and involved 168 severely brain injured patients randomized to receive either HBOT or standard treatment. The treatments, begun within 24 hours of injury, were 60 minutes in length and at 1.5 atmospheres. They were administered every 8 hours for two weeks or until the patient was either brain dead or could follow simple commands. On average, patients received 21 treatments. After one year, patients who received HBOT treatment had an almost 50% reduction in mortality (17% vs 31%). However, the proportion of those who were dead or severely disabled was unchanged (approximately 50% in each group). Thus, although mortality decreased, the rate of a favorable outcome was unchanged. This study was rated as "fair" by the AHRQ. The only other controlled trial, also in the acute care setting (176) was conducted in 1976. Unlike the later study, it did not find any statistically significant difference between the HBOT and control groups (although there was a trend towards better outcomes in the treatment group). This study was also rated as "fair" by the AHRQ task force. Unfortunately, it is difficult to apply the findings because the study was conducted when the care for TBI was substantially different than it is now.

There were also two uncontrolled acute care trials that reported on clinical endpoints (177, 178). Both

reported benefits to HBOT treatment; however, both had serious methodological flaws and were rated as “poor” quality by the task force. The remainder of the studies in acute TBI was all observational studies or case reports. Although promising, most of these studies used intermediate endpoints such as cerebral blood flow, cerebral metabolism, CSF biochemistry, and intracranial pressure (179–184) thereby limiting their clinical applicability.

In chronic TBI, there have been no HBOT trials in the past twenty years. In fact, there are only three case reports and two case series (excluding abstracts or conference proceedings) (185–189). One case series reported a benefit for HBOT but reported only on intermediate outcomes (e.g. measures of cerebral metabolism) (185). The other case series found in evidence of clinical benefit in chronic TBI (186). Of the case reports, one reported a benefit to HBOT treatment but involved a patient only 6 weeks post-injury, thus making it difficult to separate out the effects of natural recovery (187). Another case report involved a patient approximately six months after BI and reported a benefit to HBOT treatment. However, the patient was also receiving rehabilitative intervention, thus making it difficult to separate the contributions of HBOT treatment from that of rehabilitation and natural recovery (188). Finally, one case report noted no benefit of HBOT treatment, but the focus was only on measures of gait and postural stability (189).

The previously published reviews (170–171) agree that there is insufficient evidence to recommend the use of HBOT for the treatment of BI. The Undersea and Hyperbaric Medical Society released a position paper on the use of HBOT for chronic brain injury, traumatic and non-traumatic. This paper concluded that “the weight of the currently available scientific literature is not felt to support an endorsement of HBOT for chronic brain injury” (172). Likewise, the evidence based review by the government of British Columbia also concluded that “the scientific literature as reviewed up until August 2001 does not support the use of hyperbaric oxygen in the treatment of head injury or stroke” (173). This is in accord with the findings of the AHRQ. In the summary, there is little evidence currently to support the use of HBOT as a treatment for chronic BI, the evidence of benefit in acute BI is more formidably but too there clinical evidence. This situation marked accordingly patients about the use of HBOT more difficult. Indeed, BI clinicians may be facing a difficult dilemma as consumer demand for HBOT increases in the BI community. This increase in demand may be fueled by several different trends including the general population’s interest in alternative treatments, the continued lack of many effective treatments for chronic BI, and the aggressive marketing by many HBOT facilities. The fact that most families will have to pay for the treatments themselves (due to lack of coverage of HBOT for BI) further underscores the importance of advising patients and families appropriately. Recently,

guidelines have been developed to help clinicians better address the ethical dilemmas this situation raises (190). In addition to supporting the evidence-based guidelines reviewed here, the authors also emphasize the importance of continued research to establish definitively the role of HBOT in the treatment of BI. Until definitive research is conducted, the authors recommend a full discussion with patients and families regarding the current lack of evidence of benefit as well as the risks involved, including the substantial financial commitment involved.

The use of CAM techniques to treat common associated sequelae of brain injury remains controversial. There is a lack of evidence to date supporting the safety and effectiveness of many CAM interventions. Nevertheless we may anticipate that brain injury survivors and their families will continue to seek CAM interventions to treat the multitude of symptomatic sequelae of brain injury, particularly where conventional medical practices may fail to provide effective relief. While the majority of CAM interventions are relatively safe the risk associated with and potential adverse effects of drug interactions and certain CAM interventions such as HBOT and some electrical therapies can be significant. With the expanding research focus on CAM interventions we anticipate further elucidation of the benefits and risks of CAM interventions and the incorporation of evidence-based CAM into conventional medical practices. It is important for physicians to recognize that their patients may pursue CAM interventions and that knowledge of the potential benefits and risk is essential in order to provide patients with the information they need for effective and safe use of CAM practices within Western health care systems.

## Community Re-entry Issues and Long-Term Care

*Sally Kneipp  
Allen Rubin*

### **THE NEED FOR COMMUNITY RE-ENTRY SERVICES AND LONG-TERM CARE**

A little more than two decades ago, following the creation of the National Head Injury Foundation in Framingham, Massachusetts (now the Brain Injury Association of America), post-acute services for persons with traumatic brain injury (TBI) began to develop, slowly at first and then at an increasingly rapid rate. Family members of individuals with traumatic brain injury and interested professionals first met informally, and later through formal associations, to identify the needs and potential service delivery systems for persons in the post-acute phases of recovery, including those with long-term needs. As more individuals with traumatic brain injury were discharged to community settings, efforts were made to design programs that would meet their short- and long-term needs. The diverse post-acute needs of persons with traumatic brain injury and the differing abilities of families to provide the support needed by individuals with traumatic brain injury over the long-term, resulted in a burgeoning of post-acute programs.

The Commission on Accreditation of Rehabilitation Facilities (CARF) established standards for brain injury programs, with growing recognition of the post-acute service delivery options in community settings. Managed care initiatives by insurance companies resulted in significant reductions in the length of stay in hospitals and

facilities, resulting in much earlier discharges to post-acute programs (or to no additional treatment). Additionally, the 1979 Report of the United States General Accounting Office had emphasized the need for a redistribution in state and federal funds for persons with disabilities in institutionally-based programs (particularly, nursing homes) to services at home and in the community. In 1981, Medicaid Waiver Programs were initiated to reduce the cost of nursing home care and to foster more community-based services. By 1997, more than 500,000 persons with disabilities were reported to be receiving services through state Medicaid Waiver Programs. Twelve separate waiver programs had been established for persons with traumatic brain injury, and those states were serving 3,000 people in that category. Cusick, Gerhart, Mellick, et al. (1) reported that, among the Medicaid Waiver Programs, the expenditures were the smallest for the traumatic brain injury diagnostic group overall, but the amount spent on services per participant was greatest for that group because of the long-term sequelae of traumatic brain injury and the individuals' complex needs.

Venzie, Felicetti, and Cerra-Tyl (2) emphasized that, although legislative initiatives and managed care directives have been responsible in large part for the trend to more community-based programs, there has also been growing awareness of the clinical advantages of providing treatment in real-world settings. They discussed challenges

inherent in, and recommendations for, the establishment of community integrative brain injury programs.

Post-acute programs whose purpose was to facilitate the individual's return to the community were variously referred to as community-based, community re-entry, community integration, community reintegration, community integrative, and community-integrated programs. For example, in the CARF medical rehabilitation standards (3), there are several accreditation categories that may address community re-entry issues and long-term care, the focus of this chapter. They include the brain injury outpatient rehabilitation programs, brain injury home- and community-based programs, brain injury residential rehabilitation programs, brain injury long-term residential services, and brain injury vocational services. There are many providers who have not sought CARF accreditation but have well-established programs to address community re-entry and long-term needs. (Most of the administrators of those programs have stated that, while they acknowledge the importance and value of accreditation, their budgets are inadequate to cover the direct and indirect costs associated with the accreditation process.)

The differences in terminology used to describe these programs has led to some confusion about their scope and purpose, particularly on the part of individuals seeking services, family members investigating services, and payers who are exploring options for cost-effective services. Given the extensive treatment and care provided to persons with traumatic brain injury by emergency medical personnel, and multidisciplinary professionals in a variety of acute care, acute and other post-acute rehabilitation settings, many third-party payers have asked why such a broad spectrum of post-acute programs is necessary at the point of community re-entry if earlier treatment was effective, and why such services are necessary for such long periods of time (frequently, for many years or lifelong). *Enabling America: Assessing the Role of Rehabilitation Science and Engineering*, the 1997 report of the Institute of Medicine established by the United States Congress to evaluate existing rehabilitation models (4), pertains to all disabilities and is not intended to be specific to traumatic brain injury. Nonetheless, the conclusions and recommendations of the report have particular relevance to persons with traumatic brain injury at the point of community re-entry and address the need for services at this point.

The 1997 Institute of Medicine report refers to the disability model proposed by Saad Nagi in the 1950s and refined in the 1991 Institute of Medicine report, *Disability in America*. Dr. Nagi's conceptualization of the disabling process included four components: pathology, impairment, functional limitation, and disability. Further refinement of this model appeared in the 1997 Institute of Medicine report. This differentiated model of pathology, impairment, functional limitation, and disability was

revised to illustrate how biological, environmental (physical and social), and lifestyle/behavioral factors are involved in reversing the disabling process (i.e., rehabilitation, or the enabling process). The modified Institute of Medicine model presented the possibility of "no disabling condition," even in the presence of pathology, impairment, and functional limitation. The point made was that disability is not inherent in the individual; it can only be understood in relation to the interaction between an individual and his/her environment. It is precisely the challenge of achieving meaningful interaction with the environment that results in the need of individuals with traumatic brain injury for treatment to address community re-entry issues and long-term needs.

This point was underscored in 1998, when the National Institutes of Health (NIH) convened a consensus development conference on rehabilitation of persons with traumatic brain injury. The conference was followed by a press release and then a *NIH Consensus Statement* (5). As stated, the objective of the *NIH Consensus Statement* was to provide information on the findings of the conference to the biomedical research and clinical practice communities including, but not limited to, physicians representing many medical specialties, and psychologists. The Introduction of the *NIH Consensus Statement* emphasized that the greatest negative consequences following a traumatic brain injury are related to the individual's post-injury cognitive abilities and behavioral and emotional issues (rather than their physical impairments), since they compromise interpersonal relationships and impede participation in major life activities such as school and work.

Treatments mentioned for the cognitive, behavioral and emotional sequelae included cognitive rehabilitation therapy, assistive technology, psychotherapy, psychopharmacologic management, and manipulation of the environment to provide an optimal context for recovery and/or rehabilitation to occur. It was pointed out that treatments are provided in a wide range of settings, from rehabilitation hospitals to the home or community at large.

The significance of the consensus conference was that the conclusions were inclusive of the input of persons with traumatic brain injury, their family members, and nonmedical specialists in addition to medical specialists. The statement reflected the opinions of many persons associated with post-acute programs who had come to appreciate the importance, for positive outcomes to occur, of including many sources of input into the rehabilitation process. Some of the conclusions of the consensus conference relevant to this chapter were that:

1. the consequences of traumatic brain injury can be lifelong, even in cases of mild traumatic brain injury;
2. individually-tailored rehabilitation services should be modified to assure relevance as one's needs change over time;

3. extended care and rehabilitation for persons with traumatic brain injury should include community-based nonmedical services;
4. supportive services (e.g., respite care, counseling and in-home assistance) should be available to family members and significant others of individuals with traumatic brain injury;
5. modification of the individual's home, school, and work environments may be necessary to allow for increased participation in daily living;
6. the input of persons with traumatic brain injury, their family members, and significant others should be regarded as essential to the development and implementation of the rehabilitation program for each individual; and
7. consideration should be given to the timing of specific interventions, since the probability of a beneficial effect may be greater at some points in the rehabilitation process than at others. Moreover, recent investigation of the effects of aging following traumatic brain injury suggests the need for a service delivery system and specific treatments that can be provided when new clinical issues arise or become more pronounced as people age.

### Program Design and Treatment Models

While some post-acute programs continue to base their treatment on a multidisciplinary model, treatment based on an interdisciplinary model has been the norm over the past decade, with a growing number of post-acute programs designing treatment using a transdisciplinary approach. From a conceptual standpoint, treatment using an interdisciplinary or transdisciplinary model is particularly relevant and appropriate at the point of community re-entry, and long-term, since the most pressing need at this time is for the individual to be able to integrate the knowledge and skills acquired or re-acquired during earlier phases of his/her rehabilitation. Additionally, treatment must be designed with relevance to the unique characteristics of the environment in which the individual will live and function. Depending on the intermittent or chronic needs of the individual, treatment may be provided by a team of rehabilitation practitioners or by a single-service provider. The individualized nature of rehabilitation treatment is more evident at the community re-entry stage of the rehabilitation process than at any other time. The value of a holistic treatment approach in maximizing potential outcomes has also been recognized.

Malec and Basford (6) summarized the state of the art in post-acute brain injury rehabilitation programs in the mid-1990s. While acknowledging limitations of the study from a research design standpoint, the authors provided a categorization of types of post-acute programs and presented a model of brain injury rehabilitation. This

model, identified as an algorithm of level of rehabilitation care after traumatic brain injury, also appeared in a subsequent publication in 2003 (7). However, of concern is the component in the model designated "No services, or community-based services only." Particularly in the past decade, there has been growing awareness of the effectiveness of community-based services offered in the home and community (of the individual with traumatic brain injury), that are goal-oriented and ecologically valid treatment options. They are on a par with the other categories of the model (i.e., outpatient community re-entry, comprehensive/holistic day treatment, residential community reintegration and neurobehavioral) and should be clearly distinguished from "no services."

In describing the contributions of postacute neurorehabilitation to a national information system, Evans (8) explained that postacute providers frequently regarded the environment of the individual with TBI (i.e., the individual's home and where he/she spends time, such as in school, at the workplace, in the community at large) to be an extension of the treatment setting. Understanding the characteristics and dynamics of the individual's "world" was considered to be essential to the development of treatment approaches of optimal value. In these naturalistic settings, the concept of the treatment team was enlarged to include persons such as the individual's family members, teachers, employer, neighbors, etc. A shared information system is advocated as a means of facilitating the delivery of beneficial services and cost-effective outcomes.

In their article on the development of systems of care for persons with TBI over the past 20 years, Cope, Mayer and Cervelli (9) point out that the conceptualization of a comprehensive system of care now includes therapy and supported living in one's natural environment, perhaps throughout the individual's life. They identify cognitive and behavioral impairments as the focus of comprehensive therapy at this stage and acknowledge the benefits of treatment protocols delivered in the home and community of the individual with TBI to develop his or her ability to carry out activities of daily living and increase social opportunities. They recognize the use of a person-centered context to assist individuals to attain their life goals, and the value of community-based interventions such as "clubhouses" and peer support in improving long-term outcomes. They also recognize the role of psychopharmacologic and neuropharmacologic interventions.

Community re-entry and long-term needs must be addressed if an individual with traumatic brain injury is to achieve a satisfactory quality of life through purposeful, productive activity. Berube (10) explained that The Brain Injury Act, as amended in 2000, mandates exploration of interventions that will facilitate school and work re-entry and reintegration in the community. However, the process of meeting these needs is complicated by the

extremely heterogeneous nature of traumatic brain injury, the prominent role of cognitive and psychosocial deficits in eventual rehabilitation outcome, and the fact that a traumatic brain injury in any family member will impact on the family system and others who relate to that individual to any degree.

When determining the optimal treatment program to address the community re-entry and/or long-term needs of an individual following TBI, the most fundamental question is whether a residential or non-residential brain injury program is indicated. In making this decision, an analysis of the individual's home environment and family system must be made, to assure the likelihood that the environment will be able to reinforce the goals of the therapy program and that the level of any supervision needed will be sufficient to assure the individual's safety. Within the scope of residential programs, a wide range of options is available to address the individual's short- and long-term needs. The spectrum of options may range from intense, highly-structured clinical protocols with 1:1 staff/client ratios for individuals with significant behavioral problems to comprehensive transitional living programs to prepare individuals for independent living, or supported living programs offering considerable flexibility, much less structure and only periodic check-ins by staff. Persons with brain injury who also have pre- or post-injury histories of alcohol or drug abuse may require residential treatment in a program designed specially to address those needs, with services provided by staff with particular expertise in substance abuse. Within the comprehensive program, there is typically flexibility to move the individual from one clinical program to the other, as may be needed. Although the services may be designed along a continuum, from the most intensive to least intensive therapeutic support, the reality is that rehabilitation following brain injury is not always linear and various treatment protocols may need to be tried.

Non-residential programs at the community re-entry or long-term stage may also offer an array of options (from comprehensive day programs offering such services as occupational therapy, physical therapy, speech therapy, psychotherapy, cognitive rehabilitation therapy, vocational services, recreational therapy, etc.) to very individualized, goal-directed programs carried out in the individual's milieu (i.e., home and community). These therapy programs have a rehabilitation focus and are different in purpose from home health programs, although home health services may also be indicated for some individuals due to needs for physical assistance with self-care and activities of daily living and/or the need for supervision due to cognitive-communication, behavioral and/or emotional issues.

Because of the highly heterogeneous nature of traumatic brain injury, there must be an array of treatment options available to address community re-entry and

long-term needs. The state-federal vocational rehabilitation program, operated in accordance with a state plan, is a frequent resource for persons wishing to return to work. [Note: Employability and placeability are major concerns of persons with traumatic brain injury and their families; for more information on vocational issues, please refer to Chapter 61 in this book.] Incentives in relation to employment are available to persons receiving Social Security Disability Insurance (SSDI) and Supplemental Security Income (SSI) because of a disability or blindness. According to a home page of the Social Security Administration (SSA), *The Work Site* (11), the Ticket to Work and Work Incentives Improvement Act of 1999 led to the awarding of 119 cooperative agreements to community organizations to establish Benefits Planning, Assistance, and Outreach (BPAO) projects. The goal is to assist persons receiving SSDI or SSI to make informed decisions about working. Social Security Online also makes available, through its electronic booklet, "The Ticket to Work and Self-Sufficiency Program," answers to questions asked frequently by participants in this new SSA program (12).

The Brain Injury Association of America (BIAA) and its state affiliates offer an extensive array of services to persons with brain injuries, their family members, professionals and the community at large. Of particular value have been the support groups (normally held once a month at various locations), family support services and mentoring projects, and the *National Directory of Brain Injury Rehabilitation Services* (13).

### **Efficacy of Community-Based Programs**

While the growth of community-based programs has been substantial, demonstrating the efficacy of such programs has been exceedingly difficult. Minnes, Carlson, McColls, et al. (14) acknowledged that community integration is an often-used outcome measure in rehabilitation research and underscored that is understandable since the aim of rehabilitation is to remove barriers to individuals' participation in daily living. They studied the relationship between community integration and salient variables that included impairment, activity, participation, quality of life, paid support and informal support. Their findings revealed the complexity of community integration and the difficulty of measuring it. They emphasized the importance of clearly defining community integration in research projects and recommended the use of subjective as well as objective measures. They also discussed the methodological difficulty of using questionnaires with research participants who have cognitive impairments and recommended that survey items be read aloud to the participants and that, with permission, collateral informants (e.g., family members) be present to increase the probability of accurate responses.

Goranson, Graves, Allison, and La Freniere (15) emphasized that the demand for accountability by payers is resulting in closer examination of the cost-effectiveness of traumatic brain injury programs offering cognitive rehabilitation therapy. They point out that functional outcomes and life satisfaction should be improved as a result of therapy to improve cognitive abilities and coping skills, but that it is difficult to establish the efficacy of such programs because of problems developing a suitable research methodology, the non-comparability of the outcome measures (given the heterogeneity of the population and the individualized treatment plans), and lack of a multidimensional analysis.

Dawson, Levine, Schwartz, and Stuss (16) acknowledged the extreme variance in outcomes and emphasized the importance of predicting real-world outcomes when establishing clinical goals. They advocated for more specific predictors of recovery (such as attention and memory and other salient variables such as coping style) rather than injury severity, and the need to find out if better long-term outcomes would be achieved by addressing process-specific variables (e.g., pre-injury personality characteristics) during the acute phase.

The difficulty conducting research with experimental or even quasi-experimental research designs during the community re-entry phase of rehabilitation has led to a limited amount of data demonstrating the efficacy of community re-entry programs. As a result, some third-party payers have denied funding for needed services on the basis that there is insufficient empirical evidence of the cost-effectiveness of the treatment. This is particularly true in relation to cognitive rehabilitation therapy, which has been a standard component of most brain injury rehabilitation programs, including community re-entry programs, for over two decades. In denying funding for cognitive rehabilitation therapy, some payers have described it as “investigative,” “experimental” or “educational,” failing to realize that addressing neurocognitive deficits is crucial to maximizing functional recovery following brain injury.

### **Treatment in Real-life Contexts**

Cicerone, Dahlberg, Kalmar, et al. (17) pointed out that, even following moderate or good recovery neurologically, one’s quality of life following traumatic brain injury may be severely compromised because of persistent cognitive deficits and maladaptive behavior. The real-life context for any given individual following traumatic brain injury must be taken into account in order to achieve a satisfactory interface between the individual and his/her environment. Cicerone and Tupper (18) emphasized that the goal of rehabilitation after brain injury must be improvement in the ability to function in real life (not just in a therapy setting) and requires learning new ways to perform daily activities in a variety of contexts. However, the individual’s

cognitive deficits may impede the ability to benefit from traditional therapies, function successfully in daily living, and learn new ways to accomplish everyday tasks. There is a need for innovative therapeutic approaches in post-acute brain injury rehabilitation and for assurance that the approaches have true relevance to the individuals’ lives, particularly at the point of community re-entry.

Gordon and Hibbard (19) concluded that evaluation studies and anecdotes confirm the benefits of cognitive rehabilitation and cognitive remediation if individualized to meet the specific needs of the individual and delivered systematically and creatively in an appropriate context. They emphasized that the treatment can be demanding for the individuals and team members, and that the intensity and duration can be significant, but that it is evident that the treatment helps individuals to adapt to challenges of daily living after a traumatic brain injury.

### **Funding for Community Re-entry Services**

Funding for community re-entry services and long-term care comes from a variety of sources, which are frequently blended. Because the majority of traumatic brain injuries occur in motor vehicle accidents, the personal injury protection (PIP) portion of auto insurance policies is a major source of funding in many, if not most, states. Workers’ compensation insurance is another large source of funding, following work-related accidents (e.g., falls). Funding for some community re-entry services is available through private long-term disability plans and some health insurance carriers, but not all. Examples of other typical sources of funding include money set aside in structured settlements for rehabilitation purposes, private pay, programs operated with state and federal funding (e.g., the Division of Developmental Disabilities, Medicaid Waiver Programs, other waiver programs, crime victims’ boards, vocational rehabilitation agencies, recently-established traumatic brain injury funds), and voluntary agencies (brain injury associations).

Many insurance companies employ or contract with case managers (usually rehabilitation nurses) whose responsibility it is to assist the claims personnel in making decisions about the suitability of services recommended for the individual and the reasonableness of the costs for the services. They serve as external case managers to the programs offering the services; the programs may also employ internal case managers to assist program personnel in determining what services the individual will receive and assuring the availability of funding for reimbursement of costs for services rendered.

### **PREVALENT COMMUNITY RE-ENTRY ISSUES**

Among the many community re-entry issues for individuals following traumatic brain injury, family adjustment,

social isolation, limited community mobility, and barriers to employment are paramount. (Please see Chapter 61 for a discussion of vocational issues.) Even given the impetus of legislative initiatives such as the 1990 Americans with Disabilities Act, intended to facilitate the inclusion of persons with disabilities in society, the reality is that many individuals with traumatic brain injury remain homebound a large majority of the time, cared for by family members and significant others who are experiencing caregiver burden.

### Family Adjustment

The normal developmental stages and transitions in family life are disrupted following the brain injury of any member of a family. Significant changes in the usual roles and functions occur, and are often permanent. If not addressed adequately, these issues (discussed by Sander in Chapter 60 of this book) result in a diminished quality of life for all persons involved. As stated in the *NIH Consensus Statement* (20), there are serious social consequences following traumatic brain injury at any level of severity. There are risks of prolonged unemployment, financial hardship, divorce, criminal activity, substance abuse, and suicide. In addition to the strain on families, the resources of social service agencies and legal systems are strained. The negative effects of the traumatic brain injury may become more evident, and more severe, following the individual's unsuccessful attempts to resume his/her usual roles and responsibilities. Psychosocial issues become evident in family members and significant others as well as the individual with the brain injury; family dynamics are frequently unsatisfactory and family functioning deteriorates. In some situations, particularly if not addressed, these problems worsen over time.

Results of a survey conducted by staff of a community re-entry program, and presented at a national brain injury symposium, supported the assertion of Williams and Kay (21) that, even at the point of community re-entry, after considerable treatment has been provided, family members are usually not prepared to cope with the persistent cognitive, psychosocial, and/or emotional problems of their family member with traumatic brain injury. Rider-Williams and Trout (22) identified the following characteristics of the individual's traumatic brain injury to be the greatest challenges for family members: problems remembering; social isolation; problems planning and organizing; poor judgment; mood swings; difficulty paying attention and concentrating; poor problem-solving; fatigue; problems with balance and coordination; poor decision-making; not being able to walk like before; and impulsivity. Rider-Williams and Trout concluded that much needs to be done to help individuals with TBI and their family members cope with the numerous long-term challenges of TBI. They emphasized that, given managed

care initiatives and the decreased inpatient stays in rehabilitation hospitals and facilities, there is insufficient time for hospital personnel to provide as much patient/family education as was typically provided in the past, prior to discharge. Moreover, even when patient and family education was available, family members and significant others may not have been able to process the information yet. Treatment providers must be sensitive to family members' needs for timely information throughout the rehabilitation process.

Laroi (23) discussed the value of family therapy sessions even after active rehabilitation treatment, to help the family be aware of, and seek attention for, any negative changes in the family system. Family therapy in the home was recommended as a way to facilitate timely changes following disruptions in the family system. Strongly advised were selection of a family therapist with expertise in brain injury rehabilitation and close collaboration between the family therapist and the professionals providing the individual's brain injury rehabilitation therapy.

Kosciulek and Pichette (24) conducted a survey of primary caregivers of individuals with TBI in an attempt to isolate factors that enhance care. They found that supportive friends; a positive family outlook; availability of family support; and family unity, loyalty, and cooperation were variables that had a positive correlation with care. The unavailability of respite services, an absence of vocational rehabilitation services, limited assistance for meeting day-to-day needs, inappropriate living situations, and emotional and behavioral problems in the injured family member were identified as variables impacting negatively on care. Kosciulek and Pichette concluded that family members of persons who have sustained a TBI require an array of support services if they are to provide a high quality of care over an extended period. They also suggested that family satisfaction may improve quality of life and contribute to positive rehabilitation outcomes.

Godfrey, Harnett, Knight, et al. (25) examined the impact on caregivers when personality changes in the individual with TBI are due to problems with emotional control or problems with motivation, and contribute to caregivers' distress, burden and depression. The Head Injury Behaviour Scale was found to have good internal consistency and reliability and to be a reliable and valid measure of caregiver distress.

Ponsford, Olver, Ponsford, and Nelms (26) also discussed the emotional burden of caregiving, the effect on family adjustment, and the need to develop models of long-term support that will help reduce caregiver burden on family members and relatives. To learn what will be most effective, they recommended studies of the attributes, values and coping styles of families who adjust well following the traumatic brain injury of a family member.

### Social Isolation

Following a traumatic brain injury, many persons experience profound social isolation that severely compromises their quality of life. Burleigh, Farber and Gillard (27) pointed out that individuals with a TBI may have difficulty fulfilling or resuming an accepted social role, or simply may not be able to do so because of psychosocial deficits and/or emotional issues. They emphasized that rehabilitation treatment for these individuals should include the skills needed to develop and maintain interpersonal relationships, since otherwise they may become socially isolated and experience a low quality of life. They also pointed out that dissatisfaction with life could lead to psychological problems in addition to already-existing post-injury problems.

The goal of social integration should be part of the individual's treatment plan at the point of community reentry. A study by Brown, Gordon and Spielman (28), undertaken by a Research and Training Center on Community Integration of Individuals with Traumatic Brain Injury, focused on social and recreational activities of persons with traumatic brain injury (TBI) that required individuals leave their homes to engage in the activity and that addressed their social goals. Sample results of the study, based on self-report during interviews, revealed that the TBI sample (N = 279) was significantly less active than the no disability (ND) group (N = 244) on the composite measure of social-recreational activity and on each of the five indicators of social-recreational activity. The authors point out, however, that substantial within-group variance suggests the need to examine more closely what constitutes disadvantage in social participation. The authors also suggest that depression and fatigue, which frequently account for reduced social participation, should be addressed and that involvement in educational or work activity (either paid or volunteer) will provide additional opportunities for persons with traumatic brain injury to participate in social and recreational activities.

### Limited Community Mobility

Following a traumatic brain injury, access to the community may be limited dramatically. Sequelae of traumatic brain injury may compromise the individual's ability to get around safely in the community by driving a motor vehicle, riding a bicycle, using public transportation (i.e., bus, train, taxi cabs or trolley), using specialized transportation (e.g., paratransit services), or simply walking. Physical or sensory impairments restricting community mobility may include gait and motor incoordination, balance problems, visual deficits, audiovestibular dysfunction, communication deficits, bladder and bowel dysfunction and conditions such as post-traumatic epilepsy. Cognitive deficits impeding community mobility may include such problems as distractibility; limited

attention and concentration spans; poor memory; inadequate planning, organizing, decision-making and problem-solving skills; limited safety awareness and judgment; poor topographical orientation; impaired time awareness; and slow processing of information. Behavioral deficits such as apathy or lack of ability to initiate purposeful behavior, or behavioral excesses such as impulsivity or disinhibition, may also compromise one's community mobility. Limited stamina and endurance, and fatigue, are also moderating variables in one's ability to access the community.

*Driving after Traumatic Brain Injury* The sequelae of traumatic brain injury often make driving after a brain injury an unattainable, although highly desired, personal goal. The inability to drive a motor vehicle is a particularly distressing circumstance for late adolescents and young adults who comprise the greatest percentage of individuals with traumatic brain injury and who are frequently at important points in their career development. It is easy for anyone who drives to appreciate how an inability to drive can alter the ability to perform usual life roles. The inability to drive contributes to the major post-injury challenges of returning to work or school, resuming family roles, and reducing social isolation. The inability to drive can lead to lowered self-confidence and self-esteem and negative self-image, as it limits one's ability to function independently and access one's community. In rural areas, one's inability to drive is particularly problematic, since it usually results in a significant decrease in community involvement and/or significant demands on caregivers who must provide necessary transportation. Nonetheless, caregivers, as well as involved medical and non-medical professionals, must guard against making recommendations for driving based on sympathy for individuals whose attainment of personal goals is unquestionably complicated by the inability to drive. Decisions about one's driving privileges must take into account the public's right to a reasonable standard of safety. The public interest is protected, as well as the individual's, when there is a means for the individual to demonstrate the capacity to drive safely. Galski, et al. (29) summarize

What is known about the residual effects of brain injury on driving has been derived from studies attempting to show the ways and extent to which specific deficits relate to driving performance. A basic but ever-growing compendium of deficits has been compiled, including, but not limited to, *sensory deficiencies*, such as defects in visual and auditory acuity, glare and contrast sensitivity, and motion perception; *motoric difficulties*, such as loss of or reduction in strength, coordination, and reaction speed; *cognitive impairments*, such as poor visual scanning of traffic and environment, difficulties in spatial perception and

orientation, slowness in information processing, and loss of attentional abilities; and *personality or behavior disturbances*, such as accident-proneness, anxiety, or confusion in the face of complex driving situations or problems (p. 896).

Executive functions (discussed by Cicerone in Chapter 41, and Eslinger in Chapters 42 of this book) are especially salient variables in driving. Self-awareness is crucial to one's ability to predict whether he or she will be able to drive safely. In studying the predictors of outcome after traumatic brain injury, Coleman, Rapport, Ergh, et al. (30) found that the significant other or caregiver is more likely than the individual with traumatic brain injury to determine whether and how much driving will be done post-injury. They concluded that family education provided in a rehabilitation setting could facilitate family members' and significant others' understanding of the abilities needed to drive safely; because driving is such a common activity, the complex cognitive demands may not be recognized. Of value would be helping them to make observations of the individual's behavior and its implication for driving. For example, family members and significant others who report that the individual is having post-injury problems with frustration, anger or impulsivity, could be helped to anticipate the potential risks of driving if exhibiting those behaviors. While it is expected that the implications of those behavioral excesses for driving would be easily understood (particularly with attention in the media to "road rage"), other behaviors, such as lack of initiation, mental inflexibility, and perseveration may need much more explanation.

In many states, physicians are regarded as possessing the knowledge to make reasonable decisions and implement statutory restrictions regarding an individual's fitness to operate a motor vehicle post-injury, whether compromised by recurrent seizures, physical impairment or only by cognitive impairment. State licensing statutes and regulations regarding driving after cerebral injuries vary, but typically require demonstration of adequate visual acuity, perceptual ability as required to respond in a timely manner to traffic control devices, knowledge of traffic laws, and skills to operate a motor vehicle. Krauss, et al. (31) provides two useful tables—one summarizing the state regulations regarding driving and epilepsy (see Table 58-1) and the other summarizing driving regulations in states with flexible driving restrictions (see Table 58-2). Physicians are strongly recommended to be aware of the regulations which apply in their region, and to discuss thoroughly the matter of driving with their patients and guardians. Some physicians may not possess the knowledge of driving capabilities per se or the ability to test driving competency in a real-life situation, and may be prone to inaccuracy when extrapolating from an office examination to a real-time driving experience. In such cases, the

individual should be referred to a qualified driving evaluator with particular expertise in the assessment of driving capabilities following traumatic brain injury.

Such driving evaluations, consisting of driving simulations and then on-the-road ("behind-the-wheel") driving observation by a therapist or trainer sensitive to the issues of cerebral impairment, may be available through rehabilitation facilities. Following the driving evaluation, the physician analyzes recommendations in relation to his/her own medical knowledge of the individual, and thereby renders an opinion about fitness to drive.

Although requiring that a driver demonstrate adequate knowledge of pertinent laws and regulations, the standards of the state motor vehicle department may be relatively minimal in relation to physical abilities. For example, it may be minimally adequate to have visual acuity of 20/40, even if extemporaneous binocular or depth visual processing is impaired. It is likely that a state driving examiner will not anticipate the difficulties an individual with a brain injury may have in making rapid decisions, filtering complex simultaneous stimuli, or adapting in unpredictable situations. The physician, on the other hand, because of the understanding of brain function under the circumstances of challenge and duress, may need to take a more critical view of driving safety than does the state. The physician should be aware of possible adverse affects which treatment may have on driving, such as sedating side effects of medications, and make patients aware of these effects as potential restrictions to driving.

While physicians have a responsibility to protect third parties from potential harm, in some states issues of privacy and confidentiality may arise if the physician notifies legal authorities without the consent of the individual. Drazkowski (32) points out that the requirement to notify authorities may discourage patients from disclosing to their physicians the frequency and intensity of their seizures, and that could lead to inadequate medical care. Nonetheless, a physician's obligation to report patients who are engaging in illegal activity or pose the risk of danger or harm to the public at large takes precedence over issues of confidentiality.

With respect to seizures, Drazkowski recommends strongly that the physician take into account how anti-epileptic drugs [AED] might affect driving capacity, the risk of AED non-compliance or discontinuation, initial reporting requirements at the time of diagnosis, and the need for adequate medical information to be provided subsequently to regulatory agencies, if called upon.

Although developed with specific reference to another medical condition with motoric, perceptual, cognitive, and executive function impairment (namely, Huntington's disease), the driving assessment developed by Rubin (33) may be useful to a physician (or other professionals) in arriving at an opinion of one's ability to

†Mitigating factors considered in permitting some patients to drive despite less than minimum seizure-free period: auras, nocturnal seizures only, seizure breakthrough during physician-directed AED change, solitary or first seizure, MD or MAB recommendation.

‡Individual = MVA medical review conducted on a case-by-case basis.

§No = physician legally immune or indemnified; Yes = physician possibly liable for driving recommendation.

//Seizure-free restriction frequently adjusted by MVA MAB and treating physicians (Table 58-2).

**TABLE 58-2**  
**Summary of Driving Regulations in States with Flexible Driving Restrictions for Patients with Epilepsy\***

STATE	FLEXIBLE DRIVING RESTRICTIONS
California	6 mo seizure free; 3 mo if seizure occurs during physician-directed AED reduction or if previously seizure free 6 mo; 12 mo if repetitive seizure (several in 1–2 mo) after 6-12 mo seizure free
Colorado	Treating physician determines; 2-y restriction if not under physician's care
Connecticut	Minimum 3 mo seizure free; MAB and treating physician determine; 6 mo without recommendation
Delaware	Treating physician determines; must have been under physician's care for 3 mo
Florida	MAB usually shortens seizure-free period from 24 mo to 6 mo if under adequate medical treatment
Hawaii	MAB determines; usually 6 mo seizure free; treating physician indicates stable prognosis
Idaho	Treating physician recommends
Illinois	MAB determines; treating physician certifies patient is safe to drive; usually require 6 mo seizure free
Indiana	Treating physician determines; 12 mo seizure-free restriction without physician recommendation
Maine	Functional ability profile: driving generally permitted if >3 mo seizure free or 2 yr seizure free and off AED >3 mo
Massachusetts	6 mo seizure free; MAB may reduce interval if recommended by treating physician; MAB may increase seizure-free restriction
Montana	Treating physician recommends; must attest condition stable and would not interfere with safe driving
New Hampshire	12 mo seizure free; MVA frequently shortens interval on recommendation of treating physician
New Mexico	12 mo seizure free; MVA frequently shortens to 6 mo
New York	12 mo seizure free; MVA frequently shortens to 6 mo based on recommendation of treating physician
North Carolina	6-12 mo seizure free; determined by medical advisor
North Dakota	6 mo seizure free; temporary license for commuting to work or school frequently authorized by MAB if >3 mo seizure free with recommendation from treating physician
Ohio	Treating physician recommends
Oregon	6 mo seizure free usual; shorter intervals considered on recommendation of treating physician
Rhode Island	MAB determines
South Dakota	12 mo seizure free; MAB may give temporary license earlier with 6-mo reviews if physician verifies patient's statement that seizures are under control
Utah	Functional profile and treating physician recommendation (commonly 3 mo seizure free); may recommend limited driving (<40 mph, local roads, daytime only)
Vermont	MAB determines; usually 6 mo seizure free

drive safely and in communicating his/her opinion to the individual with brain injury, family members and/or significant other. A tabular presentation (see Table 58-3) may increase the likelihood that the basis for the physician's opinion is understood. In this assessment, the less obvious impairments which fall into the categories of efficiency and accuracy of information acquisition and processing, multi-tasking, problem-solving ability, response to simultaneous stimuli and a rapidly changing environment, as well as judgment, self-awareness, impulse control, and emotional status, are taken into account. Each observed quality is rated "normal," "sub-normal" (an abnormality is detected, but is considered acceptable for driving), or "impaired" (representing potential interference with safe driving). The logic of this assessment is that it allows for the recognition of some impairments for which compensatory actions may be possible, while an

abundance of "sub-normal" findings, or a single "impaired" finding, would indicate that the physician should intercede to guard against the individual driving unless/until these component abilities recover adequately.

Schultheis, Hillary and Chute (34) compared the Neurocognitive Driving Test (NDT), a computer-based driving assessment tool, with a comprehensive hospital-based driver's evaluation of individuals with acquired brain injury (ABI). Participants included 15 adults with ABI and 15 matched healthy control (HC) participants. A significant relationship was found between the NDT and the comprehensive driving evaluation, and confirmed the value of the NDT in discriminating between the individuals who passed the comprehensive, hospital-based driving evaluation and those who failed. Additional research was recommended with larger sample sizes as was the inclusion of neuropsychological measures and

TABLE 58-3 (continued)

**Overall Assessment and Disposition:**

- (1) No clinical impediment to driving is suspected.
- (2) Early or minor/acceptable difficulties are recognized. Reevaluate in six months. Patient able to compensate, adjust driving circumstances, or exercise adequate judgment to provide safety.
- (3) Safe driving capacity is not definite. Patient instructed to obtain special assessment, and instructed not to drive until that assessment is obtained. If patient cannot or does not comply, see (4).
- (4) Patient's driving constitutes a danger to public safety. Reporting may be obligatory in some states.

medical information in order to understand better the individual's cognitive impairments and the implications for driving performance.

Pietrapiana, Tamietto, Torrini et al. (35) described a study of 66 persons in Italy with severe traumatic brain injury, to explore the possibility of predicting post-injury fitness to drive. Predictor variables consisted of 16 measures representing demo/biographic, medicofunctional, neuropsychological and psychosocial domains. Driving outcomes were driving status (i.e., whether they returned to driving), driving safety (based on post-injury accidents) and driving violations. The findings were that the 50% resumed driving; the main difference was the shorter duration of coma in those individuals than the non-drivers. The variables that offered the best prediction of driving safety were the years post-injury, the number of pre-injury car accidents and driving violations, a pre-TBI risky-personality index, and pre-TBI risky-driving-style index. In combination, these four variables predicted 72.5% of the variance. The authors suggested that reports of pre-TBI histories be obtained from close relatives and/or significant others in making predictions about fitness to drive safely post-injury.

Although one's fitness to drive may be clearly evident in some cases, and the decision regarding driving is straightforward, in other cases one's fitness to drive may be marginal. In those cases, driver's training by an instructor with expertise in traumatic brain injury should be considered. The number of sessions would be determined based on the presenting issues, but should be provided at different times of the day and for sufficient lengths of time to be able to assess the possible effects of common sequelae such as fatigue and reduced physical and cognitive endurance on one's capacity to drive safely. Driver's training may also be recommended even in situations where the driver's evaluation clearly confirms one's capacity to drive, as a way for the individual, who may not have driven in quite some time post-injury, to have beneficial support and feedback while gradually returning to driving.

*The Use of Public Transportation or Paratransit Services*  
While many persons would assume that public transportation or specialized transportation (i.e., paratransit

services) offer persons with traumatic brain injuries a means to access the community, that is often not the reality. Physical, cognitive-communication, psychosocial and/or behavioral sequelae present enormous obstacles to the use of these systems. In rural areas, bus service may not be available or the nearest bus stop may be far enough away that non-drivers usually must walk to the bus stop. Persons with mobility impairments may be unable to walk that distance. In heavily trafficked areas, the individual may not be able to cross the street quickly enough to assure his or her safety. For individuals with cognitive impairments, inadequate time awareness and attentional deficits can lead to missing the bus, and poor problem-solving may result in impulsive behavior that puts the individual at risk.

Specialized transportation services are also often too complex for persons with traumatic brain injuries to utilize without assistance. Issues arise even when applying for such services since lack of awareness of one's disabilities may lead to inadequate information on application forms for eligibility, resulting in a decision that someone with no apparent mobility impairment does not require the services even when a significant cognitive impairment precludes his/her use of standard public transportation. If the individual is declared eligible for specialized services, cognitive-communication problems can undermine attempts to plan and schedule the trips. In particular, difficulty is encountered when transportation is not available at the time it is requested and the individual must consider, quickly, an alternative schedule. Moreover, when being picked up or dropped off by the transportation service, a 15-minute "window" is usual. Persons with attention deficits may become distracted and fail to be ready when the transporter does arrive. Many systems only allow this to happen twice before canceling one's eligibility for services. Trying to rectify some of these problems, the individual may attempt to contact the transportation service and encounter an automated telephone system with a menu of options that is too complicated for him or her to use successfully.

Cognitive rehabilitation therapy (offered by community re-entry programs) is strongly recommended to address these potential difficulties and should be

individually tailored to enable the individual to handle the cognitive demands of the transportation systems he or she will actually use. While cognitive rehabilitation can be aimed at remediating functions (e.g., improving attentional abilities as required to signal a bus to stop), the focus is typically on ways to compensate for lost or reduced abilities. For example, compensatory strategies may include the development of structured forms and a telephone script to use when calling to schedule a trip, visual cues or electronic devices (e.g., a watch alarm or timer) to remind the individual to prepare to leave the house at a specified time in order to reach the bus stop on time, role-playing of appropriate verbal exchanges with the bus driver and other passengers, etc. Accompanying the individual on bus rides initially should be part of the therapy process, followed by shadowing, and then independent trips with strategies for problem-solving situations if necessary. Sufficient repetition and rehearsal is essential to mastery of the skills required for use of public transportation.

### **THE ROLE OF THE PHYSICIAN IN COMMUNITY RE-ENTRY AND LONG-TERM CARE**

With respect to community re-entry programs and long-term care, the role of the physician can be discussed in relation to the responsibilities of medical management/medical consultation, and other professional activities, including education and training, research, and expert testimony. Discussion of these roles and responsibilities, in broad terms, follow.

#### **Medical Management/Medical Consultation**

Given the diversity in community integration programs, which may be residential or non-residential and based on multidisciplinary, interdisciplinary or transdisciplinary treatment models, the role of the physician will be dictated in large part by the specific focus of the program. Many community re-entry programs employ a medical director, on a full-time or part-time basis, whose responsibilities to the program include, in addition to patient care, functions such as strategic planning, program development, and program evaluation. In recent years, largely because of reductions in reimbursement and recognition of the growing extension of services into the community, many community re-entry programs have chosen to have physicians as consultants to these programs rather than employees. In either case, with respect to patient care, patients in some programs will have been discharged by their physician at an acute rehabilitation hospital (most often a psychiatrist, neurologist or neuropsychiatrist) to follow-up by their primary care or family physician. In other

cases, the hospital-based physician may continue to follow the patient post-discharge, for an indefinite period of time. Moreover, physicians in private practice may interface informally with community re-entry providers, providing medical management/consultation on an as-needed basis. The physician serves as a guiding resource to the program or to other providers (medical and non-medical) to define and solve problems of patients or clients (the term preferred in many community re-entry programs) as they arise, with special emphasis on the problems which arise as a direct result of the brain dysfunction and the problems of secondary disruptions that result.

Zasler (36) emphasized that directing a brain injury rehabilitation program requires a shift from the traditional medical model with a disease orientation, to a holistic treatment approach with a functional orientation. In particular, he pointed out that the physician must understand how an individual's functional capabilities can be compromised by neurological and/or musculoskeletal impairments, and what may cause functional decline at various points post-injury. The physician must also recognize when other medical and/or psychological issues and non-injury factors are not directly related to the traumatic brain injury but may compound the disability resulting from TBI and impede the brain injury rehabilitation process.

Physicians with expertise in brain injury rehabilitation also perform a vital role in relation to the individual's return to work following traumatic brain injury. The individual's physician may be asked to provide an opinion of the suitability of a particular job for an individual and to delineate any work restrictions and reasonable accommodations. The need for work restrictions and/or accommodations may be related to physical or cognitive impairments. In some federal agencies, such as the United States Department of Labor's Office of Workers' Compensation Programs (OWCP), a physician's review of the potential job is a mandated part of the reemployment process. Physicians may also be hired by OWCP to evaluate workers' compensation claimants and provide a second opinion or independent medical examination (IME).

Zasler (37) discussed the neurologic sequelae that frequently impede one's ability to return to work, which may include post-traumatic epilepsy, post-traumatic hydrocephalus, olfactory dysfunction, visual deficits, audiovestibular dysfunction, oropharyngeal dysfunction, communication deficits, bladder and/or bowel dysfunction, visuoperceptual deficits, neuropsychological issues, sexuality issues, neurophysical deficits, and orthopedic issues. There is clearly a role for the physician to help agency personnel, employers, vocational rehabilitation personnel, and case managers, as well as the individual with TBI and his or her family members and significant others, to understand the vocational implications of traumatic brain injury sequelae.

Breed, Flanagan and Watson (38) studied 258 individuals with traumatic brain injury and 65 individuals without any disability, to compare the frequency with which they reported health problems and to explore the effects of age and traumatic brain injury on one's perception of his/her health. They pointed out that the limited amount of information on long-term health problems following traumatic brain injury is surprising, given the "central regulatory role" of the brain in physiologic functioning. The results of the study revealed that the individuals with traumatic brain injury reported more endocrine, genitourinary and neurologic problems, and had more complaints of joint pain and sleep disorders. The differences were statistically significant.

With respect to medical management and/or medical consultation, it is important to recognize that community re-entry models of rehabilitation draw primarily upon origins within a variety of pragmatic rehabilitation-related disciplines (e.g., neuropsychology, psychology, occupational therapy, speech pathology) rather than on medical management based on pathophysiology, diagnosis, and prognosis. As in the case of individuals with developmental disabilities, the role of the physician evolved historically through a secondary and consultative role that was problem-oriented and typically specific to the subspecialty area of concern (for example, orthopedic interventions, epilepsy or hydrocephalus management, interventions for depression and psychosis, plastic surgery, visual and auditory/vestibular dysfunctions). Those needs were addressed *ad seriatum* in the consultants' offices without integration to the rehabilitation program as a whole. Moreover, cognitive rehabilitation programs in the United States, developed initially with a focus on traumatic brain injury, have more recently included persons with non-traumatic cerebral injuries: anoxia-hypoxia, encephalitis, stroke and aneurysmal subarachnoid hemorrhage, and survivors of brain tumor resection. The design of intervention by most of the rehabilitative team draws on the clinical features which these disorders have in common rather than drawing on their pathophysiological differences. At times the physician must introduce knowledge and direction leading to program design recognizing differences between types of brain injury.

An integrated approach to residential and outpatient care requires the physician to broaden the scope of practice, and requires an evolution in treatment paradigm within residential and long-term rehabilitation programs. In presenting a neurological model of rehabilitation, Mills and Alexander (39) and Mills, Cassidy, and Katz (40) have outlined the necessary components to achieve suitably informed integration of treatment within an interdisciplinary program that encompasses neuroscience and neuromedical diagnosis and intervention. Diagnosis in rehabilitation ideally addresses the mechanisms and

pathophysiology of impairment, and does not merely describe states or lists of functional impairments and disability. From a knowledge of pathophysiology, placed in the framework of neurological syndromes, predictions of improvement and outcome can be derived. That is, the physician is likely to bring to the treatment planning a critique which takes into account a more extensive knowledge of correlation between differentiated types of brain injury and consequent alterations of behavior. Moreover, the physician may articulate the rationale for a revision in expectations of recovery to higher or lower goal set-points, or a longer or shorter duration of treatment, to the treatment team who may define treatment needs in terms of observed functional deficits alone. The physician makes a pivotal contribution in defining the appropriate point of transition to long-term supervised situations for some, and in defining the need for redoubled rehabilitation-oriented efforts in others.

To some degree, all members of the rehabilitative team must be cognizant of premorbid personality and the premorbid endowment of abilities and limitations in defining an individual context for treatment planning. To this context is added behavioral analysis (which takes into account the environmental and interactive aspects of action) and symptom analysis (which generates hypotheses of involuntary and/or intentional generators of specific actions, expressions, or perceptions). The attribution of the meaning of both seemingly normal and seemingly disordered behaviors is drawn from these contexts, and placed in social, psychological, and biological frames of reference. In analyzing a given problematic behavior, understanding predisposing and precipitating factors, and the patient's manifest adaptive capacity, will be essential. The capacity of the individual with traumatic brain injury to adapt to his/her circumstances may reflect such factors as misperception, memory impairment, mental inflexibility, impulsivity, or hyper-reactivity. The physician or other professional who imports knowledge of mechanisms operant within specific neurological impairments will add an additional vital component. For example, a mechanistic view isolates perceptual errors, attribution errors, disconnection errors, overgeneralization errors, encoding vs. decoding errors in memory, and affect regulation vs. disinhibition errors. When grounded in a knowledge of the potentially reversible and potentially irreversible aspects of the brain injury, the rehabilitation strategy is transformed and redirected optimally. The presumed "natural history" of the disorder is then opened to interventions targeted to critical components.

In the modern era, the physician brings to the treatment team a perspective based on knowledge and practice of emerging neurochemistry, neurophysiology, functional neuroimaging, and cognitive neuroscience. These areas represented by the physician include psychopharmacology, cognitive-enhancing treatment, neuro-protective

treatments, techniques of physiologic neurorehabilitation, and biomechanical interface. In addition, there are rapidly developing areas of study in neuroplasticity, intracerebral transplantation and regeneration, and hormonal and neurochemical aspects of brain injury and recovery. Many of these issues have been introduced in other chapters of this book.

In the phases of community re-entry, the opportunity arises for the physician to address components of the disordered behavior with a rapidly expanding repertoire of agents. Focusing on the neuropsychiatric and neurobehavioral domains in particular, the components which may yield to pharmacological intervention include inattention, states of hyper- or hypoarousal, depression, mood cycling or lability, aggression, obsessiveness and rigid inflexibility, sleep cycle disturbances and daytime somnolence and/or fatigability, anxiety states (including posttraumatic stress disorder), pseudobulbar incontinence of emotional expression, hypersexuality or sexual dysfunction, psychosis (delusions, hallucinations), states of apathy, abulia, or failure of motivation and initiative. This is not an exhaustive list. At the same time, it is often the better strategy to integrate such interventions with non-pharmacological modalities, such as psychological support, cognitive rehabilitation therapy, structuring of routines, and education.

At present, many of the newer or experimental modalities of intervention are currently confined to the specialized outpatient clinics at university settings or research institutes, but it will be appropriate for the physician consulting in the community re-entry setting, in particular, to import these new modalities of treatment into the care of the individuals who are far into their post-acute recovery. In the future, rehabilitation may also include implantation of augmenting systems, for example, sensory devices for augmenting hearing and vision. At the present time, the physician is the representative of medical vigilance for such late complications as hydrocephalus, shunt failures, seizures, infections, endocrine disorders, and spasticity, as well as vigilance for adverse complications attributable to medications (SIADH, thrombocytopenia, extrapyramidal movement disorders, psychotoxic adverse side effects, and sedation being particularly common examples). In the population of individuals with traumatic brain injury, drug and alcohol abuse may be demographically over-represented. Accordingly, the physician's vigilance must extend to concerns over hepatitis, drug induced vasculitis, HIV infection, syphilis, tuberculosis, and vigilance for ongoing drug and alcohol abuse, including agents which may advance the degree of brain injury during the period of rehabilitation (toluene inhalation, and "recreational" psychostimulant abuse, for example).

In addition, non-traumatic factors such as late post radiation vasculopathy (in brain tumor survivors) and

anoxic encephalopathy may also be present, the latter adding to impairments in movement (cerebellum and basal ganglia), perception (visual cortex), and memory (hippocampus), in addition to the above. (Discussion of the diagnosis and management of late complications of traumatic brain injury is found in chapter XX of this book, by Long.) The cumulative effects of neurologic aging, and the superimposed impairment of acquired brain neurodegenerative diseases in elderly persons, will also occur in those injured by trauma, and will require a refreshing of medical differential diagnosis when a progressive worsening of the pattern of impairments is detected. By far, the most prevalent late complications are those which fall into the neurobehavioral and neuropsychiatric domain, which are closely linked with the nature of the individual's emotional and neurocognitive deficits.

Structures of the brain which are known to be disproportionately vulnerable in brain trauma include the frontal and temporal lobes, but also the amygdala, hippocampus and basal ganglia. Late neuropsychiatric complications are at least equally prevalent though less well localized, and include depression, psychosis, a spectrum of disinhibited and unrealistic behaviors, and a persisting failure of insight, self-observation, or initiative. These represent disruption of the interface between the individual with brain injury and the environment which, at times by analogy or by comparison to recognized neurological and psychiatric syndromes, benefits from a medical understanding or intervention. The involvement of neurology, neuropsychology, and psychiatry in the understanding of the behavioral consequences which are intrinsic to these lesions, while built on a long history of the clinical pathological correlation of discrete lesions, has enjoyed an ascendance only in the last few decades, coincident with the emergence of the bridging subspecialties of behavioral neurology and neuropsychiatry.

Psychiatry, while historically not as often relying on clinical-pathological correlation, has allusion to a nosology of discrete syndromes which serve as reference points for intervention. The knowledge of the constellations of impairments which follow typically from traumatic brain injury should be known to any physician involved in the care of these individuals, including the broad range of other specialists and primary physicians.

### **Determining the Need for and Choice of Community-Based Treatment**

After being discharged from the acute and subacute phases of rehabilitation, the status of treatment goals will determine the setting in which further recovery optimally will take place. Outpatient treatment and direct community re-entry will be possible if the individual with TBI has sufficient self-awareness of the need for it, and if outpatient resources are available to address persisting cognitive,

behavioral, emotional, vocational, and physical needs. If self-awareness is sufficiently impaired to result in unsafe or disruptive behavior, the consideration for residential community treatment will be stronger.

Circumstances which may prompt a referral to a residential or nonresidential community re-entry program for persons with brain injuries include, but are not limited to, the following:

1) When community re-entry programs can provide essential, ecologically-valid observations and treatment that cannot be provided otherwise. Treatment rendered in a clinic, facility or office setting may not yield a clear picture of the sources of failure to function adequately. The importance of gaining a better understanding of the individual's needs is underscored when the individual is caught in a cascade or vicious cycle of repeated failures to function adequately and requires external reinforcement of adaptive and compensatory strategies, and/or continual feedback.

2) When intervention is required because of failed executive functioning. This circumstance may become apparent in relation to individuals who attempt living on their own following traumatic brain injury but who are unable to resume functioning at, or close to, their pre-injury level. Common problems for those individuals include inability to follow a prescribed medication regimen, to manage family, financial or personal responsibilities, or to maintain an environment conducive to satisfactory functioning. Crises of disorganization can result, exemplified by hoarding of possessions or accumulation of items/objects, leading to overwhelming clutter and chaos.

3) When the individual is unable to establish functional routines as needed to accomplish activities of daily living. Sequelae of traumatic brain injury may include memory problems, inadequate planning and organizing, difficulty making decisions and impaired ability to initiate purposeful activity, contributing to the inability to carry out daily routines. Other variables compromising one's ability to establish and maintain a productive daily activity pattern include apathy syndrome, severe obsessive disorder (whose rituals or unresolvable obsessions create "paralysis" of activity), depression, and anxiety. There may be repeated failures to resume work, school or social/leisure activity.

4) When outpatient programs are not available (for reasons of lack of funding, distance, or other reasons) or are not intensive enough to meet the individual's needs. This circumstance may be particularly problematic if the individual's family is unable to provide adequate support for, or reinforcement of, treatment interventions and when inadequate daily structure leads to maladaptive behavior.

5) When continued supervision is necessary. Once individuals are discharged home, other family members often anticipate they will be able to resume their usual roles (e.g., return to work) and do not fully appreciate the

need for supervision that may be required by the individual with traumatic brain injury. Potential problems when adequate supervision is not provided include the use of alcohol or drugs, frontal syndrome with impulsivity and poor judgment, aggressive or disinhibited behavior, and frontal syndromes with anosognosia. Of paramount importance is the safety and well-being of the individual with traumatic brain injury and his/her family members. For example, memory problems may result in the individual forgetting to turn off the stove or oven, increasing the risk of fire. Fatigue is also common following traumatic brain injury and may result in the individual falling asleep while smoking. These possible scenarios underscore the need for supervision.

When the rehabilitative phase of post-TBI care yields to chronic maintenance or "custodial care," the physician's role remains vital. A number of factors, both physiological and psychological, may intrude and erode further the individual's quality of life and access to optimal level of functioning. It is also true that chronicity does not preclude the possibility of treatment targets that, when addressed, may improve function in the client who is many years beyond the scope of brain tissue recovery.

### **Other Physician Roles in Community Re-entry**

*Education and Training* In patient care settings, education and training by the physician (often in collaboration with other professionals) may be directed to family or caretaking staff, to the programmatic design staff and/or to the patient himself or herself. When providing education to the individual with traumatic brain injury, the physician will attempt to help the individual understand the commonalities that persist despite cultural differences and, at the same time, represent the essential voice of culture in steering the rebuilding of self. The physician can be called on to recognize, or ideally to teach others to recognize, physiological disorders which mimic psychological disturbances. For example, a disorder of initiation, motivation, or "apathy" may arise from brain injury and may mimic amotivational or apathetic mood states. Dysfunction of cortical-subcortical circuits are particularly implicated in such amotivational states, including the medial prefrontal area, anterior cingulum, nucleus accumbens, ventral pallidum or medial dorsal thalamus. It is essential that the treatment providers understand the difference, in order to select and render appropriate treatment methods. To assure optimal management of the patient, the treatment team must understand the pathophysiology of symptoms and signs of a given neurological disorder, and the natural history of both the disease and the impairments. When directing the treatment, the physician must assure that the team members understand the patient's impairment(s), diagnosis

and prognosis, and how to implement the interdisciplinary treatment.

Mills and Alexander (41) identified four essential educational components for every team member: 1) the neurological diseases they will treat; 2) goal-setting and plan development for patients with complicated cognitive problems; 3) appreciation of the treatment outside his/her own specialty; and 4) development and use of cost-effective, affordable approaches to assessment and treatment.

Continuing education and training of other physicians and nonmedical personnel will also help to increase understanding of the needs of persons with traumatic brain injury. Conferences sponsored by professional associations are a frequent venue for such offerings. Because of the multidisciplinary nature of the field of rehabilitation, the American Congress of Rehabilitation Medicine ([www.acrm.org](http://www.acrm.org)) and the American Society for Neurorehabilitation ([www.asnr.com](http://www.asnr.com)) are particularly relevant.

*Research* The National Institute on Disability and Rehabilitation Research (NIDRR), United States Department of Education, has been funding projects in the area of community integration through TBI Model System grants and Rehabilitation Research and Training Centers, which should provide valuable information to enhance understanding of the benefits of such programs, and opportunities for physicians to pursue research interests.

*Expert Testimony* The physician may be called upon for a variety of official tasks. He or she will be called upon to mediate in medicolegal issues (e.g., designation of payee for entitlements, statements of capacity/competence, assessment for guardianship proceedings, driving licensure, designation of impairment for professional work, or letters of medical necessity) and may also provide expert testimony in personal injury cases. See Chapter 62 by Cantor on medicolegal aspects of traumatic brain injury and Chapter 63 by Ameis et al. on ethical issues in clinicolegal practice.

Manifestations of frontal dysfunction, which pervasively undermine normal adaptations to social environments, are difficult to represent to the legal system (42, 43). The physician may be called upon to justify continued compensation under auto insurance policies (e.g., personal injury protection [PIP] or workers' compensation policies). In the current era, the precertification of treatments may require the physician to act as advocate, at times in opposition to third party payers who would profit by nihilism.

### Conclusion

There has been rapid growth in community re-entry services and long-term care for individuals with traumatic brain injury, spawned by greater understanding of their needs at this point in the rehabilitation process and augmented by legislative and managed care initiatives resulting in

shorter hospital stays and earlier return to the community. While the methodological problems inherent in conducting empirical studies at this point, with such a highly heterogeneous population and extensive array of services, have resulted in limited scientific evidence of the efficacy of these programs and services, their value to the individual and his/her family cannot be questioned. Findings of studies that have been conducted and anecdotal reports support the value of these services in improving the functional outcomes and enhancing the quality of life for individuals with traumatic brain injury.

Services and supports at this point in the rehabilitation process are typically provided by nonmedical as well as medical personnel. There continues to be a vital role for the physician in relation to medical management and consultation as well as in relation to education, training and research.

It is through the familiarity with neurobehavioral constellations (which can be interpreted to the injured individual himself or herself and to the involved family) that the physician's involvement may impact uniquely upon rebuilding of personhood and the integrity of self, a goal of intervention distinct from, but no less valuable than, the more narrow focus of remission of medical problems. The concept of self has a grounding presence in the neurorehabilitation of those in whom the cerebral substrate of self has been undermined. Kircher (44) conceptualized the self as the sense of being a whole person constant over time but different from others, and the center of all our experience. A challenge, both cognitive and emotional, is frequently placed before the individual with brain injury to synthesize and evolve a novel posture from which to carry his or her transformed life forward. At times this new synthesis must encounter or master social developmental issues which may have, or may not have, been mastered prior to trauma, and frequently this new synthesis involves great losses or compromises of deeply set life goals and pre-morbid self-definitions. The brain's impairments may interfere with the adaptation, reframing, or flexibility, which would be required to escape a negative self-definition of incompetence, disappointment, or abandoned aspiration in an individual whose mental repertoire and capacity is forever altered. The physician may offer the important contribution to that individual of informed wisdom, both hopeful and realistic, about the brain's potential, and offer a continuing and long-term commitment to the individual's progress, even as that person shifts from setting to setting, and from one challenge to the next.

### Note

*National Directory of Brain Injury Rehabilitation Services 2005 Edition*, Brain Injury Association of America, Inc., McLean, VA, 2005. This directory is published annually and includes listings of types of brain injury programs

and service specialties, state and national resources, and information about military/veterans services through the Defense and Veterans Head Injury Program. Also included are explanations of common abbreviations in the field of brain injury rehabilitation as well as the Rancho Los Amigos Levels of Cognitive Functioning Scale and the Glasgow Coma Scale (GCS). In the 2005 edition, Appendix A consists of a guide to selecting and monitoring brain injury rehabilitation services, and Appendix B contains a glossary and definitions of commonly used terms. The directory can be purchased by calling the Brain Injury Association of American at 1-800-444-6443 or accessing the association's website (www.biausa.org).

## The Treatment of Substance Abuse in Persons with TBI

*John D. Corrigan*

### **THE TREATMENT OF ALCOHOL AND OTHER DRUG ABUSE IN PERSONS WITH TBI**

Clinicians working with people who have incurred a traumatic brain injury (TBI) cannot avoid the issue of alcohol and other drug use. Whether consumption of these substances contributed to the cause of injury, or their use after injury places the individual at risk for medical complications, alcohol and other drug use must be addressed with adolescents and adults in order to preserve the benefits of rehabilitation. In addition to medical complications, substance abuse also limits outcomes by undermining environmental supports such as familial care or access to services. Indeed, alcohol and other drugs may be so detrimental to recovery of function and lifestyle and, in aggregate, to the case that can be made for the benefit to society of rehabilitation services, that it would be short-sighted not to do all we can to minimize their negative effects.

This chapter provides a review of current research on TBI and the use of alcohol and other drugs. There is far greater information describing this problem and its scope than there is research on treatment approaches to ameliorate use-related disorders. Studies of the risks of substance abuse after TBI are discussed, including who is at risk. A review of interventions and treatment approaches that have specifically addressed substance use following TBI precedes explication of a theoretical

model for the development of interventions to treat substance use disorders following TBI. Use of this model is intended to better focus both research and program development.

### **WHAT ARE THE RISKS OF SUBSTANCE USE AFTER TBI?**

Persons with TBI and substance abuse problems are less likely to be working (1–3), have lower subjective well-being (4, 5), increased likelihood of suicide (6) and are at greater risk for seizure (7). There is also evidence from studies of incarcerated populations that the increased risk for aggressive behavior after TBI is further exacerbated by substance abuse. In addition to these psychosocial consequences, several studies have found an additive effect of negative consequences for both brain structure and function (8, 9).

### **Psychosocial Consequences**

Numerous studies have observed that substance use problems preceding injury are often a significant predictor of post-injury unemployment. MacMillan, Hart, Martelli and Zasler (3) studied 45 adults two years after moderate or severe TBI. They hypothesized that severity of

premorbid psychiatric and substance use disorders, as well as less social support following injury, would be associated with poorer post-injury employment, independent living and neurobehavioral symptom manifestation. They found that both pre-injury psychiatric and substance abuse histories predicted a lower likelihood of employment and that pre-injury substance abuse also was associated with less independence in living situation. Sherer, Bergloff, High, and Nick (2) studied 76 persons with moderate or severe TBI who received services through a specialized day treatment program. Employment status three months following discharge from this program was assessed, on average, two years post-injury. Predictors of employment status included severity of injury, premorbid education, pre-injury substance abuse, and need for physical, cognitive and behavioral supervision at discharge from acute rehabilitation. Multiple logistic regressions revealed that only level of pre-injury substance use was predictive of later productivity. Subjects with no history of pre-injury substance abuse were more than eight times as likely to be employed at follow-up.

Bogner and colleagues (4) investigated the relative contribution of substance abuse and violent injury etiology in a sample of 351 consecutive admissions for acute brain injury rehabilitation. At one year following injury prior history of substance use disorder was a significant predictor of post-injury employment, as were age, pre-injury employment and cognitive function at rehabilitation discharge. Despite the consistent finding that pre-injury substance abuse is associated with post-injury unemployment, the relationship with post-injury use may be more complex. Sander, Kreutzer and Fernandez (10) found that employed persons who had incurred moderate or severe TBI and were on the average 16 months post-injury reported consuming greater amounts of alcohol than similar subjects who were unemployed. This finding may be consistent with clinical observations that return to work can be a trigger for substance use because of having financial resources to purchase alcohol or other drugs, as well as increased stressors arising from the work environment.

Corrigan and colleagues (5) reported that a prior history of substance use disorder was highly associated with life satisfaction both one and two years after injury. At year one, prior substance abuse was the strongest independent predictor of life satisfaction and continued to be a significant predictor two years after injury, even after the effects of depressed mood, social integration and employment had been accounted for. Bogner and colleagues (4) considered whether life satisfaction was more affected by substance abuse history or violent injury etiology. As with employment, they found substance abuse history was the more important predictor, along with pre-injury employment and motor function at discharge.

In the general population there is a well documented relationship between depression and substance abuse (11),

and given the high rate of depression following TBI, the co-occurrence of depression and substance abuse would be expected in this population as well. Indeed, there has been some indication of an independent relationship between substance abuse and the likelihood of suicide following TBI. Teasdale and Engberg (6) examined suicide after TBI using the Danish population register for hospital admissions between 1979 and 1993. Standardized mortality ratios stratified by sex and age indicated the incidence of suicide relative to the general population was increased by 2.7 for concussions, 3.0 for cranial fractures and 4.1 for intracranial hemorrhage. When substance use diagnosis x TBI diagnosis was examined, standardized mortality ratios increased significantly. Silver, Kramer, Greenwald and Weissman (11) reported the relative risks of psychiatric problems for a randomly selected subgroup of the New Haven portion of the NIMH Epidemiologic Catchment Area study. TBI alone significantly increased the risk of suicide by an odds ratio of 5.7. After controlling for alcohol abuse and dependence, the likelihood of suicide attempt declined 4.5, suggesting that alcohol use accounted for approximately 20% of the risk of suicide after TBI.

Verma, Policherla and Buber (7) looked at the relationship between chronic abusers' withdrawal from alcohol and the occurrence of a seizure episode. They separated a sample of 54 adult male alcoholics who had experienced seizures into three groups—those for whom there was always a clear relationship between withdrawal and the seizure episode (the last drink occurring between 6 and 96 hours prior to seizure), those for whom some but not all seizure episodes were associated with withdrawal, and a third group in which none of the seizure episodes were associated with withdrawal. They found that a history of severe TBI preceding the onset of seizure disorder was present for none of those patients in the first group, approximately 40% of those in the second group, and more than 75% of those in the third. They concluded the lack of a constant relationship between alcohol withdrawal and seizure precipitation for the second and third groups appears to be a result of the higher incidence of prior TBI in those subjects, and that this relationship may account for the previously observed heterogeneity in the relationship between alcohol withdrawal and seizure episodes.

Finally, regarding substance abuse and poorer outcomes following TBI, there is mounting evidence of associations with aggression and criminal activity (12). Increased aggression following TBI has been reported in multiple studies (13–15). Persons with TBI are more likely to be involved with the criminal justice system (12, 16), and there is evidence of a high prevalence among prisoners. A sample of 1,000 consecutively admitted offenders to the Illinois state prison system found 25% had incurred at least one TBI (17). Of those reporting

TBI, approximately 20% indicated they experienced residual symptoms—most often problems with memory and learning, followed by changes in mood or behavior, seizures, and difficulties with balance and coordination. In a follow-up study Merbitz and colleagues (18) found that those inmates with a history of TBI had 50% more disciplinary tickets accrued per day of stay than a comparison group of inmates without.

In some studies of the prevalence of TBI and criminal activity and/or incarceration, there is additional evidence of a three-way co-occurrence of involvement with the criminal justice system, TBI and substance abuse. A study of medical center patients with TBI found those who had pre-injury histories of arrest were more likely to be males, with lower education, who were injured in assaults, and had a history of substance abuse (19). Barnfield and Leathem (20) studied persons with TBI and substance abuse problems in the New Zealand prison population. Their sample was considerably smaller than Morrell and colleagues', consisting of 118 prisoners who both were allowed to participate and agreed to do so. Subjects were asked to "estimate how many head injuries they had sustained, how each had occurred, and the duration of any loss of consciousness associated with each injury." Barnfield and Leathem used a combination of reported loss of consciousness and frequency of injuries to derive a categorization system for severity that classified each subject as having none, light, mild, moderate, or severe TBI. Half of their sample incurred a TBI that was mild or worse, with 17% reporting moderate or severe injuries. Inmates with mild or worse TBI were approximately 17% more likely to have severe substance use disorders.

Walker and colleagues (21) studied 652 male inmates in four Kentucky prisons. Subjects had used drugs at least three times during the year prior to incarceration, and had had at least two months outside of a controlled setting prior to being incarcerated. There were relatively equal proportions of inmates who were currently being treated for substance use disorder, had been previously treated but were not currently, and those who had never been treated. Subjects were asked to report prior histories of "head injury" caused by various etiologies. Within this sample, 32% reported no head injuries, 38% one head injury, and 30% more than one. Self-reported cognitive and behavioral issues in the 30 days prior to incarceration showed that inmates with head injuries were more likely to have experienced depression, suicidal ideation, and cognitive problems. Those inmates who reported multiple head injuries were also more likely to experience anxiety and violent thoughts. These differences were more pronounced when lifetime symptoms were reported. Subjects with TBI were more likely to have experienced hallucinations and have suicide attempts. Furthermore, for symptoms of depression there were significant differences

between those with just one head injury and those with multiple. A similar pattern was evident for problems of cognition. Subjects were also asked about lifetime health problems. While there were no differences in terms of urogenital, hepatic, or dental problems; there was a significant relationship between a prior history of TBI and respiratory, musculoskeletal, circulatory, gastrointestinal, neurologic, dermatologic, and otolaryngial problems. Problems with alcohol, other drugs, and mental health were significantly related to a history of TBI. For alcohol and mental health problems, those with multiple injuries had significantly greater problems than those with just one injury. These results accentuate those from other studies of prison populations that have found greater difficulties in cognitive processing, mental health disorders and violent behavior. This study also suggests that health problems related to multiple systems may be associated with a history of TBI.

### **The Effects on Brain Structure and Function**

Several studies have found that substance use disorders and TBI have a negative, additive effect on brain structure and function. Bigler and colleagues (9) reported results of quantitative magnetic resonance imaging (QMRI) for 99 adults with TBI and 197 without. Of the TBI subjects, 18 were identified as having a history of substance use disorder. All TBI subjects differed significantly from the non-injured controls for various indices of structural brain damage reflecting atrophy, including the ventricle to brain ratio (VBR). The TBI subjects with a history of substance use disorder showed even greater atrophy when compared to those TBI subjects without. However, a sub-group of the TBI patients without substance use history matched for initial Glasgow Coma Scale score did not show significantly different measures of cerebral atrophy from those with substance use disorders. While this may indicate that the effect was not additive, it is also possible that GCS scores for those with substance use disorders were artificially lowered by intoxication at the time of injury. Despite this bias toward the abusing group having potentially less severe injury than the group matched on GCS, the abusing group still had a higher VBR, though not statistically significant. A follow-up study by Barker and colleagues (22) that examined polysubstance abusers with and without TBI concluded that when the effects of TBI severity are controlled, the effects of substance abuse in combination with TBI resulted in greater brain atrophy than that observed with either substance abuse or TBI alone. In this study, neuropsychological test performance did not show a similar additive effect. The authors conclude that the neuropathological changes detected by QMRI may be more sensitive than neuropsychological performance.

The interaction of alcohol abuse and TBI was studied by Baguley and colleagues (8) using event related evoked potentials. Forty male subjects constituted four equal groups based on the presence or absence of TBI and history of heavy social drinking. Subjects with TBI had experienced a severe TBI one year or more before being evaluated. Heavy social drinking was determined by the Alcohol Use Disorders Identification Test (AUDIT, reference) and is often considered equivalent to a diagnosis of alcohol abuse. Neuropsychological testing was also performed. No significant differences in average age or neuropsychological performance were observed among the four groups defined by TBI and alcohol abuse, TBI or alcohol abuse, or neither. Both the N200 latency and P300 amplitude were impaired in persons with either alcohol abuse or non-drinking subjects with TBI when compared to the control subjects. Significant impairment was observed in subjects with both TBI and alcohol abuse. A similar relationship was not observed for neurologic processes resulting from less complex cognitive tasks. These authors concluded that heavy social drinking after TBI has a measurable impact on electrophysiological correlates of cognition. While two of these studies looking at brain structure and function did not find differences in neuropsychological performance among subjects, other studies have shown more definitive findings. Dikmen and colleagues (23) found that individuals with chronic alcohol use disorders had greater neuropsychological impairment immediately following injury and two years later.

### WHO IS AT RISK FOR POORER OUTCOMES?

Patients who are known to have been intoxicated at time of injury often receive the most scrutiny of their substance use. However, persons with prior histories of substance use disorders (who may or may not have been intoxicated at time of injury), and those who use excessively after injury (who may or may not have had a prior substance use disorder) may be at risk for the greatest functional impairment. There is considerable overlap among groups defined by intoxication at injury, prior history and post-injury abuse, though comprehensive epidemiologic data is lacking.

#### Intoxication at Time of Injury

A number of patients are intoxicated at the time of their TBI (24, 25). The only population-based estimate of occurrence of intoxication at the time of TBI comes from the Colorado TBI Surveillance Follow-up System (26). For persons 16 and older admitted to hospitals in Colorado with a diagnosis of TBI, 20.8% had a blood alcohol content tested above 80 mg/dL, the legal limit for

intoxication in Colorado. As Corrigan (24) has observed, there is a tendency for persons with TBI treated in rehabilitation to have more severe markers of substance use disorders, including intoxication at the time of injury. Based on 3,787 acute rehabilitation admissions included in the TBI Model Systems National Dataset, 37% had a blood alcohol content greater than or equal to 100 mg/dL, the legal limit in most states during the time these data were being collected (27). A consecutive sample of 356 patients admitted for acute rehabilitation on the Brain Injury Unit at the Ohio State University Medical Center, 25% were found to have blood alcohol content greater than 100 mg/dL. Those with positive toxicology screens for other drugs comprised 12% of the cohort. Because there is extensive overlap between those intoxicated due to alcohol and those due to other drugs, the percentage of patients intoxicated due to either was 32%. Estimating the rate of intoxication among persons with TBI from these few studies, for all patients hospitalized it would be reasonable to project that 20% to 30% will be high at the time of the injury. Among patients admitted for rehabilitation after TBI, the rate appears to be between 30% and 40%.

Corrigan (24) summarized reports from the research literature indicating that those acutely intoxicated were more likely to have more severe injuries, require intubation, develop pneumonia and have other forms of respiratory distress; manifest greater neurologic impairment at discharge, have longer agitation and lower cognitive function at acute hospital discharge, and require greater time from admission to rehabilitation. However, other studies that examined the effect of intoxication found no relationship to mortality and morbidity, and in some cases an inverse relationship. Even highly reliable indices of outcome such as neuropsychological effects have been found by some but not others. For instance, Kaplan and Corrigan (28) found that there was no difference in neuropsychological performance among those with and without acute intoxication. However, Tate and colleagues (29) concluded that after controlling for pre-injury history of alcohol abuse, alcohol intoxication at admission was predictive of poor delayed verbal memory, greater decrement in verbal memory over time, and poor visuo-spatial functioning. Tate's methodology controlled for prior history of abuse, which may account for this discrepancy in findings. The ambiguous findings regarding the consequences of intoxication also have been mirrored in results from animal models in which there have been studies showing both the deleterious effect of intoxication at time of injury (30) and a neuroprotective effect posited by Kelly and colleagues (31, 32). Whether there is a neuroprotective effect in humans for the presence of ethanol at the time of injury is beyond the scope of this chapter. However, the question cannot be easily extracted from determination of the effects of a prior history of substance use, which based on

clinical studies, appears to exert a greater impact on initial acuity and longer term outcomes.

### **Prior History of Substance Use Disorder**

A person's prior history of substance use disorder may be a more important risk factor for poorer outcomes than whether they were intoxicated at the time of injury. Corrigan (24) found that studies of the effect of a prior history of substance abuse were far less equivocal in finding immediate consequences than the studies of intoxication. Prior history was found to be associated with mortality, likelihood of mass lesions, poor Glasgow Outcome Score at discharge, and poorer neuropsychological performance at both one month and one year post-injury. Only one study found no differences between persons with and without a history of substance use disorders (33). In the only study that compared the relationship to outcome of both history and intoxication (34) significant effects on mortality and morbidity were found for a history but not intoxication. This greater likelihood of morbidity may have in part accounted for the observation that a greater proportion of persons with prior histories of substance use disorders are found in rehabilitation populations of persons treated for TBI when compared to those treated in trauma centers only (24).

The Colorado TBI Registry and Follow-up System reported that 10% of persons age 16 and older hospitalized in Colorado had been treated previously for substance abuse, and 17% had used an illicit drug in the 12 months preceding their injury (35). In both cases, males, those younger, and those with more severe initial Glasgow Coma Scale scores were more likely to manifest these conditions. There have been two epidemiologic studies suggesting the onset of substance abuse precedes the onset of TBI (36, 37). Fann and colleagues (36) conducted a case control study in a large staff model HMO and found that persons diagnosed with a substance abuse disorder in a given 12-month period had a 60% greater chance of incurring a TBI requiring hospitalization or treatment in an emergency department or physician office. Timonen and colleagues (37) examined the birth cohort of Northern Finland for indications of childhood TBI as a risk factor for development of psychiatric disorders, substance use disorders, or criminality. While TBI in childhood was found to be associated with certain psychiatric diagnoses and criminality, childhood injury did not appear to predict the occurrence of substance use disorders.

From studies that used a prospective method of detection to evaluate rehabilitation populations, Corrigan (24) concluded that approaching two-thirds of adolescents and adults treated in rehabilitation for TBI have prior histories of substance use disorders. Since that time, at least three studies have provided additional data about the frequency of a prior history of abuse and dependence

among rehabilitation patients. Corrigan and colleagues (38) analyzed the TBI Model System National Database for the rate of prior histories of problem use. Problem use was defined as either at-risk consumption of alcohol or use of an illicit drug. They found that 43% of subjects in the TBI Model Systems National Database had prior histories of at-risk alcohol use, 29% reported pre-injury use of illicit drugs, and 48% showed either levels of use pre-injury. In a prospective study of 356 consecutive admissions to acute rehabilitation at the OSU Medical Center, Corrigan and colleagues (39) reported that 54% were diagnosed as having pre-injury alcohol dependence or alcohol abuse, and 34% were diagnosed as having pre-injury abuse or dependence of other drugs. Given the high rate of co-occurrence of alcohol and other drug use disorders, 58% of the sample showed one or the other or both. Bombardier, Rimmel and Zintel (40) reported very similar results for 142 consecutive admissions to acute rehabilitation at the University of Washington. In this sample, 58% had active alcohol use problems (or worse), 39% had recently used illicit drugs, and 61% had either or both histories. The rates from these three sources suggest relatively consistent results in terms of the frequency of prior history of substance use disorder in persons receiving rehabilitation for TBI. Because the OSU and University of Washington studies used more thorough methods of detection, it would appear to estimate that as many as 60% of adolescents and adults treated in acute rehabilitation for TBI are problem drinkers or have diagnosable substance use disorders.

### **Use Following TBI**

The Colorado Follow Survey reported 10% of persons hospitalized with a TBI used an illicit drug in the first year after injury (35). Silver and colleagues (11) found that approximately 25% of a population-based sample of persons with TBI also had alcohol use disorders (versus 10% for those without TBI); and 11% had other drug use disorders (versus 5% without TBI). Like other patients hospitalized due to injury, persons with TBI consume less alcohol or other drug in the immediate post-injury period (41–44); however, there are also indications that a significant proportion return to pre-injury levels of use relatively quickly (44–46).

Horner and colleagues (47) reported results from the South Carolina Traumatic Brain Injury Surveillance and Follow-up Registry. One thousand, six hundred and six adults were interviewed by phone one year after hospitalization for TBI. Among other questions, alcohol use in the month prior to the interview was classified in to three levels: heavy, moderate, or abstinence/infrequent/light drinking. Of survey respondents 15% reported heavy drinking in the prior month, 14% a moderate level of drinking. Risk factors for heavy drinking included a

pre-injury history of substance abuse, a diagnosis of depression since the injury, better physical functioning, male gender, younger age, being uninsured or on Medicaid, and not being married. Similar patterns were evident for moderate levels of drinking. There was no association between post-injury drinking patterns and TBI severity.

Kreutzer and colleagues (48) first reported that persons with TBI consumed significantly more alcohol before their injuries than same-aged peers; but after injury reduced to comparable levels. Those authors questioned whether drinking as much as other young adults was appropriate for persons who had sustained significant TBI. Later data from the TBI Model Systems National Dataset indicated that significant individual changes occur in drinking patterns over the first four years after injury (49). Of particular interest was the number of subjects who were abstinent and infrequent drinkers at one year post-injury who had increased their consumption by the second year—almost 25% of this longitudinal sample increased alcohol use between the first and second years. Other drug use was not examined. Kreutzer, Witol and Marwitz (49) studied 87 16–20 year olds at an average of 8 months and 28 months post-injury. Before their injuries, 51% were moderate or heavy alcohol users. At 8 months, this proportion was halved with 25% reporting moderate and heavy drinking; however, by the second follow-up this proportion had increased to 35%. Illicit drug use appeared to follow a different pattern, with 29% reporting any use before injury, dropping to 6% and 8% at the first and second follow-ups, respectively. Corrigan, Smith-Knapp and Granger (46) found that substance abuse problems increased dramatically between the second and third year in a cross-sectional study of rehabilitation patients with TBI. Bombardier and colleagues (41) studied 197 adults hospitalized with TBI and found that 65% were moderate and heavy drinkers pre-injury, a proportion that declined to 41% one year after injury. When only heavy drinking and whether the subject experience functional problems as a result of alcohol use were included in a composite index, the pre-injury rate was 51%, while that for one year post-injury was 26%. This study may have been confounded by the sample composition (a disproportionate number of subjects with known risks for seizures) and the failure to include other drug use.

Finally, there is evidence that some proportion of persons with no pre-injury substance use problems develop them after. For instance, among clients with TBI admitted for substance abuse treatment after injury, approximately 20% of those who had abstained from alcohol or were infrequent drinkers pre-injury, became high volume users after (45). This rate may have been inflated by including clients whose TBI occurred in childhood. However, Bombardier (41) found that 15% of pre-injury abstinent and light drinkers were consuming moderate or heavy amounts

by one year post-injury. Neither study consider other drug abuse onset; however clinical experience suggests that some proportion of patients with TBI initiate other drug use to alleviate pain, depression or anxiety. More research on the onset of other drug use would clearly be useful.

### WHAT INTERVENTIONS WORK?

While descriptive information is beginning to accumulate about the scope and nature of substance use and TBI, research on interventions for this problem is almost nonexistent. The only randomized controlled trial was a test of methods for improving engagement in treatment (50). Quasi-experimental studies have provided modest support for the efficacy of motivational interviewing and case management, respectively. There is ample reason to suspect that persons with TBI present for treatment with characteristics unique enough that the effectiveness of proven substance abuse treatment approaches should be evaluated specifically in this population. The greater the cognitive and emotional sequela of the TBI, the more necessary this research becomes. The effectiveness of both pharmacologic and behavioral interventions is required.

There are approaches to treatment being developed for special populations within the substance abuse treatment field that merit further consideration for persons with TBI. For instance, several treatment models have been developed for persons with co-occurring substance abuse and mental illness (51). There are many parallels between these dually diagnosed clients and persons with TBI and substance use disorders. Both populations have cognitive and emotional sequela arising from their disorders; members of both groups report using for regulation of emotional symptoms; and both groups often have multiple other psychosocial needs (e.g., housing, finances, transportation) that arise from or are interdependent with their treatment needs. Techniques developed and lessons learned in the treatment of persons with substance abuse and mental illness may be a fruitful source of ideas for addressing the needs of persons with substance abuse and TBI.

### Intervention and Treatment of Substance Use Following TBI

Clinicians and researchers have repeatedly observed that cognitive and emotional impairments caused by brain injury present unique problems when addressing co-existing substance use disorders (52–54). While several models of how substance abuse treatment can be adapted to TBI rehabilitation were proposed in the past (52, 55), most presumed protracted inpatient or residential treatment that is no longer available to most persons with TBI. Bombardier and colleagues have promoted brief interventions based on motivational interviewing techniques for use

during acute rehabilitation (56, 57). Cox, Heinemann, and colleagues (58) found some support for the efficacy of Motivational Counseling based on a quasi-experimental design using a non-random comparison group. In contrast, Corrigan, Bogner, Lamb-Hart, Heinemann & Moore (50) found a brief motivational intervention did no better than an attention control condition in terms of engaging clients with TBI and substance use disorders in substance abuse treatment. In contrast, a financial incentive condition and a condition in which logistical barriers were systematically addressed both resulted in significantly better engagement than the motivational interviewing and attention control conditions. However, the very brief duration of the intervention, delivered via telephone, may have served to undermine the effectiveness of the motivational interviewing.

The only community-based model other than Cox, Heinemann and colleagues (58) Structured Motivational Counseling is the model proposed by Corrigan and colleagues (42, 59, 60). This model uses consumer and professional education, intensive case management, and inter-professional consultation to address substance use disorders in adults with TBI. Program evaluation data suggest significant differences in outcomes depending on whether discharge occurred before an eligible client could be engaged in treatment (eligible but untreated), after initiation of treatment but before treatment goals were met (premature termination) or upon mutual agreement with staff that goals had been met (treated). The Network's three programmatic outcomes (abstinence, return to work or school, and subjective well-being) assessed three months post-discharge are shown in Figure 59-1. The median length of stay for those discharged successfully is 2 years. As might be expected, drop-out is a significant problem in this model. Retrospective analysis of 1,000 consecutive referrals indicated that 66% of those eligible for treatment either are not engaged or drop out prematurely. Heinemann, Corrigan and Moore (60) used a quasi-experimental design to study initial progress in two programs using the model and a non-random, comparison group of persons with TBI and substance use

disorders who were not receiving treatment. Nine months after admission to treatment, actual use did not change for either the treatment or comparison groups; however life and family satisfaction were significantly better for the treated group. Program referral earlier after injury was associated with larger gains in physical well-being, employment and community integration. The authors concluded that change in substance use requires longer duration treatment, and also noted the challenge of premature termination. If a case management model is found to be an efficacious treatment approach for this population, its effectiveness would be improved by determining better methods to engage and retain clients in treatment.

There is also substantial evidence of the co-occurrence of TBI and substance use disorders in the caseloads of substance abuse treatment providers. Alterman and Tarter (61) found 53% of a sample of 76 male alcoholics had histories of TBI. Hillbom and Holm (62) observed that 38% of a sample of 157 alcoholics had a history of TBI with loss of consciousness or hospitalization. Malloy and colleagues (63) found 58% of a sample of 60 alcoholics had TBI marked by loss of consciousness, hospitalization, or major neurological change. In a more recent study Gordon and colleagues (64) reported finding 63% of 243 consecutive admissions to 13 publicly funded programs in upstate NY were positive for TBI, as were 48% of 404 clients screened in 12 facilities in New York City. Researchers at Ohio State University studied a sample of 119 clients receiving residential treatment, intensive outpatient or ambulatory detoxification in a publicly funded substance abuse facility (65). They found that 68% had at least one TBI with loss of consciousness  $\geq 5$  minutes or requiring Emergency Department care or hospitalization. Perhaps more remarkably, 35% the entire sample had at least one TBI with loss of consciousness of at least one hour or requiring hospitalization. Furthermore, 53% of the sample had at least one TBI from which symptoms persisted at the time of screening. This study also found that clients with substance dependence and TBI showed selected differences on tests of cognitive functioning and emotional control when compared to clients with substance dependence only.

When considered together, it appears justified to expect as much as half of clients in substance abuse treatment to have histories of TBI. Cognitive impairments arising from TBI may affect a person's learning style, making participation in didactic training and group interventions more difficult. Misinterpretation of attention or memory problems as resistance to treatment can undermine a treatment relationship. Damage to the frontal lobes affects executive thinking skills and promotes socially inappropriate behavior. It is easy to interpret these behaviors as intentionally disruptive, particularly when the individual with TBI shows no visible signs of disability (53).

FIGURE 59-1

Outcomes at 3 months post-discharge for randomly selected, treated and untreated clients

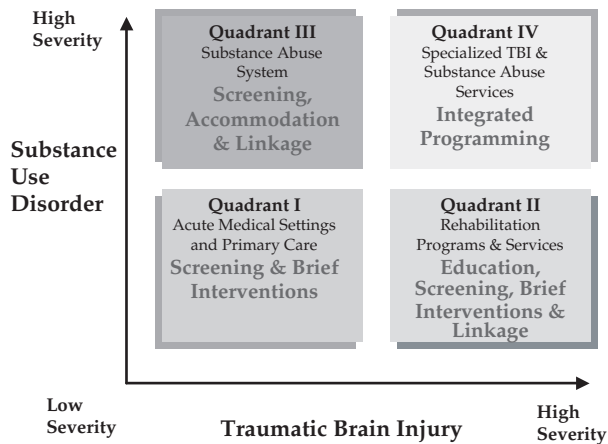

FIGURE 59-2

The four-quadrant model of interventions for substance abuse intervention

#### A 4-Quadrant Model of Substance Abuse Intervention

To help establish a context for a comprehensive research agenda, we have proposed a model for considering variations in the severity of these co-occurring conditions and the association with treatment venues and approaches. The starting point for the schema was borrowed from the literature on persons with co-occurring substance abuse and mental illness (51). As shown in Figure 59-2, persons with substance abuse and TBI are assumed to vary according to the severity of each condition. When mapped orthogonally, four quadrants are defined by high or low severity of each condition. While dichotomizing severity is relatively arbitrary, it proves useful in considering the service delivery systems where individuals are likely to be found. For instance, persons with low severity substance use disorders (e.g., high risk use or substance abuse) and low severity TBI are not found in treatment systems dedicated to substance abuse or TBI as often as they are found in primary care settings and treatment systems for injury (e.g., emergency departments or trauma centers). Only with more severe substance abuse or TBI, is a person likely to receive treatment in programs dedicated to chemical dependency or TBI, respectively. In our model, the co-occurrence of severe presentations of both conditions requires specialized treatment programs; however, given the essential absence of such services this quadrant of the model is mostly hypothetical.

Differences in the service delivery systems where individuals are most likely to be identified dictate different treatment approaches. For instance, in Quadrant I, the most effective interventions will need to be compact in order to accommodate the more pressing agenda of primary care or emergency treatment of an injury. Thus, screening and brief intervention are the most likely services to be provided. Indeed, there is a significant body of literature on

screening and brief interventions for both primary and emergent care (66). Similarly, quadrants II-IV dictate different service delivery opportunities, though in contrast to Quadrant I, there is very little research to guide clinical practice. We expect that an advantage of this model is that research questions can be generated specific to each of quadrants II-IV, and provide guidance both to clinical practice and the configuration of health care delivery systems.

#### Best Practice in Rehabilitation Settings

Though evidence for effective treatment is scant, the scope and nature of the problem requires that substance use be addressed in TBI rehabilitation. Corrigan, Bogner & Lamb-Hart (54) have suggested that all rehabilitation centers provide patient and family education, screening, and, for those at greater risk, referral to community resources. Education should be provided for all patients and families, independent of prior history. Although light or occasional alcohol use does not constitute a substance abuse problem in the general population of healthy adults, multiple factors necessitate different criteria for assessing substance use after TBI. There are several risk factors for development of substance use disorders, or complications accompanying them, applicable to the TBI patients:

- young age;
- high frequency of a prior history;
- unknowns regarding effect on the recovery process;
- decreased tolerance for any drugs;
- interaction with prescribed medications;
- potential to cause seizures;
- exacerbation of sequelae of brain injury; and
- the stresses of prolonged recovery from serious brain injury.

While a “safe” amount to drink for the general population of healthy adults can be recommended, risk factors associated with brain injury make it difficult to identify a level of consumption, other than abstinence, that is certain to not be detrimental. A palatable message for persons who have had a TBI is that no matter the extent of one’s use before an injury, the occurrence of TBI dictates a re-examination of health factors associated with any substance use. Thus, every patient, regardless the prior history or potential risk, should receive education regarding risks associated with substance use following TBI. The information provided should include the potential effects of alcohol and other drugs on recovery, detrimental impact on cognition and behavior, as well as health risks associated with substance use. Families also need this information, as well as additional suggestions for supporting behavior change. While education should be designed for all patients regardless of risk, it provides initial groundwork for those with prior substance use

disorders who need to reconsider their use after TBI. A consistent message about substance use after TBI provided by the entire rehabilitation team creates dissonance between the desire to use and the desire to achieve an optimum recovery. Subsequent referral for treatment is more likely to be successful if the individual is beginning to consider consequences of substance use.

Screening should be conducted during rehabilitation to determine which patients have prior histories of substance abuse or dependence, and thus require referral for on-going treatment. Laboratory tests for alcohol or other drugs are not adequate to determine which TBI patients' substance use is likely to interfere with their rehabilitation and long-term recovery. The presence or absence of drugs at any given point in time cannot confirm or rule out pre-existing substance use disorders, or the potential for them to emerge after discharge. Tests of liver function will be prone to false negatives. A prior history of substance use disorder is best determined from information provided by the patient or a knowledgeable family member. There are standardized measures for inquiring about alcohol abuse and dependence (e.g., the Brief Michigan Alcohol Screening Test (67), the AUDIT (68) or the CAGE (69)), as well as illicit drug use (the DAST (70), or the SSI (71)). However, standardized instruments may be compromised by cognitive impairments common in the acute phase of recovery. A sensitively conducted interview may be the most flexible way of gaining the information necessary to make a determination of prior history and future risk; however, a staff member must be adequately trained and comfortable with the subject matter and method.

Those patients at greater risk for substance abuse after discharge need additional attention. If specialized services are not available through the TBI rehabilitation program, then a referral to community resources needs to be made. Referral is not just providing a name and phone number, it is an intervention. Every TBI rehabilitation program should have a method for making a referral in such a way that patients will find the community resource accessible, acceptable, and useful. The program should develop a referral network of providers who, through experience and training, have some understanding of the unique issues of TBI. Community providers can be most effective when they are adequately prepared for the client. The rehabilitation program should provide educational materials or in-service training regarding TBI in general, as well as common characteristics of persons who may be referred. Cultural congruence should play a role in choosing an appropriate resource, whether AA group, individual counselor, or culturally-specific treatment programs (if available) in the home community. When possible, staff should visit referral sources to gain a better appreciation of the program and facility. For instance, will there be issues of physical, cognitive or financial access? Patients and family members should be prepared for the first meeting with a

provider in order to increase the likelihood that they will accept the services offered. Furthermore, the rehabilitation program's responsibility for referral is not complete until it is determined that at least an initial contact occurred. Better yet, follow-up communication with either the person served or the provider should be undertaken to ascertain that premature termination did not result.

Ultimately, the problem of substance abuse affects all aspects of a person's recovery and all staff members should be a part of the education, screening and referral process. Attention should be given to the attitudes, beliefs and knowledge of the entire professional, if not non-professional, treatment staff. A formal policy should be developed to identify which team members have responsibility for conducting patient and family education, compiling information regarding alcohol and other drug history and risk factors, and making referrals to outside resources. All treatment professionals should support the process, as relevant information or insights may come from statements expressed spontaneously during any staff members' interactions. Substance abuse is a complex behavior, and changing it is difficult. Though there are many issues to confront during rehabilitation, there is a unique opportunity to address substance use and abuse. The consequences of a TBI may cause a patient to question risky behavior. Detoxification has occurred by the time rehabilitation commences. Family members may be more willing to intervene after experiencing the emotional trauma of serious injury to a loved one. Acute rehabilitation following injury is an opportunity for substance abuse intervention that should not be squandered.

## CONCLUSIONS

Rehabilitation professionals lack the empirically based evidence for treatment of persons who incur a TBI and experience substance use disorders. There is considerable need for research to determine the extent to which interventions found effective with the general population are also effective with this group of patients. The anecdotal clinical experience from substance abuse treatment is that many approaches are either not effective or have to be substantially adapted to address persons with TBI. In addition to research on interventions, the field would benefit from additional epidemiologic data about who is at risk for substance use and why. Some patients significantly reduce use after injury while others start or resume. Furthermore, it would be very useful to know how neurobehavioral impairments that result from TBI differ from those that arise from chronic substance use, and whether and how such differences affect treatment.

For our health care systems to be more capable of addressing this population, we need research based recommendations as to what methods of screening for substance

use disorders are the most effective in persons with TBI. Similarly, how do neurobehavioral impairments due to TBI interact or moderate the efficacy of brief interventions for substance use. Within the substance abuse system, we need to know the most effective methods for screening for TBI and to have research based recommendations for how treatment can be adapted and impairments can be accommodated. As suggested by the Four Quadrant Model, we are sorely in need of models for integrated treatment of those individuals with more severe manifestations of both TBI and substance use disorders. Assuming effective models can be identified, we then need to determine how treatment can be made widely available to persons needing this level of care.

## A Cognitive-Behavioral Intervention for Family Members of Persons with TBI

*Angelle M. Sander*

**T**he current Zeitgeist in the field of rehabilitation emphasizes the role of the environment in the ability of persons with impairments to participate fully in all societal roles and to integrate into their communities (1–4). The environmental context can foster the full integration of persons into the community or can provide barriers.

With the increasing emphasis on the importance of the environment, the role of the family in fostering the community integration of persons with TBI has gained more recognition. As the most basic unit of society, the individual's family has the potential to aid or impede recovery from TBI. Persons with TBI are frequently dependent upon family members in a variety of areas, including transportation, finances, leisure, and emotional support (5). A healthy family environment is likely to contribute to better adjustment for the person with injury. Unfortunately, there is ample evidence that TBI results in substantial emotional distress for family members. Family members who are distressed are less likely to be able to provide the support that persons with TBI need as they transition from the rehabilitation setting into the community. In spite of the evidence for family distress after injury, there has been relatively little focus on family intervention as part of the rehabilitation process. With the decreasing length of rehabilitation

stays, the focus is often on training family members to care for the most immediate needs of the person with injury. There is minimal time to prepare family members for long-term cognitive and behavioral changes in the person with injury. There is even less time available to address the emotional needs of family members and to assist them in coping with the impact of injury on their life and relationships.

The purpose of the current chapter is to provide a framework for intervening with family members to assist them in managing injury-related stress and in helping the person with injury to compensate for difficulties in a way that will maximize participation. The chapter will begin with a brief review of the research on the impact of TBI on family members. A framework for conceptualizing the factors that contribute to family members' distress after injury will then be introduced. This framework will be used as a basis for proposing components of a family intervention program. Next, a theory-driven and comprehensive intervention program for family members will be introduced. The chapter will close with recommendations for future directions in conducting interventions with family members. The information in this chapter will be applicable to family members of persons with moderate to severe injury. There has been minimal research on the impact of mild TBI on the family.

## WHAT IS THE IMPACT OF TBI ON THE FAMILY?

The research conducted over the past 30 years has been unequivocal in showing the emotional impact of TBI on family members (6–9). Family members report clinically significant amounts of depression and/or anxiety at the period between 3 months and 1 year post-injury (10–14). They also report significant levels of stress or “perceived burden” related to symptoms in the person with injury (13–17). While most persons with TBI show some improvement in symptoms over time, the research has shown that family distress actually persists and in certain cases increases over time. Substantial emotional distress has been noted in family members as long as 5 and 7 years after injury (12, 16–18). The persistence of distress is likely related to the type of symptoms that tend to endure in the person with injury. While substantial improvements are usually noted in physical, cognitive, and emotional symptoms over the first year after injury, some type of impairment often remains (19). The most enduring symptoms tend to be changes in emotions, social interaction, and higher level cognitive skills (e.g., organization, self-monitoring) (19). Changes in emotional functioning and social interaction skills have been shown to contribute most to family members’ distress (20–23). Evidence of family members’ emotional distress is manifested in the fact that they seek services for mental health problems more frequently after injury and they make greater use of alcohol and other drugs (24). There is evidence that a large proportion of family members have backgrounds that could predispose them toward having adjustment difficulties following injury. These backgrounds include pre-existing emotional difficulties and unhealthy family interactions (25).

Family members’ emotional distress may be partially related to other types of changes that they experience after injury. Relationships among family members often change in a negative way after injury (12, 26, 27). The person with injury is often unable to resume the roles formerly held within the family. Some of the roles vacated by the person with injury may be action roles, such as earning money or performing chores, and others may be emotional, such as being the person who people turn to in times of trouble. The roles that the person with injury can no longer fill are usually taken over by another family member. The result is often that certain family members are attempting to fill too many roles, resulting in role strain. Role strain can have a negative impact on physical and mental health. Another type of change in relationships resulting from TBI is decreased communication among family members (12). Due to the increased time demands related to caring for the person with injury and taking over unfulfilled roles, there is typically less time for quality family interaction. Impaired communication,

particularly with regard to social skills and pragmatics, is common in persons with TBI and may impact the ability of family members to interact with one another. In certain cases, the person with TBI may have difficulty controlling verbally and/or physically aggressive behaviors, affecting the quality of family relationships.

Injury-related stress and changes in the person with injury may have a negative impact upon sharing of warmth and affection among family members (12). Especially for marital partners, injury often results in decreased intimacy and satisfaction with the relationship (26–28). Decreased intimacy can result from a combination of cognitive and behavioral changes in the person with injury, the emotional reaction of spouses or intimate partners to the injury, and environmental stressors, such as decreased finances and decreased time to devote to relationships. Spouses have reported that serving in the caregiving role for a person with TBI places them in a parent-like relationship that is incompatible with their role as an intimate partner (29). Partners often find changes in the person with TBI, such as dependent behaviors and disinhibited sexual comments, unattractive (30). Intimacy is further decreased by the fact that 1/3 to 1/2 of persons with TBI experience some form of sexual disturbance, including decreased drive and/or arousal, impaired physiological response, and decreased ability to achieve orgasm (31–34).

Another type of difficulty that family members often face after TBI is social isolation (6, 35). Immediately following the injury, family members typically experience an increase in social support. Friends, neighbors, church associates, and extended family typically rally during a catastrophic event such as a life-threatening injury. This immediate increase in support often wanes with time. Recovery from TBI is a long process, and for some persons, impairments endure for a lifetime. Sustaining social support for this length of time is rare for most family members. As time goes on, persons who initially provided support often visit and call less frequently. This decline in social support over time is a phenomenon that is typical following most catastrophic events. However, it may be compounded in the case of TBI due to emotional and behavioral deficits in the person with injury. Changes in social interaction skills are difficult for persons unfamiliar with the effects of TBI to understand. People who could provide support for family members may feel awkward interacting with the person who is injured, and may react by avoiding interactions with them and their family. In other cases, family members of persons with injury may withdraw from others because they are embarrassed by the social behaviors of the person with injury (6). In either case, the result is usually that the person with injury, as well as their family members, become isolated. This isolation usually occurs at longer post-injury intervals, when rehabilitation and other medical services have ended, further increasing isolation.

## WHAT PREDICTS FAMILY MEMBERS' RESPONSE TO TBI?

Understanding what enables some family members to adjust relatively well to injury-related changes while others deteriorate physically or mentally is an important first step toward developing appropriate interventions. One possibility is that the family members of persons with more severe injuries and greater impairments will experience greater distress. However, this hypothesis has been only partially supported. While injury severity has been shown to be related to caregivers' distress at 3 to 6 months post-injury, little relationship has been found at longer follow-up periods (10, 11, 15, 21–23, 36). Regarding impairments in the person with injury, changes in emotional functioning and social interaction changes have been found to be related to caregivers' distress (14, 18, 20–23, 37). The relationship between caregivers' distress and cognitive deficits in the person with injury has generally been moderate (15, 22, 23). Physical impairments in the person with injury have not been found to contribute much to caregivers' distress (15, 22, 23).

There is some evidence that spouses of persons with TBI experience greater stress than do parents (22, 23). There are a couple of possible reasons for this. First, parents who care for adult children with TBI are returning to a caregiver role that is familiar to them. While they may not have been in that role with their child for many years, the familiarity of the role may reduce stress somewhat. In contrast, a husband or wife caring for an injured spouse is forced into a role that is likely unfamiliar and uncomfortable. Many family members describe the behavior of the person with injury as being more childlike. It is possible that parents may have an easier time accepting childlike behavior in their adult child than will a spouse. A second possible reason for decreased stress in parents relative to spouses may be that many parents will have a spouse or partner to assist them in the caregiving role. In contrast, a husband or wife caring for an injured spouse does not have the instrumental or emotional support of a partner. In addition, their relationship may have changed in a way that has them grieving for the loss of a significant partnership. It is important to realize that the research has not been conclusive in showing that parents experience less stress than spouses (10, 11, 21, 38). Many parents caring for an injured adult child may experience substantial stress on having their child return to a dependent role at a time in life when they were looking forward to retiring and relaxing. The switch in role may also lead to the emergence of dependence and autonomy struggles that had been earlier resolved during the child's transition to adulthood. Reemergence of these struggles can be very stressful for all involved.

There has also been some evidence that male family members experience greater stress in the caregiver role

compared to females (39, 40). This finding may be partly due to the fact that the caregiving role may be more familiar for many females. Males may also be overwhelmed by the variety of roles they have to assume if their wife is injured. In many households, the wife typically bears the primary responsibility for childcare, household chores, and planning social activities. When the wife is injured, her husband is faced with taking over these roles, as well as maintaining employment. For many men, this results in substantial role strain. Finally, males may be less likely to seek emotional support or to share their emotions with others, making it more difficult for them to cope with stress.

The research to date has shown that injury-related characteristics and demographics only partially explain family members' response to TBI. Professionals who work with families after TBI realize that individual characteristics unique to different family members impact the way that they cope with the injury and related changes. Characteristics unique to individuals, such as coping style, cognitive appraisals of the caregiving situation, and social support can impact their response to stressful situations (41, 42). Coping skills, cognitive appraisals, and social support serve as a buffer between stressful events and family members' physical and mental health. This model has recently been adapted for caregivers of persons with TBI (40, 43). Due to its applicability to designing family interventions, the model and supporting evidence for caregivers of persons with TBI will be discussed in detail below.

## A GUIDING MODEL FOR UNDERSTANDING FAMILY RESPONSE TO TBI

The model below has been adapted from previous research on stress and coping theory in individuals and in families (41, 42).

The model proposes that the relationship between the injury and family members' response, as operationalized by their physical and mental health, is not a direct one. Response to the injury is mediated by family members' coping styles, their perception or appraisal of the caregiving role, and the social support they have available. The model explains why 2 different family members who are caring for persons of similar injury severity with similar types of impairments can have different responses. Each individual is unique with regard to coping skills, the way they view events, and their social networks.

In the past 5 years, several studies have investigated the relationship of various components of this model to caregiver distress. Several studies have found that the coping style of caregivers is related to their distress (37, 40, 44, 45) Specifically, the use of strategies such as escape-avoidance (e.g., wishing that the problem would go away)

and accepting responsibility or blaming oneself is related to higher levels of emotional distress in caregivers (46). Use of spiritual support, use of social support, and reframing of negative thoughts have been found to be associated with less stress and burden (45). The amount of social support that caregivers have available has also been shown to be related to distress (44, 47). However, one study indicated that it is caregivers' satisfaction with social support rather than the actual amount of support that predicts distress (40). The contribution of cognitive appraisals to caregiver distress has not received as much attention as the other components of the model. Struchen and colleagues (48) adapted a measure of caregiver appraisal, The Caregiver Appraisal Scale (49), that had been developed for use with caregivers of persons with dementia. They showed that the scale had validity for use with caregivers of persons with TBI and that negative appraisals were related to greater emotional distress. The subjective burden measure used by Brooks, McKinlay, and colleagues (15-17) can be conceptualized as an appraisal of the impact of injury, since it requires caregivers to rate the overall stress resulting from the injury. Sander and colleagues (40) found that scores on the subjective burden scale were significantly related to symptoms of emotional distress on a psychiatric inventory. They also provided evidence for the utility of the model shown in Figure 60-1. Level of impairment in the person

with injury (stressful event), coping strategies, subjective burden, and social support accounted for more than half of the variance in emotional distress.

### Implications of Research for Family Interventions

The research to date has shown that impairments in the person with injury contribute to family members' distress, and that impairments in emotional functioning and social behavior are most stressful for family members. However, family members' distress is also determined by characteristics unique to family members, including the coping strategies they use, how they perceive the injury and its consequences, and the social support they have and make use of. This information has implications regarding areas to target for intervention. Interventions may also be guided by the research on family needs conducted by Kreutzer and colleagues at the Medical College of Virginia. In a series of studies using their Family Needs Questionnaire, they documented that the needs rated as most important by family members were the needs to receive medical information (50, 51). Family members reported that they wished to receive information on the physical, cognitive, and emotional/behavioral changes in the person with injury. They also reported that they wished to have information presented in a clear and honest

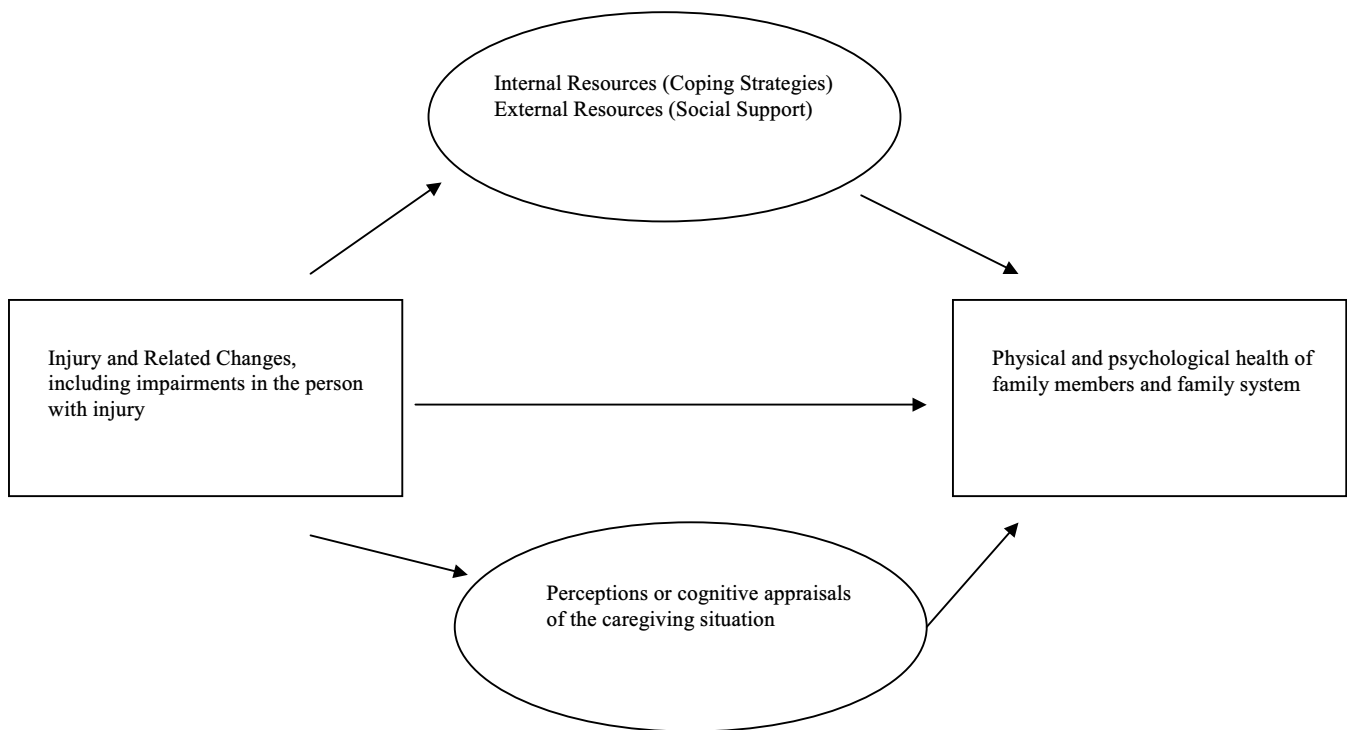

FIGURE 60-1

Model of family adaptation to TBI

manner. As part of these studies, family members were also asked to rate the extent to which various needs had been met. Family members routinely reported the majority of needs for medical information as being met. In contrast, they reported needs for emotional support and instrumental support (e.g., help with practical things like house-keeping) as primarily unmet. These needs were reported as unmet by most family members at long-term periods ranging up to 2 years post-injury (52). Unmet needs have been shown to be related to burden/stress for both African American and White caregiver of persons with TBI (53).

With funding from the National Institute on Disability and Rehabilitation Research, investigators at Baylor College of Medicine and The Institute for Rehabilitation and Research (TIRR) have developed an intervention for family members of persons with TBI. Guided by the research, they have proposed several crucial components of a family intervention program. The components are shown in Table 60-1.

The components shown in Table 60-1 address all of the areas that have emerged as important based on existing research, including provision of information, a focus on strengthening family relationships, improving coping skills, building support networks, and changing cognitive appraisals. These are all components that are proposed as important contributors to caregiver health, as shown in Figure 60-1. The interventions that have typically been offered in the acute and post-acute rehabilitation settings are usually focused on one only or two of these components. For example, education regarding the injury and its consequences, and how to manage cognitive and behavioral problems are a typical focus of many programs. Family members are usually referred to support groups in an attempt to meet their emotional needs. There is generally a lack of use of theory and research to guide interventions, with the result that there is not an integrated

program of intervention for family members that addresses all of the areas shown in Figure 60-1 to be important for family members' adjustment.

At Baylor College of Medicine and TIRR, investigators have developed an intervention program for family members that addresses each of the components shown in Table 60-1. An educational manual has been developed that provides information in all of these areas (54). The intervention has been carried out as a group treatment and as an individual treatment. The remainder of this chapter will be devoted to detailing this treatment and discussing caveats encountered when implementing the interventions.

### A Cognitive-Behavioral Intervention for Family Members

As mentioned above, the treatment has been conducted in both group and individual settings. The research regarding the use of the treatment in individual settings is still ongoing. It is believed that the group approach to family intervention will be the most convenient and economical in acute and post-acute rehabilitation settings. For this reason, the discussion below will describe implementation of the intervention in the group setting.

The group intervention takes place across 6 sessions, occurring weekly for 2 hours each. The intervention is a combination of psychoeducational and cognitive-behavioral treatment approaches. The group is led by a Master's level therapist, such as a Licensed Social Worker or a Licensed Professional Counselor. Each session combines didactic training with group therapy. Thus, participants benefit from the instruction of a professional experienced in TBI, but also benefit from sharing their experiences with other family members and forming a social network that can endure beyond the group. The contents of each group session are described below.

**TABLE 60-1**  
*Components of a Family Intervention Program*

- General education regarding TBI and its consequences
- Direct training in management of physical, cognitive, and emotional/social impairments
- Discussion of changes in family relationships and strategies to improve communication and positive interactions within the family
- Training in stress management techniques for family members
  - Education regarding negative impact of stress
  - Teaching of a relaxation technique
  - Training in effective problem-solving
  - Training in positive reframing of negative thoughts
- Education regarding local and national community resources, including support groups

*Session 1 (Introduction)* Session 1 begins with a general introduction to the group. The therapist explains that the group is being conducted because TBI affects the entire family. Emphasis is placed on normalizing family members' experiences. The therapist commends family members for their efforts to cope with the injury, and provides examples from clinical experience and from the literature regarding difficulties that other family members have faced. Emphasis is placed on the importance of family members attending to their own needs in order to be able to provide adequate care for the person with injury. The importance of emphasizing this point derives from the findings of Kreutzer and colleagues that family members typically place more importance on information regarding the person with injury and less importance on their own emotional needs. Family members often feel selfish if they focus on their own needs when their loved one with

injury requires attention. Family members may feel less guilty about attending to their own needs if they are convinced that doing so will also have a positive impact on the person with injury. Following the general introduction by the therapist, each participant introduces him or herself and tells their story regarding the injury and the events that have led them to the group. The sharing of these stories is an important part of the group experience that allows participants to form a bond that will enable them to be comfortable sharing information in future sessions. Following the sharing of stories, the therapist presents a metaphor that will be used throughout the remainder of the sessions. The metaphor is borrowed from Marilyn Colter Maxwell's book *Missing Pieces: A Coping Guide for the Families of Head Injury Victims* (55). Ms. Maxwell is the wife of a man with a brain injury, and she stated that "Living with head injury is like trying to work a jigsaw puzzle without all the pieces." Group participants are asked if they have felt this way at any time since the injury, and they are asked to share their experiences. The therapist makes notes regarding experiences of individual family members that can be used to personalize concepts taught during later sessions. The first session ends with an overview of the next 5 sessions. All participants are provided an educational manual to take home.

*Session 2 (General Education and Management of Specific Problems)* The second session contains the largest didactic portion of the intervention. The session begins with education regarding different types of TBI (closed versus penetrating) and the mechanisms of injury in each. The metaphor of jello floating in a container is used to illustrate what happens to the brain during injury. A neuroanatomically correct model of the brain is used to demonstrate the most common points of injury (frontal and temporal) and to describe coup-contrecoup lesions and the impact of diffuse axonal injury. Family members responded well to this portion of the intervention. For most participants, this was the first time the injury had been explained in such detail. Following the discussion of the cerebral changes resulting from injury, the therapist describes the most common changes occurring in the physical, cognitive, and emotional areas. Emphasis is placed on the fact that all human brains share many similarities, but each also has unique differences. Thus, participants are made aware that their family members' difficulties may share much in common with those of others, but may also be unique. The therapist discusses the typical pattern of improvement after TBI. Participants are told that the most rapid improvements occur within the first 6 months, with slower improvements occurring between 6 months and 1 year. They are informed that spontaneous improvement typically peaks between 1 and 2 years. However, they are provided with hope that daily functioning and quality of life can improve beyond 2 years

based on the implementation of compensatory strategies and environmental modifications to increase support. This is used as a segue to begin discussing strategies for specific problems in the person with injury. Participants are asked to complete a checklist of neurobehavioral symptoms observed in the person with injury. A checklist was developed as part of the educational manual, but any of the existing neurobehavioral inventories may be used. Once family members have completed the checklist, they are asked to pick 2 problems that result in the most stress for them and their families. The second half of the session is devoted to teaching family members specific strategies to assist the person with injury to compensate for deficits. The educational manual that was provided to family members during the first session contains strategies for all typical problems, so participants have access to help for difficulties that are not discussed during the session.

The strategies taught by the therapist are tailored to be specific to the needs of the participants and their particular family situation. For example, one of the problems that was particularly stressful for the wife of man with TBI was that her husband could not remember what to make for dinner. Her husband had been in charge of cooking dinner prior to injury, and apparently the family had very particular tastes with regard to meal plans. They were partial to certain combinations of food. For example, pork chops were always accompanied by applesauce, corn, and rice. Following the injury, this man no longer had accurate recall of the menu combinations, which was upsetting to his wife and daughter. Since flexibility in the meal plan was not an option that they would consider, the therapist suggested posting a weekly menu containing all the meal plans in the kitchen. The husband and wife wrote the menu together, and he successfully used it to independently prepare meals without having to call and interrupt his wife at work. Rather than attempting to change the dynamics of family interactions with regard to flexibility, which would require a family systems approach and more intensive therapy, the therapist was able to train this man's wife to compensate for the problem in a way that was satisfying to all involved.

The intervention has also shown success in teaching simple behavior management strategies to family members in the group setting. For example, the mother of a 20 year-old man with TBI experienced stress due to her son's perseveration on asking for money. He received a \$50 allowance once per week, but would repeatedly ask for money in between allotments. He would phone his mother often while she was at work, and would begin asking for money as soon as she got home. The mother was exasperated by this behavior, but felt helpless to change it. The therapist presented a simple behavior management plan to her. The first time that her son asked for money after his allowance was given, he would be reminded

that he was given money on Friday and would not be receiving more until the following Friday. He would be informed that the next time he asked for money, \$5 would be deducted from the following week's allowance. Five dollars would subsequently be deducted each time he requested money. The therapist cautioned the mother that this behavior could result in an increase in requests at first, but encouraged her to remain firm in carrying out the plan. This young man stopped requesting extra money within one week, resulting in less stress on his mother and an improvement in their interactions.

The two examples discussed in the paragraphs above are typical of the types of difficulties reported as stressful by family members. While neither of these examples represented life-threatening changes, they resulted in significant daily hassles and stress for the family members. When family members experience a catastrophic event such as TBI, their resources to cope with daily hassles is restricted. Helping them to gain a sense of control by attacking small problems can instill feelings of self-efficacy that can allow them to tackle larger problems. Within the confines of a group therapy situation, it is important for therapists to acknowledge their limits. It will be difficult to change family dynamics or solve large problems. Therapists should be aware of when to refer group participants for individual or family therapy. For example, attempting to alter severely aggressive behavior in the person with injury via group therapy with family members would not be recommended. Altering this behavior would require the therapist to have a detailed understanding of the environmental antecedents of the behavior and contingencies supporting the behavior. The time required to change this behavior is greater than that which could be given during the group session. The danger of escalating aggressiveness during the initial stages of a behavior management plan is an issue that should be closely monitored and is beyond the scope of the group setting. On the other hand, the group setting has been effective for teaching simple behavior management to reduce mild to moderate cussing behavior.

Therapists should always caution family members that each strategy does not work for everyone. Successfully implementing a strategy often requires practice and persistence, and initial failures are common. Family members are encouraged to phone the therapist between sessions to discuss difficulties implementing strategies in the home. The first minutes of the remaining 4 group sessions are devoted to discussion of participants' experiences implementing the strategies. This allows other group members to benefit from hearing the experiences of others and the therapist's suggestions for remediating difficulties. Other family members in the group often offer their own suggestions for strategies that may work. Participants are encouraged to abandon strategies that do not seem to work after repeated attempts. They are

referred to their educational manual for other strategies to try.

*Session 3 (Relationships)* The goal of this session is not to alter family dynamics or to impact the overall family system. Individual family therapy sessions would be required to accomplish that goal. Rather, the goals of the session are to help family members accept that changes in relationships are a natural occurrence after TBI, to help them become aware of changes in their own family and process their feelings regarding these changes, and to help them develop ways to improve communication within their families and increase the quality of time spent together. The session begins with the therapist discussing some changes that family members have typically noted after TBI, including changes in roles, decreased communication, and less quality time together as a family. The therapist begins discussing common role changes within the family, including action roles (e.g., breadwinner, cooking, financial management) and emotional roles (e.g., the "rock" whom everyone turns to in times of trouble; the "clown" that makes everyone laugh in hard times). The therapist discusses the likelihood of role strain after injury and the negative impact that this can have on physical and mental health. Family members are encouraged to complete a chart stating the roles of different family members before and after injury. They are invited to share their stories about role changes in their families. The therapist assists them in finding ways that roles can be renegotiated to reduce strain on family members. Following the discussion of role changes, the therapist initiates discussion of changes in communication and positive interactions within the family. Changes in communication and interactions are explained as resulting from a combination of changes in roles and schedules, as well as the overwhelming nature of the injury and the prominence it has gained in dictating daily life. Participants are encouraged to share their stories regarding changes in communication and interaction within their families. The therapist assists them in developing ways to improve communication and time spent together. For example, family members are encouraged to spend some time together viewing old photos and reminiscing about happier times. Such activities reinforce their unity and emphasize the positive aspects of their relationships.

The topic of sexuality is addressed in an educational way within this session. The therapist mentions that many persons with TBI experience a disturbance in sexuality and explains some of the most common forms of sexual dysfunction. The therapist also explains how the self-esteem of persons with injury can be affected, and how this can impact their sexuality. Finally, the therapist normalizes the feeling that some partners may feel less attracted to a person with TBI.

The session on relationships is the least structured of all the sessions. Therapists should be sensitive to the

level at which various participants have processed changes within their family relationships. Participants should not be pushed to acknowledge changes that they are not ready to process. Some family members may be using denial as a way to cope with negative relationship changes. Therapists should not attempt to break through this denial within the group setting. Sexuality is often a difficult subject for family members to discuss. Therapists should provide an atmosphere open to discussion of these topics by family members who are ready, but should not push them to disclose personal information. The goal is to normalize relationship changes within the context of TBI and to set the stage for later change if family members feel the need. The therapist emphasizes the positive impact of family therapy, including sexual therapy, for some families, and informs participants that they can request a referral at any time.

*Session 4 (Stress Management I: Education, Relaxation, and Coping)* The goals of this session are to educate family members in the negative impact of stress on the mind and body, to train them to use a simple breathing exercise to relax, and to teach them to identify their coping strategies and evaluate their effectiveness. The therapist begins with a visualization exercise. Participants are asked to close their eyes and imagine themselves walking through a forest on a beautiful spring day. Various sensory aspects of the scene are described, and participants are encouraged to imagine themselves feeling completely relaxed. They are then instructed to visualize a snake, coiled and hissing, on the path in front of them. The therapist then leads them through a discussion of the physical changes they notice in their bodies (e.g., sweating, rapid heartbeat, rapid shallow breathing). This segues into a discussion of the adrenaline response and the negative impact of stress on the mind and body. Participants complete a stress symptom checklist to help them become aware of signs that can warn them of stress. Each participant shares their pattern of stress symptoms with the group.

The therapist then introduces a simple breathing exercise. This exercise was adapted from the workbook *Managing Stress Before It Manages You*, by Caudill (56). The exercise involves participants lying down on mats or sitting in a position that is comfortable for them. They are instructed to close their eyes and imagine a balloon in their abdomen. They are told to breathe in deeply and slowly and to imagine the balloon filling with air. They are then told to exhale slowly and fully, imagining the air seeping out of the balloon. The therapist encourages them to imagine the stress leaving their bodies like the air leaving the balloon. Participants complete a visual analogue scale to rate the amount of stress they are experiencing immediately prior to and immediately following the breathing exercise. They are encouraged to practice the exercise at least twice per day for the next week and to

rate their stress before and after each practice. In order to increase the possibility of them practicing the techniques, the therapist asks them to schedule specific times of day to perform relaxation exercises. The therapist emphasizes that learning to relax takes practice and encourages them not to give up if it doesn't seem to be working right away. They are also informed that not every relaxation exercise will work for everyone. They are referred to their educational manuals for other relaxation exercises that may work for them. The manual includes details about how to carry out progressive relaxation and visual imagery exercises. The breathing exercise was chosen over these others for implementation in the group because it is simple, brief, and can be used easily by family members in a variety of settings, even outside of the home.

The second half of session 4 focuses on the development of effective coping strategies. The therapist begins by pointing out that family members are all coping the best way that they know how. However, TBI is different from anything that they have experienced before, and not all of the coping strategies that they've used in other situations may work well in their new situation. The therapist presents several coping strategies that other family members have reported as helpful, as determined by Willer and colleagues (57). These strategies include taking time out for yourself, maintaining a sense of humor, being more assertive, trying to see things more realistically, being careful not to blame everything on the injury, and renegotiating roles and responsibilities. Group members are asked to discuss whether they've found any of these strategies to be helpful in coping with the results of TBI and are encouraged to provide additional strategies that they have found beneficial. The therapist next emphasizes the importance of evaluating coping strategies to make sure they are helpful. Participants are provided with a chart to use when evaluating coping strategies. The chart is shown in Appendix A. The goal of evaluation is for family members to learn to question whether the things they do to cope are leading to the results they desire. They are encouraged to think of alternative coping strategies for those that do not lead to the desired result. The therapist encourages family members to use the chart to evaluate strategies that they use to cope with stressful situations over the next week.

*Session 5 (Stress Management II: Problem-Solving and Overcoming Negative Thinking)* The goals of session 5 are to train family members in a systematic approach to solving problems and to teach them to reframe negative thoughts into more positive, self-empowering thinking. The session begins with the therapist defining a problem as anything that requires a solution or decision. Thus, problems can be very small (e.g., deciding what to have

**TABLE 60-2**  
**Steps Toward Effective Problem-Solving**

Identify the problem
Brainstorm solutions
Evaluate the alternatives
Choose a solution
Try the solution out
If the 1st solution doesn't work, try another one and repeat the evaluation procedure

for dinner) or very large (e.g., deciding which bill to pay when you only have the money to pay one). The therapist emphasizes that the injury has likely resulted in family members having to make so many decisions that they become overwhelmed. The therapist explains that when people feel overwhelmed, even making small decisions can become difficult. Participants are informed that the purpose of learning a systematic way to approach and solve problems is to help narrow down alternatives so that decision-making is easier. They are encouraged that effectively solving problems will lead to reduced stress and an increased confidence in their ability to solve larger problems. The therapist then introduces the problem-solving steps shown in Table 60-2.

When identifying the problem, participants are taught to break complex problems down into smaller steps in order to make it more manageable and to increase the probability of success. They are encouraged to choose the easiest problem first in order to build confidence for more difficult problems. Participants are taught to brainstorm all possible solutions to the problem, even ones that may appear unrealistic at first glance. They are then taught to generate pros and cons for each possible solution, and choose the solution that should lead to the best outcome. The therapist explains that the best solution is not always the one with the highest number of pros and the lowest number of cons. Some pros or cons carry more relative weight than others. When a solution does not seem to work, participants are encouraged to attempt to determine why. At times, this will lead to a new problem that requires a solution. At other time, it will lead to abandonment of the solution and the trying out of new solutions. The therapist emphasizes persistence in repeating the problem-solving steps until a satisfactory solution is achieved. A particular problem that was raised by a group participant during a previous session is then used by the therapist to illustrate working through the problem-solving steps. Family members are encouraged to practice the steps on a real-life problem during the following week.

The second half of session 5 focuses on training in overcoming negative thoughts. The session begins with a simple exercise aimed at helping group members

become aware of the impact that thoughts can have on feelings and behaviors. The exercise follows:

*Your friend says to you, "I found a great new hairstylist and I'll give you the number." How would you feel if you thought that your friend was implying that your hair is looking terrible, and you need some help? [Have them discuss how they would feel and how they might act toward the friend.] Now think about how you would feel if you thought that your friend was really excited about finding a great hairstylist and simply wanted to share it with people she cares about. [Have them discuss how they would feel and how they might act toward the friend.] In this situation, you would feel and act differently depending on the way you thought about what was being said.*

The therapist next explains the ABC model of the relationship between thoughts, feelings, and actions (58). The model specifies that an event or situation (A) does not directly impact feelings and actions (C). The event results in certain thoughts (B) that in turn impact feelings and actions. The therapist emphasizes that while family members may not be able to change the injury or its consequences, they do have power to change the way that they think about things. Participants are provided with a handout containing "The Ten Forms of Twisted Thinking", from David Burns' *Feeling Good Handbook*. (59) This handout describes common forms of irrational thinking that are considered counter-productive to combating stress. For example, overgeneralization is an irrational thought that occurs when someone views a single bad event as indicative of all past and future events. An example is thinking, "My husband's disability claim was denied the first time we tried. I guess we'll never be able to get any financial help." Group members are provided a chart with which to evaluate their thoughts in different situations. The chart is shown in Appendix B, along with an example. Family members are taught to reframe negative thoughts into positive thoughts that instill hope and self-confidence. As shown in Appendix B, the positive alternative thought for denial of the disability claim would be that many people are denied the first time and that better documentation of deficits may result in approval of the claim. Family members are encouraged to use the chart to evaluate their thoughts in different stressful situations over the next week. During the session, the therapist helps group members to identify one negative thought that they have often and to develop a positive alternative thought. They are provided with index cards, with the phrase "DON'T THINK \_\_\_\_\_; THINK \_\_\_\_\_." For example, a card may read "DON'T think we'll never get financial help; THINK we will gather more information in support of our claim and try again." These cards can be placed on their refrigerator, on their desk at work, or anywhere else they find convenient. The

card will serve as a reminder to them to replace negative thoughts with positive ones.

*Session 6 (Accessing Local and National Resources and Wrap-Up)* The last session begins with the therapist reviewing the most common local and national resources family members can turn to for help. The therapist next reviews the highlights of the 6-week group in order to reinforce the material learned. Group members are encouraged to discuss their thoughts about the group, including which parts they found to be beneficial and what they were sorry to not see included. Participants are referred to local support groups in order to continue social support. Family members have also benefited from encouragement to become involved in state Brain Injury Associations and/or in local advocacy groups. The final session is also used to complete satisfaction surveys and any evaluative measures. Areas typically assessed include emotional distress, caregiver appraisals, coping skills, and social support before and after completion of the group.

### **Initial Experiences with the Group Intervention**

As part of a NIDRR-funded project, the group intervention was piloted at 3 centers: The Institute for Rehabilitation and Research (TIRR) in Houston, Methodist Rehabilitation Center in Jackson, Mississippi, and The Mayo Clinic in Rochester, Minnesota. The groups were conducted with family members of persons who had sustained TBI 1 to 2 years prior. In all cases, the persons with injury had received comprehensive inpatient rehabilitation at the participating center. However, family members and the person with injury were not receiving any rehabilitative services at the time of their participation in the group. Two separate groups were conducted in Mississippi and Minnesota, and one was conducted in Houston. There were 3 to 4 participants in each of the groups. All group participants reported satisfaction with the contents of the group. In all cases, they reported that they learned information in the group that they had not heard previously regarding the injury and its consequences. While all family members had been participants in the inpatient rehabilitation process, they had obviously either not been exposed to this detailed information or had not been ready to process it at the time they had heard it. Some specific comments made by group members on the satisfaction survey were that they had learned not to feel guilty about wanting to take time for themselves and that they had learned that the behavior of the person with injury was due directly to brain injury and not to purposeful behavior. Family members also verbalized satisfaction with the social networking afforded by group participation. Some family members exchanged contact information in order to keep in touch after the group disbanded. At one center, one of the groups made plans to

continue meeting after the therapist-led group was completed. While the intervention has shown success in small pilot groups, its effectiveness should be tested in clinical trials. Plans are currently underway to conduct this research.

### **Future Directions for Interventions with Family Members**

*Home-Based Therapies* One of the reasons that the treatment groups described above were so small was that it was difficult to find a common time that was convenient for several family members to meet. The daily lives of families are particularly hectic in the months following TBI. Persons with injury and their family members often have difficulty attending facility-based treatments, even when they report on needs surveys that they desire services. This may be especially true for persons from low educational and/or socioeconomic backgrounds. Persons from these backgrounds often have difficulty obtaining transportation to appointments. In addition, they may feel less comfortable in a research facility or rehabilitation facility. On surveys conducted at TIRR, persons have often reported that they feel more comfortable receiving treatments in their own home or communities. Conducting treatments in the settings where people carry out their daily activities has been proposed as an important alternative to facility-based treatments (60). Conducting family interventions in the home has several advantages. First, it is convenient and economical for most family members. Second, it allows therapists to observe families and the person with injury within the home environment, where they can view problems as they occur. This allows therapists to suggest compensatory strategies that are truly tailored to the environment in which activities will be carried out. Third, facility-based interventions often result in uncertain generalizability to the home and community. Conducting therapy in the home has the potential to improve generalizability. Finally, intervening in the home environment often improves the rapport between the therapist and client. Trust and acceptance are more likely when the client sees the therapist as willing to enter their world and attempt to understand them in their own environment. A study is currently being conducted at TIRR to evaluate a family intervention conducted in the home setting. The family members are from primarily low education and low socioeconomic backgrounds. The rate of therapy completion using home-based treatments has been superior to that obtained when conducting facility-based treatments. Therapy members have generally welcomed research staff into their homes and the information gained through observation in the home setting has been invaluable. Given these advantages, it is recommended that family intervention be conducted in the home setting when possible.

*Culturally Sensitive Interventions* TBI is not a disorder that occurs equally among persons of different backgrounds. TBI is disproportionately represented among minorities and among persons of low socioeconomic status (SES) (61, 62). In spite of this, most persons from minority and low SES backgrounds do not have access to rehabilitation services. Family members in these groups are left to care for persons with injury at an early stage in the recovery process, with minimal training or assistance. Targeting interventions at this population of family members is very important. However, conducting therapy with these family members is often a challenge. They typically read below the 7th grade level, which renders many existing educational materials unhelpful. They often have difficulty relating to the language used by most therapists. For example, they may have difficulty describing their “feelings” about events and may focus more on concrete changes. They also may have difficulty trusting medical professionals due to previous difficulties and disappointments.

Family members from different racial/ethnic groups may hold beliefs that put them at odds with the practices of rehabilitation professionals. For example, many Hispanic persons place primary importance on physiological recovery and do not have a conceptual framework with which to discuss cognitive and emotional issues (63). Professionals should take extra time when providing education to these family members and should avoid using psychological terms. Hispanic persons also tend to subjugate their individual needs to the needs of the family (63). This belief may make it difficult for family members to express negative emotions regarding the injury and any negative feelings they may have toward the person with injury. Normalization of negative emotions will be especially important for these families. Another commonly held belief among Hispanic persons is that external agents (e.g., God) have a greater role in determining their future than they themselves do (63). This belief may result in difficulty understanding the importance of making changes in the environment of the person with injury and developing compensatory strategies. Consulting with experts in the areas of cultural sensitivity will be important for establishing rapport with these groups and for developing interventions that can serve the needs of these populations.

It is also possible that persons from different backgrounds have different priorities in terms of family needs. For example, many minority family members have extended family and support networks, which may result in less distress compared to Caucasian family members. Future development of family interventions that are tailored to the needs of diverse groups of people would be beneficial. Educational materials should be written at a 7th grade level or below. The use of the World-Wide web to disseminate materials to family members is likely to

result in a cultural gap in access to information. In a recent survey conducted within the Houston Harris County Hospital District, family members from a low education and low socioeconomic background expressed a preference for receiving videotaped compared to written educational materials. Translation of materials into languages other than English is crucial for equal access. Finally, extensive outreach will be important in reaching persons from low education and/or low SES backgrounds. Family members in these groups often do not seek help within medical facilities, and they often fall between the cracks of traditional rehabilitation services. Reaching these family members will require actively reaching out within community settings, such as health care clinics and churches.

*Timing of Interventions* The group treatments conducted at TIRR have included family members of persons who sustained their injuries one to two years ago. Studies currently underway are investigating home-based interventions with family members at approximately 6 months post-injury. Conducting interventions beyond the acute period is important based on the research showing that family members’ distress often increases with increasing time post-injury. This is thought to occur because during the initial 6 months after TBI, rapid improvements are usually noted. During this time, family members often hold out hope that things will return to normal. It is only when spontaneous recovery starts to peak and change becomes slower that family members begin to realize there may be permanent change. Unfortunately, this is also the time that rehabilitation services have usually been terminated and family members are caring for the person with injury on their own. Family members typically have many unanswered questions at this point. Providing education during the acute phases of recovery may not always prepare family members for long-term changes. Over the years, it has been noted that family members typically do not recall information that was provided to them early after injury. They tend to only process information that is applicable to the situation at the time. Furthermore, the shock and grief experienced by family members early in the recovery process may be an obstacle to learning information. Future interventions should be tailored to the phase of recovery that family members are experiencing. Recent studies have indicated that needs for information and involvement with care are predominant during the acute phases of recovery (64). Once persons are discharged and are living in the community, family members report needs for service delivery, advocacy/empowerment issues, and social support (65). The research supports that family members need intervention at all time points after injury, including in the long-term. Development of outreach services will be crucial for meeting these needs.

## APPENDIX A

*Evaluating Coping Strategies*

SITUATION	WHAT I DID TO COPE	WHAT HAPPENED	POSITIVE OR NEGATIVE?	OTHER STRATEGIES THAT MAY HAVE WORKED
We needed to see the Doctor because my family member ran out of medications, but there was a 2 month wait list.	Yelled at the receptionist and told her that was a ridiculous amount of time to wait.	Appointment time was not changed. My family member still didn't have his medicine.	Negative	
	Did nothing- just waited until the appointment.	Appointment time was not changed. My family member still didn't have his medicine.	Negative	
	Explained that he's out of medications and asked if he could get a temporary refill until the appointment.	Appointment was scheduled. Medication was refilled.	Positive	

## APPENDIX B

*Evaluation of Negative Thoughts*

UPSETTING OR STRESSFUL SITUATION	NEGATIVE THOUGHTS	WHY THIS ISN'T REALISTIC	POSITIVE, REALISTIC THOUGHT
Example: Your family member's application for Disability benefits was denied.	<p>"We will never be able to get any financial help."</p> <p>"They should have approved our application the first time."</p> <p>"No one cares about us."</p>	<p>One instance doesn't tell you how things will be in the future. People are just following the rules and may not understand the details of your situation.</p> <p>This situation has nothing to do with people's feelings for you or your family member.</p>	Lots of people are denied the first time. We will try again and explain our situation in more detail. If we don't get approved, we will look for other sources of assistance.

## Return to Work Following TBI

**Michael West**

**Paul Wehman**

### INTRODUCTION

Vocational rehabilitation efforts in traumatic brain injury (TBI) have paralleled the increasing survival rate for those experiencing severe injury. Clearly, there have been more expanded efforts at ways of assessing and intervening vocational outcomes of persons with traumatic brain injury in the United States and worldwide. Work is increasingly viewed not only as an extremely worthwhile outcome economically, but therapeutically as an excellent means of enhancing cognitive and physical rehabilitation (1).

The natural course of work return as established by Dikmen et al. (2) suggests that 38 percent of adults with a severe injury, 66 percent of those with a moderate injury, and at least 80 percent of those with a mild TBI return to work within two years of injury. This particular study involved 366 consecutive admissions to a level 1 trauma center who considered their primary role activity to be working. Job retention, however, was not taken into consideration. Vocational rehabilitation intervention may or may not have occurred for this sample.

From the perspective of vocational rehabilitation research and demonstration projects with definite vocational intervention, most of these efforts are focused on adults experiencing a severe injury—Glasgow Coma Scale (GCS) score  $\leq 8$ , post-traumatic amnesia  $>7$  days, or duration of coma  $>24$  hr. A summary of these studies suggests work access in the range of 50–80 percent, with

retention dropping into a range of 50–65 percent of those placed (3) with a second placement considered “almost normative.” Wehman et al. (4) have suggested the use of a standard “monthly employment ratio” (percentage of months in which an individual worked half-time or more divided by months available for work) as a more standard manner of assessing employment success across projects. The reasons for variance in work return across studies, however, is a function of a range of study differences (e.g., lack of clear severity indicators, varying neuropsychological baseline measures, variance in time to rehabilitation and follow-up points, variance in defining outcome variables, etc.) (4).

There have been a wide and varied range of brain injury vocational rehabilitation research and demonstration efforts. Under private sector managed care, companies such as New Medico, Sunrise-Mediplex, Learning Centers, and others were unable (due to funding limitations) to sustain post-acute rehabilitation programs. As a result, a number of professionals who were focusing their energies in the TBI vocational rehabilitation field were forced to find other work endeavors. The Affirmative Industries (leased employee) work transition model, as described by Fraser et al. (5) at a Wisconsin New Medico program, was a benchmark program allowing *diverse, paid work evaluative experiences* for program participants in a residential program. This comprehensive program has not yet been replicated.

As has been noted, most of the existing vocational rehabilitation research has been focused on the moderate to severe injury cases. This is chiefly because most of the individuals involved in post-acute rehabilitation efforts, to include neuropsychologists and other rehabilitation staff, indicate that more than 80 percent of individuals with a mild traumatic brain injury or post-concussive syndrome concerns respond well to rehabilitation and have their issues resolved within a year of onset (6) or don't really need rehabilitation. Much of the concern here can really be the need for diagnostic specificity in mild TBI or post-concussive syndrome cases (e.g., a specific memory deficit, headaches, post-traumatic stress disorder concerns, etc.) and tailored intervention. In general, individuals with mild TBI are not referred to intensive vocational programs or relevant programs are simply not available.

In this chapter we will focus not only on specific return to work issues, but also those critical related factors such as health insurance, benefits planning, community supports, and career counseling in terms of work supports but community issues which affect employment. We begin with a review of the return to work (RTW) literature, with emphasis on those who experience more significant TBI.

### **Review of TBI Return to Work Literature**

Traumatic brain injury can result in variety cognitive deficits, impaired psychosocial functioning, and physical or sensory functioning (7). As a result, individuals with TBI often experience difficulty becoming competitively employed post-injury and maintaining employment for extended periods of time (8–12). Young male adults have the highest risk in sustaining TBI (13), and because the survival rates after injury have dramatically increased due to medical advancements, they are anticipated to have long life expectancies and it becomes imperative that they become employed after recovery. However, high post-injury unemployment rates are continuously being reported. Post-injury employment rates range from 10 percent to 70 percent depending on the study, while pre-injury employment rates range from 61 percent to 75 percent (14–17). It is suggested that this variance in post-injury employment rates is mainly caused by various measures used for injury severity, method of return-to-work process, inconsistency among employment status, and absence of long-term follow-up (3, 14).

Numerous studies have been conducted in an attempt to determine variables that influence individuals returning to work after sustaining TBI. The relationship between injury severity and regaining employment has been examined extensively, but the findings vary depending on the measure used (17). The relationship between returning to work and duration of posttraumatic amnesia

has not been identified (18, 19). Those who returned to work were likely to have shorter duration of coma and were in inpatient rehabilitation for a shorter period (2, 19). Those who returned to work obtained better scores on standardized instruments at admission such as Glasgow Coma Scale (20).

Age at injury was a significant predictor of returning to work for individuals over age 60 (21). Age between 40 and above at the time of injury negatively affected returning to work (2, 17–19, 22–24). The age of individuals returning to work or to school was younger than those who did not (16, 19).

Marital status has been found to have significant relationship with returning to work (16). Individuals classified as married had a lower rate of returning to work compared to those classified as single. There is contradictory evidence regarding gender. While Ip et al. (16) reported no significant difference between gender and returning to work, McMordie et al. (17) reported that females are more likely to regain employment than males, possibly due to females sustaining less severe injury than males.

Educational level and occupation pre-injury has also been examined. Low education level negatively influenced returning to work (16, 18). Persons whose previous employment was either semi- or unskilled manual jobs were reported to have less success in regaining employment (25) and individuals who worked in structural occupations such as building and trades were more likely to return to their former occupation compared to those who were professional, managerial, clerical, or service workers (15). This contradicts studies that indicate greater likelihood of individuals with more education and technical skills having success in returning to work (26). Among those who regain work after TBI, more individuals start a new job rather than going back to their previous one. However, those who were hired by their previous employer remained successfully employed and had higher hourly wages than those who were employed by a new employer post-injury (27).

The effect of race on regaining work after TBI has only recently begun to be examined and the results are contradictory. For example, Greenspan et al. (28) reported that race appeared to be related to failure to regain employment one year post-injury, whereas O'Connell (29) found race to be not significant. Rosenthal et al. (30) examined whether minority status affected short-term and one year functional outcomes and community integration for TBI patients. Regaining employment after TBI was found to have a significant relationship with both pre- and post-injury employment status. This may be due to the relatively low percentage of pre-injury employment rate among minority subjects, if the assumption is made that pre-injury employment provides the skills and attitudes that are needed in post-injury employment (31) and may also

be caused by differences in access to health care (32). Wright (33) summarizes that minorities with disabilities are less likely than whites to receive rehabilitative services, do not receive the same quality or quantity of services, and have poorer outcomes after rehabilitation.

A low level of social support is reported to have negative influence on returning to work (25, 34). Individuals with TBI receive a considerable amount of support while they are in post-acute care facility and also during return-to-work process from vocational rehabilitation personnel. However, after they are discharged and begin the return-to-work process, many require non-professional support, such as from families and community. This becomes an issue for persons sustaining TBI because many individuals with TBI are at a risk of becoming socially isolated (35).

Cognitive issues such as new learning and memory, impaired self-awareness, pre-existing and post-injury dysfunctional behaviors to impede return to work (4). However, not all impairments were identified as being barriers for persons with TBI to return to work or in maintaining employment. They became barriers if they affect achievement of their vocational goal and job maintenance for that particular individual (36). These included cognitive issues followed by emotional functioning, physical impairments such as hemiparesis, stamina or motor deficits, and characteristic and behavioral propensities that existed pre-injury.

Having a significant physical disability (37), psychosocial impairment (38), and cognitive impairment (39), history of alcohol abuse (16, 40) have been associated with impeding returning to work. Acquired deficits in the areas of social behavior, cognitive functioning and personality, all of which can result from TBI, also becomes barriers for persons with TBI to become successfully employed (14, 38). Cognitive deficits and personality change may have greater impact than physical impairment (18, 22, 41).

A combination of variables has been reported to increase the predictability of persons with TBI returning to work. These include: level of education, productivity status pre-injury, and overall functioning at discharge from acute rehabilitation (42); occupational category pre-injury (43); age, GCS score, and Disability Rating Scale score at rehabilitation admission (23); number of neuropsychological impairments (44); post-traumatic epilepsy, paralysis, visual field loss, verbal memory loss, psychological problems, and violent behavior (45).

Much of the prior research has focused on the symptoms and conditions of the individuals that influence returning to work. It is becoming more imperative to examine returning to work after TBI as an interaction between the needs and motivations of the individuals with TBI and the supports available within vocational, social and economic environments (46–48). Factors that lead to successful employment include socially inclusive work

environments and availability of health insurance (48), level of social interaction on the job and return to jobs with greater decision-making latitude (47), and environmental modifications and focusing on vocational strengths of the individual (46).

### Challenges in RTW

The preceding literature review indicates that investigators have typically focused on characteristics of individuals with TBI and the problems they exhibit, with a limited number of studies of the effects of workplace environment (e.g., Refs 47 and 48). However, it is important to realize that there are other influences on RTW that are often underestimated. Foremost among these is likely to be financial disincentives to RTW, such as when the individual is either pursuing or receiving public benefits such as Social Security disability benefits or other financial settlement. It is very likely that these individuals will be reluctant to pursue employment because they may believe that working negatively affect the financial well being of themselves and their families. This perception may seem contradictory and illogical, so some explanation is in order.

The Social Security Administration (SSA) administers disability benefits under two programs: the Disability Insurance (DI) program and the Supplemental Security Income (SSI) program. These two programs were designed to provide “safety net” levels of income and health care to individuals who are not capable of self-support due to disability. Unfortunately, SSI and DI are frequently cited as causes of high unemployment and underemployment of persons with significant disabilities. For example, *Bowe* (49) writes that these two programs are “dependence-oriented.” To be eligible, individuals who seek benefits must prove themselves to be incapable of engaging in Substantial Gainful Activity (SGA), currently determined by earnings of over \$800 per month. Fear of losing benefits, particularly medical coverage under Medicaid (typically tied to eligibility for SSI) or Medicare (tied to DI), persuades most beneficiaries to limit their earnings well below SGA or, more commonly, not enter the labor force at all. Further in this chapter, we will describe some of the ways in which SSA has attempted to counteract work disincentives and encourage their beneficiaries to attempt RTW. Understanding and accessing those work incentives is essential for convincing disability beneficiaries with TBI that attempting to return to work will not cause financial harm to themselves or their families.

In addition, a challenge that is common to many individuals across the range of disabilities is obtaining reliable and affordable transportation to and from work. This may be due to physical problems (i.e., vision, movement, etc.) that may preclude driving, lack of public transportation or paratransit services, or economic limitations

that come with long-term unemployment and high medical costs. Accommodations or alternative work arrangements, such as allowing the individual to telework from home, might be used to mitigate this barrier.

### THE CHANGING LANDSCAPE OF DISABILITY POLICY IN THE UNITED STATES

RTW services are delivered within a “landscape” of disability policy that defines such factors as eligibility criteria, types of services available, funding priorities and restrictions, mandates on providers and employers, and the rights and responsibilities of the recipient of services. Goodall and Ghiloni (50) present a thorough description of recent disability legislation in the United States that impact RTW for individuals with TBI, and brief summaries are provided in Table 61-1. We would like to focus on the most recent piece of legislation, the Ticket to Work and Work Incentives Improvement Act of 1999 because of the impact on Social Security Disability beneficiaries.

It is difficult to assess the participation in SSA disability programs by individuals with TBI because until recently SSA did not include TBI as a distinct impairment. SSA added TBI to its Listing of Impairments in August of 2000, and provided guidelines for disability assessment (51). The Listing of Impairments is used by SSA to determine if an individual’s impairments are severe enough to prevent

gainful activity. Because of this change, in the future it will be easier to estimate the numbers of individuals with TBI who receive SSA disability payments, engage in work activity while in disability status, and use Social Security’s work incentives. Within our own RTW program, nearly 100 percent of supported employment participants enter the program as SSI or DI recipients. It would be a logical assumption the participation of individuals with TBI in SSI or DI is high as well, and particularly for those who have the desire and motivation to return to work.

Hennessey (52) undertook an examination of the factors that influence successful attempts to sustain work effort by 1,003 SSA Disability beneficiaries. The following factors were found by Hennessey to be most significantly related to RTW:

- The individual had a financial need to work (81.8 percent of successful RTWs);
- The individual wanted to work (55.2 percent); and
- The individual’s health improved such that they could work (35.9 percent).

Other factors that were statistically significant included (a) knowledge of all the work incentives that were available to the beneficiary, (b) availability of job placement assistance, (c) flexible work scheduling as an accommodation, and (d) return to the same job and/or employer as before disability.

**TABLE 61-1**  
*Recent Disability-Related Legislation in the Individuals with TBI*

NAME	YEAR	MAJOR PROVISIONS
Rehabilitation Act Amendments	1986	Added supported employment as a service option for individuals with the most severe disabilities who require ongoing employment support.
Individuals with Disabilities Education Act (IDEA) Amendments	1990	Adds TBI as a specific educational disability; mandated school-transitional services for students beginning age 16.
Americans with Disabilities Act (ADA)	1990	Title I prohibits discrimination against individuals with disabilities in hiring, termination, promotion; also mandates reasonable accommodations for otherwise qualified individuals with disabilities.
Workforce Investment Act	1998	Designed to consolidate, coordinate, and improve employment, training, literacy, and vocational rehabilitation programs in the United States; funds One-Stop Career Centers for local service coordination.
Ticket to Work and Work Incentives Improvement Act	1999	Created the Ticket to Work program for SSA Disability beneficiaries; created national networks of authorized employment service providers and benefits advisement centers; strengthened several work incentives for beneficiaries.

Although this study is certainly not conclusive, it provides insight into the practicalities of RTW for SSI and DI beneficiaries. First, successful RTW is dependent on motivation to work, through intrinsic desire to be productive, financial demands, or both. Knowledge of work incentives under SSA programs can help beneficiaries overcome their initial fears about returning to the workforce and the risk of failure. Returning to a comfortable, supportive and accommodating work situation is also critical.

### Work Incentives

To remedy the concerns on the part of beneficiaries regarding employment and loss of benefit, Congress has enacted a number of work incentives for SSI and DI recipients (53, 54). Some of the more commonly used incentives are described in Table 61-2.

Increasing frustration with poor RTW within the SSI and DI programs led Congress to pass the Ticket to Work and Work Incentives Improvement Act of 1999 (TWWIIA, PL 106–170). This section will describe the enhanced Federal and State benefits programs and work incentives that either are or will soon be available to

individuals with TBI and other significant disabilities receiving SSI or DI.

**Benefits Planning and Assistance** TWWIIA establishes a community-based benefits planning and assistance program designed to provide accurate information on work incentives to SSA beneficiaries. SSA has funded entities across the nation to provide benefits planning and assistance, and conduct ongoing outreach efforts to inform beneficiaries of available work incentives. That program, the Benefits Planning, Assistance, and Outreach Program (BPAO), will increase opportunities for beneficiaries to receive information and services needed to become employed and perhaps attain self-sufficiency. Additional information about the BPAO program, including lists of BPAO projects by state, can be found at The Work Site along with information regarding all work incentives ([www.ssa.gov/work/](http://www.ssa.gov/work/)).

**Ticket to Work and Self-Sufficiency** The Ticket to Work and Self-Sufficiency Program is a voluntary program that is designed to allow SSI and DI recipients the opportunity to direct their own employment services and choose the services and providers they feel they need to initiate or

**TABLE 61-2**  
*Most Commonly Used SSA Work Incentives*

WORK INCENTIVE	AVAILABLE TO	DESCRIPTION
1619[a] and [b] Impairment	SSI recipients	These two options allow SSI/Medicaid recipients to retain either a cash benefit ([a]) or Medicaid coverage ([b]) for a period of time after achieving SGA.
Related Work Expenses (IRWE)	SSI and DI recipients	Certain expenses required for employment can be excluded from an SSI or DI beneficiary's earned income in determining monthly countable income. SSA must approve the work expenses.
Trial Work Period (TWP)	DI recipients	DI beneficiaries are given the opportunity to test ability to work without jeopardizing benefits. The TWP continues until a beneficiary accumulates nine months of work (not necessarily continuous work) in a rolling 60-month period.
Plan for Achieving Self-Support (PASS)	SSI recipients	Allows recipients to set aside income and/or resources to be used to achieve specific work goals. For example, money could be set aside for education, vocational training, transportation, or starting a business. The PASS must be approved by SSA.
Extended Period of Eligibility	DI recipients	Allows recipients to retain DI and Medicare eligibility while working.
Continued Payment Under a Vocational Rehabilitation Program	SSI and DI recipients	Allows for continuation of benefits while the recipient is engaged in Vocational Rehabilitation services.

return to work. SSI and DI recipients use a “ticket” or voucher to purchase needed services within an employment network, or EN. An EN can be a single provider agency, a one-stop delivery system, a group of providers that combines resources into a single delivery system, or even employers. If the individual enters and maintains employment above SGA, the EN will receive payment through one of two plans: (i) a fixed percentage of SSI or DI savings, or (ii) at achieved employment milestones.

Each EN in the ticket program serves a designated area and develops individualized work plans with beneficiaries from their service area who seek employment. A work plan will include statements of (i) the beneficiary’s vocational goal; (ii) services and supports necessary to reach the goal; (iii) terms and conditions related to the provision of supports and services; (iv) rights and remedies available to the beneficiary; and (v) the beneficiary’s right to modify the plan. Additional information about the ticket program is available at [www.yourtickettowork.com](http://www.yourtickettowork.com).

*Medicaid Buy-In* The Medicaid Buy-In provisions of TWWIIA address probably the most severe disincentive to employment of SSI or DI beneficiaries, the loss of health care coverage. Many, if not most individuals with significant disabilities will not enter the workforce in full-time positions with medical benefits, and therefore face the loss of health care when their earnings reach SGA. The Medicaid Buy-In component of TWWIIA will allow working individuals with disabilities (not just those receiving Social Security disability benefits) to purchase Medicaid services, just as if they were purchasing health care coverage through an employer-sponsored program.

A state can initiate a Medicaid Buy-In program through a relatively quick and simple amendment to its State plan that redefines eligible populations. This can be done through one or more of the following ways, such as raising income limits for eligible participants, disregarding earned or unearned income of the beneficiary or his/her spouse, or exempting certain assets (such as work-related assets).

In addition to the Medicaid Buy-In, TWWIIA allows working DI recipients to extend premium-free Medicare Part A (hospitalization) coverage for an additional 40 years beyond current limits, to a potential duration of 80 years, under certain conditions. Because each state defines eligibility and limitations for the Buy-In, the state Medicaid agency or local BPAO would be the best source to receive information about the options available.

*Other TWWIIA Incentives* TWWIIA contained two other major provisions that alleviate disincentives to work. Many beneficiaries are reluctant to attempt RTW out of fear that they would be unable to regain benefits should their physical or mental condition worsen and they would be unable to continue working. TWWIIA allows

an individual to receive immediate reinstatement of benefits that were terminated due to earnings. To be eligible for reinstatement, an individual must request reinstatement within 60 months of termination of benefits.

Another major disincentive was the potential impact of work on a Continuing Disability Review (CDR). CDRs are periodic reviews to determine if an individual’s medical condition has improved sufficient to terminate disability benefits. Any earnings reported to SSA might “trigger” a CDR before the individual is working at a self-sufficient level. TWWIIA addresses this concern by, first, disallowing CDRs for any beneficiary who is using a ticket, and second, disallowing CDRs triggered by work activity. CDRs that are regularly scheduled are allowed.

### CAREER DEVELOPMENT OF PERSONS WITH TBI

Career development theories have evolved during the last ten years and the pressure to address the needs of racial and ethnic minorities is making those more and more useful to people with disabilities. However, despite this fact, applicability of career development theories for people with disabilities remains a concern. Empirical research on the impact of disability on careers is at a relatively early stage. According to Szymanski et al. (55), outcome on career development for persons with disabilities has been strikingly similar to the study outcomes on racial and ethnic minority groups. Research has revealed that people with disabilities are underrepresented in the labor market and that certain contextual factors like education are related to employment. Outcomes have not indicated what mechanisms are involved in the career development of people with disabilities.

Szymanski et al. (55) also report, that there are some methodological problems inherent in studying the career development of people with disabilities. Various studies, and in particular those related to career indecision, have been plagued by poor design, conceptual ambiguities, methodological weakness, and low statistical power. Thus, it is not surprising that the data have resulted in conflicting findings. Even in light of these discouraging findings, career development theories can provide a conceptual framework that can be useful when providing career counseling to persons with disabilities. The key is to adjust the approach to the individual circumstances at hand (6).

Future research on career development for people with disabilities presents some interesting challenges. On the one hand, it is important to study this population due to their limited access to employment opportunities. On the other hand, it is important to recognize that there are inherent flaws in studying this or any population in isolation or in simple comparison with another group (33).

To better understand the career development of people with disabilities in a broader context future research should include people with disabilities and those from racial and ethnic minority groups in larger scale research. Qualitative research should also be considered to improve our knowledge of the complex interaction between disability and career development.

### Career Interest Assessments

Career assessment interventions are important tools that allow people with or without disabilities to take control of their career planning. The 1992 Amendments to the Rehabilitation Act emphasize consumer involvement in the rehabilitation process, including vocational assessment; self-rating instruments and interviews appear to provide the individual with the disability with more involvement over the assessment process. In this section we will review several types of interventions that were selected by the authors due to their availability and applicability for people with Traumatic Brain Injury (TBI).

Many career assessment tools are available on the Internet. One of the most popular career interest inventories is the Self Directed Search designed by John Holland. There are three versions one for adults, one for college students, and one for secondary school students and adults with limited reading skills. It is based on Holland's theory that there are six basic personality types: Creative, Realistic, Investigative, Artistic, Social, and Enterprising. The theory assumes that there are six corresponding work environments, and that individuals will find "person-environment fit" in work environments that most closely match their personality (56).

The Strong Interest Inventory may also be useful in assessing career interests of individuals from middle school through adulthood. The instrument reports a score for the six areas of interest described by John Holland, as well as 23 basic interest scales and 207 occupational scales. Myers-Briggs provides information on personality type, and will give added perspective to self-exploration exercises. Both the Strong Interest Inventory and the Myers-Briggs are online at Career By Design at [www.careers-by-design.com/](http://www.careers-by-design.com/).

The ability to reason is not a single process, but an extremely complex network of related processes. After a TBI, even simple tasks like completing an interest inventory, can require a great deal of thought. The inability to reason, make sound judgments and initiate, and plan or organize, may become virtually impossible, and this can affect a person's ability to independently perform career exploration activities. In such an instance a vocational specialist can provide the necessary support to enable the person to complete this type of activity.

Another popular career counseling strategy involves using computer assisted systems. These systems are able to handle vast quantities of information and assist with

integration of information (78). Many computer assisted career guidance (CACG) systems are available: CHOICES, SIGI Plus, and DISCOVER to name a few (57). These interventions provide individuals with current, accurate, locally relevant occupational, and educational information.

Discover is a computer program that assists people with self-assessment and provides information related to making career decisions. SIGI Plus is similar, however it does not provide information on postsecondary education. Choices should be used under the guidance of a vocational counselor. It helps the jobseeker learn more about abilities and interests and how they may relate to different careers.

Some persons with TBI may be able to use these tools with out assistance, while others may need help with reading, writing and interpreting the results. In addition, to learning more about vocational interests and aptitudes the opportunity to work through a career search exercise with a person with a TBI can also provide valuable information about current physical, cognitive, and social skills.

A number of career planning books are available to assist persons with identifying their skills and abilities. For example, Melanie Witt's book *Job Strategies for People with Disabilities* (58) contains a wide range of self-assessment tools to help a person define their career direction. Another career planning book, *Coming Alive from Nine to Five* by Betty Michelozzi provides a number of self-assessment exercises that may be useful to person seeking a first job or switching career tracks. Again, some job seekers with TBI may require assistance with completing the assessments, as well as interpreting the results and translating this data into useful career search information.

### Experiential Assessment

Work experience and similar interventions like volunteering or job shadowing may be useful for some people with TBI. If an individual has very limited experiences from which to make an informed career decisions, a work experience may help the person choose a career direction (55). Volunteering in various work settings may give some individuals with TBI ideas on abilities, preferences, and support needs. Job shadowing, can also serve this purpose. This strategy typically involves observing or "shadowing" a person who is performing a job. Some persons with TBI will need assistance with setting up and participating in either type of activity. A vocational rehabilitation specialist can assist an individual with contacting employers and making the necessary arrangements. Then while the activity is taking place, the vocational rehabilitation specialist can accompany the person to the jobsite and make notes on the person's likes and dislikes for certain types of jobs and work settings. This type of information can be very

valuable in the future when the person is actively trying to determine an initial direction for the job search or making decisions about whether or not to accept a job offer. Please note that neither of these activities should be viewed as a prerequisite to going to work, instead both are time-limited career exploration activities.

### **Home Visits**

Whenever a vocational rehabilitation specialist is involved with assisting a person with a TBI with locating work, a home visit can provide important vocational assessment and career search information. During the home visit the individual with the TBI is asked to share details on current abilities, work interests, and values. The person is also observed performing various tasks in their home environment, which demonstrates current physical, cognitive, and social skills. In addition, casual conversations about activities of daily living, tasks completed around the house, and leisure pursuits can also lead to some ideas on vocational abilities and interests (59).

### **Career Information Interviews**

This approach provides a valuable means for learning more about an occupation or industry. It involves setting up an appointment with someone in a particular field and interviewing the person to learn more about a specific occupation or industry. Some people with TBI may need assistance with setting up and conducting the interview. In this instance, a vocational specialist assists the person with determining the businesses to contact, making contacts, coordinating the interview, formulating questions to ask, and actually conducting the interview. The person with a TBI is encouraged to participate in each activity as much as possible. The vocational specialist should assist as needed and if present at the interview should take notes, as well as make observations of the individual's abilities. This type of exploratory interview offers the job-seeker information on minimal qualifications, education or training needed, for certain types of work. Information on how a particular career choice might impact future earnings and quality of life can also be gleaned from an informational interview (59).

## **VOCATIONAL ASSESSMENT**

### **Functional Assessment**

As mentioned earlier, through the years, traditional evaluation practices that use aptitude batteries, work samples, and behavioral inventories have dominated vocational evaluations for persons with severe disabilities. However, problems related to reliability and validity has demanded

that the process of assessment be conceptualized once more, so persons with disabilities are not being considered "too disabled" and unable to work. The traditional evaluation process is a linear process that identifies interests, abilities, and aptitudes at one point in time and assumes that this will not change overtime. Then these outcomes are used to predict subsequent learning, performance and success at work. Simply said, they focus on what someone cannot do rather than tuning in to the power of workplace accommodations and on the job supports.

Since many persons with severe disabilities like TBI enter the vocational assessment or evaluation process with limited marketable skills, they are likely to be excluded from work. Instead, they may be told that they need a longer recovery period prior to seeking work, or that they are not likely to ever work again and should be resigned to staying at home and collecting government benefits. In the worse case scenario, they are advised to enter programs to "get ready" to work, offered pre-employment training for menial jobs, sent off to day activity centers, or to work in an enclave. An enclave involves having a small group of people with disabilities working together in a community-based job, while under the constant supervision of a vocational rehabilitation specialist. For example, a group of five people may work as a team to clean a department store.

Traditional vocational evaluations occur in artificial and simulated environments, which are not reliable or valid indicators of what someone can do in the real world. There are a number of limitations in traditional approaches to vocational evaluation for persons with significant disabilities. The authors strongly believe that the most fair and reliable way to assess a person's abilities is within the context of real work environments. And furthermore they believe that the focus of a vocational assessment should be on interests, abilities, supports available, and supports needed to succeed at work.

### **Consumer-Focused Alternatives to Traditional Vocational Assessment**

An approach to career planning that is gaining more and more popularity, particularly in the medical community, are customized functional vocational assessments in real work environments (60). A functional vocational assessment provides a specific appraisal focusing on the needs, skills, and interest of the person within the context of future work environments.

This practical approach can provide valuable career development information to individuals with disabilities and particularly those with the most significant disabilities. All too often persons with severe disabilities are considered either too disabled to work or not ready for employment. This approach focuses on current strengths and abilities and the types of supports that will enable a

person to succeed in the workplace. Since the assessment is customized, the design depends upon the person's previous work history and any current employment options. If the individual was working at the time of injury the assessment may be geared toward examining one of the following options: Return to Pre-injury Employer (includes self employment) performing pre-injury job (with or without accommodation), or return to Pre-injury Employer with reassignment to a different position (with or without accommodation). If the person does not have the option to return to the pre-injury employer, but desires information on whether or not he or she can use a specific skill set in the workplace, a Residual Skills Assessment may be warranted. If the person has limited or no work history or has been absent from the workplace for an extended period of time then a Career Exploration Assessment may be conducted. No matter which approach is used it is important that the evaluator is knowledgeable of any work medical work restrictions in advance to planning the assessment approach. A brief description of each approach will follow.

### **Accommodation and Support Needs**

People with traumatic brain injury who are returning to work may need to perform their job in a different way or require modified workstations, compensatory strategies, or other accommodations or supports (61). In this approach a vocational rehabilitation specialist works closely with both the employer and employee to assess the person's vocational abilities by taking data on some specific vocational skill and if warranted recommend support strategies.

Once the person receives a release to return to work, the vocational rehabilitation specialist (with the employer's permission) accompanies the employee with TBI back to work and makes observations on the person's ability to perform the essential job functions. This criterion-referenced assessment measures the individuals' ability to do a specified task by collecting data on the steps of that task. Depending upon the nature and complexity of the job, other job-site personnel may need to be involved in planning and implementing the assessment. If difficulties arise, the specialist makes recommendations on ways to remove barriers and enhance independent performance.

For example, the returning employee and/or employer may need assistance with identifying and implementing accommodations like compensatory memory strategies. The return-to-work assessment is not used to determine whether or not someone can return to work but instead can provide ideas on types of possible accommodations and supports needed to enhance a successful return to work.

### **Residual Skills Assessment**

While some individuals may have work to which they can return to, others may not, but may have a keen interest in pursuing an employment opportunity that requires the use of his/her specialized skills, training, or educational background. In order to make an informed decision about whether or not to return to this type of occupation, the individual may need information on his or her current skills, abilities, and possible accommodations. A customized vocational assessment specifically designed to explore current level of functioning in a previous line of work and support needs may prove useful, and instill the confidence the person needs to return to this type of work. Sometimes the assessment may also relate to using one's educational background in the workplace and might help someone determine whether or not to pursue a career in a specific field.

Depending on the nature and complexity of the occupation in question, a consultant who is actively engaged in such work may be needed to assist with designing and implementing the assessment. The consultant should be someone who could be considered an "expert" in the field or area that is under exploration. The vocational specialist usually takes responsibility for locating and securing the consultants' service, coordinating the effort, assisting with the assessment design and tools, and writing a report. The specialist may also actively participate in the assessment process by making observations and collecting data on the individual's abilities and support needs.

### **JOB SEARCH AND EMPLOYER NEGOTIATION STRATEGIES**

Career development and planning are necessary first steps toward going to work and once a vocational direction has been established the job search should begin. As the search unfolds, the direction should be modified based on any new information that surfaces during this process. This section will review some of the issues that impact the job search and suggest strategies that may be useful when assisting persons with TBI with going to work.

### **Disability Issues**

According to a recent Louis Harris and Associates (77) national survey of people with disabilities, more than 71 percent of working age adults with disabilities are unemployed, despite the fact that two-thirds of these individuals want to work. Moreover, in 1992, an extensive national longitudinal study of students with disabilities who had exited schools found that the employment rates of individuals with disabilities lagged significantly behind those of their peers without disabilities (62). Other studies

confirm a continuing troublesome trend toward high rates of unemployment or underemployment for former recipients of special education services (63, 64).

These results suggest that the issue has never been whether or not persons with disabilities want to work, but instead has been on what is inhibiting their participation in the workforce. Several interrelated issues have made securing work a significant issue for persons with TBI. These include misperceptions and prejudice by employers, the general complexity involved in conducting a job search, and effectively representing one's abilities and support needs to an employer either during an interview or once hired.

Despite protections under the ADA, many people with disabilities remain unemployed. The law protects only qualified applicants or employees with disabilities. Some persons with significant disability may have a difficult time qualifying for an existing position or competing with all who apply for a given work opportunity. If an applicant or employee does not disclose that he or she has a disability he or she is not covered under the ADA. But at the same time, revealing this information may lead to being screened out of a job.

To avoid this conflict, it often pays to explore the "hidden job market". This requires learning about job opportunities before anyone else knows about them; these are the positions that are not being advertised. The best ways to tap into the hidden job market area by networking with personal contacts and contacting employers directly.

Individuals with TBI may have very limited personal networks due to social isolation (35). And in the instance where a personal network exists the individual may not be able to independently use his or her network to locate job opportunities. Memory problems can also make it difficult to manage the job search. For example, the person may not follow up for lead in a timely manner or may miss appointments with employers. Transportation can also be a problem. Some individuals may have difficulty getting to and from places of businesses without some assistance. Also, due to the myriad of cognitive problems that may result from a TBI some individuals may experience great difficulties with exploring occupations as well as conducting pre employment activities like completing employment applications, interviewing for a job, completing pre employment testing, and advocating for necessary on the job supports or accommodations.

It typically is the responsibility of the job applicant to best present his or her abilities to employers, and some people with TBI may have a difficult time doing so. Some individuals will not be able to explain to employers how their particular skills and abilities match the qualifications for the job. If the person is in need of an accommodation, he or she may experience difficulties explaining to the employer what is needed to allow him or her to

succeed. Some persons with TBI may need to convince an employer to redesign task, location, or restructure a job that was originally designed with individuals without disabilities in mind. This may present difficulties for the applicant with a TBI if he or she has a myriad of cognitive difficulties and is unsure of what he or she may need to succeed on the job. If the job seeker is unclear on how his or her abilities can best match an employer's needs, it is unlikely that a job offer will surface.

Sometimes, employers may not see a "new or different" way to get a task done or may see the request for change as bothersome. Instead the company representative may simply choose to hire someone else who does not require any accommodation. On the other hand, many employers may be willing to hire individuals with TBI, but may need support to determine how best to make reasonable accommodation. Vocational rehabilitation specialists can be a valuable resource for employers in this area.

Vocational rehabilitation usually offers a range of job search and placement services, from the least to most intrusive approach. The approach selected generally depends upon the individual's abilities and support needs. We will review a couple of these approaches and then focus in on what the author's view as the most favorable strategy for assisting persons with severe TBI with gaining employment; a customized and tailored approach to this process.

### **Minimal Intervention**

The first approach generally involves a minimum amount of intervention from a vocational rehabilitation specialist. For example, the jobseeker may simply need information on the labor market, insights concerning their interviewing skills, or leads on employment opportunities. Or perhaps the person simply needs information on adaptive aids or effective compensatory strategies. These individuals often know what they want, but need specific information to put their plan in to action. They may have previous work history and have a good work ethic. These individuals are usually able to read, write, and can follow through on complex directives without assistance. They take the information given to them, generalize it, and apply it to their lives. There need for vocational assistance is often minimal. Unfortunately, vocational rehabilitation professionals, who are unfamiliar with TBI may feel that a person with an injury is much more capable than he or she truly is and may only offer minimal job search and placement assistance. Afterwards, in instances where the person does not follow through on specific directives this may be perceived, by the vocational rehabilitation provider, as a lack of motivation to work on the part of the individual with TBI and in some instances may lead to termination of services.

### **Education and Preparation Approach**

The second vocational placement approach is for those individuals who appear to need some type of intervention, but not an extensive intervention. Usually, these individuals do not assimilate information quickly, and require assistance with carrying out a job search, but once employed may need no or limited assistance on the job. Often times, these individuals participate in classes designed to get ready or prepared for conducting either an independent job search or a job search with some limited assistance from a job placement specialist. This approach is usually not very effective for persons with significant TBI since most of the training takes place in a classroom type setting. Usually classes are conducted to teach job seeking and maintenance skills. For instance students learn about various occupations and how to analyze themselves and the job market to choose an appropriate career path, or receive information on how to complete employment applications or learn how to interview for a job.

Sometimes, particularly for persons with severe TBI, an inordinate amount of time is expended trying to get the person ready to conduct a job search, when in reality it is highly unlikely that the learning that takes place in the classroom will ever generalize into the real world. Instead, the authors feel that time could be better expended by providing individualized job placement assistance that is tailored to each job seekers specific needs and abilities.

### **Customized Approach**

This approach can be helpful to anyone with a disability, but is particularly useful for people with more severe disabilities like TBI. Using this strategy the type and intensity of services and supports are adapted to each individual's needs and under some circumstances involve extensive intervention. Generally, individuals with significant cognitive impairments need more assistance with obtaining employment than those who have moderate physical or sensory disabilities. These individuals tend to learn best in the milieu where they will be expected to perform instead of learning away from that environment. Generally, they need one to one assistance with identifying their vocational strengths, support needs, and conducting a job search. Once employed, they may need assistance on the job. One vocational service option that offers individualized and intensive support services for both gaining and maintaining employment is Supported Employment. This approach encourages full inclusion of the person with the disability in his or her job search and offers reality-based activities. A person does not have to get ready to work instead a vocational support person sometimes called a job coach provides assistance with helping the person identify his or her abilities and support needs, contact

employers to discuss hiring needs, and offers on the job assistance and long term follow along. This service option will be discussed in more detail in the next section.

## **WORKPLACE SUPPORTS**

No two individuals with TBI are alike, nor are their abilities or disabilities similar. Add in the different types of occupations and the huge variances within work environments and you have a totally unique situation on hand. Therefore, individuals with TBI who are attempting to return to work will need supports that are customized to meet their individual needs at a specific workplace. The type, level, and intensity of support will vary depending on the person's abilities and the particular circumstances on hand. Some individuals with TBI may simply need information and guidance on how to conduct a job search or ways to compensate for memory deficits on the job, while others particularly those with severe disabilities will need more intensive intervention and one to one assistance. Furthermore, the type, level and intensity of support someone will need, does not remain static, but changes over time. For example, after learning how to do a job task, the individual may need additional instruction when new duties are introduced. Individuals with TBI, may benefit from a combination of workplace supports. Some examples follow. For example, someone who has a job to return to will not need assistance with locating a new occupation, however once back to work he or she may need assistance with learning how to get organized and manage their workload.

### **Accommodations**

Some people with TBI will benefit from accessible building, particularly if the person has difficulty walking or uses a wheelchair for mobility. For example, a wheelchair lift was installed outside of the entrance of an inaccessible older historical building that allowed the employee who uses a wheelchair access. Those who have changes in vision post injury may also benefit from access supports. For example, raised letter directional signs may be posted in a building to help an employee identify restrooms or elevator controls.

A modified work schedule that allows an employee to get to work on time may also be necessary. For example, a person may be allowed to work 10 a.m. to 6 p.m. rather than 9 a.m. to 5 p.m. due to limitations on the availability of transportation to and from work. In other instances a person may need part-time work due to changes in one's stamina level or an increase in fatigue. Other people with TBI may be able to work full-time, but may need to have an opportunity to take additional scheduled breaks throughout the workday.

Job restructuring is another important accommodation. This involves having a non-essential (not major) work function or a marginal duty removed from an employee's job description or a difficult task that the employee cannot do is exchanged for one that can be done. For example, a general worker at a retail store is not able to climb ladders to change the light bulbs. Management agrees to allow another employee to do this and in exchange the worker is responsible for checking the parking lot and returning customer carts to the building.

Sometimes, particularly if the person has a physical disability or slowed movements post injury it will be useful to purchase assistive equipment or devices to improve their ability to get the job done. More often existing items in the workplace may be modified or added on to accommodate the person. Assistive technology ranges from high tech to no tech, costly to no cost. Fortunately most auxiliary aids are not expensive.

For some individuals a change in where their work is performed may be helpful. This may simply involve allowing the employee to move to a different workstation or in some instances and if applicable allow telecommuting or working from home.

Some individuals with TBI may need support services. Examples of support services may include assisting the person with carrying out activities of daily living like eating or going to the restrooms, having a "buddy" assigned to alert the worker to an emergency situation, or helping the individual take notes during an employee training, or staff meeting.

Perhaps one of the most useful accommodations for workers with a TBI are internal or external compensatory strategies. Internal strategies require the use of a mental support system and do not rely on external devices. Examples include, making associations or drawing on analogies to remember how to do a task or using word mnemonics to remember a specific sequence. External strategies involve the use of objects like checklists or flowcharts to remember a sequence of steps to follow to complete a work activity. These strategies can serve multiple purposes. They not only promote learning, but can also serve as a reminder of what needs to be done and helps keep the worker organized, so the job can be completed in a proper and timely manner.

It is important to remember that all workplace supports and adaptive solutions that are used to compensate for functional limitations are highly individualized. In addition, the solution to the presenting problem will be highly dependent upon the user's willingness to use a strategy, as well as, the type of job tasks involved, the work environment, and the employers' consent to allow the use of the accommodation. Although, these examples were presented in isolation it is often the unique interplay and right combination of supports that will lead to success at work.

Table 61-3 below provides some examples of the types of workplace strategies used by employees with TBI, who used a Supported Employment approach to assist them with going to work post injury.

Sometimes there are existing cues in the workplace that the new employee can learn to attend to that will promote successful job performance. Consider the following examples, a landscaper who is required to mow the lawn in a large office complex, is given a diagram on a daily basis that illustrates what areas are to be cut that day. A patient transporter works in a hospital that has different colored signage that helps him find his way to the correct destination. A medical supply order puller receives a printout indicating where in the warehouse the items needed are located.

In other instances the necessary support will be simple ergonomic modifications to the workstation or a change in the way the work is performed. This might include adapting the layout of a workstation so that the task can be better sequenced, raising a worktable to accommodate a wheelchair or customized seat, or using jigs or adaptations to mitigate the employees limitations in vision, dexterity, judgment, etc.

### **Job Coaching**

Most individuals with severe traumatic brain injury will need assistance with locating work, as well as assistance learning how to perform the job. One approach that has successfully been used to assist people with TBI with going to work is supported employment (4, 41). Using this approach a vocational rehabilitation specialist known as an "employment specialist" or "job coach" provides one to one individualized assistance to assist a person with a severe disability with finding a job, and once employed provides or facilitates the supports needed to help the person succeed at work. The type, level, and intensity of support varies depending upon the newly hired employee's abilities, the job, the work environment, existing supports in the workplace. Table 61-4 provides a brief overview of the role of the employment specialist, the person with a TBI, and other return to work process team members.

The level of involvement of the rehabilitation team will vary depending upon the time post injury and who is currently following the individual when he or she goes to work. The authors advocate for return to work as soon as possible. If a person has a job to return to it is important that some member of the team or family member act as a liaison with the employer to keep them abreast of the individual's progress in rehabilitation. In some instances the person may not be able to return to the same job, but there may be some other type of work within the organization. Some people maybe able to begin to return to work while involved in day rehabilitation on a part-time

**TABLE 61-3**  
*Examples of Workplace Supports*

<b>POSITION TITLE</b>	<b>JOB-RELATED FUNCTIONAL LIMITATION</b>	<b>PRESENTING ISSUE</b>	<b>WORKPLACE SUPPORT</b>
Receptionist at small business	No use of arms or hands, unable to walk	Taking messages on the telephone	Tape records voice messages then uses voice activated software to type messages
Garment bagger at dry cleaners	Unsteady gait, loss of balance while walking or standing; becomes tired easily	Pulling bags over cleaned garments from a standing position; maintaining stamina	Fabricated metal stand to maintain balance while standing; has flip down seat to rest on when tired
Inventory clerk/order puller for retail store	Becomes frustrated when interrupted and yells at others	Appears angry when new coworkers ask for instructions on how to do the job	Created oversized document to refer new employee's questions
File clerk at insurance company	Becomes defensive or denies having any difficulty when given personal feedback	Appears angry when given constructive feedback on job performance	Uses self monitoring tool and discuss ways to improve performance
Cashier for fast food company	Socializing with strangers in an appropriate manner	Asked customers for their telephone numbers	Posted reminder "Don't creep me out" with picture of unhappy looking female on the phone
Activities assistant at nursing home	Remembering sequence of things to be done throughout the day to complete normal routine	Could not remember what order to complete various job duties	Organized master schedule of various duties to complete on certain days and a list of things to do once duties are done
Plant installer at green house/plant retail store	Remembering how to complete a certain task	Could not remember how to clean and care for various types of plants	Created manual with instructions and cross referenced by plant typical and phylum name
Houseman at hotel	Remembering what to do outside of normal routine	Could not remember what tasks to do outside of normal work routine	Manager on duty writes daily list of things to do in order of occurrence

basis. Some people will not have a job to return to or were unemployed at the time of injury. These individuals will need to seek new employment.

Again the composition of the team will vary depending upon a number of factors. For instance, if the person is involved in or has recently completed out patient rehabilitation the team is likely to be made up of the individual with a TBI, a physiatrist, an occupational therapist, a physical therapist, a neuropsychologist, a social worker, the parents or significant others, a state vocational rehabilitation counselor and if supported employment is being used, an employment specialist or job coach.

Over the years business have become more confident in their ability to manage a diverse workforce and more cognizant of the abilities of workers with disabilities. Also, with the passage of the ADA, larger companies are more open to making reasonable accommodations in

the workplace. Thus, individuals who lack access to Supported Employment may still be able to achieve success at work, by simply working with the pre-injury employer or by seeking out flexible and accommodating employers.

### **INTERNATIONAL PERSPECTIVES**

This chapter has focused largely on RTW programs, supports, and legislation within the United States. However, many of the European and other developed countries have well-established neurotrauma and neurosurgical management for traumatic brain injury (e.g. Refs. 65–69). These countries have comprehensive rehabilitation programs in place, with the emphasis on comprehensive interdisciplinary rehabilitation program that includes therapy to overcome the disability which are caused by physical,

**TABLE 61-4**  
**Overview of Supported Employment Services and Roles of Interdisciplinary Team Members**

EMPLOYMENT SPECIALIST	INDIVIDUAL WITH TBI	OTHER TEAM MEMBER ROLES
<i>Supported Employment Activity:</i>		
Getting to know one another and establishing a direction for the job search		
<ul style="list-style-type: none"> <li>• Conducts functional community based activities to get to know the jobseeker and observe current skills, abilities and potential support needs;</li> <li>• Interviews those who know the person best to determine the above;</li> <li>• Identifies jobseekers personal support network;</li> <li>• Discusses impact of earnings on benefits;</li> <li>• Discusses disclosure issues;</li> <li>• Provides feedback to others (i.e. family, team and funding source)</li> </ul>	<ul style="list-style-type: none"> <li>• Becomes familiar with service option;</li> <li>• Gets to know the job coach;</li> <li>• Participates in activities to learn more about self and job market;</li> <li>• Expresses needs and wants related to employment;</li> <li>• Decide who will disclose disability to potential employers.</li> </ul>	<ul style="list-style-type: none"> <li>• Makes referral and introductions to SE;</li> <li>• Advocates for SE services with funding source if needed;</li> <li>• Shares information, current records, and insight on a person's abilities and support needs;</li> <li>• If returning to pre-injury job, is liaison between employer and SE provider;</li> <li>• Provides insight on family dynamics;</li> <li>• Develops questions for neuropsych evaluation and or assessment.</li> </ul>
<i>Supported Employment Activity:</i>		
Conducting the job search, applying for jobs and interviewing		
<ul style="list-style-type: none"> <li>• Locates work opportunities by tapping in to the hidden or unadvertised job market;</li> <li>• Meets with employers to describe SE services and job seeker's desires and abilities;</li> <li>• Analyzes workplace and job to determine pros and cons that may impact success at work and long term job retention;</li> <li>• Discusses above with job seeker;</li> <li>• Practices interviewing skills;</li> <li>• Arranges interviews;</li> <li>• Helps negotiate accommodations;</li> <li>• Provides feedback to others (i.e. family, team and funding source)</li> </ul>	<ul style="list-style-type: none"> <li>• Uses personal network and other resources to identify businesses to contact;</li> <li>• Decides whether or not to learn more about a work opportunity;</li> <li>• Completes applications for employment;</li> <li>• Attends job interviews;</li> <li>• Decides whether or not to accept job offer.</li> </ul>	<ul style="list-style-type: none"> <li>• Shares ideas on employers to contact;</li> <li>• Provides ideas on types of tasks or jobs that may maximize use of personal strengths;</li> <li>• Reviews job descriptions and provide release for work if needed;</li> <li>• Makes suggestions on types of accommodations or strategies that may prove useful;</li> </ul>
<i>Supported Employment Activity:</i>		
Providing ongoing long-term job retention services.

<i>Supported Employment Activity:</i>		
Providing or facilitating off the job support case management services.		
<ul style="list-style-type: none"> <li>• Assists with problem solving issues outside of work that if left unaddressed could adversely effect work;</li> <li>• Makes referrals to other resources</li> </ul>	<ul style="list-style-type: none"> <li>• Identifying problems outside of work that are effecting performance;</li> <li>• Helps problem solve</li> </ul>	<ul style="list-style-type: none"> <li>• Provides resources;</li> <li>• Makes referrals to other resources</li> </ul>

communicative, cognitive, and behavioral impairments, providing assistance in community integration in terms of living situation, productivity, and social and recreational activities, and providing psychosocial support for patient and family members (e.g., Refs. 8, 23, 70, 71).

The importance of RTW after injury is being recognized, and these rehabilitation programs also offer similar types of vocational assistance, such as work trials, training at workshops, or work training organized on the open job market. However, some programs limit the provision of vocational rehabilitation to those who are eligible in terms of capabilities. For example, Rehab UK assesses the abilities and potential of the applicants before accepting them into the program, offering vocational rehabilitation opportunities only to those who have good cognitive skills (72).

In the developing countries, challenges that individuals with TBI are faced with are further magnified due to either short supply or unavailability of rehabilitation professionals, in addition to lack of service centers to cater for their requirements (73–75).

### IMPROVING FUTURE OUTCOME THROUGH A TEAM APPROACH

Traumatic brain injury (TBI) results in disability that requires comprehensive and often lengthy rehabilitation efforts. It is expensive from the standpoint of rehabilitation costs, lost earnings, and therefore, loss to the gross national product, but moreover, costly due to human suffering. Although healthcare and vocational rehabilitation professionals are continually challenged in their efforts to return individuals with TBI to work, the likelihood of successful vocational rehabilitation for persons with traumatic brain injury can be enhanced by utilizing a team approach (76). Key members of the return to work team include the person with TBI; significant others; the employer; neuropsychologist; occupational, speech, and physical therapists; social worker; and vocational rehabilitation counselor or specialist often under the leadership and direction of a psychiatrist. Through interdisciplinary collaboration, the team can communicate frequently and set mutual treatment goals for recovery.

The task before the team is to maximize the potential of the individual with brain injury to return to as high a level of pre-injury productivity as can be achieved. Further efforts related to return to work might focus upon establishing new and different life goals and activities. The overall goal of rehabilitation, therefore, involves an enormous effort on the part of both the survivor and rehabilitation team.

While there is no typical length of TBI rehabilitation, there is often a long and arduous process of treatment and therapies that assist the person with returning to pre-injury

lifestyles, including work. Much depends on the severity level of the TBI, the nature and extent of problems, availability of social support networks, accessible and available appropriate rehabilitation, and the circumstances surrounding re-employment and the current labor market. Fewer individuals return to work at the same level, for the same pay, and at the same number of hours per week as before the injury. Some return to a similar job at a full-to part-time level, with a reduced rate of pay, others do not pursue competitive employment. Psychosocial outcomes encompass a similar range, from those being able to resume a familiar social and family life to those who become divorced, separated, or experience shrinking social networks and eventual isolation.

In the best-case scenario, a psychiatrist will be integrally involved in and oversee the team efforts to assist the person with the returning to work. And once employed, the psychiatrist and other team members continue to assist with either an advisory role or on an as needed basis.

As mentioned earlier, a neuropsychological evaluation is often used to assist in planning for employment or re-employment. A sound evaluation can provide valuable data to use when determining occupations or work settings that may be more suitable for the person with TBI to consider. The results of a good evaluation can help the person with TBI and team determine the best fit between cognitive assets and deficits, behavioral functioning, interpersonal propensities, overlearned skills or old learning ability, with specific job tasks and work environment for the person with TBI. The results can generate probability statements about the type of job, sort of tasks that may be most appropriate, as well as the types of environmental factors, and supports that may promote the person's success at work.

However, the relationship between neuropsychological test scores and the demands of daily life can be weak. These is why the evaluation should include more than just testing, but also involve gathering other relevant historical, medical, psychosocial, and vocational information from the person, significant other, and team members.

The return to work team can make suggestions on what specific information needs to be obtained from the neuropsychological evaluation and provide other relevant information. For example, inquiring about the personal assets can often be more helpful than dwelling on what the person is unable to do, particularly when planning for a return to work. Also, whenever deficits are mentioned, asking what areas are amenable to remediation and to what extent training or supports can contribute to change is critical. For example, the neuropsychologist may be able to state functions that are expected to improve due to spontaneous recovery or can be assisted by compensatory strategies or other means like job restructuring or environmental modifications.

The use of simple assistive technology is often pivotal to a successful return to work. Technology can help eliminate difficulties in physically accomplishing work activities or improve cognitive functions, like the ability to attend, organize, sequence, and evaluate the result of work activities. Often the process and effort involved in identifying an appropriate intervention can be more involved and costly than the intervention itself. Thus, consultation with experienced team members is very important, as it can not only expedite this, but enhance probability of success.

Using assistive technology at work may be the first time the person is offered assistance that does not appear to be typically clinical. Such interventions are often very empowering and can contribute significantly to the person's ability to be productive at work, as well as more effective in other activities of daily living.

A TBI interferes with a person's identity and social roles. The results of the injury and particularly the inability to work often disrupt a person's sense of purpose, productivity, and self-worth. Therefore, counseling may prove beneficial and help a person with reestablishing a satisfactory level of self-sufficiency. Also, after returning to work, the individual may experience depression or increased frustration at not being able to do things as easy as pre-injury levels. Furthermore, not being accepted by peers or rejection from coworkers can lead to problems. In some instances counseling may be warranted, in others medication may be helpful. The psychiatrist can recommend interventions to assist here. As illustrated, the role of the team, under the direction of a physiatrist, cannot be over emphasized (76). Unfortunately, however, in some instances, a physiatrist may not be accessible. In such an instance a competent general medical practitioner, who is willing to consult with a physiatrist, can lead the team.

**MEDICOLEGAL AND  
ETHICAL ISSUES**

*This page intentionally left blank*

# 62

## Medicolegal Aspects of TBI

*Irvin V. Cantor*

### INTRODUCTION

According to the Brain Injury Association, each year at least 1.5 million Americans sustain a traumatic brain injury (“TBI”). TBI has been called “the silent epidemic” of our society. Associated with this epidemic is a myriad of legal issues specific to persons who have sustained TBIs and their families. Since it would be far too ambitious a task to analyze all of these legal issues in the space available, this chapter is intended as a basic outline and discussion of some of the pertinent medicolegal aspects of TBI.

### SPECTRUM OF MEDICOLEGAL ISSUES OF TBI

There exists a vast array of traumatic brain injuries in our society. The contexts in which TBIs may arise are many, including motor vehicle collisions, recreational accidents, watercraft accidents, workplace accidents, defective products, and medical malpractice. The injury to the brain may be mild, moderate or severe. The mechanism of injury to the brain may involve blunt trauma, acceleration—deceleration of the head, or a metabolic process which may result in hypoxic or ischemic insult to the brain. TBIs may cause physical, cognitive and emotional dysfunction. Unlike most other injuries to the human body, an injury to the brain may not be noticeable to others. All of these

factors result in an enormous spectrum of medicolegal issues.

The issues discussed in this chapter are intended to reflect a basic and broad discussion of the medical legal aspects of TBI:

1. Finding the Right Attorney
2. Competency and Capacity Issues
3. Right To Die and Do Not Resuscitate Laws
4. Anatomy of a Worker’s Compensation TBI Case
5. Anatomy of a Personal Injury TBI Case
6. Anatomy of a Medical Malpractice ABI Case
7. Independent Medical Examinations
8. Expert Witness Testimony in a TBI Case
9. Lay Witness Testimony in a TBI Case
10. Demonstrative Evidence in a TBI Case
11. Protection and Preservation of the TBI Client’s Recovery After Settlement, Verdict, or Award

There are several books which have been written on the subject of the legal aspects of TBI, which provide a detailed discussion of many of the issues addressed in this chapter (1–4).

### FINDING THE RIGHT ATTORNEY

Traumatic brain injury litigation is one of the most complex areas of trial law. It requires a working knowledge

of the anatomy and function of the human brain combined with an understanding of how best to present evidence to prove or disprove the mechanism, nature and extent of the TBI. In recent years, there has evolved the field of neuro-law, comprised of trial lawyers who have training and experience in traumatic brain injury litigation. It is usually advisable for someone seeking legal help for a TBI to seek out an attorney who has knowledge and experience in handling such cases.

The context of the TBI is a key element in finding the right attorney. The four primary areas of law involving TBI litigation are: (1) Personal injury, where the injury was caused by a motor vehicle or other type of accident; (2) Worker's Compensation, where the injury occurred in a workplace accident; (3) Medical Malpractice, where the injury was due to the negligence of a hospital, physician, or other healthcare provider; and (4) Products Liability, where the injury was due to the use of a defective product. Generally speaking, trial attorneys specialize in one or more of these areas of law. However, just because an attorney regularly handles TBI cases stemming from motor vehicle collisions, for example, does not mean he or she has any experience with worker's compensation or medical malpractice cases. It is almost always advisable for the person seeking legal help to choose an attorney who specializes in the particular area of law in which his or her case arises.

The best way to locate the right attorney is often to seek referrals from healthcare professionals who regularly are involved in TBI litigation or others who are knowledgeable of those attorneys in the community who regularly handle TBI cases. The Brain Injury Association of America (5), the statewide brain injury associations and the local brain injury associations, are also excellent referral sources. The Brain Injury Association of America publishes a book, *National Directory of Brain Injury Rehabilitation Services*, which lists attorneys who regularly handle TBI cases in each state in the United States (6). Likewise, the American Trial Lawyers Association (ATLA) (7) and the statewide and local trial lawyers associations often will provide names of attorneys who regularly handle TBI cases. Martindale-Hubble, a national legal directory which lists attorneys in every locality in the United States, includes information about the attorney and his or her areas of practice, including TBI litigation and neurolaw (8).

Most importantly, the person seeking legal help for his or her TBI case must feel comfortable and confident with the attorney chosen. TBI litigation is often a long, tedious and uncomfortable process, in which a strong relationship between the client and the attorney is invaluable.

## COMPETENCE AND CAPACITY ISSUES

Issues involving competency and capacity often arise following traumatic brain injuries. Cognitive dysfunction

caused by injuries to the brain may range from mild problems with attention, concentration or memory, at one extreme, to being in a comatose or vegetative condition, in the other extreme. Consequently, it is important to determine the ability of the person who has sustained a TBI to understand and comprehend the consequences of his or her actions.

"Competency" generally refers to someone's ability to perform an act or understand the consequences of an act. "Capacity" is generally a legal term, describing one's adjudicated ability to perform an act or form an intent regarding an act. The adjudication of incompetency by a court determines one's capacity. This adjudication is issue specific, limited to only those acts or actions which the person is unable to do or comprehend. For example, one may be adjudicated incapacitated to handle his or her own financial affairs, but fully capable of making his or her own decisions about medical care. The law is designed to protect incompetent individuals. Minors under the age of 18 are generally deemed incompetent. Adults are presumed to be competent. In the author's home state of Virginia, Virginia Code Section 37.1-134.6 defines "Incapacitated Person" as:

. . . an adult who has been found by a court to be incapable of receiving and evaluating information effectively or responding to people, events, or environments to such an extent that the individual lacks the capacity to: (i) meet the essential requirements for his health, care, safety or therapeutic needs without the assistance or protection of a guardian or (ii) manage the property or financial affairs or provide for his or her support or for the support of his legal dependents without the assistance or protection of a conservator. A finding that the individual displays poor judgment, alone, shall not be considered sufficient evidence that the individual is an incapacitated person within the meaning of this definition. A finding that the person is incapacitated shall be construed as a finding that the person is "mentally incompetent . . . [for the acts and actions listed in the court's order]."

Health care providers often treat TBI patients who are obviously incompetent, but have not yet been adjudicated incapacitated. In these situations, the patient's next of kin are typically vested with the statutory authority to make health care decisions for the patient. This surrogate decision-making by family members is usually the determinative factor when it comes to decisions involving do not resuscitate orders or terminating life support efforts.

Attorneys who are requested to represent the interests of the TBI patient must be sure the patient is competent to manage his or her affairs. If not, the attorney must quickly take steps to have the patient adjudicated incapacitated and have a legal fiduciary appointed. Only the duly appointed fiduciary has the authority to actually

engage the attorney to represent the incapacitated person. Additionally, since the fiduciary may serve as the patient's surrogate for medical decisions, the attorney should advise the patient's family of the applicable right to die and related medical decision—making statutes.

One commonly overlooked area of TBI litigation is the competency of the TBI litigant to manage any funds recovered as a result of the litigation. It is not uncommon for the TBI litigant to be fully competent to hire counsel, initiate a lawsuit, and make his or her own medical decisions, yet be incompetent to manage his or her financial affairs. In such situations, the attorney must be careful to have a court order the proper disposition of the funds. Typically, this will result in the court having the funds placed in trust for the TBI litigant.

### RIGHT TO DIE AND DO NOT RESUSCITATE LAWS

When someone suffers a catastrophic brain injury, there are tremendous consequences not only to the patient, but also to the family, the healthcare providers, and many others who have a connection to the patient. Hopelessness, futility, and despair are common emotions felt by these persons. In this framework, ethical and moral dilemmas abound.

There is a wide disparity of recovery after severe brain injury, ranging from the person who substantially regains his or her pre-morbid level of functioning to the person who has remained in a vegetative state for a prolonged time. Moreover, predicting outcome after traumatic brain injury can be difficult. Consequently, extreme caution should be employed by those who consider the quality of the patient's life and issues involving the patient's right to die.

One's quality of life is a personal and subjective determination. Obviously, the patient's awareness of his or her environment is a key factor in this determination. In patients in permanent vegetative state, questions arise on both personal and societal levels. Should the patient be kept alive by artificial means or be allowed to die? Does it make sense to continue to provide the enormous costs necessary to keep the patient alive or should our limited societal resources be used for others who have a better medical and functional prognosis? Such questions have also come up in legal challenges involving patients in a minimally conscious state, where there is clearly more ethical debate in the medical community at large regarding issues of medical futility. Non-vegetative patients who demonstrate low level neurobehavioral response, such as those in a minimally conscious state ("MCS"), by definition, have some level of awareness. Such severe disability may seem like a poor quality of life to one person, but quite acceptable to another person given the potential of

death. Consequently, decisions to allow MCS patients to die are extremely emotional, controversial decisions to make.

One significant area of debate in vegetative state cases is whether or not a patient should be made a "DNR" (do not resuscitate), and if so, when. There actually exists a continuum of medical orders which will and/or could result in death to the patient in VS: (1) do not resuscitate orders ("DNR"); (2) withholding medical treatment such as antibiotics or surgery; (3) removal of a feeding tube; (4) removal from a respirator; and (5) withholding or withdrawing other life sustaining care, noting that withdrawing care reaches a greater level of potential moral and ethical compromise than withholding care. The decision to take such actions, first and foremost, belongs to the patient, and if the patient is incapable of making an informed decision, or had no advance directive, then to his surrogate, usually his family. Most states have laws regarding one's right to die based upon the person's living will or advance directive, such that any decision to withhold or withdraw medical treatment is based upon the patient's previously expressed preferences. Most states further provide that the attending physician may withhold or withdraw medical treatment upon compliance with the applicable state law and the proper authorization of the patient's surrogate. In the author's home state of Virginia, Va. Code Section 54.1-2986 enumerates an order of priority of persons who may be such surrogate, beginning with the patient's guardian or committee and then to the patient's next of kin. The Virginia statute dictates that where the patient has not previously expressed a preference regarding withholding or withdrawing medical treatment, the surrogate "shall (i) prior to giving consent, make a good faith effort to ascertain the risks and benefits of and alternatives to the treatment and the religious beliefs and basic values of the patient receiving treatment. . . and (ii) base his decision on the patient's religious beliefs and basic values and any preferences previously expressed by the patient regarding such treatment to the extent they are known, and if unknown or unclear, on the patient's best interests." Va. Code Section 54.1-2986(A). Virginia Code Section 54.1-2987.1, Virginia's Durable Do Not Resuscitate Order statute, provides, among other things, that a physician may issue a durable do not resuscitate order "for his patient with whom he has a bona fide physician/patient relationship as defined in the guidelines of the Board of Medicine, and only with the consent of the patient or, if the patient is a minor or is otherwise incapable of making an informed decision regarding consent for such an order, upon the request of and with the consent of the person authorized to consent on the patient's behalf".

In *Cruzan v. Director, Missouri Department of Health*, 497 U.S. 261, 110 S. Ct. 2841 (1990), the U.S. Supreme Court stated that a person has a constitutionally

protected right to refuse lifesaving medical care, including hydration and nutrition. With regard to an incompetent person, such as Nancy Cruzan who was presumptively in a vegetative state (although experts on the two sides debated this), the State of Missouri had a statutory scheme which allowed a surrogate to elect to withdraw hydration and nutrition and thus cause death upon clear and convincing proof that such withdrawal was what the incompetent desired. The Supreme Court upheld the statute as constitutional in a case where the surrogates, Nancy Cruzan's parents, requested withdrawal of hydration and nutrition, but failed to meet the clear and convincing standard embodied in the Missouri statute. In a dissenting opinion, Justice Brennan argued that the incompetent should not have such "improperly biased procedural obstacles" preventing her from dying with dignity. *Id.* at 302. He pointed out that "Missouri is virtually the only state to have fashioned a rule that lessens the likelihood of accurate determinations" because of its heightened evidentiary standard. *Id.* at 326.

Virginia, like most other states, has a statute which does not contain a heightened evidentiary standard such as Missouri's statute, which was the subject of *Cruzan*. Rather, Virginia's statute simply provides the surrogate shall "make a good faith effort" in analyzing the factors enumerated in the statute. Va. Code Section 54.1-2986(A). The statute further provides that anyone may petition the court to enjoin the withdrawal of medical care "upon finding by a preponderance of the evidence that the action is not lawfully authorized by this article or by other state or federal law." Va. Code Section 54.1-2986(E).

In two 1997 cases, *Washington v. Glucksberg*, 521 U.S. 702, 117 S. Ct. 2258 and *Vacco v. Quill*, 521 U.S. 793, 117 S. Ct. 2293, the U.S. Supreme Court held that state statutes banning assisted suicide are constitutional. In both cases, Chief Justice Rehnquist, citing *Cruzan*, *supra*, emphasized that there was a "distinction between letting a patient die and making that patient die." *Washington*, *supra*, at 715; *Vacco*, *supra*, at 802-803.

Although a constitutionally protected framework exists in most states for the patient's family to elect to withdraw medical care of the incompetent patient, it is still extremely difficult for the family to make such an election. The family members often cannot emotionally accept the futility of the situation even if they intellectually understand it. This may be true even where the family has been previously told by the patient that he or she would want to be allowed to die if in a vegetative condition. The conflict experienced by the family may be immense. There may be disagreement among family members regarding termination of treatment. Many states, such as Virginia, set forth a priority of persons, based upon kinship, who have the authority to make the decision. Nonetheless, as a practical matter, even if the ultimate decision maker wants to terminate treatment,

he or she will often defer to those other family members who do not want to terminate treatment. In one highly publicized case in Virginia, *Gilmore v. Finn*, 259 Va. 448, 527 S.E. 2d 426 (2000), the Governor of Virginia, James Gilmore, actually filed a petition to enjoin the withdrawal of hydration and nutrition to a patient in a vegetative condition where there was disagreement between the patient's wife and guardian and the patient's parents and sibling regarding whether or not the patient should be allowed to die. Ultimately, the court held that while the Governor had the right to intervene in the case in order to seek an "authoritative construction" of Virginia's right to die statute, the patient's wife and guardian indeed had the authority to direct her husband's physicians to withdraw hydration and nutrition for him since she was the first person in priority as enumerated in Virginia Code Section 54.1-2986. *Id.* at 455, 458.

Perhaps the most highly publicized case has been the Terri Schiavo case. As in *Finn*, there was a controversy between the spouse of a vegetative patient who wanted his wife to die and the parents who did not. Ms. Schiavo collapsed in her home in 1990, suffering from heart failure causing a severe anoxic brain injury, which left Ms. Schiavo in a vegetative state. Ms. Schiavo remained in a vegetative state for 15 years. During this time period, the parties litigated the case in the state and federal court system. After Ms. Schiavo's husband prevailed in the Florida courts, the Florida legislature actually passed legislation, authorizing the Governor to issue a one-time stay of withdrawals of life sustaining measures where the patient did not have a written advance directive and a family member had challenged such withdrawal. Immediately after the legislation was enacted, Governor Jeb Bush issued a stay against the withdrawal of nutrition and hydration for Ms. Schiavo. In September, 2004, the Florida Supreme Court ruled that this legislation was unconstitutional. After this ruling, Ms. Schiavo's parents pursued every available judicial and legislative avenue to avoid having Ms. Schiavo's feeding tube removed. In March, 2005, the U.S. Congress passed a law, signed by President Bush, to allow Ms. Schiavo's parents to seek redress in the federal courts to prevent removal of Ms. Schiavo's feeding tube. Subsequent thereto, the parents filed a petition in federal court to enjoin the removal of the feeding tube, which was denied in the U.S. District Court for the Middle District of Florida, the 11th Circuit Court of Appeals, and the U.S. Supreme Court. With no other forums left to seek an injunction of removal of the feeding tube, Ms. Schiavo's tube was removed, and she died on March 31, 2005. The controversy surrounding the case was covered extensively by the media worldwide. As a result of the Terri Schiavo case, the debate regarding a person's right to die has intensified to a level never previously seen. Only time will tell if the debate results in revisions of the states' right to die laws.

In the context of the dilemmas which arise in such cases, the clinician should be honest and direct in conveying diagnostic and prognostic information to the family. If the physician is not comfortable providing such information, then an adequately qualified professional should be consulted. Likewise, the trial attorney, too, should be forthright in his discussions with the family about the legal directives which are in place. At the same time, both the clinician and trial attorney must be sensitive to the family's emotional needs and dynamics. For a discussion of the medical and ethical issues facing a clinician in severe traumatic brain injury cases, see "Medicolegal Aspects of Severe Traumatic Brain Injury", co-authored by Dr. Nathan Zasler and Irvin V. Cantor (10).

### **ANATOMY OF A WORKER'S COMPENSATION TBI CASE**

Worker's compensation is a statutorily created program which exists in each state to compensate workers who get injured in the workplace. Unlike the general tort system, where liability is generally determined by fault, worker's compensation is not a fault-based program, but rather compensates the injured worker so long as the injury arose out of the job while the worker was in the scope of his employment. If an injury is deemed compensable, then the worker is usually entitled to indemnity benefits for his lost wages and medical benefits for any medical expenses incurred as a result of the injury.

Many TBI's arise as a result of workplace accidents. Most of the worker's compensation litigation involving TBI's deals with either: (1) causation, whether or not the injury to the brain was caused by the workplace accident, or (2) the extent of damages, what sequelae are attributable to the TBI. Some states provide for lifetime benefits for workers who suffer TBI's. The central issue in lifetime benefit litigation is whether or not the worker is permanently unable to work as a result of the TBI. For example, Virginia Code Section 65.2-503(C)(3) provides for lifetime awards "when there is injury to the brain which is so severe as to render the employee permanently unemployable in gainful employment."

The worker's compensation case is generally initiated by the filing of a claim by the employee or employer. If the case is not contested, then generally the employer's worker's compensation carrier will voluntarily provide benefits to the worker. In most states, the worker's compensation carrier has the right to designate the treating physician for the injured worker. If the case is contested, then generally the claimant and the employer will be represented by counsel, who will litigate the case in the worker's compensation system.

The worker's compensation system is typically administered outside of the state's general court system,

usually by a Worker's Compensation Commission. Worker's compensation cases are generally heard by an administrative judge or deputy commissioner, and not by juries. Pre-trial discovery is typically allowed in worker's compensation cases, including subpoenas of documents, interrogatories, and depositions. Attendance at the hearing of the case may be compelled by subpoena. Most states provide that the expert witness fees for the professionals who testify in worker's compensation cases must be approved by the Worker's Compensation Commission.

The percentage of TBI worker's compensation cases that are contested is much higher than other types of injuries. This is due primarily to the fact that disagreements between the parties in TBI cases often arise over causation, extent of damages, and whether or not the claimant is permanently unemployable. Consequently, TBI healthcare providers often are called to testify in worker's compensation cases. It is usually a wise idea for the healthcare provider who is asked to testify in a worker's compensation case to clarify at the outset with the attorney requesting his or her testimony what the rules are regarding the format of the testimony and the payment of the fees for testifying.

### **ANATOMY OF A PERSONAL INJURY TBI CASE**

TBI's resulting from motor vehicle collisions, recreational accidents, use of defective products, trips and falls at dangerous premises, and many other sources are the subject of personal injury cases. These cases are litigated in the traditional court system and usually by a jury.

TBI personal injury cases are becoming increasingly prevalent as society and the legal community is being made more aware of the silent epidemic of traumatic brain injuries. The vast majority of TBI litigation in the United States involves mild TBI's. The most contested issues in TBI personal injury cases are the same as in worker's compensation cases, namely causation and extent of damages.

The TBI personal injury case is initiated by the plaintiff filing a lawsuit, usually called a Complaint. The defendant responds to the lawsuit, usually with an Answer. The parties then engage in pre-trial discovery of the lawsuit. Discovery typically consists of interrogatories between the parties, subpoenaed documents from the parties and others, including the treating healthcare providers of the plaintiff, depositions of the parties and others, including the treating healthcare providers of the plaintiff, and independent medical examinations of the plaintiff by healthcare providers selected by the defendant or the court. Discovery is usually a lengthy process, often taking many months and sometimes years.

Discovery in TBI cases is usually more extensive than in other types of injury cases. The defense often

wants to know everything it can about the plaintiff's pre-morbid condition, in order to determine if the plaintiff's problems can be attributed to conditions or events that existed before the incident in question. Additionally, it is not at all uncommon for the defense to request multiple independent medical examinations of the plaintiff, including examinations by a physician and neuropsychologist.

After discovery is completed, the case is scheduled for trial. Trial of a personal injury case typically consists of the following segments: (1) voir dire, where the prospective jurors are questioned by the court and counsel; (2) selection of the jury by counsel; (3) opening statements by counsel; (4) presentation of the plaintiff's case, the plaintiff proceeding first since the plaintiff has the burden of proof; (5) presentation of the defendant's case; (6) presentation of rebuttal evidence by the plaintiff regarding new matters raised by the defendant's case; (7) instructions of the jury by the court; (8) closing argument by counsel; and (9) deliberation by the jury. Trial of a TBI case usually takes longer than trials of other types of injury cases. This is due, in large part, to the fact that the court and the jury must be educated about traumatic brain injury, often resulting in counsel spending more time in talking to the jury, calling more lay and expert witnesses to the stand, and presenting more demonstrative evidence.

### **ANATOMY OF A MEDICAL MALPRACTICE ABI CASE**

Medical malpractice cases involve claims of negligence in providing medical care, brought by a patient or patient's representative against a health care provider. Most states have statutes which define "health care provider" and set forth procedures for bringing and litigating medical negligence claims. Like personal injury cases, medical malpractice cases are generally litigated in the traditional court system and usually decided by a jury.

The plaintiff must prove three basic elements to prevail in a medical malpractice case: (1) the health care provider deviated from the standard of care in his medical treatment; (2) the deviation of the standard of care caused the injury suffered by the plaintiff; and (3) the plaintiff suffered damages as a result of the injury caused by the deviation of the standard of care. Standard of care is generally "that degree of skill and diligence practiced by a reasonably prudent practitioner in the field of practice or specialty" of the defendant. (Va. Code Section 8.01-580.20, which definition is typical of most state statutes in the United States.) In order to prove a breach of the standard of care, it is almost always necessary for the plaintiff to present one or more expert witnesses to testify at trial that the defendant's actions constituted such a breach. It is also usually necessary for the plaintiff to present one or more expert witnesses to testify on the

subject of causation and damages. As a practical matter: (1) it is often quite difficult for plaintiffs to locate good, qualified expert witnesses to give the testimony required to prevail and (2) physicians, nurses, and other health care providers are often well liked and respected in their community and by the juries in their community. Consequently, over 70% of all medical malpractice cases taken to trial in the U.S. result in defense verdicts.

Many states have statutes which provide for certain screening procedures and caps on damages applicable only to medical malpractice cases. Among these statutes are: (1) requirements that a plaintiff have a qualified expert witness provide an opinion that the medical care provided deviated from the standard of care as a condition precedent to filing a lawsuit; (2) requirements that the case be reviewed by a medical malpractice review panel before the case can proceed to trial; (3) requirements that certain allegations of medical negligence (such as birth related injury claims) be brought as administrative proceedings outside of the traditional tort system; and (4) caps on damages, wherein the plaintiff may not recover more than a certain maximum recovery, determined legislatively.

Brain injuries are the subject of many medical malpractice cases. Birth injury cases resulting in either anoxic/hypoxic/ischemic or structural injury to the brain are probably the most prevalent type of acquired brain injury ("ABI") medical malpractice case. Cases involving hypoxic-ischemic brain injuries ("HIBI") caused by alleged negligence in surgery, anesthesia, or other circumstances of intubation or extubation are perhaps the second most prevalent type of ABI medical malpractice case. Other types of ABI medical malpractice cases brought with some frequency include allegations of negligent surgery resulting in structural injury to the brain and failure to diagnose malignant brain tumors and meningiomas.

As a general rule, medical malpractice cases involve a much higher percentage of severe brain injuries than personal injury cases. This is due primarily to the fact that so many of these cases involve anoxic, hypoxic or ischemic injuries resulting in profound sequelae for the patient.

The discovery and trial of a medical malpractice case are generally the same as that for personal injury cases, as set forth in the previous section. ABI medical malpractice trials are usually quite complicated for the jury, for not only does the jury need to understand the medical procedures in question, but also the mechanism of the brain injury. The voir dire questioning of jurors in ABI medical malpractice cases often takes a longer period of time than in other types of negligence cases. There are usually more expert witnesses called to trial in ABI medical malpractice cases than in other types of cases. Also, counsel in ABI medical malpractice cases frequently use demonstrative illustrations, models, and charts to aid the jury on understanding the issues in the case.

## INDEPENDENT MEDICAL EXAMINATIONS

The rules of civil procedure in federal court and in almost all state courts provide that a party in a lawsuit involving the physical or mental condition of a person may request an examination of the person by a physician or health care provider of the party's choosing. Federal Rules of Civil Procedure, Rule 35 (11), which serves as the model for many states' procedures, provides as follows:

### (a) Order For Examination

When the mental or physical condition (including the blood group) of a party or of a person in the custody or under the legal control of a party, is in controversy, the court in which the action is pending may order the party to submit to a physical or mental examination by a suitably licensed or certified examiner or to produce for examination the person in the party's custody or legal control. The order may be made only on motion for good cause shown and upon notice to the person to be examined and to all parties and shall specify the time, place, manner, conditions, and scope of the examination and the person or persons by whom it is to be made.

### (b) Report of Examiner

If requested by the party against whom an order is made under Rule 35(a) or the person examined, the party causing the examination to be made shall deliver to the requesting party a copy of the detailed written report of the examiner setting out the examiner's findings, including results of all tests made, diagnoses and conclusions, together with like reports of all earlier examinations of the same condition. . . .

These examinations are commonly referred to as "independent medical examinations" ("IME's"). The physician or other health care provider who performs such an examination does not have a traditional physician-patient relationship with the examinee. On the contrary, the examiner's role is to serve as an independent resource to provide an unbiased forensic opinion regarding the mental or physical condition of the examinee. The AMA ethics guidelines (12) define the IME physician—patient relationship as follows:

. . . .IME's are responsible for administering an objective medical evaluation but not for monitoring patients' health over time, treating patients, or fulfilling many other duties traditionally held by physicians. Consequently, a limited patient—physician relationship should be considered to exist. IME's still are expected to evaluate objectively patients' health or disability, maintain confidentiality, and disclose potential or perceived conflicts of interest. In addition, upon discovering important health information or abnormalities during the course of the examination, IME's are expected to inform the patient about the condition, ensure that they understand fully the diagnosis, and suggest that they seek care from a qualified physician.

Ideally, even though the examiner is chosen and paid by the party requesting the examination, he or she should resist the temptation to try to please the party who engaged his or her services. The written report prepared by the examiner should be thorough and complete, listing all of the written materials reviewed by the examiner, the results of all of the examinations and/or testing conducted by the examiner, the opinions of the examiner, and the basis for each such opinion.

IME examiners should realize that once they undertake an IME, they will in all likelihood have to give a deposition, usually requested by the examinee's attorney, and if the case does not settle, testify at trial. Sometimes in lieu of testifying at trial, the deposition of the IME examiner, usually taken by audio-visual means, may be used. The deposition which is used as evidence at trial is often referred to as a "de bene esse" deposition. If there is a reason the IME examiner is unable or unwilling to attend trial, he or she should make that known at the outset to the attorney requesting the IME.

In TBI cases especially involving mild TBI's, there is often disagreement between the parties about: (1) whether or not the plaintiff suffered a TBI; (2) the extent of the TBI and the true sequelae resulting from it; and (3) the cause of the deficits and problems suffered by the plaintiff. Consequently, IME's are routinely requested in mild TBI cases. In fact, it is not at all uncommon for the defense in TBI cases to request multiple IME's, including an examination by a physician specializing in neurorehabilitation and a full battery of testing by a neuropsychologist.

A frequently litigated issue in mild TBI cases is what role does the plaintiff's pre-morbid history play versus the traumatic event, such as a motor vehicle collision, as a causative factor in the plaintiff's post-accident functioning. When faced with this issue, the IME examiner should request and review all available pre-morbid records of the plaintiff, including medical, educational and vocational records, and be sure to list in the IME report all of the documents so reviewed. It is wise for the IME examiner to pay close attention to documents dealing with the level of functioning of the plaintiff to determine if there is a discernible difference between the pre-morbid and post-accident performance. In the event the IME examiner is of the opinion that the deficits suffered by the plaintiff are multifactorial in nature, then he or she should set out in detail in the IME report each of those factors and how they have impacted the plaintiff.

In TBI cases there seems to be an unusually high number of experts who are overly dependent financially on medico-legal cases in their practice. These "professional" expert witnesses sometimes derive a very large percentage of their income from certain attorneys or sides in the litigation who hire them. Unfortunately, there are some experts who routinely find in favor of the party that hires them. It is strongly recommended that those experts

who make themselves available for IME's do not compromise their impartiality and objectivity. For a discussion regarding the ethical considerations in IME's following TBI, there are several in-depth articles, co-written by Nathan Zasler, M.D. and Michael Martelli, Ph.D. (13–16).

### EXPERT WITNESS TESTIMONY IN A TBI CASE

As a general rule, only expert witnesses, qualified as such by the court, are permitted to give opinion testimony at trial. Rule 702, Federal Rules of Evidence (17), upon which many state statutes are based, reads as follows:

*Rule 702. Testimony by Experts*

If scientific, technical, or other specialized knowledge will assist the trier of fact to understand the evidence or to determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education may testify thereto in the form of an opinion or otherwise, if (1) the testimony is based upon sufficient facts or data, (2) the testimony is the product of reliable principles and methods, and (3) the witness has applied the principles and methods reliably to the facts of the case.

It is not necessary that a person be a practitioner of a science or technical profession in order to qualify as an expert. Rather, the person must have sufficient expertise in his or her field that the expert's opinion will be of benefit to the trier of fact. The court has discretion to qualify the person as an expert in a particular field so long as the person is shown to possess sufficient expertise in the professional field.

An expert's opinion testimony must be based upon reliable facts and assumptions. Testimony which is speculative, based upon faulty assumptions, or is otherwise determined to be "junk science" is inadmissible. In *Daubert v. Merrell Dow Pharmaceuticals, Inc.*, 509 U.S. 579 (1993), the Supreme Court of the United States, applying Rule 702 of the Federal Rules of Evidence, set forth the following factors for the trial judge, as the "gatekeeper" for the admissibility of such evidence, to determine if the expert's testimony possessed requisite scientific validity:

1. The theories and techniques employed by the scientific expert have been tested;
2. The theories and techniques have been subjected to peer review and publication;
3. The techniques employed by the expert have a known error rate;
4. The techniques employed by the expert are subject to standards governing their application; and

5. The theories and techniques employed by the expert enjoy widespread acceptance.

Using this test, the Supreme Court remanded a birth injury case back to the trial court so that the trial judge could decide if the proffered expert testimony, regarding whether or not the mother's prenatal ingestion of the drug, Bendectin, was shown to cause birth defects, was admissible. Prior to the five-prong test of *Daubert*, the rule was that expert opinion based upon a scientific technique was inadmissible unless the technique is generally accepted as reliable in the relevant scientific community. *Frye v. United States*, 54 App. DC 46, 293F. 1013 (1923). Since 1993, the *Daubert* test has been used by a multitude of trial judges to determine the admissibility of scientific expert testimony. This litigation has resulted in a complicated, often contradictory set of results. A useful website dedicated to the rule espoused in *Daubert* and links to post-*Daubert* cases, articles, tactics and other materials regarding determination of the scientific validity of expert testimony is "Daubert On The Web", [www.daubertontheweb.com](http://www.daubertontheweb.com) (18).

TBI cases, perhaps more than any other type of injury case, typically involve multiple expert witnesses. This is due primarily to the fact that the court and the jury are generally unfamiliar with brain anatomy and function. A sampling of expert witnesses often involved in TBI cases includes neurologists, neurosurgeons, psychiatrists, neuropsychiatrists, neuropsychologists, neuroradiologists, nuclear medicine specialists, speech language therapists, physical therapists, occupational therapists, vocational specialists, life care planners, accident reconstructionists, forensic engineers, and economists.

TBI physicians, as a general rule, have little trouble qualifying as expert witnesses and giving opinion testimony at trial. For example, since it is well established in the medical literature that complete loss of consciousness is not a prerequisite for a diagnosis of TBI, opinion testimony from a TBI physician to that effect is uniformly permitted. However, when the physician bases his or her opinions on assumptions that are controversial and speculative, then such specific opinions may not be allowed. One area of much litigation is the reliance by the physician on abnormal functional imaging studies of the brain to diagnose TBI, discussed in more detail herein on pages 30–31.

Non-physician experts in TBI cases are much more likely to have their testimony excluded as unreliable. Some of the experts in TBI cases whose opinions have been disallowed include accident reconstructionists, who try to determine the speed of crash vehicles by crush analysis, and forensic engineers, who try to determine the amount of force exerted on an occupant of a vehicle in a collision. In most states, neuropsychologists are permitted to give their opinion as to whether or not a person suffered a TBI. However, a recent Virginia case, *John v. Im*, 263 Va. 315, 559 S.E. 2d 694 (2002), held that since the

neuropsychologist was not a medical doctor, he was “not qualified to state an expert medical opinion” regarding the cause of the patient’s brain injury.

Expert witnesses generally bill hourly for the time they spend on medico-legal matters. The party who has hired the expert generally pays the expert’s fees. The opposing party is required to pay the expert for the fees incurred in responding to pre-trial discovery, whether by deposition or interrogatories. Rule 35(b) (4)(c)(i), Federal Rules of Procedure, states that:

(i) the court shall require that the party seeking discovery pay the expert a reasonable fee for time spent in responding to discovery. . . .

A “reasonable fee” generally includes the customary hourly fee the expert charges for medico-legal work. It is strongly suggested that the expert keep detailed, accurate records of his or her time in a case. This is especially true in TBI cases where the expert may have voluminous records to review and longer than usual depositions to give.

Some practical tips for expert witnesses are:

1. Always maintain your impartiality and objectivity.
2. At the outset of a case, clearly communicate with the attorney who has engaged your services about the scope of your role, your availability for litigation, and the financial terms of your engagement.
3. Carefully and thoroughly record your examination results, observations, or other notes in a legible, preferably typewritten, manner.
4. Review all pertinent records and data.
5. Accurately keep and record the time you spend on the case.
6. Always remain courteous and professional with all litigants and their attorneys.
7. Thoroughly review all relevant records and data prior to any deposition or trial.
8. Understand the disparate roles of the participants: your role as the expert is to provide objective scientific or technical opinions, whereas the role of the attorneys and the litigants is to win.

### LAY WITNESS TESTIMONY IN A TBI CASE

While much time and attention is given to the testimony of expert witnesses in TBI litigation, the most important evidence usually is the testimony of the plaintiff and those persons who best know the plaintiff. Invariably, if you ask trial attorneys who regularly handle TBI cases what is the most critical element in a TBI case, they will tell you it is the quality of the plaintiff and his or her lay witnesses. The reason for this seems obvious: the jury, whose job it is to decide if, and how, the plaintiff is affected by the TBI, is most influenced by: (1) how the plaintiff presents at trial

and (2) what those who best know the plaintiff say about how the plaintiff has been affected by the TBI.

Despite this seemingly obvious focus, health care providers and attorneys often fail to consider the reports of those closest to the person who sustained a TBI. This emphasis on opinions by experts, to the exclusion of reports by lay witnesses, not only fails to provide a comprehensive view of the case, but typically results in an unsatisfactory outcome at trial.

Individuals who sustain TBI’s usually do not have good insight about their deficits. This phenomenon is probably due to the nature of the injury, itself, (e.g. frontal lobe dysfunction) or to the fact that the patient is in denial over his or her condition or to a combination of these factors. The most accurate description of the TBI patient typically comes from a spouse, a sibling, a child, a best friend or someone else who best knows the patient.

In diagnosing a TBI and the resulting deficits suffered by the patient, the physician, neuropsychologist, or other health care provider should make an effort to learn the reports of family, friends, co-workers, and others close to the patient about the ways the TBI has affected the patient. It is helpful if the health care provider talks to those who know and regularly interact with the patient. It is also wise for the health care provider to obtain school records, job evaluation reports, or other documents which memorialize the observations of others about the TBI patient. Without consideration of the reports and observations by others of the TBI patient, it is very difficult for the health care providers to accurately determine the pre-morbid and post-traumatic conditions of the patient. Moreover, if the health care provider has not considered the reports of lay witnesses prior to reaching his or her opinions, then the health care provider will be quite vulnerable to attack in cross-examination at deposition or trial.

The trial attorney should make sure to discover and develop lay witness testimony about the TBI patient. Without such testimony, the jury will be left with many unanswered questions and will not be motivated to render a verdict in favor of the party who disregarded such testimony.

Sometimes the inquiry regarding lay witness observations of the TBI patient will result in the discovery that the patient had complained of similar deficits many times before the traumatic event. Other times, the inquiry will result in the discovery that the patient’s life has been completely altered as a result of the TBI. In all cases, proper analysis of the TBI case can only be achieved if due consideration is given to the reports by those who best know the TBI patient-plaintiff.

### DEMONSTRATIVE EVIDENCE IN A TBI CASE

Individuals who suffer TBI’s frequently appear perfectly fine. They often do not have any disfigurement, no scars,

no limp, and no visible sign of impairment. It is no wonder TBI victims are referred to as “the walking wounded.” Consequently, in the trial of TBI cases, there is much use of visual aids to assist the jury to understand the TBI and its sequelae. This type of evidence is commonly referred to as “demonstrative evidence” because it is used to demonstrate and clarify testimony. There is perhaps no other type of injury case which necessitates the use of demonstrative evidence more than the trial of a TBI.

Since the TBI was caused by a traumatic event, evidence to explain how the forces of the accident were exerted on the plaintiff’s head and brain are often used. In motor vehicle collisions, photographs of the vehicle are almost always introduced into evidence. Such photographs may include not only the body damage to the vehicles, but also a bent steering wheel, a broken headrest or seat, or a shattered windshield. In many cases, photographs of the interior and exterior of a windshield, which has a spider web pattern as a result of contact with the plaintiff’s head, are introduced into evidence.

A simple but powerful way to demonstrate an acceleration/deceleration injury to the brain is for the physician to use a model of the skull and brain in his or her testimony. While using the model, the physician can explain that the skull is a rigid structure, but the brain has the consistency of jelled gelatin, and that rapid changes in direction of movement of the skull and brain can cause stretching and shearing of tissue and fibers to the brain. There are some interesting short animated films available to depict this process. Two such films are: (1) “Closed Head Injury”, produced by Technical Medical Animation Corporation, Denver, Colorado (19) and (2) “Understanding Mild Traumatic Brain Injury”, produced by Body Mind Publications, Olympia, Washington (20). Another excellent source for video animations of types of TBI, brain functioning and mechanics of TBI is the Traumatic Brain Injury Resources Guide website, [www.neuroskills.com](http://www.neuroskills.com) (21).

Structural imaging tests of the brain, x-rays, CT Scans, and MRI’s, are routinely used in TBI trials, especially where the plaintiff has suffered a skull fracture, an intracranial or extracranial bleed, or other discernible brain lesion. Sometimes it is helpful to construct 3-D models from the CT and MRI computer tapes since these 3-D models can show shape, form and color for the jury.

Functional imaging studies, testing brain activity, are also used quite often in TBI cases. This is due in large part to the fact that structural imaging studies of persons sustaining mild TBI’s generally are negative. The most often used studies are PET Scans (Positron Emission Tomography), SPECT Scans (Single Photon Emission Computerized Tomography), EEG (Electroencephalography) and QEEG studies (Quantitative Electroencephalography).

Abnormalities in brain function are not diagnostic of brain injury in and of themselves. Many clinical conditions can produce abnormalities on PET and SPECT. Consequently, caution must be exercised when using abnormal functional imaging studies in TBI litigation. The use of such tests at trial depends upon several factors: (1) the type of equipment used in the test procedures; (2) the credentials, expertise and experience of the technician conducting the test procedures; (3) the credentials, expertise and experience of the clinician interpreting the test results; and (4) the manner in which the test results are used in the clinician’s analysis. The admissibility of functional imaging tests of the brain have been the subject of much litigation throughout the country, where the focus of the courts has been on whether or not the test results are “reliable scientific evidence”. The overwhelming majority of these cases hold that the results of functional imaging tests are admissible at trial for a qualified expert to use as a factor (as opposed to “the sole factor”) in arriving at his or her opinion about the TBI. Consequently, when an expert intends to use a functional imaging test in his or her testimony, it is strongly recommended that the expert make it clear that the results of the functional imaging test are being used as a confirmatory factor in his or her opinion about the TBI and the resulting brain function. When a PET or SPECT Scan is used at trial, as with CT’s and MRI’s, it is often helpful to have 3-D models made from the computer tape of the PET or SPECT.

Most TBI trials include testimony from neuropsychologists who have performed neuropsychological evaluations of the plaintiff. Often the plaintiff has undergone multiple neuropsychological evaluations prior to trial. Many times these serial evaluations will result in clear patterns of test performance. When a clear pattern is demonstrated, sometimes graphs and charts depicting test performance are used to help the jury understand the person’s deficits or lack thereof. Such visual aides of neuropsychological test results should be used only when such results are significant, correlate with the clinical examinations of the person, and are otherwise not subject to attack on cross-examination.

There are a myriad of other types of demonstrative evidence commonly used in TBI cases. Some of these are: (1) illustrations of the brain and its network of neurons; (2) “day in the life” videos of the plaintiff, depicting some of the problems the plaintiff experiences on a daily basis; (3) surveillance videos, surreptitiously taken by the defense, to show the plaintiff actually engages in activities inconsistent with his or her claimed deficits; and (4) blow-ups of academic records and job evaluations.

A knowledge of the use of demonstrative evidence in TBI cases is helpful for the clinician or expert witness involved in a TBI case to interact with counsel or the injured plaintiff.

## PROTECTION AND PRESERVATION OF THE TBI CLIENT'S RECOVERY AFTER SETTLEMENT, VERDICT OR AWARD

The TBI case is not over just because the plaintiff has achieved a settlement or verdict. Rather, attention must be given to how the monetary proceeds achieved in litigation should be received and structured. Failure to properly structure these funds is a trap for the unwary and may result in the loss of benefits otherwise available to the injured person.

Individuals who sustain a TBI are often eligible for Social Security, Medicare, and Medicaid benefits. Social Security and Medicare benefits are generally available to the person (or his relative) who has made the requisite payments of FICA taxes to the federal government. These benefits provide monthly income and medical coverage. If the person does not qualify for Medicare, he or she still may be eligible for Supplemental Security Income (SSI) and Medicaid benefits. SSI provides monthly income benefits and Medicaid provides medical benefits. SSI and Medicaid are "needs based" programs, insofar as the individual must meet an asset-based test in order to qualify. In addition to monthly income and medical benefits, SSI and Medicaid recipients are also eligible for long-term care and various rehabilitation programs. For the TBI victim facing substantial long-term care expenses, SSI and Medicaid benefits are a vital resource.

The creation of a properly drafted trust to hold the funds recovered by the plaintiff in a TBI case can serve to protect the plaintiff's eligibility for needs based programs. Assets held in these trusts, often referred to as "Special Needs Trusts" or "Settlement Trusts", are not considered available to the beneficiary because title to the assets does not vest in the beneficiary until and unless the trust is terminated. The beneficiary of such a trust, having retained his or her eligibility for needs based benefits, continues to receive SSI and Medicaid benefits, and uses the funds held in trust to pay for needs not covered by SSI and Medicaid, hence the name "Special Needs Trust."

Special Needs/Settlement Trusts not only preserve the beneficiary's eligibility for needs based benefits, but typically also provide for professional investment management of the trust funds, a function many TBI victims are unable to properly perform. The trust must be created by a court. The court's jurisdiction is based upon the incapacity of the beneficiary to reasonably understand and/or manage the proper disbursement of the TBI case proceeds.

The constantly evolving laws regarding trusts and federal and state benefits are quite complex. Consequently, it is generally wise for a competent trust attorney to draft the Special Needs/Settlement Trust. A complete understanding and working knowledge of these laws is usually not within the province of the plaintiff's trial attorney.

The proper use of a Special Needs/Settlement Trust can maximize the funds and benefits available to the TBI victim. This can often result in a dramatic enhancement of the life of the person who has sustained a TBI.

## CONCLUSION

The epidemic of TBI in our society has spawned an ever-increasing myriad of legal issues. These issues are vast and complex. Hopefully, this chapter has shed some light on some of the pertinent medico-legal aspects of TBI.

## Ethical Issues in Clinicolegal Practice

**Arthur Ameis**  
**Nathan D. Zasler**  
**Michael F. Martelli**  
**Shane S. Bush**

### INTRODUCTION

The general requirement for ensuring ethical conduct in any form of clinicolegal evaluation is rendered even more imperative when confronted by the complex, often subtle range of effects and severities of impairments of the traumatized brain. The clinicolegal evaluator must be especially cognizant of rules and guidelines for assigning causation for singular etiologies, or relative attribution for multifactorial circumstances; of the pathomechanics of various traumatic scenarios; of the differential diagnosis of psychological versus neurological disorders; and of the interplay of emotional states and needs with psychological functions and cognition.

Pronouncements on the severity or even existence of any impairment must be rigorously supported by objective evidence and strictly limited to reasonable inference.

If *'the past is often prologue'* then it becomes critically important to establish an accurate, complete prior history of all injuries or illnesses capable of affecting the brain. It is equally critical to clarify all potentially relevant comorbidities, especially social/situational distress, sleep deficit, pain, OTC and prescription medication 'side' effects, and surreptitious substance use/abuse.

The evaluator must be fully aware of active controversies concerning the therapeutic efficacy of various interventions, for both minor and severe brain injury: while long, expensive programs of care can lead in some

cases to profound improvements in insight, impairment control and quality of life, in other cases the result may be financially profligate, devoid of discernible benefit, or even tainted by serious iatrogenic harm.

Setting the bar high, creating specific, rigorous criteria for ethical and competent evaluation and testimony, with suitable tests and benchmarks, appears to be the trend in the courts (1), wherein clinicolegal expertise is most needed. It behooves each clinician to know where the risks lie, and to avoid falling into practice patterns of substandard work, or permitting exposure to real or even apparent ethical misconduct. A key risk area concerns lack of familiarity with relevant, and especially with recent important developments including: court rulings; new diagnostic procedures and measures of functional capacity; improved validity and reliability data for currently used clinical tests and outcome measures; and changes in relevant ethics codes (e.g. the 1999 AMA Ethics Guidelines on Physician/Patient Relationships in the Context of Independent Medical Evaluation, and the 2003 NAN position paper on independent and court-order forensic neuropsychological examinations (2–4).

Similarly, it is appropriate to expect health care professionals to take a proactive role in individual professional as well as general quality assurance. When lack of competence, apparent or actual ethical misconduct is observed in one's colleagues, the evaluator is obligated to take appropriate steps to defend the consumers of our

services and thereby safeguard the public's trust in the healing professions in general and in independent expert evaluation in particular.

Ongoing education is required at all levels, from student to practitioner to academic, on the application of ethical principles to clinicolegal practice, in order to create and sustain ethical professional behavior in ourselves and in our colleagues; and as a legacy for the generation of evaluators who will surely follow us.

## SPECIAL ETHICAL CHALLENGES OF THE ADVERSARIAL ENVIRONMENT

### The Practice Paradigm Shift

The adversarial clinicolegal environment contrasts sharply with that in which health caregivers train and work. Within the health care environment the emphasis is on selfless aspects of professionalism including personal sacrifice, devotion to duty and to public health; with the primacy of the fiduciary 'duty of care' reflected in patient advocacy. These principles shape the attitude of each healthcare professional when assessing and treating in his/her clinical practice.

However, the clinicolegal environment is typically dominated by adversarial polarization. The person, already having (inadvertently) assumed a *sick role* by being rendered a *patient* through loss of health secondary to injury or illness, acquires (by having taken legal action) some of the typical characteristics of certain sociolegalistic identities or roles: with labels such as *Client*, *Litigant*, *Victim*, *Claimant*, *Disabled Person* and/or *Evaluee*.

Advocacy, by parties supporting or opposing the litigation, tends to be a common basis of request for services, including professional evaluation, caregiving reports, and court testimony. Infrequently, the request may be 'neutral', an invitation for a substantive review expressly for the objective education of the triers of fact. Thus, for many clinicians, upon accepting a request for expert examination of a litigant, the transition from the classroom or treatment clinic to the evaluation setting or courtroom will require a substantial and abrupt perceptual paradigm shift from fiduciary duty to forensic functions; and a corresponding, often ill-informed struggle with novel, sometimes subtle ethical, moral, and legal issues.

As with any anticipated paradigm shift, preventative measures are preferable to remedial actions. Effective professional education can create a heightened appreciation of and corresponding sensitivity to the pitfalls that may be created when conflicting interests encroach upon the clinician who is suddenly challenged to apply general guidelines of routine practice ethics in unfamiliar clinicolegal circumstances.

Unfortunately, many, if not most, clinicians who evaluate and/or treat persons with traumatic brain injury,

as well as those serving on panels that establish policy involving training and certification of professional competency, would acknowledge having had insufficient education/training in the prevalence and nature of special ethical challenges and ethical guidelines specific to the clinicolegal setting.

### Prevalence of Ethical Challenges

The results of a 1992 survey of the membership of the American Psychological Association (APA) regarding ethical concerns in clinical psychology (5) are generally applicable to all evaluating clinicians. Critical incidents were separated into 23 categories of ethical dilemmas. Issues involving forensic psychology ranked fifth, due to concerns about the presentation of false testimony, the attorney's role in eliciting desirable (but possibly false) testimony, the rendering of conclusions that are not grounded in objective data or scientific principles, and the potential for unintentional harm that could result from reporting inaccurate data.

Specifically pertinent to TBI casework is a survey of the membership of the National Academy of Neuropsychology (NAN) which revealed that the majority of the respondents were concerned about examiner competence (64%), inappropriate use of tests (61%), and conflict between the law and ethics (55%) (6).

### Adapting General Biomedical Ethics to TBI Casework

Building upon the universal commitment of the clinician to his/her patient, four core bioethical Principles have been described: *Autonomy*, *Non-Maleficence*, *Beneficence*, and *Justice* (7).

*Autonomy* refers to self-determination; that is, the ability to make healthcare-related decisions independently.

*Non-Maleficence* is closely related to the Oath of Hippocrates, loosely translated from Greek into Latin as: *primum non nocere* (First, Do No Harm!).

The concept of *Beneficence* is more proactive, requiring that there is a promotion of that which is in the best interest of the patient.

In healthcare, the concept of *Justice* typically concerns the equitable distribution of the burdens and benefits of care.

Common to these four Principles is the expectation of a fundamental obligation to respect the patient at all times. Certainly, the fundamental obligation of respect applies equally to when the interaction is solely one of evaluator-examinee, with no clinician-patient relationship. Clinicians are expected to provide equal measures of respect to a person, whether seen in the context of patient or that of evaluee, including courtesy, dignity and

fairness; and spending adequate time during the assessment process.

While the concepts of non-maleficence, beneficence and justice remain closely tied to the universal commitment of respect for the person, there is a need for adaptation to the special circumstances of the medico-legal context, in which the person's goals are those of a litigant, potentially unrelated to his/her concurrent goals as a patient. Although an examiner must recognize and respect the responsibility to bring no direct harm to the examinee during the examination, certain forms of examinations may need to be provocative in order to evoke and test symptoms and signs, including pain, or emotional distress. Thus, the psychiatric interview or neuropsychological testing may result in temporary frustration from challenging cognitive tasks, or in changes in mood due to emotionally sensitive query.

Moreover, although potentially true (tangentially) of the treating clinician examination, findings from a clinicolegal evaluation may have the potential of significantly and directly impacting upon the examinee's diagnostic label, future financial status, treatment or vocational options, environmental modifications, and/or even level of credibility. The successful reconciliation of these three Principles to the clinicolegal environment rests with the appreciation that the duty is owed – as it is with the judiciary – equally impartially to all litigating parties. It is the evaluator's task to conduct the evaluation in a fair manner and to present the results objectively, fully and dispassionately. The court or other party requesting the examination will then have the responsibility to see that the outcome is just. Outcome must never be a factor in the presentation of findings, conclusions or opinions by a clinicolegal evaluator.

An examinee who is denied services or monies based in full or in part on the results of an independent examination may believe that he/she was not treated justly and that the examination did indeed cause harm. However, the evaluator who has treated that individual respectfully and with dignity and has facilitated a meaningful interview, (including listening carefully and reasonably patiently to the examinee's expressed concerns), and then spent sufficient time in examination and in report preparation, will be less likely to be perceived as unfair or acting with maleficence.

With independent examinations, the principle of beneficence does not apply directly to the examinee. The examiner's role is an impartial one, favouring neither the examinee nor the opposing party. Unlike caregiving situations, promotion of the examinee's well-being is not a primary goal. Instead, the examiner's evaluation is conducted to inform the referring party and by extension is for the benefit of the trier of fact or other decision-making body to whom the parties turn for dispute resolution. The examinee, like the other parties to a clinico-legal dispute,

may benefit in whole or in part, or may not benefit at all, from the results of the evaluation and any decisions based upon the results. The examiner has no responsibility to the examinee, and to his/her needs or wishes, beyond courtesy, expertise, thoroughness and objectivity, and must take no interest in the process or outcome, of settlement negotiations or judicial determinations.

As a corollary, the ethical examiner must not be drawn into making partial decisions on the basis of 'universal' axioms such as: '*benefit of the doubt always goes to the patient*'. That axiom certainly belongs within 'when in doubt' decision algorithms relating to patient safety, such as the management of acute chest pain complaints. It does not necessarily apply equally to circumstances where parties have opposing interests in causation or settlements, and have a right to expect an evaluator to function without any decision bias. An inherent, consistent preference for one position or party, no matter how beneficent in intent, not only projects the appearance of bias but may in fact cross the ethical boundary of neutrality, as well as, reduce the utility of the evaluator's conclusions.

There is another aspect to beneficence, related to the clinician's universal societal-legal obligations, from which there is no exemption created within a clinicolegal context. A physician who discovers a clinical condition that could be harmful to the individual or to others has a direct obligation to report that condition to the appropriate body: in the case of unsafe driving (in some jurisdictions), to a driver's licensing authority (e.g. impaired vision / cognition, or seizures); in the case of child neglect/abuse to a children's aide agency. Typically, where mandatory reporting exists, special protocols are created by the authority / agency to safeguard anonymity, in addition to legislation to protect the reporting clinician from lawsuit. Typically the attending clinician or clinicolegal evaluator has no concurrent obligation to the evaluatee, to disclose the fact of reporting.

## AVOIDING ETHICAL MISCONDUCT

### Proactivity

Clinicians, whether they are placed in or place themselves in clinicolegal situations, must make themselves aware of potential ethical pitfalls and must actively take steps to avoid them. Passive reliance on a sincere belief, that by performing competent work one is *a priori* assured of being perceived as 'ethical', is not sufficient protection in the face of the complex and wide range of potential ethical dilemmas, and will not necessarily safeguard against a perception of boundary-crossing leading to an accusation of ethical misconduct. The clinician must instead be assertive in seeking out knowledge, skills, and feedback related to ethical practice; constantly vigilant for evolving dilemmas; and briskly proactive in avoiding or remediating same.

### **Developing and Maintaining Reliable Expert Qualifications**

It is axiomatic that one's qualifications and expertise must be consistent with or exceed currently accepted professional guidelines. Clinicians should strive to maintain high standards of competence in their work, including recognition of and deference to the boundaries of their competencies and the limitations of their expertise, and to provide only those services and use only those techniques for which they are qualified by education, training, or experience.

While variability in education, training, and experience remain, the achievement of eligibility for Board certification (e.g. diplomate or fellowship status) is an accepted basic standard for clinical specialist expertise. This standard is superseded only by acquisition of formal Board specialty or subspecialty certification, which is conferred only through successful completion of a rigorous examination process.

In general, the attainment of Board specialty or subspecialty certification provides the clearest single universal evidence of competence in the relevant area of specialty. Given that Board eligibility is a widely recognized basic standard for expert witness qualifications, it is recommended that clinicians not opting for Board certification should have their credentials independently evaluated by appropriate bodies to verify meeting Board eligibility threshold requirements.

Many organizations offer 'Board certification'. The criteria for attainment of these "Board certifications" vary from merely paying a fee, through varying levels of training, practical experience, written and oral examination. Prior to expending time, effort and funds towards such certification, it is important for the clinician to carefully investigate the organization as well as its certification's inclusionary and exclusionary criteria, including both the stringency of the eligibility requirements and the thoroughness and applicability of the examination processes. Affiliation with an organization which offers certification examination to virtually any applicant, notwithstanding possession of a suitable professional background, or whose certification examination has a 100% pass rate, offers no real validation to one's knowledgeable peers or to a critical court system.

It can be recommended that clinicians involved with clinicolegal evaluation of persons with complex conditions such as TBI: (a) seek rigorous peer review to ensure competence in the general area of assessment, as well as, any special areas of interest, and obtain supervision and documentation that any identified deficiencies have been remediated, (b) obtain Board certification as the most rigorous mechanism of peer review, and (c) exercise care to practice only within the boundaries of competence, and seek consultation from other experts when appropriate.

Continuing education is critical for maintaining expertise. Given the rapidly evolving field of TBI and of brain function research in general, clinicians must maintain a reasonable level of awareness of current general scientific theory and applied practice knowledge. This should include awareness of general trends in the relevant literature, the state of current knowledge, and the significant limitations in said knowledge. Documented, regular attendance at specialty-focused professional conferences and seminars formally signals a significant investment in furthering one's knowledge.

Additional professional activities may demonstrate expertise in specific areas of knowledge or skill. Publications, lectures or seminars given, academic appointments, and administrative positions may all reflect high levels of expertise. However, as with board certification, the manner in which these credentials are obtained can vary considerably. Publications in peer-reviewed media with stringent acceptance criteria represent the highest standard of publication.

Professionals making presentations at national or international conferences are often regarded as accepted authorities in their field, as inferred from the fact of invitation from highly credentialed and merit-discriminating peer conference organizers, particularly those who have a broad spectrum of choice of experts. Faculty or administrative appointments should be evaluated on the manner in which they are earned and the degree of selectivity of the process.

### **Neutrality and Sphere of Expertise**

The American Medical Association's (AMA) Council on Ethical and Judicial Affairs publishes a Code of Medical Ethics (8). The AMA Ethics Code is fairly general; however, it does state that medical experts should "have recent and substantive experience in the area in which they testify and should limit testimony to their sphere of medical expertise." The code further stipulates that the "medical witness must not become an advocate or partisan in the legal proceeding." It further suggests that the medical witness inform attorneys of "all favorable and unfavorable information developed by the physician's evaluation of the case." The latter is of course a universal criterion. Failure to make full disclosure has the appearance of deliberate selectivity, from which flows the inevitable inference of an unbalanced, partial evaluation.

The lay-person is at a significant disadvantage with respect to appreciating the subtleties of the various subspecialty scopes of practice, and the significance of 'positive' (what was found that should not be there) and 'negative' (what should have been there and was not found) findings. Thus, in the assessment of apparent hysterical blindness after a head injury, appreciation of the distinction

between the abilities of a general ophthalmologist and a neuro-ophthalmologist, or between a general psychiatrist and a neuro-psychiatrist, may be critical to appreciating the relative value of various ‘expert’ findings of normality or abnormality. Moreover, a notation that a patient with TBI could not read a sample text is of little value in the absence of clarification of the potential modifying conditions such as prior literacy; or the confirmation that the eyes did not suffer from corneal opacity or medication-induced loss of acuity, uncorrected/poorly corrected vision or poor fitting contact lenses or retinopathies; or that there were no cranial nerve palsies creating diplopia, etc.

### Material Contribution to Case Resolution

The American Academy of Physical Medicine and Rehabilitation (9) published a ‘white paper’ with recommendations for expert witness testimony. This document indicates that the expert witness should serve to educate the court as a whole, rather than representing one side or the other, notwithstanding that the expert may have been retained by one party. The document suggests that the ultimate test for accuracy and impartiality is a willingness to prepare reports or offer testimony that could be presented without alteration for use by either the plaintiff or the defendant. As a corollary, judges have remarked that the ability to accurately discern the identity of the requesting party, merely from reading reports or reviewing transcripts of testimony, potentially signals a lack of genuine neutrality on the part of the evaluator. Three additional recommendations are emphasized: (a) the physician should identify opinions which are personal and not necessarily held by other physicians, (b) a distinction should be made between medical malpractice and medical maloccurrence when analyzing case evidence, and (c) there should be a willingness to submit transcripts of depositions and/or courtroom testimony for peer review.

The American Academy of Neurology and the American Board of Medical Specialties have presented the following guidelines for the physician expert witness: (a) the physician expert witness should be fully trained in a specialty or a diplomate of a specialty board recognized by the American Board of Medical Specialties, and qualified by experience or demonstrated competence in the subject of the case; the specialty of the physician should be appropriate to the subject matter in the case, and (b) the physician expert witness should be familiar with the clinical practice of the specialty for the subject matter of the case at the time of the occurrence, and should be actively involved in the clinical practice of the specialty for the subject matter of the case for three of the previous five years at the time of the testimony. Similar guidelines have also been published by the American Academy of Psychiatry and the Law (10).

### Avoidance of Relational Conflict Issues

The ethical guidelines governing the relationship between an examiner and an evaluatee are special adaptations of universal clinical practice ‘caregiver’ guidelines in which the primary concern is for the safety and welfare of the patient. The caregiver role is ‘active’, involving a ‘fiduciary’ ‘duty of care’ with a predominant focus on *individual outcome*.

In clinical practice, given the perceived power differential between doctor and patient, entering into any personal, scientific, financial, or other relationships with a caregiver has the potential of being exploitative to the patient. Clinical training emphasizes the need for avoidance of excessively intimate personal relationships with a current patient (and sometimes even a former patient).

Building on the Hippocratic Oath, the AMA explicitly expresses the concerns of the profession towards any blurring of the boundaries between the personal and professional relationships of the physician, where boundary violations “may exploit the vulnerability of the patient” or “may obscure the physician’s objective judgment concerning the patient’s health care”. The AMA formalizes its proscription against exploitation of any former patient by declaring any post-caregiving relationship unethical: “if the physician uses or exploits trust, knowledge, emotions or influence derived from the previous professional relationship” and: “At a minimum, a physician’s ethical duties include terminating the physician-patient relationship before initiating a dating, romantic or sexual relationship”.

In direct contrast, the role of the clinicolegal evaluator is ‘passive’ in relationship to the evaluatee and his/her family. The evaluator neither seeks nor accepts any duty of care, and must also firmly and unambiguously discourage any expectation of care. The value of clinicolegal work lies not only in the examiner’s clinical expertise, but equally in impartiality and objectivity, and the extent to which critical powers are applied to case evidence and scientific knowledge – making a material contribution to case resolution.

The guidelines for clinicolegal practice should be adhered to as rigorously as those applicable to the most worrisome of clinical practice circumstances. To ensure that neither real nor apparent conflict of interest enters into the clinico-legal evaluation, an examiner must decline any evaluation involving an evaluatee with whom the examiner has, or has had, a personal, social or therapeutic relationship. The examiner should also decline any evaluation involving an evaluatee who has a personal relationship with any member of the examiner’s immediate family. In essence, safeguarding the perception of neutrality requires that an examiner decline any evaluation circumstance in which he/she can not be entirely free of pressure in regard to presenting candid, complete opinions on issues such as causation, entitlement to benefits, disability, or prognosis; or circumstances in which an observer could develop a reasonable concern.

Clearly, for the clinicolegal examiner, ethical guidelines for encounters and relationships are simple and unequivocal. Aside from the provision of urgent therapeutic services, there must be absolutely no advice or caregiving during the encounter, and no contact or relationship of any kind in the future with an evaluatee or his/her immediate family, until at least the formal conclusion of all clinicolegal proceedings. Clearly, violation of such boundaries carries considerable risk of appearance, if not actual, conflicts of interest. Otherwise, the evaluator could be placed in a position of considerable power and potential exploitation; ironically, the reverse could also be true since the evaluatee or family member might attain a position of considerable influence over the evaluator.

This raises the question of associated or prior relationships. Concerning the former, it is readily evident that the evaluator should avoid any case in which subtle influence might be exerted on him/her, such as when the evaluatee or immediate family is somehow connected through employment, friendship, social or professional group, acquaintance or family relationships. For example, given the likelihood of social encounters it might be prudent to avoid evaluating the parent of a child who is in the same school class as one's own child.

For the purposes of clinicolegal evaluation, any pre-existing relationship that was more than a casual acquaintanceship creates the potential for real or apparent conflict of interest (11). As a general rule therefore, any relationship that may be seen by others, as well as by the parties involved, as having the potential to bias the opinion of the examiner should eliminate that professional from consideration as an examiner (12). However, exceptions may be required, particularly when no other expert in a particular field is readily available and where entitlement to benefit issues requires urgent evaluation. Prioritizing provision of a needed service may outweigh many potential objections. When any such exception is required, the nature of any pre-existing relationship and its potential ramifications on the results of the clinicolegal examination must be disclosed to all parties prior to conducting the examination and should be clearly documented in the subsequent written clinicolegal report. In addition, all safeguards that will be employed to ensure objectivity should be described. As a final corollary, should circumstances change outside of the control of the examiner, as might happen during the course of a clinicolegal case that lasts many years, such that the examiner no longer feels that neutrality and freedom from influence exists, the examiner should notify all parties and offer to withdraw from the case.

### Professional Role Distinctions

The ethical codes discussed to this point emphasize prescription of creation of dual relationships in which the

examiner had/has both a professional and a nonprofessional relationship with an evaluatee. Avoiding conflicts between differing professional roles is of equal importance given the potential for undermining the professional's objectivity and credibility, negatively affecting the parties served.

Equally applicable to physicians and other professionals, Blau (13, 14), identified three different and conflicting professional roles for professionals working in clinicolegal settings: Treating Doctor, Expert Witness, and Trial Consultant.

The *Treating Doctor* is in an active role, with a duty of care. The clinician tends to seek or accept an empathic bond with the patient, and is expected to advocate for the patient in ways intended to improve mental or physical health, or facilitate stable, supportive circumstances. When offering testimony, the Treating Doctor is a special type of fact witness, relying on expertise in helping the triers of fact while describing the symptoms and signs, the investigations done, the treatments provided, and the course and impact of the condition. As a fact witness, the Treating Doctor's reports and testimony must be anchored in his/her findings, diagnoses and treatment records. However, the Treating Doctor is also capable of service as an expert resource to the court, subject to qualifications being reviewed and a determination made as to the limits of testimony for each individual professional. Unlike the lay person, who as a fact witness cannot offer expert opinion but rather can only describe what was personally seen or heard, clinical professionals may be permitted to offer the court more general information about differential diagnosis, natural history of diseases, investigations, treatment paradigms, and prognosis, drawing on professional training and experience. It is of course understood by all parties that any such testimony may be potentially influenced by the underlying treating relationship, but it is expected that when so requested, the clinician will strive to assist the court with full disclosure and cooperation, careful consideration of responses, and avoidance of argumentativeness or disproportionate, impassioned advocacy. The triers of fact will later assign appropriate weight to the testimony. It is never appropriate for a Treating Doctor to enter into contractual arrangements for fee-for-service evaluations of a current or former patient on any basis other than that of the physician-patient relationship.

The *Expert Witness*, having no prior direct knowledge of the examinee, is obligated to obtain special and often exceptionally complete information in order to render an expert opinion. In order to facilitate objectivity, no emotional or other bond can exist with the examinee. All clinical evidence must be evenhandedly reviewed with an approach founded in critical appraisal. It is appropriate to approach the case from a perspective of reasonable skepticism, testing all evidence for reliability and applicability.

The *Trial Consultant* is retained to assist with the critical scrutiny of expert opinions. Given the realities of the adversarial process, the trial consultant may be expected to identify experts on the opposing side who are potentially susceptible to impeachment and to then lay the groundwork for that effort. Clearly, an objective and dispassionate status towards the evaluatee, and towards all other professionals involved in the case, is essential to trial consultancy, in order to offer sound, unemotional advice to retaining counsel.

A further role existing in some circumstances is that of *Case Reviewer*, retained to review the case evidence without direct assessment (evidentiary review), and/or to critically evaluate the assessing evaluators and treating clinicians (peer review). Not all clinicians are comfortable with performing an evidentiary review solely confined to documentation, and leading to expert opinions about a claimant that one has not interviewed and examined. The peer review involves at least the potential of having to state findings critical of one's colleagues' knowledge, clinical acumen, ethics or practices. The Case Reviewer must always declare at the outset of the report precisely what information (such as specific documentation) was relied upon, and that the opportunity for a direct evaluation was not provided. It is appropriate to state whether a direct evaluation might alter the opinion being presented. It is necessary to state whether the documentation was found to be clear and complete, and to indicate the limits of scope and certainty of the opinions that could be derived. For example, a Reviewer might be asked to determine the total percent Impairment of the Whole Person by applying documented clinical findings to the AMA Guides to the Evaluation of Permanent Impairment (15). While the Reviewer is able to offer expert analysis of the proper Chapters, Tables and Figures and Combined Values, the opinion remains entirely dependent on other clinicians' work for the comprehensiveness of the list of diagnoses and impairments and the reliability of the clinical findings. Oftentimes, in the context of a review, incomplete records are provided to the clinician – yet opinions are requested based on the information available. It can be argued that any ethical clinician should never provide opinions without first requesting an opportunity to review all relevant materials. Lastly, given that there is, by definition, no opportunity availed to the clinician to directly examine the injured party in the context of a review, clinicians must be careful, on ethical clinicolegal grounds, regarding opining as to specific impairment and disability related issues.

In general these four roles are separate and distinct and represent differing interests and obligations. Failure to clarify the limits of one's role for both oneself and the other parties involved may lead to inappropriate mixing of roles, with a resultant loss of objectivity and professional accuracy. Notwithstanding which role the clinician is asked to assume, any fixed-outcome oriented solicitation should be

promptly and firmly responded to in unequivocal terms, with clear instruction to the requesting party concerning the ethical limits which govern the professional's participation. Similarly, the professional should decline any request in which remuneration is made contingent on 'satisfactory' outcome (as defined by an interested party) or in which the final fee paid may differ according to settlement terms.

For the Treating Doctor, role conflicts may be further avoided by providing the patient's treatment record instead of a report or testimony (16).

Any role conflicts that do nevertheless arise should be acknowledged in reports and in testimony.

### Immunity of Clinicolegal Work and Expert Testimony

Illustrative of the special role of the Expert Witness is an Ontario court ruling which arose from a class action law suit for damages by several plaintiffs against two clinicians whose clinicolegal evaluations were in compliance with dispute resolution requirements of Ontario's no-fault auto insurance legislation. In dismissing the lawsuit the judge reviewed prior court decisions on point and concluded that the *only* relationship between the plaintiffs and their evaluators involved the assessment of and report on each of the plaintiffs by one or both of the defendants. The legislated dispute resolution process required the defendants to intervene as evaluators, which they did. The ruling set out that clinicolegal evaluators cannot be sued for carrying out their statutory duty because they owe no duty of care to the plaintiffs. They cannot be sued for malpractice because their contact with the plaintiffs was not sufficient to create a medical duty of care to the plaintiffs. They cannot be sued for breach of fiduciary duty because the assessment relationship lacks the element of expectation that the assessor will act in the interests of the plaintiff and so does not give rise to a fiduciary duty in favor of the plaintiffs, and such a duty would be inconsistent with their neutral position. Lastly, they cannot be sued for what they say in their reports because such reports are absolutely protected by witness immunity.

We would note, however, that not all judicial systems act as logically as the Ontario Courts, and one of the authors (Zasler) has personal knowledge of several claims that have come out of clinicolegal expert testimony involvement where experts were sued for, among other things, claims of slander consequential to claiming that someone was symptom magnifying or malingering. Another author (Ameis) has had personal experience with cases in which regulatory bodies have held formal reviews of clinicians in response to complainants objecting to medicolegal reports containing similarly 'provocative' terms. Clinicians should not assume, therefore, that they are totally immune for their actions in the capacity as an expert witness.

There are ways to protect oneself from the effects of such claims, such as by carrying additional insurance (most malpractice policies do not cover clinicolegal work).

Medical Boards and professional peers may also take various actions against unethical clinicolegal conduct when observed with fellow professionals although all too often such conduct is left to fester and propagate as professionals would rather “not get involved” due to potential personal and political ramifications.

## ETHICAL CLINICAL OFFICE PRACTICES

### Use of Objectively Validated Assessment/Reporting

Professionals demonstrate nonmaleficence and beneficence and promote justice in clinico-legal settings by conducting unbiased examinations and testifying honestly. Sweet and Moulthrop (17) have offered relevant and pointed self-examination questions that should be utilized when conducting assessments in adversarial contexts. These contain questions for procedural conduct, including, for example, favorability of findings to referral source, comparison of current findings with base-rates, and presence of emotions and actions suggesting advocacy. They also contain questions for written reports which include whether a panel of peers / experts would agree with findings and conclusions; whether contradictory facts and evidence were included or excluded; and whether exaggerated or dramatic descriptors were employed. Thus, the merits of a report might be determined in part by whether opinions flow logically from findings or seem to be pre-formed, whether equivocal test results (i.e., from high false-positive radiological, laboratory or neuropsychological tests) are appropriately employed to inform or merely selectively chosen, overweighted and exploited to persuade; and whether terminology was dispassionate, measured and proportionate; or emotionally charged and inflammatory.

Lees-Haley (18) has suggested that, in addition to self-examination, examiners should develop and employ externally validated safeguards to increase the probability of objectivity. Until such safeguards are developed, proposed guidelines (14, 19–22) offer good starting points for attempting to maintain examiner objectivity.

### Avoidance of Outcome Dependency

When the definition of success of two groups of professionals differs dramatically, their ability to work together on a project will be very limited. Hence when plaintiff lawyers define success as the development of a case capable of attracting a large settlement, no matter how modest the TBI impairment sequelae and how high functioning the claimant, then the report of the clinician who defines success solely by expertise, objectivity, and candor, will not be well received.

Attorneys must answer to their clients, who require them to be advocates and to maximize the benefits at outcome: it is natural that such attorneys will seek out experts whose viewpoints are more likely to be strongly supportive of their clients' cases, irrespective of case merits. Therefore, unless the referral is by mutual consent of the parties, or arises from the court itself, or unless the identity of the referral source is masked, the examiner must deal with the reality of being cognizant of the referral and payment source, and associated potential disincentives to full candor.

Unfavorable examination findings may trigger an undesirable set of consequences such as the attorney's inability or refusal to pay for services provided if the case is 'lost', or loss of further referrals by that attorney and perhaps his/her colleagues, with consequent decreased clinico-legal income. Given the restrictions in reimbursement in other areas of healthcare, there are considerable pressures and reinforcements that serve as disincentives to producing 'unfavorable' findings. Consequently, subtle processes, such as suggesting limited reliability/credibility to contradictory information sources and making selective interpretations in unclear situations, would seem especially vulnerable to influence. Subtle- to not-so-subtle influences involving the preference/need of the referring attorney may also predispose examiners to unidirectionally interpreting all findings or to advancing unusually firm or unequivocal views. Such influences represent threats to objective, ethical practice and to professional credibility.

Many jurisdictions have made, or at least contemplated, practical attempts to neutralize the potential for influence related to outcome. In 1996 the Provincial legislature of Ontario created a system of Designated Assessment Centres (DACs). An impartial governmental team would randomly assign a case to Center, where expert evaluators were expected to make benefit determinations while adhering to standards of neutrality, transparency, cost-efficiency and timeliness. Competence and cost were monitored, and Center administrators were held accountable for quality assurance, always subject to loss of designation. Within this system, evaluator selection was independent of either party; fees were predetermined and payment was assured. Evaluators were highly insulated from outcome, by virtue of a random referral process in which determinations had no influence on future referrals, payment arrangements or income. The primary determinants of case load related to delisting from DAC rosters for persistent failure to maintain expertise, timeliness or neutrality. Unfortunately, the DAC system fell victim to political 'reforms' and was eliminated in March 2006 in favor of an Insurer Examination system.

### Neutrality and Selectivity in Office Practices

Avoiding the *appearance* of lack or loss of Neutrality is often as important as the actual state of neutrality. Both

perception and existence of neutrality require active as well as passive measures, more easily achieved in group practices than for the individual practitioner. A balanced and fair, written referral policy is a reliable passive approach. The appearance of neutrality of a clinician is reinforced by the appreciation that the clinician is prepared to evenhandedly accept suitable cases from plaintiff and defense.

High selectivity in case acceptance can indicate the clinician's commitment to working strictly within scope of practice, and general or special expertise. However, it can also work against positive perception. Thus, a consistent policy of accepting only severe TBI cases, evenhandedly from plaintiff and defence, signals a neutral interest in a specific condition suitably challenging to the clinician's expertise, while by contrast an indiscriminate policy of accepting 'all comers', including cases of dubious brain trauma or impairment, or worse, a selective policy of taking primarily dubious claimant cases, may signal a pattern of self-marketing, as an advocate and "case builder".

Clearly, perceived neutrality is enhanced by the degree of perceived distance between the referring party and the clinician. Thus, selectivity within a group practice may be particularly significant. While the group may have an open policy on acceptance of referrals, there may be an internal agreement (1) to randomly assign cases, or (2) to 'stream' on the basis of individual member expertise and experience. Additionally clinical examiner groups may have their staff mask all information about the referral source, substituting a briefing paper, which sets out the goals of the evaluation without specifying whether the referral is for plaintiff or defense sides.

In some cases, in order to resolve clinical ambiguities, establish the current scientific understanding, or otherwise clarify issues before trial, the presiding judge may select an examiner and order an expert examination, or may order the parties to jointly select a mutually agreeable examiner. Either approach may significantly advance the process of settlement through neutralization of the expert referral process.

Attorneys who recognize the potential that their act of referral may itself 'taint' the expert should carefully craft the referral request in neutral terms to identify the issues that remain in dispute, and fairly set out the difficulties existing between the parties owing to their understandings and positions, requesting diagnostic or management opinion or clarification of existing opinion so as to best inform the parties and the triers of fact.

Unfortunately, a clinician's commitment to neutrality may be compromised by a selection process which is intended to 'take advantage' of clinical proclivities; the clinician then becoming the unwitting tool of advocacy. Attorneys are often well versed on which clinicians consistently favor a certain scientific theory or a particular threshold, or test finding. Thus, in order to garner support for a weak case, an attorney may refer to a clinician known

to uncritically accept all complaints and claims as entirely reliable. Similarly, in order to attack a strong case, an attorney may refer to a clinician who is an unremitting skeptic of all subjective matters and prefers to rely solely on the results of MRI and objective clinical findings.

Toward the goal of maintaining examiner objectivity, Brodsky (19) suggested that examiners calculate an *objectivity quotient* in order to quantify the degree to which the expert clinician's findings have been in agreement with, or different from, a referring attorney's position. The objectivity quotient is calculated by dividing the number of cases in which findings support the referring attorney's position by the total number of cases the clinician has been involved in as a consultant and/or expert. A cutoff score of 0.7 has been proposed for potential examiner bias.

### Expert Witness: Trial Consultant Role Boundaries

Experts must be vigilant against the possibility that their assistance of the retaining party in the clinico-legal aspects of a case could extend into ethically questionable behavior. Expert Witnesses must not go beyond providing their own independent and objective opinion about the examinee. There should be no crossing of the line that separates disinterest in outcome from outcome promotion.

It is proper for the Trial Consultant to focus on outcome and to work towards optimization of outcome terms satisfactory to the referring party, but nevertheless based on the evidence and merits of a case. He/she is expected to assist with strategic or tactical "trial preparation" by participating in efforts to accumulate a complete case database, and to effectively cross-examine concerning the procedures, opinions or other testimony of clinician witnesses. However, partisan criticism against experts and advocacy for the adversarial attorney team in its battle to "win" through impeachment (e.g., by preparing deposition or trial questions or strategy or discussing stylistics or cases beyond the current one) strains ethical clinical boundaries. An ethical Trial Consultant assists with identification of the strengths and weaknesses of all opinions, and advises in balanced fashion on the current science.

It is ethically inappropriate for any professional to participate in preparation of *ad hominum* personal attacks, or in selective, misrepresentative citations of literature, or misuse of statistical analysis, with the ultimate intention of confusing or misinforming the triers of fact.

## CONDUCTING THE CLINICO-LEGAL EXAMINATION

### Establishing Ground Rules in Advance

Most commonly, referrals of a strictly clinico-legal nature come from attorneys, insurance companies, and other

third party payors and are clearly intended for use in litigation. The clinician has a clear opportunity to decide on involvement. By contrast clinical referrals from physicians or other referral sources may start out as requests for consultation or for participation in caregiving, with the clinician's caregiver involvement making inevitable some linkage to any subsequent litigation process. Indeed, a 'Trojan horse' phenomenon is sometimes seen, in which the clinical referral for consultation is in fact instigated or influenced by a plaintiff lawyer, whose intent is either to later obtain a relatively inexpensive expert clinicolegal report, or ensure the clinician's involvement in an eventual trial, or at least ensure that no other party can obtain that clinician's services as Expert Witness in the case.

In a clinicolegal referral it is critically important to establish the basis of the referral and the parameters of anticipated or permissible interaction with the evaluatee, since many patients confuse the roles and may resent or even actively complain to regulatory boards about perceived failure to give the advice or care expected. This is particularly important for the patient with impairments of cognition, where concrete thought or memory deficits reduce the ability to appreciate the distinction between caregiving and independent assessment.

Equally, prior to carrying out an independent evaluation, it is important to ensure that the referral source appreciates that no therapeutic relationship of advice or care will exist. The evaluator should not be expected to provide direct advice or care to the examinee at the time of the evaluation or at any time thereafter, and there is no ongoing relationship or obligation to the evaluatee beyond normal ethical and professional behaviour. As a corollary, it is improper for an evaluator to offer direct advice following an IME, and instead this potentially disrupts existing therapeutic relationships and thus is an ethical violation.

In parallel, the source of funding for the referral must be carefully established. Seeking concurrent fees from both a clinicolegal referral source who requested an independent examination along with billing any other party such as a health care insurer, has been referred to as 'double billing' or 'double dipping', and is unethical.

### **Communicating Ground Rules to the Examinee**

Examinees very often present for independent examinations with ambivalence, anxiety, or even distrust (19, 21–23). For the TBI patient, such psycho-emotional states may be superimposed on neurological impairments of cognition, emotion, or behavior; physical impairments; and/or financial, vocational and/or interpersonal difficulties that are the reasons for the examination. Apprehension may be due in part to inaccurate or incomplete information provided to them by their attorney, family members, treating health professionals, or others regarding the purpose and nature of the independent examination.

Not uncommonly, the referral by an insurance company for clinicolegal examination is interpreted by the evaluatee as hostile in nature, implying or even seeming to overtly accuse the evaluatee of unreliability or deception, or the attending clinicians of incompetence. For example, the lack of proper understanding of the nature of an independent clinicolegal evaluation accounts for the majority of all complaints to the College of Physicians and Surgeons of Ontario, with the most common complaint involving the perceived improper behaviour of the physician in either not offering or refusing to provide, on request, advice or prescription.

The examiner who provides accurate information about the purpose of the examination and the procedures to be employed at the outset of the evaluation will likely help to reduce the examinee's anxiety and distrust and to increase his or her cooperation. Recognizing the potential for anxiety that is inherent in such examinations and emphasizing the objective nature of the examination should serve to increase the examinee's comfort level and perception of fairness, while fostering reliable performance. Clearly, as Binder and Thompson (24) have noted, in the case of the neuropsychologist but with general application to all clinicians, one must attempt to minimize any potential discomfort associated with the examination.

The Canadian Society of Medical Evaluators has developed educational pamphlets specifically for dissemination by clinicians or insurers to evaluatees. Separate pamphlets were prepared to meet the somewhat differing circumstances of physical medicine and psychiatric independent examinations. By anecdotal reports, its use by CSME members has been associated with a marked decrease in regulatory body complaints, and/or facilitation of complaint resolution.

### **Response Bias**

Response bias is the deliberate or inadvertent presentation of oneself as more or less impaired than one actually is. Its presence must always be considered, assessed and commented upon as it might pertain to the clinician's findings, and in regard to the findings of other clinicians. This provides the report's readers with a reference point as to how fairly and competently this confounding element was assessed, what finding was made, and whether the implications were considered and applied to the balance of the report. It may serve to provide a basis of understanding for some differing clinical opinions.

Employing formal and informal means of assessing response bias, followed by formal, structured reporting of related findings is a critically important component of a comprehensive TBI evaluation. The official position paper of the National Academy of Neuropsychology on symptom validity testing now posits both that response bias assessment, and any specific symptom validity tests deemed necessary for evaluation of symptom validity, is

medically necessary (NAN Position paper reference) National Academy of Neuropsychology Position Paper: Symptom validity assessment: Practice issues and medical necessity: Official Statement of the National Academy of Neuropsychology, Approved by the Board of Directors 2/28/05. [www.nanonline.org/downloads/paio/Position/NANsvt.pdf](http://www.nanonline.org/downloads/paio/Position/NANsvt.pdf). Retrieved 4/21/06 (25). However, the examiner should exercise caution in regard to going further, by inferring motivation - the intent and goal of the evaluatee. The evaluator should instead discuss the differential diagnostic list of potential sources of the unreliability detected: including inadvertency, medication, pain, fatigue, personality or pathopscho-emotional mechanisms. As a corollary of a careful assessment for response bias, the examiner will be in an enhanced position to consider the reliability and validity of the apparently abnormal findings of those clinicians who did not look for inconsistencies or otherwise allow for response bias. (See Chapter by Martelli, et al. in this text on response bias assessment, and National Academy of Neuropsychology Position Paper on symptom validity testing) National Academy of Neuropsychology Position Paper: Symptom validity assessment: Practice issues and medical necessity: Official Statement of the National Academy of Neuropsychology, Approved by the Board of Directors 2/28/05. [www.nanonline.org/downloads/paio/Position/NANsvt.pdf](http://www.nanonline.org/downloads/paio/Position/NANsvt.pdf). Retrieved 4/21/06 (26).

As a further quality control measure, prior to examination the evaluatee should be given an explanation of the anticipated examination process; as a component of this description, the examiner should emphasize the importance of displaying one's real capacities, including consistently putting forth one's best efforts throughout the examination. It should also be explained that the consistency and extent of the examinee's effort and degree of disclosure will be assessed and may impact on the examiner's rating of reliability.

It is ethically necessary to give the evaluatee notice before the evaluation that response bias and reliability may be tested. It is not necessary or even advisable to disclose the nature of the testing, or that there may be use of informal, as well as, formal means. However, it is imperative that the evaluatee also understand that pain, fatigue, confusion, memory lapses, or other neurological impairments will not be regarded solely as evidence of lack of cooperation or effort.

### **Perceived Control and Quality Assurance**

It is important for the evaluatee undergoing a clinicolegal examination to retain a sense of control over the proceedings, including to a reasonable extent the right to control its pace, and the right to ask why a particular question is being posed or test procedure performed. The evaluatee has an absolute right to decline to proceed with a given

question, exam procedure and/or the evaluation itself. Within reason, accommodations should be made for breaks to use the restroom, or to rest due to fatigue and/or the need to take medication. It is often instructive to encourage the evaluatee to comment during and particularly towards the end of the evaluation if any element of questioning or testing was new, unfamiliar, or omitted. The examinee should be informed of the importance of reporting any sense of difficulty or distress to the examiner in 'real-time', not later.

It may also be necessary to notify the evaluatee of "zero tolerance" rules regarding any inappropriate verbal or physical behavior, and of potential negative inferences from lack of cooperation, or from premature termination of the evaluation, without reasonable basis. The expert examiner must always allow for the possibility that in TBI evaluation, response bias, lack of consistent cooperation, or problematic verbal or physical behaviors may be the inadvertent and uncontrollable consequences of pain, fatigue, medication, seizure, or behavioral disinhibition.

### **Confidentiality Issues**

The clinicolegal evaluation is one in which a limited duty of confidentiality is owed to the evaluatee. The referring party is entitled to full disclosure of anything learned by the examiner at any time during the evaluation. The evaluatee should be under no misapprehension that the evaluator can be held to instructions of 'strict confidence', including disclosures involving sexual orientation; sexual, physical or substance abuse history; STDs or abortion.

The absence of a therapeutic relationship does not prevent the examiner from communicating verbally or in writing with a treating clinician, regarding any concerns or suggestions, particularly emerging issues such as suicidal rumination or inappropriate regimen or dose of medication. A memo must be made of the date, name and content of any verbal communication. Written communication by mail, fax or email, must be retained with the file. The appropriate means of communication will depend upon the nature and priority of the circumstance; a note should not be entrusted to the evaluatee if there is any doubt as to whether and when it will be delivered or concern over the evaluatee reading the contents.

### **Informed Consent**

Once the examinee understands the purpose of the examination, the process of the examination, rules of disclosure, expectations for cooperation and effort, evaluatee rights, and the extent of feedback regarding the results of the examination, the examiner should invite questions and provide further clarification as needed. Only after these issues are seen to be clearly understood by the examinee should his or her informed consent to participate be sought. Consent

forms are necessary to document the examiner's efforts to inform and the examinee's consequent understanding and agreement. In addition, consent forms can facilitate communication between examiner and examinee. A checklist can be incorporated into the consent form, allowing examinees to systematically consider, seek clarification if necessary, and then indicate their understanding of each major point by initialing each point on the list and/or signing the bottom of the form along with a witness.

Clearly, informed consent cannot be obtained and should not be sought directly from evaluatees with marked cognitive or communication disorders or from minor children. In such situations, consent must be obtained from the individual's legal guardian. In some circumstances the evaluator should seek written proof of guardianship.

### **Third Party Observers—Direct and Indirect**

The issue of allowing a person other than the examiner and examinee into the examination session is complicated. Without exception, the physician examiner should consider use of a staff person as chaperone, to assist and to attest that no inappropriate conversation or action took place. In many jurisdictions it is the right of the evaluatee to designate another, suitable third party to be present for his/her comfort and/or as an observer, a witness to what transpires.

Where the evaluator retains a veto right, persuasive pro and con arguments can be considered: a 'pro' argument may exist when the claimant can be expected to be exceptionally apprehensive unless accompanied. In fact, the issue often benefits from avoiding the polarization of the "either/or" proposition, and instead clarification of who should be able to observe and in which settings and with what relative benefit to evaluator or evaluatee. The evaluator should however bear in mind that, oftentimes, skilled third party witnesses such as nurses are specifically designated owing to their ability to testify as credible observers about what happened during the examination. Evaluators should always keep in mind that they almost always retain the option of declining the referral if any of the imposed conditions of evaluation appear unacceptable, including designation of a third party.

A claimant-designated third party is, ideally, a passive witness to the procedural events, with no role beyond reassurance of the claimant. No third party should ever be permitted to participate, advise or interfere unless invited to do so, and no third party disruption that compromises the quality of the evaluation should ever be tolerated.

Several authors have presented reasons why the presence of a third party may be contra-indicated during examinations in which standardized tests are used. These reasons include (a) compromise of test security and subsequent misuse of tests, (b) invalidation of results due to tests not having been standardized for third party presence,

and (c) invalidation of results due to social facilitation, (27–31). A policy statement from the American Academy of Clinical Neuropsychology made the distinction between involved observers and uninvolved observers (32). An involved third party observer is someone who has some investment in the outcome of the examination, whereas an uninvolved third party has no stake in the outcome, and instead is strictly a source of emotional support to the evaluatee. In contrast, a NAN policy statement distinguished between settings, with third party observers being acceptable in clinical settings for training purposes but unacceptable in forensic settings (29). Issues of observer training, observer involvement, and examination context have all been considered relevant in the debate on the appropriateness of having a third person present during neuropsychological examinations.

The Canadian Society of Medical Evaluators (CSME) has developed guidelines for assisting in the determination of 'who and when' for the presence of a third-party, where there is a choice. The Society recommends that its members maintain a written protocol, not only to assist them but also to demonstrate to others the rational basis and consistency of their decisions. Thus, one's protocol might set out that a chaperone will always be present; in addition, a first order family member is mandatory for examining any minor. The Society notes that a medical professional such as a nurse is preferable to a non-family lay third party, as an evaluatee-designated observer, owing to insight into what constitutes acceptable questions and routine examination practices. Any third party must agree to be placed outside the visual field of the evaluatee, to prevent any cueing or other interaction.

We would also note that there is both extensive experience and now some recent literature to support the position that despite best intentions and circumstances, examinee performance may be adversely affected by observers, even or especially when they are their own family, friend or case representative (e.g., case manager or lawyer). Negative consequences of third party observers become difficult if not impossible to factor out when considering apportionment of sub-optimal or otherwise misleading performance.

Videotaping and audiotaping are seemingly less intrusive means of monitoring the examination process. However, these methods of observation can also introduce atypical dynamics into the examination process (analogous to the abruptly altered behaviours evident in home movies or the 'frozen' look of one's colleagues, stuttering into a reporter's microphone. Evaluatees may 'act out' for the future audience, or may withhold candor anticipating abreactions of family viewers. At particular disadvantage may be certain TBI evaluatees, who are anxious about being perceived as abnormal, embarrassed by paretic facial appearance or speech impairments, or behaviourally disinhibited.

Examiners too may experience alteration of well-established, efficient and effective routines, due to inadvertent effects on body language, tonality, questioning style, or pace (unnaturally slow or hurried).

The setting too is usually not ideal, since the medical office is neither a recording studio nor a well-lit television studio complete with camera- and soundmen. People mumble, tummies rumble, clothes brush on microphones, clocks tick, computers hum, tapes run out and batteries fail. Voices may be non-uniformly distorted in tonality or nasality, or unnaturally amplified or suppressed, subtly influencing the viewer long accustomed to the quality of TV and movie. Voice activation, ambient noise suppression mechanisms, static, activity outside the microphone or camera range, or involving soft speech, shadows or reflections, may cause an audio or video to fail to clearly capture words or events that the examiner observed and found sufficiently relevant to make notes about. This may create a 'Hobson's choice' dilemma for the reviewer, compelled to assign relative weight to the electronic record and to the version of events noted and/or recollected by the examiner.

Preliminary studies suggest that formal testing results may be negatively affected by the presence of observers or recording devices, in a selective, non-uniform fashion. In one study, audio recording appeared to negatively affect verbal learning and recall but not motor performance (33). In another, video recording negatively affected immediate and delayed memory performance but not motor performance or recognition memory (34). Such studies indicate that both direct observation and indirect observation via recording devices may have a negative effect on psychological test results, posing a threat to the validity of tests developed without scrutiny for such variables, and placing in jeopardy the reliability of the test results and the relevance to the specific evaluatee of subsequent interpretations of test results.

### **Selection of Assessment Procedures**

It is routine for TBI assessment reports to be closely scrutinized by all parties, and actively critiqued, particularly by opposing counsel who may retain professionals for that specific and sole purpose. The examiner should be aware that every aspect, including the selection of questions and tests, the method of carrying out the tests, the findings, and their interpretation, will be subject to retrospective analysis and possibly to aggressive criticism. Clinicolegal examiners do not have the option of citing as excuses the practical exigencies of daily practice; examiners are expected to set aside as much time as necessary to carry out all relevant testing, to review all potentially significant documentation, to seek a complete data base and only then to comprehensively analyze data and formulate opinions without urgency. Nevertheless, even the most thorough and methodical approach is not safe from criticism.

Due to differences of opinion regarding optimal methods of investigation, no set of medical, psychological or neuropsychological test procedures is beyond the critic's reach. However, criticism is far less successfully applied to tests and assessment procedures that are standardized, have a strong research base for relevance, validity and reliability, are well accepted and commonly taught and used within the profession for the same general or specific purpose, and have a history of acceptance in the courts.

Testing must comply with accepted standards and protocols; to further ensure the perception of even-handedness the clinician may benefit from consistently applying the same test protocols to all patients seen with the same condition. (e.g., a medical evaluation of functional recovery, for all TBI claimants whose residual symptoms include excess daytime fatigue, might routinely include an Epworth Sleepiness Scale for severity quantification, and a differential diagnostic screening for comorbid but non-traumatic nocturnally disruptive conditions such as sleep apnea or benign prostatic hypertrophy).

It is appropriate to omit or take particular precautions with administering, considering and, reporting tests that have poor validity and reliability – which nevertheless remain in widespread usage. To a reasonable extent the clinician may need to explain why each such commonly used test was not employed, and what other tests was substituted and with what advantages.

Not uncommonly, rather than developing and defending their own protocols, examiners rely reflexively upon published authorities, without ensuring familiarization with both strengths and weaknesses. One widely used reference is the American Medical Association Guides to the Evaluation of Permanent Impairment (GEPI) (35), which throughout its' five editions to date (2001), has provided, in substantial detail, sets of standardized measurement procedures; describes means of determining the tolerances of intra-observer variability; and offers alternative methods to direct measurements – such as Diagnosis Related Estimates (DRE). Critics of the GEPI complain that the authors do not adequately acknowledge the limitations inherent in consensus-based guidelines, the dearth of strictly validated sets of test processes for impairment measurement in the various bodily Systems, lack of specific identification, correlation and weighting of impairments to various instrumental and personal activities of daily living (ADL), or the perpetuation of confusion regarding such terms as impairment and disability, among numerous other limitations.

The examiner should acknowledge limitations in current knowledge. Moreover, if, under special circumstances, experimental procedures or normative data not representative of the examinee's condition are used, test results must be interpreted cautiously, and clear documentation of these procedures and the rationale for their use and potential for erroneous labelling (e.g. selectivity and specificity) should be provided.

There is a danger in utilizing test procedures that are anecdotal in origin, such as those one might develop over the years within one's own practice, or might acquire from mentors and colleagues. Proving validity and reliability may require blind testing of substantial groups of subjects, with comparison of results and interpretation to tests of established reliability. Caution should be employed in the use of tests which may be well accepted in certain domains of impairment evaluation, but have no known reliability or usefulness in other domains. For example, JAMAR grip testing is routinely employed in functional capacity testing for chronic pain and orthopaedic impairment cases; consistent, full effort is required for the results to be valid for peak strength. Falsification is a serious concern. The Rapid Exchange Grip (REG) test (rapidly alternating right and left hand grips) has been found to be very difficult to falsify and REG results are considered relevant to the question of whether full effort was consistently exerted, and thus whether the measurements obtained on routine JAMAR grip testing were representative of peak strength. However, the typical test subject has no neurological impairment of coordination, pace, proprioception, or motor tone. The validity and reliability, for applying the REG to TBI patients with hemiparesis, spasticity, or apraxia, remains insufficiently tested and thus unknown.

### **Delegation in Testing**

Delegation of testing to one's subordinates is a source of potentially critical flaws. Delegation may be found in certain procedures such as electromyography, neuropsychology, or even interview taking, test administration and/or physical examinations. However, delegation of interpretation is never acceptable. Standardizing methods, order and choice of procedures, ensuring training and maintenance of competence, and minimizing or excluding subjective input are all elementary requirements of appropriate delegation.

It is self-evident that delegation of interviewing not only reduces the evaluator's total contact time with the evaluatee but also reduces the dynamic interview element of following leads created by hesitation or special comment, facial expression, vagueness and/or ambiguity. On the other hand, the accusation that the interviewer rushed the interview or selected questions that precluded the evaluatee from providing complete or balanced information is offset when an assessment is allotted a standard amount of time and pace, and a standardized, core set of questions and checklists is employed, an essential approach to TBI cases.

While it would seem that there is no 'right' answer applicable to all clinicians, or all circumstances, the general principles remain applicable: the evaluator is ultimately responsible for the comprehensiveness and validity of all data collection, and for its interpretation. When it can be shown that more direct evaluation or testing

time, with either a more standardized or a more dynamic, responsive approach, would have led to a better outcome then valid criticism can be applied; and the weight given to the examiner's opinion proportionately diminished.

## **TBI CLINICOLEGAL REPORTING**

### **Critical Components**

The report of any comprehensive independent examination should include the following: demographic details; referral source; party responsible for payment; basis of report (file review alone, claimant alone, family interview etc.); documents requested and reviewed; documents requested but not received; history of present illness; past medical history; family medical history; psychosocial history; educational history; vocational history, including military history if applicable; legal history, including both civil and criminal, as applicable; review of medical systems; comprehensive review of examination findings, including pertinent negative findings; validity of findings, including results of response validity assessments; diagnostic impressions; opinions regarding current and expected future status; maximum medical improvement (MMI) and prognostic opinions; causality and apportionment opinions; risk and restrictions as related to the injury or disease in question; recommendations for treatment or further diagnostic studies; degree of confidence in findings and conclusions; and relevant appendices, clauses and caveats. All opinions should be qualified by degree of certainty (e.g. likelihood with greater than 50% confidence is termed 'probable', while 50:50 or less is termed 'possible'; strong qualifiers of confidence in common clinical use include 'balance of probabilities' and 'reasonable medical certainty').

### **Review of Documentation**

A critically important component of the report is the thoughtful review of specific findings and opinions from medical records. Although some readers with access to all medical records may find this integration of information to be repetitive, the independent examination report is sometimes the only place where a comprehensive integration of the totality of relevant information can be found. A review of background information and medical opinions serves to (a) demonstrate that the records were reviewed, (b) establish the temporal relationship of complaints to the reported injury, (c) facilitate an analysis of the symptom profile in relation to the type of injury being claimed, (d) evaluate the consistency of symptom reporting over time and across contexts, (e) evaluate indicators suggestive of recovery, if present, over time, and (f) provide clear delineation of the inferential reasoning process employed.

It is important to identify and discuss the potential relevance of any materials or other sources of information

not available to the examiner for review. Not uncommonly in TBI case work, this may include prior records which might indicate fetal problems, birth trauma, childhood trauma or infection. School records of achievement and behaviour, as well as any learning deficit, and any intelligence, personality or aptitude testing, can all be of enormous value in appreciating acquired deficits.

There may be situations in which the examiner is not provided with all consultant, treatment or investigative records related to a case. Such restrictions limit the confidence that the examiner can place in his or her own findings. It is relevant to realize that the same shortcomings of database were likely in effect when other professionals reviewed the case, and the same reservations can be fairly applied to the balance of opinions already advanced by others and thus to be found in the file.

Materials not provided can be ranked as to potential importance to report completion. Thus, material may be deemed either Critically Required for a competent evaluation, or merely of Potential Value to clarification or confirmation of existing evidence.

Critically required documentation contains data expected to be of considerable importance, such that without access it would be impossible and improper for the ethical, expert examiner to offer informed, authoritative final conclusions. Thus, certain past medical records may contain information critical to establishing date of onset or other causation-related facts; disinterested clinical or other observer records may enhance one's understanding of the nature and sequence of an event, or provide independent sources of information about daily function, to supplement the narrative interview of the evaluatee or family members. As a specific illustration, when a student suffers a TBI and claims subsequent impairment of academic abilities, corroboration or clarification may be critically influenced by a direct review of prior as well as subsequent academic records of attendance, behaviour and marks, essays and test answers.

Materials of potential value might include documents whose review would be prudent, to ensure thoroughness. For example, one or more 'silent periods' in which there are no entries in either prior or post-injury medical records provided, out of keeping with established care-seeking patterns and/or spanning long periods of time, might well be corroborative of claims of interim good health or stoic self-reliance; alternatively these chronological 'black holes' may reflect undisclosed health care in the same or another community, or even episodes of incarceration. Completion of the healthcare record may reveal unsuspected premorbid or comorbid social, familial, legal, vocational, financial, psychiatric or physical problems - including instances of prior traumatic, vascular, infectious or other brain injury.

It may also be prudent, and sometimes it is critically important, for examiners to request (where appropriate

to scope of practice) raw data from certain testing procedures or hard copies of pertinent radiologic studies and to consider seeking opportunities for corroboratory interviews to round out information collection.

Regarding the overall analysis of assembled information, including examination findings already carried out and documented in prior records, it is reasonable for the examiner to comment on the appropriateness of diagnostic procedures and processes employed, and the consequent reliability and validity of the findings, including estimation of the degree to which the measures used were specific and sensitive to the condition being examined, and the degree of confidence that can be placed in the interpretations and opinions presented. Many examiners feel uncomfortable commenting on the methods and/or conclusions of their colleagues, especially in the absence of the raw data. However, balanced, expert, critical reviews are essential to promotion of thoroughness and objectivity and thus are essential to quality assurance in examinations in clinicolegal settings. Each step in the examination process should be open to critical evaluation in the context of the case and the research literature. The reviewer needs to establish that there has been appropriate choice and administration of tests, proper and balanced interpretation of all of the test data, appropriate data assembly, and sufficient and unbiased reporting of all data. However, in the absence of required raw data, informed critical review may not be possible and report completion may have to be suspended.

### **Completeness of Records and Disclosure of Findings**

Clinicolegal examinations require complete documentation of all procedures conducted and results obtained. The examiner must create appropriate documentation in the expectation that one's records will be critically reviewed by independent professionals both within and outside of one's areas of professional specialty. In addition to formal reports, all information generated during an examination, including handwritten notes and test protocols, may be subject to review by others. Some practitioners advocate for inclusion of all handwritten notes as part of their final report, including copies of all testing results (sans any copyrighted materials). Notes must be legible and abbreviations universal or otherwise unequivocal in interpretation.

### **Drafts and Final Reports**

Ethical practice requires that examination findings be presented objectively, fully and carefully in a report, that no inaccurate documentation be generated, especially for information not obtained or findings not made, with no salient information excluded. Notably, distinct from internal drafts, some professionals will release preliminary reports prior to preparing a final report. Like most other

areas of practice, the reasons for such procedures and the manner in which they are handled determine the degree to which these may potentially challenge ethical principles. Certainly, offering the referring party one or more drafts and soliciting 'feedback' will introduce potential for perception of, as well as actual, biasing of the final report.

Distinct from the above might be a circumstance in which a preliminary report is released to apprise the parties of the status of a continuing evaluation, including justification for requests for further visits, tests or documents. Similarly, a preliminary draft may be released to the referring party along with a specific request for confirmation that all issues of concern have been addressed fully and clearly. It follows that no material alteration in the findings or conclusions, reflecting the referring party's censorial or advocatorial preferences should appear in the subsequent final report.

A report may be released in stages, involving independent components. Any released report component should be considered final for its purpose. Thus, while pending neuropsychological testing or current school year marks prevents completion of a report on spectrum and severity of impairment from TBI, an initial report may be released in which the evaluator addresses questions of causation, mechanism, and diagnosis.

The temptation to request 'tweaking' (alteration to enhance value) of the final report can be irresistible to advocatorial referring/paying parties. Once a final report is issued, the examiner must carefully consider whether and how to respond to any subsequent requests for alterations by the referring party, the evaluatee or others. The examiner should always insist on first receiving any such request in writing. Some requests for changes are fully justifiable, including typographical, chronological or factual errors. It is also appropriate to respond to requests for clarification or amplification or requests of similarly constructive nature, while avoiding altering or debating the findings or opinions. Common instances include requests for clarification of technical terms or reasoning for the court, or for the clinician's opinion to be stated in accord with the formulaic language of legislation – as an example, it may be required that the report unequivocally establish whether impairments meet a verbal threshold such as 'substantial', 'permanent' or 'severe'; an opinion regarding a treatment may require specific reference to whether it is both 'necessary and reasonable'.

Options for rectification of factual errors include: 1) attaching an amended page to the report, 2) marking through the incorrect portion of the report by putting a single line through the incorrect material so that the original can still be read, and then writing (and initialing) the correction in the space above the line, or 3) producing a corrected version of the report and documenting the

rationale within a cover letter. All draft and amended versions of reports, (other than those which fall under solicitor-expert privilege such as notes and other work-products made solely for purposes of discussion with the referring party), should be maintained and produced upon request, as a proof of credibility. Self-tweaking an unsupported conclusion in advance of report release is not ethical; the examiner's report should closely correspond to his/her written records.

### **Use of Disclaimer Statements**

It is recommended that examiners have a disclaimer at the beginning or end of their reports reiterating the basis of the report and the opinions, as related to his/her qualifications. It should be noted that all opinions were provided with the strength of "probability", (greater than 50%) unless otherwise indicated. It is also advisable that examiners include a statement noting that their conclusions are based, in part, on the assumption that the materials provided for review are complete and correct and that if any additional information becomes available at a later date, opinions may be subject to change. It will be relevant to state, in the case of a file review, whether the opportunity for direct clinical assessment was offered, and to what extent such an opportunity might have resulted in a different set of conclusions and recommendations. It is relevant to state the nature and source of the referral, and any special instructions. For example, the examiner may wish to clarify that referral originated with plaintiff's counsel, relating to an MVA claim of a certain date, and that the referral request included a specific request for, or direction to deal only with, the management and prognosis of post-TBI seizures.

It is relevant to declare the absence of any known conflict of interest, or to explain how any potential conflicts were identified and addressed. For example, where two physicians work in an assessment centre, and one has been a treating practitioner, the second – in the role of independent examiner – should state that the case was never discussed between them; that the provision of a second opinion is common in medical practice; and that the examiner felt no reservations about discussing in his/her report any area of disagreement over diagnosis involving his colleagues.

## **USE OF EXPERT WITNESSES**

### **Expert Witness Fees**

Examiners are typically entitled to be paid at higher rates for clinico-legal work than for routine clinical services, owing to factors such as (a) requirements for an expanded, and specialized scope of knowledge and assessment skills; (b) special stressors and exceptional rigor required in maintaining the standards and following guidelines associated

with the litigation process; (c) the exceptional impact of such work on clinical responsibilities, including detracting from normal patient scheduling, and need for arranging clinical coverage, under circumstances of deadlines and unpredictable scheduling, etc.; (d) requirements for careful reading and note taking of substantial amounts of material; and (e) special precision in note taking and record keeping, report structure and preparation, proofing, correction, issuance, privacy issues, etc.

However, the creation of differential fee structures also creates a set of serious ethical issues. The primary concern, from the perspective of perception if not reality, is that differential fees introduce financial incentives, capable of exerting at least a subtle influence on the assessment process and formulation of opinions. The aforementioned must be counteracted by avoidance of any contingencies to the payment arrangement. Neither the size of the fee nor the timing and assurance of payment should ever be contingent upon the outcome of the case. The prospects of future referrals should not be contingent on favourability of opinion to the referring party. Such factors introduce bias, and such behavior is clearly proscribed in professional ethics codes.

Professional fees and terms should be agreed upon at the outset, involving mutual understanding of the feasibility and level of challenge of the type and scope of assessment contemplated. It is preferable that there be clarification of whether the fee is fixed or can be adjusted by the evaluator according to actual time, effort, and complications encountered during the assessment. Clearly, the establishment of fixed fees carries a greater perception of disinterest in individual cases; however, in order to avoid a negative bias against the referral source it is important to ensure appropriate adjustments for unanticipated and specially onerous circumstances such as urgency, need to seek further documentation, special research, language barriers, multiple or last minute cancellations and rebookings, or the especially difficult to examine evaluate. A reasonable compromise may involve either a set of standard fees that factor in exigencies, or a set of fee ranges, with terms for payment that do not change for particular referring parties.

The ethical burden can be somewhat alleviated by consistently referring to or utilizing published fee schedules and application guidelines from professional organizations. Ultimately the ethical test will be one of justification: can the evaluator explain how a fee and terms were developed within the context of a specific case. Clear records for that case and for comparable cases must be kept and kept available. Ethical behaviour therefore includes both internal consistency within one's own practice, and general consistency to the practices of one's ethical colleagues. In the latter context, ethical standards for medical experts can be expressed in terms of "reasonableness" and "consistency" of fees (36). In this case,

"reasonableness" is defined as the degree of similarity to fees charged by other examiners in similar specialties and localities; "consistency" is defined as the degree to which fees are compatible with other medical procedures of similar demand provided by the practitioner or his peer group, as well as for similar time units.

### **Court-Selected and Court-Hired Experts**

The use of court-nominated examiners is a potential solution to problems of partiality or advocacy. Recently, judges in Virginia have begun playing an increased role in the selection of experts for independent evaluations. Specifically, the presiding trier of fact may solicit a list or panel of experts from one or both counsel, from which the judge, or the judge in collaboration with opposing counsel, selects the professional to perform an independent evaluation. Although initially applied in situations where opposing counsel protested or attempted to block utilization of a particular expert, this practice seems to be expanding to other contexts.

Ideally, this approach to neutrality would find the trier of fact supervising or making the referral decisions, after a consensus process which ensures through careful selection that the experts will provide the court with objective, reliable, complete information. However, the experts must be commensurately remunerated for their consensually agreed upon capability, objectivity and ethics, and as a corollary their commitment to avoid the various degrees of "scientific perjury" which some other referral systems may encourage. Joint commitment to funding also ensures that payment is never contingent on outcome, and will not be subject to delay/discount/ bonus. There is the further attraction that the expert and the court are relieved of the time consuming and stressful process of impeaching experts by opposing counsel.

### **Admissibility of Expert Witness TBI Testimony**

The type of testimony that is admissible in court depends on the type of professional role that the expert plays in a given case (e.g., treating doctor/fact witness or expert witness). The treating doctor is permitted to present information related to clinical assessment and treatment conducted based on medical judgment of necessity and reasonableness. In contrast, the expert witness (in federal court and those state courts which accept Daubert (1)) may now be held to the Daubert standard (1) that scientific testimony must be supported by valid scientific theory or techniques. Specifically, Daubert requires that the scientific strategy or procedure has been tested, published under peer review, and is well accepted in the scientific community. Because the skills that make a good expert witness are not always consistent with reliance on "good

science”, the Daubert ruling seems to offer attorneys and the court a useful strategy for evaluating the merit of expert testimony. Given the complexity of many diagnostic procedures, particularly in TBI, scrutiny of the scientific methodology on which diagnoses are based is warranted, indeed essential.

### Monitoring Bias in Examiners and Examinees

In the context of personal injury examinations, clinical attribution bias refers to the consistent and predictable tendency to incorrectly attribute current symptoms to the injury or to the event in question. It typically results in a confounding of accurate diagnosis and appropriate treatment. Patients demonstrate inadvertent attribution bias when they incorrectly interpret periodic, common cognitive inefficiencies as being pathological, entirely attributable to a resolved Mild TBI. Ironically, attribution bias may interact with true neurogenic symptoms to increase impairment. Attribution bias can be influenced by others (e.g., family, attorneys or healthcare professionals) and, unfortunately, can also occur intentionally.

An examinee’s presentation and approach to test taking exists on a continuum ranging from valid to response biased. Due to the financial incentive to misrepresent one’s optimal performance during examinations in clinicolegal contexts, evaluation of the examinee’s response validity is a necessary component of the examination. The examiner must ensure that assessments, recommendations, reports, and diagnostic or evaluative statements are substantiated by sufficient information and techniques. Formal assessment of response validity is essential in order to increase the likelihood that interpretation of test data will be based on reliable results of valid tests; that is, the results will reflect the examinee’s true abilities and deficits.

Examiner misattribution bias represents a problematic source of error that can violate the core ethical principle of avoiding harm. Clinicians sensitized to the signs and symptoms of their particular specialty may misdiagnose or over-diagnose problems, with inadequate attention to competing explanations. For example, a Neurologist and a Psychiatrist, when confronted with a same symptom set, may be prone to speciality-specific diagnoses of, respectively, either brain injury or psychosocial distress (37). Inadequate rigor in developing appropriate diagnosis causes increased medical costs, inappropriate treatment, treatment failures and even chronic disability in the injured person. These errors can be prevented in TBI patients by comprehensive assessment that integrates data from observation, history, examination, radiological and neuropsychological testing and collateral sources, with a critical appraisal of base-rates of relevant symptoms (38–40) and careful differential diagnosis of all possible explanations for symptoms.

Chapman and Elstein (41) have discussed how biases can occur in the face of uncertainty in medical decision-making. Examiners can signal decision bias through any predictable tendencies: such as consistently discounting certain complaints as either not credible or unimportant; or to the contrary, consistently accepting all complaints uncritically, as self-validating (42). Compelling evidence of perceived expert witness bias is offered from a Federal Judiciary Committee sanctioned study, by Johnson, Krafka and Cecil (43), of active Federal judges and lead attorneys who presented the docket cases before them. For 1991 to 1998, the primary problem with expert testimony was experts who “abandon objectivity and become advocates for the side that hired them” (p. 5). Mean rating of partisan bias of experts on a 1–5 Likert rating scale was approximately 3.7. Clearly, there is a need for development, dissemination and universal acceptance of bias-avoidance guidelines, and of active promotion of objectivity and ethical conduct in clinico-legal contexts. However, when serious ethical violations are observed in colleagues, carefully deliberated action is indicated.

### ADDRESSING ETHICAL VIOLATIONS

Consistent with previously mentioned survey results, it is not uncommon in clinicolegal practice to observe apparently unethical work by colleagues. In order to protect patients, referral sources, and payors, and to preserve the reputation of one’s profession, it is necessary to actively but appropriately address potential ethical violations, when they are observed (44). Perhaps nothing so diminishes a profession’s reputation as the disclosure that the ‘community’ has known and tolerated or even covered up a colleague’s substance abuse, patient abuse, incompetence or unethical clinicolegal behaviour over an extended period of time.

Competency and objectivity may be the most frequently violated ethical standards. However, caution must be exercised in order to ensure that perceptions of incompetence or non-objectivity in a colleague are not overly reflective of professional or ideological differences. Certainly, there exist widespread differences of opinion in a number of areas of practice. Sensitivity to such differences is paramount.

However, the clinician who practices or makes judgments outside of even these diverse positions is at risk for justifiable implication of ethical misconduct if such practices or judgments cannot be defended through referral to published standards and guidelines, and recent research literature.

It is important to consider that consistent attribution bias may merely reflect a particular, sincere viewpoint rather than crass claim advocacy. In such instances, the identical attribution pattern can be expected no matter which side made the referral, or how sizable was the fee.

The authors acknowledge that the decision regarding whether or not to confront the poor judgment or apparent ethical misconduct of a colleague may be one of the more difficult professional decisions. That difficulty may be related to a number of factors, including uncertainty about the nature of the behavior and whether or not it occurred, as well as personal feelings toward the colleague, fear of retaliation, and uncertainty about how to address potential misconduct. However, the clinician must be candid with him/herself, as to whether such explanations and excuses are merely self-justifications for an attitude of complacency, or truly necessitate exemption from responsible actions.

Regulatory professional Boards and Colleges may bear some responsibility in this regard: by excess tolerance of either unethical behaviour or revealed instances of collegial complacency; or by lack of mechanisms for efficiently and confidentially receiving notifications of ethical violation concerns by professional colleagues and then promptly and professionally investigating them.

## CONCLUSIONS

Given the potentially devastating impact on all facets of life, TBI represent an very important subset of overall clinico-legal casework. Sadly, as with clinico-legal casework in general, TBI casework offers considerable potential for apparent or real ethical misconduct. The potential for harm is commensurately increased with patient vulnerability, particularly true of the TBI patient.

The ability to identify, for oneself, any areas of particular risk is the essential first step in avoiding not only actual ethical misconduct, but also the appearance of same. For competent professionals, the *loss of objectivity* is the primary risk factor for ethically compromised behavior.

In addition to competency and objectivity, a *lack of awareness and familiarity*: with relevant recent legal cases e.g., *Daubert vs. Merrell Dow* (1), with new methods and procedures, and with changes in relevant ethics codes, place the examiner at an ethical disadvantage. Thus, ongoing education on the application of ethical principles to clinico-legal practice is required for ethical professional behavior.

In order to promote consistently high levels of competent and ethical clinico-legal practice, the legal system must continue to establish *contingencies* and to use reliable *indices*, in order to genuinely increase the likelihood of objective examinations and testimony.

*Proactivity* is the proper response, when ethical misconduct is observed in one's colleagues. Appropriate steps need to be taken to prevent the abuse of the consumers of clinico-legal services and to promote the public's perception of fairness and consequent trust in the clinico-legal process. Ultimately, this is also of great service to one's profession, to one's professional colleagues, and to

the generation of clinicians who will follow, emulate and ultimately replace us.

### INTRODUCTION

Evaluation of neurologic impairments and associated disability presents a significant diagnostic challenge. In cases of more catastrophic or functionally disabling injuries, the evaluations and opinions of different medical practitioners are often fairly consistent. In other cases, however, the evaluations and opinions of practitioners may vary widely.

Impairment and disability evaluation following neurologic injury typically involves such contexts as social security disability application, personal injury litigation, worker's compensation claims, disability insurance policy application, other health care insurance policy coverage, and determination of competence to handle finances or other important life functions (e.g., parenting) or decisions. Traditionally, these evaluations have fallen within the purview of the general fields of physical medicine and rehabilitation, neurology, neurosurgery, psychiatry, psychology and neuropsychology. More recently, and especially in cases of less catastrophic and more subtle cognitive impairment and disability, practitioners who specialize in brain injury evaluation and treatment are increasingly relied upon.

Impairment and disability evaluation may be one of the more misunderstood areas of work as it applies to assessment and treatment of persons with injury residual and/or functional limitations due to injury. The task of making determinations regarding impairment and

disability in persons with neurologic impairment and injury is fraught with potential obstacles and confounding issues. This is due in part to the frequently subtle yet complex nature of the deficits involved, as well as the lack of formal, scientifically validated "rating systems" for many of the deficits associated with these disorders. There are multiple possible types of problems associated with brain or other neurologic injury and there are often a number of other associated problems such as chronic pain or psychoemotional problems. Disentangling the multiple contributors to cognitive dysfunction and to impairment and disability presents a diagnostic challenge and requires careful scrutiny (1).

### IMPORTANCE OF RESPONSE BIAS IN BRAIN INJURY EXAMINATION

Persons with brain injury may present with some response bias to report or demonstrate impairment or related disability. Response bias, in this chapter, is defined as a class of behaviors that reflect less than fully truthful, accurate or valid symptom report and presentation. Importantly, response bias is a ubiquitous phenomenon affecting almost any domain of human self-report. Some forms of response bias may be associated with conscious manipulation or intent to deceive but many, or most, are not. However, in the context of impairment and disability evaluations, or

insurance related evaluations, the importance of conscious or other bias becomes more acute (2–4).

Given the frequent incentives to distort performance during impairment and disability examinations, assessment of examinee motivation to provide full effort to do well during assessment becomes a necessary component of such evaluations. The importance of detecting response biases is critical with regard to providing accurate diagnosis. Accurate diagnosis is prerequisite to provision of appropriate and timely treatment, to obtaining optimal recovery, to prevention of iatrogenic impairment and disability reinforcement, and to appropriate legal compensation decisions. The impairment / disability context and other internal or environmental variables make ensuring accurate representation of a patient's functional status essential. In order to ensure accuracy, a number of factors must be considered including decisions regarding validity of observed impairment and disability, symptomatology displayed during the examination, sensitivity and specificity of assessment measures, and generalizability of test findings to functioning in everyday life.

Blau (5) has expounded on the importance of determining response biases and measuring true levels of impairment in medicolegal situations. Essentially, in this arena, an alleged victim of a wrongful act or omission attempts to establish (a) causality to demonstrate entitlement to compensation for damages, which is awarded based on (b) level of damages suffered. In cases of less obvious, clear cut and significant trauma with psychological, neurologic or soft tissue damage, causality and level of current and future damages are more difficult to prove and expert evaluation and opinion is heavily relied upon for making legal determinations. In the parallel insurance situation, the insured attempts to access entitlements to health care treatment and disability benefits, and expert evaluation and opinion are relied upon for making policy determinations. In both cases, financial and other incentives clearly represent motivational factors that increase the likelihood of response bias in the form of exaggerated or feigned symptoms.

## RESPONSE BIAS ASSESSMENT

### Examinee Response Biases

Examinee response bias can take several forms. Bias ranges from symptoms that may be minimized to those that are exaggerated or feigned. Exaggeration or accentuation of symptoms is usually associated with other psychological factors such as catastrophizing and are less often associated with conscious deception for the purposes of obtaining financial or other compensation, i.e., feigning or malingering. Symptoms may be accurately or inaccurately attributed to different events. For instance, pre-existing symptoms may suddenly be attributed to an

accident, or pre-existing problems previously not noticed can suddenly be given more prominence due to attention and anxiety. Similarly, an accident may cause an aging person to do a self-inventory of health that reveals age related symptoms that were previously minimized or ignored. As awareness of these symptoms or difficulties, many of which may well be "normal" or common in the general population, are temporally related to an accident or injury, they are frequently misattributed to such an event. In addition, social realities also exert influence over response to injury and symptoms. For example, the vastly different consequences for diagnoses of cancer versus mild traumatic brain injury (MTBI) or back injury produce differential reinforcement. The former is clearly undesirable, negative and highly stressful, while the latter can result in desirable consequences (e.g., monetary compensation, avoidance of stressful work demands).

Martelli, Zasler, Mancini and MacMillan (6) reviewed the literature and found several injury context variables associated with poorer post-injury adaptation and recovery and increased likelihood of response bias. These are listed in Table 64-1.

These variables represent vulnerability factors, which can reduce effective coping with post injury impairments and increase the likelihood of maladaptive coping and response bias. They are not mutually exclusive and, as with the variables presented below, more than one can contribute to symptom report and presentation.

Additional review of the literature (7–15), combined with clinical experience, indicate several other sources of poor post-injury adaptation and increased likelihood of significant response bias that may be encountered during examinations. These are included in Table 64-2.

A frequently overlooked form of bias is that which is iatrogenic to an increasingly restrictive insurance and adversarial medicolegal system. In an effort to elucidate expectancy influences and bias for persons who have sustained injuries, Martelli and colleagues (6, 36) conducted convenience attitudinal surveys of professionals who evaluate and treat injured workers, rehabilitation and worker's compensation (WC) case managers, and injured workers. They found an overall 25% estimate of exaggerating or malingering WC patients, with highest estimates from WC case managers (29%), suggesting a general skepticism and distrust faced by injured workers. Furthermore, the majority of professionals and case managers filling out the survey believed that they would personally be treated unfairly by the WC system if they were injured, suggesting an even stronger general skepticism and distrust of the extant systems that fund evaluation and treatment of injury and disability. Although these data are preliminary, the findings are characteristic of the levels of diffuse distrust often observed by the authors in impairment and disability evaluation situations across the United States and Canada. These findings highlight the

--	--

importance of considering the motivational factors that operate on examinees that present for impairment and disability evaluations.

In an interesting conceptualization of a major type of response bias in chronically disabled workers, Matheson (7, 10–12) defined symptom magnification as a conscious or unconscious self destructive and socially reinforced pattern of behavior or symptom production intended to control life circumstances of the sufferer, but which impede health care efforts. He further defined three major subtypes. The Type I “refugee” displays illness behavior that provides escape or avoidance of life situations perceived as unsolvable. Somatization, conversion, psychogenic pain, and hypochondriacal disorders are conceptualized as extreme subcategories for this type. The Type II “game player” employs symptoms for positive gain. Although this type seems associated with malingering, Matheson argues that true malingering is a medicolegal concept, while the Type II symptom magnifier is a treatable self-destructive syndrome. The Type III “identified patient” is motivated by maintenance of the patient role as a means of life survival. Associated psychiatric diagnoses include factitious disorder.

Main and Spanswick (15) examined the response bias of simulated or exaggerated incapacity in persons claiming physical disability. They identified a list of features associated with and suggestive of simulated or exaggerated incapacity associated with chronic pain. These include: failure to comply with reasonable treatment; report of severe pain with no associated psychological effects; marked inconsistencies in effects of pain on general activities; poor work record; previous litigation. Features that they found to be not primarily suggestive of response bias included: mismatch between physical findings and reported symptoms; report of severe or

continuous pain; anger; poor response to treatment; behavioral signs / symptoms.

### **Attribution and Bias**

Several sources of attribution bias which require assessment during evaluation of physical, sensory and neurocognitive impairments need to be considered.

*Examinee* attribution biases can confound accurate diagnosis. Examples include mistaking physical, cognitive, and motivation problems associated with depression and sleep disturbance for neurologic injury or sequelae. This can occur due to misattribution, over-attribution, retrospective attribution, illusory correlation, or to heightened awareness due to vigilance biases. Importantly, the previously mentioned conditions (e.g., depression, sleep disturbance) are reversible and may have been present prior to the injury without producing significant limitations. Furthermore, the emotional states or fatigue may be interacting with actual physical injury symptoms to increase impairment.

*Examiner* misattribution can similarly occur. Only methodical neurologic, psychologic and other assessment can differentiate sequelae secondary to brain injury from factors with overlapping presentations such as cranial/cranial adnexal and cervical trauma impairments, chronic pain, motivational factors and/or other psychological sequelae or other non-neurologic factors. When “abnormal” neurocognitive findings and/or non-specific somatic complaints are obtained, tendencies toward “over-diagnosis” of neurologic disorders, such as MTBI, can only be avoided through careful differential diagnosis. Brain injury specialists sensitized to neurologic symptoms have

**TABLE 64-2**  
***Additional Variables Associated with Poor Post Injury Adaptation and/or Response Bias***

*Cultural Differences.* For example, different cultures mix emotional and physical pain and symptoms at a conceptual and phenomenological level in different ways. Also, some cultures see failure to impose severe penalty / extract significant compensation for harm as a sign of weakness and disgrace in God's eyes.

*Conditioned Avoidance Pain Related Disability (CAPRD).* CAPRD represents phobic reactions associated with fear of pain wherein behavior, either gross motor activity (kinesiophobia) or cognitive exertion (cogniphobia), is avoided due to fear of exacerbation of pain. Such behavioral reactions are typically beyond or minimally within the realm of conscious awareness and control.

*Desperation Induced Malingering/ Symptom Exaggeration.* Individuals that are particularly prone to these types of response bias may include the following: insecure immigrant workers, immigrants who attempt cultural assimilation but feel resentful that they were not rewarded, aging workers, tired workers, workers insecure about work changes, workers fearing their own limited or declining abilities, persons whose premorbid coping was tenuous and who feel too overwhelmed and unable to cope with an additional stress, those with real or imagined abuse from others, such as employers, family, etc., immigrants who feel rejected by the culture and feel entitled, immigrants who feel disillusioned because the new land was not everything they had hoped (i.e., those who believe this to be a viable solution to a desperate situation). A second group of patients represented by this category are those making desperate pleas for help and those who, upon confronting tests that seem different and maybe easier than the real life situations where they have problems, reduce effort to highlight their problems. Again, in some individuals such responses may not be within conscious awareness or control but, in others, there may be more explicit and conscious attempts at deception.

*Sociopathic, Manipulative and Opportunistic personality traits.* These personality traits can be found in all groups, but may be associated with a greater incidence of conscious dissimulation.

*Passive Aggressive, Impatient, or Rebellious personality traits.* Such individuals tend to resent others for not listening to them and believing them. They tend to resent imposed evaluations or doctor's visits, especially ones that examine psychological function or motivation. They may play games with doctors by withholding or undermining procedures or treatments, and may alter performance on tests that seem non-challenging or do not appear face valid.

*Factitious and Somatoform Disorders.* Individuals with factitious disorder and somatoform disorders (i.e., conversion disorders including non-epileptic seizures [pseudo-seizures], somatoform pain disorder, somatization disorder, and undifferentiated somatoform disorder) may present symptoms that represent a combination of several items in this table or other factors.

*Psychological Decompensation.* These individuals usually display conspicuous psychological distress and pathology that differentiates them from others.

*Skepticism.* Many individuals are very skeptical of doctors, examinations and examination procedures, and may be poorly motivated to comply with the conditions required for valid assessment.

*Diagnosis Threat.* This refers to the effect of negative expectations on cognitive test performance. Suhr and Gustad (13, 14) demonstrated that subjects with a history of mild head injury performed significantly worse on general intellectual and memory measures, and rated themselves as putting forth less effortful performance, when attention was called to their head injury ("diagnosis threat"). This effect may play an important role in many situations where response bias and poor adaptation are noted.

*Iatrogenic bias.* A frequently overlooked form of bias is that which is iatrogenic to the nature of the insurance and adversarial legal system. Preliminary attitudinal data gathered from injured workers and the individuals who treat and case manage them (6, 36) indicates a strong and prevalent skepticism and distrust faced by injured persons in the extant insurance systems. This real or perceived mistrust reflects fear and expected unfair treatment from doctor's and insurance companies that can result in a deliberate and reactive magnification of symptoms. Persons most vulnerable to this type of bias may be persons or groups with tendencies toward suspiciousness, including immigrants, outcasts, outsiders, and those who feel chronically underprivileged, "slighted" or "short-changed". As indicate above, the increased attention called to head injuries can undoubtedly produce a "diagnosis threat" effect.

been observed by the authors to often misdiagnose chronic pain sequelae as post-concussive symptoms, which may result in an escalation of medical costs, prolongation of inappropriate treatment, and eventual treatment failure which may contribute to a sense of helplessness and

chronic disability in the injured person. Conversely, similar observations have been made for psychiatrists and psychologists prone to infer psychiatric or psychological etiologies for all pathology, including brain injury or actual physical injury (1, 6, 16).

## Response Bias Assessment

Formal response bias assessment procedures, which may be lacking or only haphazardly attended to in clinical examinations, must be employed in order to increase the probability that clinical examination findings are accurate and valid reflections of impairment. Response bias exists on a continuum that extends through denial and unawareness of impairments, symptom minimization, no bias to symptom magnification and malingering. While many examinees approach testing in a forthright and adequately motivated manner, it is necessary to examine the potential for response bias with each patient.

*Anosognosia* or unawareness of one's deficits is a neurologic phenomenon owing to dysfunction of brain operations subserving awareness (6, 16). This condition is usually more pronounced early after injury, is typically associated with more significant neurologic insults, and can lead to chronic under appreciation of deficits.

*Symptom minimization*, in contrast, may be a consciously or unconsciously motivated phenomenon. It is usually motivated by either a desire to engage in activities that might otherwise be restricted or to maintain a positive view of oneself and one's life (e.g., persons high in trait "social desirability"). *Denial* is a psychological defense employed unconsciously to protect one from facing painful realizations about losses that may be overwhelming and threaten the integrity of the self. Failure to detect such biases can result in failure to identify important impairments and an overestimation of abilities that could potentially endanger the welfare of the examinee.

*Symptom magnification*, in contrast, refers to accentuation or exaggeration of impairment. This can occur in relation to multiple factors, can represent an attempt to inflate financial compensation, and can serve a wide range of psychological needs. Some examples include efforts to legitimize latent dependency needs; resolve pre-existing life conflicts; retaliate against employer or spouse or other; reduce anxiety; fulfill self-denigrating or self-abasement personality patterns; exert a "plea for help"; or solicit acknowledgment of perceived difficulties. Symptom exaggeration can also occur in patients with pre-morbid histories of psychiatric and psychoemotional problems who "latch on" to a specific diagnosis which not only becomes responsible for all life problems, but also promotes passivity, helplessness, and an external locus of control. When patients are assessed for claims of major disability following uncomplicated mild and often even more significant brain injury, non-neurologic contributors should be closely scrutinized. Depression, post traumatic stress disorder and other anxiety conditions or other psychiatric syndromes or psychological processes such as catastrophizing can produce symptoms that are mistaken for neurologic impairment.

Misdiagnosis of these conditions serves to promulgate misperceptions and amplify functional disability and health care costs.

*Malingering* is deliberate symptom production for purposes of secondary gain, especially financial compensation. Malingering in the examination setting will often be associated with unexpectedly poor performance (6). Measures of response bias should always be administered regardless of the context of the evaluation. However, this should be considered imperative in cases of medicolegal presentation or suspicion of any incentive to make less than fully effortful or accurate presentation.

Importantly, the identification of unambiguous cases of malingering is difficult. Whereas the most convincing evidence of certain or definite malingering is a confession or admission, this seldom occurs and may not be truthful. A secondary form of evidence, also unreliable, is when the person or examinee is detected, via surveillance, performing an act that they reported that they could not do. Many persons will sometimes report being unable to do certain things which may represent a response bias to report problems, negative self-evaluations or poor self-judgment. A third form of evidence comes from corroboratory report, i.e., third party contradiction of what the examinee claims. There are also various problems associated with this evidence as is true of many situations when there is a discrepancy between what one party and another reports. Finally, a variety of instruments and examination procedures are available as indicators of response bias. Any of several measures designed to assess atypical, worse than chance performance, or non-organic responses can be employed to assess response bias in cognitive, motor, sensory or physical performances or self report. However, again, most of these measures also require careful clinical interpretation as there may be a number of possible alternative explanations for performance. *Importantly, the presence of response bias, although required, is not sufficient evidence of malingering as this is a probabilistic evaluation predicated on converging evidence from a thorough analysis and integration of history, contextual information, behavioral observation, interview data, examination and test data, collaborative data, and personality and emotional status data. It requires thoughtful analysis of all data (e.g., consideration of both secondary gain and secondary losses), as well as competent differential diagnosis to consider alternative explanations* (16). It also requires cautious and critical consideration of the probability of malingering vis-à-vis the limitations of the assessment and response bias measures and the potential consequences of incorrect impressions. *Measures of response bias provide valuable information for estimating the degree to which a person was presenting accurately, exerting full effort and the degree to which test results are reliable and valid and reflect actual*

*abilities. They do not provide reliable evidence of malingering.*

Evaluating clinicians should be familiar with psychological syndromes that may present as organic disorders, including factitious disorder and somatoform disorders (e.g., conversion disorders including non-epileptic seizures [pseudo-seizures], somatoform pain disorder, somatization disorder, and undifferentiated somatoform disorder), which may be important in the differential diagnosis of malingering. Of course, the presence of a psychological syndrome and/or response bias does not necessarily exclude the diagnosis of an actual neurological syndrome or malingering. This certainly complicates the process of disentangling multiple clinical entities that sometimes co-exist. Unfortunately, the art and science of methodical differential diagnosis is too often under-appreciated in the evaluation process (1).

### Examination Strategies

Physicians should be familiar with examination strategies designed to evaluate non-organic musculoskeletal and neurologic disorders, including the use of specialized bedside examination techniques for physical and cognitive dissimulation. Examples include such strategies as Hoover's test for evaluation of malingered lower extremity weakness, sideways/backwards walking for assessment of feigned gait disturbance, and a positive Stenger's test on audiologic assessment for non-organic hearing loss. Other tests that might be of value in the context of response bias detection on the physical examination include: Mankopf's maneuver, strength reflex test, arm and/or wrist drop test, hip adductor test, axial loading test, Gordon-Welberry toe test, Bowlus and Currier test, Burns bench test, Magnuson's test, and others (1, 17).

Examination findings that suggest a possible non-neurological basis for the observed impairments include patchy sensory loss, pain in an improbable nondermatomal distribution (such as a midline sensory demarcation), non-pronator drift, and/or astasia-abasia (18). Motor and other impairment inconsistencies that fluctuate or disappear under hypnosis, drug assisted interviews, or "presumed" non-observation may also suggest some psychophysiological or functional substrate and cast doubt on a hard-wired or intractable organic deficit. Importantly, some non-organic or non-neurologic signs such as hemisensory loss may be in response to central psychophysiological factors associated with actual changes in brain function (19). Both feigned and conversional hemiparesis are typically more common on the left side (18–20), perhaps due to the fact that most persons are right hand dominant. Consistency regarding laterality of symptoms, particularly with neurologic impairment and/or referred pain, should be evaluated.

When of central (versus peripheral) origin, pain complaints should be assessed, in part, by concurrently assessing temperature perception, given that the same neural pathways mediate these sensations. When temperature sensation is preserved in the presence of a loss of pain sensation, after either brain or spinal cord injury, the deficit is not likely to reflect direct CNS impairment (the loss should occur contralateral to and below the level of the lesion). This point also reinforces the need to understand the neuropathology/pathology of the lesion based on imaging studies and to appreciate the implications that these findings have for anticipated clinical exam findings. Alleged pain imperception can be evaluated, as can nearly any reported neurological impairment for that matter, with appropriately designed forced choice testing (21). Additionally, examiners should realize that alleged pain imperception or loss of sensation is difficult to fake upon repeated bilateral stimulation. This is due to the fact that examinees that exaggerate rely on subjective strategies rather than truly responding to the strength of the stimuli. Therefore, assessments with such techniques as Von Frey hairs could be utilized in the aforementioned scenario to provide further objective evidence of the validity of reported symptoms.

Defining pain and its possible deception is extremely challenging. The standard accepted definition of pain describes it as a physiologic and psychologic response to noxious stimuli, the latter being defined as a stimulus that may or does produce tissue damage (22). One must, however, differentiate between psychic and physical pain, or pain and suffering, in the context of performing an Independent Medical Evaluation (IME). These may be inextricably intertwined with each other as well as with affective conditions such as depression and anxiety. Examiners must understand that multiple variables may impact on pain reporting and behavior and be totally valid yet potentially appear invalid. For example, arousal, stress, tension and anger all may exacerbate subjective reporting of pain and pain behavior, as may depression, through psychophysiological effects. Psychoemotional and psychosocial concomitants of chronic pain must be appreciated, including loss of self-esteem, lowered frustration tolerance, depression, sexual dysfunction, including decreased libido, anger, and guilt.

A very recently disproved screening procedure frequently used by physical therapists, physicians, and chiropractors for estimating when psychological factors are significantly influencing pain related responses is the assessment for Waddell's Non Organic signs (23, 24). These signs include: Overreaction (guarding/limping, bracing, rubbing affected area, grimacing, sighing); Tenderness (widespread sensitivity to light touch of superficial tissue); Axial Loading (light pressure to skull of standing patient should not significantly increase low back symptoms); Rotation (back pain reported when shoulders and pelvis are passively rotated in the same plane); Straight Leg

Raising (marked difference between leg raising in the supine and seated position); Motor and Sensory (giving way or cog wheeling to motor testing or regional sensory loss in a stocking or non dermatomal distribution, when peripheral nerve dysfunction has been ruled out). Additional non-organic signs that have been considered have included: lower extremity give-away, no pain-free spells in the past year, intolerance of treatments, and emergency admissions to hospital with back trouble (15, 20, 23).

Initially thought to indicate degree of non-organic or psychological contribution to pain experience, the Waddell signs were never intended to exclude physical components as a cause of low back pain, or imply that psychological factors were a cause versus result of pain. More recent evidence indicates that the Waddell signs are not valid measures of non-organicity. In a structured, evidence based review of all available evidence, Fishbain (24) concludes that Waddell signs are neither correlated with psychological distress or secondary gain and do not discriminate organic from nonorganic problems. In fact, they may represent an organic phenomenon and are associated with greater pain levels and poorer treatment outcomes.

This finding has significant implications. By demonstrating the invalidity of one of the most heavily relied upon methods for making inferences and medical diagnostic conclusions about nonorganicity, it calls into question the general diagnostic validity of many physical and medical evaluations. Moreover, it almost certainly limits the utility of all commonly used psychological measures that were developed to predict medical diagnoses that relied on these invalid measures.

With regard to assessment of psychological and neuropsychological impairments and chronic pain, response bias represents an especially important threat to validity. As these assessments usually begin with an interview about self-reported symptoms and subsequently rely heavily on standardized measures of performance on well-normed tests, the validity of the results requires the veracity, cooperation, and motivation of the patient. Recent evidence, however, suggests that some patients seen for presumptive brain injury-related impairments over-report pre-injury functional status (25). This may be especially true with post-concussive deficits since these symptoms appear with similar frequency in the general population (26). In addition, the demonstrated ability of neuropsychologists to accurately detect malingering in test protocols has been less than impressive (e.g., 27). Finally, the common practice of utilizing technicians to administer tests, as previously noted, has been called into question for reasons that include adequacy to detect and manage response bias issues (28). Nonetheless, various instruments, techniques and strategies are available which have demonstrated at least some utility in detecting response bias, as a means of increasing confidence in the validity of assessment findings.

In Table 64-3, what have often been considered as hallmarks signs of response bias are presented (29). The signs can be applied to most aspects of a medical examination. However, as noted, caveats exist for most.

Notably, in the evaluation of response bias, as in evaluation of all aspects of pre- and post-injury status, the following investigative tools may be used in conjunction with client interviews and testing: 1) school records; 2) medical records; 3) driver records; 4) military records 5) criminal records; 6) employment records; 7) evaluations from other psychologists; 8) interviews with family members, friends, teachers and employers, etc.; and 9) all materials available to the attorney through formal discovery or otherwise.

These guidelines and strategies are presented as important possible indicators for interpreting patient examination data. Integration of contextual information, history, behavioral observation, interview data, collaborative data, and personality data, with measures of effort and neuropsychological test data provides the best information for estimating the degree to which a person was exerting full effort and the degree to which test results are reliable and valid and reflect actual abilities.

The recent increase in attention to response bias assessment and malingering may reflect a pendulum like overcompensation to earlier times when such issues were not properly appreciated and when excessive compensation packages or awards may have been made due to an assessment of disability that did not take into account response bias. In the current and increasingly restrictive healthcare environment, where services and benefits are more critically evaluated, and where legal and decision making policies favor either-or and black or white conceptualizations, there are tendencies to consider response bias as dichotomous and to consider response bias and malingering as synonymous. In fact, response bias measures are often erroneously referred to in many publications as "malingering measures". This undoubtedly contributes to what the authors note as too frequently haphazard and overzealous application of poorly validated detection procedures, failure to critically and objectively evaluate both the weaknesses, as well as strengths, of these procedures, and tendencies to overinterpret or overgeneralize them.

Again, it is especially important to realize that response bias and malingering are not synonymous. For example, Moore and Donders (30) showed that psychiatric history and financial compensation seeking were associated with a similar increase in likelihood of invalid responding on cognitive symptom validity and neuropsychological measures. Grillo, Brown, Hilsabeck, Price and Lees-Haley (31), using several indicators of response bias that included the Fake Bad Scale (FBS), offered evidence that characterologic / personality

**TABLE 64-3**  
**Response Bias: Typical Hallmark Signs**

**I. Inconsistencies Within and Between:**

1. Reported Symptoms
2. Examination / Test Performance
3. Clinical Presentation
4. Known Diagnostic Patterns
5. Observed Behavior (in another setting)
6. Reported Symptoms & Exam / Test Performance
7. Measures of Similar Abilities (inter-test scatter)
8. Similar Tasks or Items Within the Same Exam or Test (intra test scatter) - especially when difficult tasks are performed more easily than easy ones
9. Different Testing Sessions

*Caveat: The potential contributions of significant psychiatric, attentional, comprehension, or other problems that often involve inconsistent presentations should be considered in evaluating inconsistency.*

**II. Overly Impaired Performance (vs. expected)**

1. Very Poor Performance on Easy Tasks Presented as Difficult
2. Failing Tasks That All But those with Severe Impairment Perform Easily
3. Poorer Performance than Normative Data For Similar Injury/Illness.
4. Below Chance Level Performance

*Caveat: Unusually poor level of performance may be due to actual interference effects associated with various psychologic, sleep or other disturbances; statistically significant levels of below chance performance may be expected in 1/20 cases with the usual significance levels.*

**III. Lack of Specific Diagnostic Signs of Impairment**

*Caveat: Many disorders do not have unambiguous diagnostic signs.*

**IV. Specific Signs of Response Bias on Psychological or Neuropsychological Tests**

1. MMPI-2 Scales: F, F-K, L, VRIN, TRIN, Fb
2. MMPI-2 "Fake Bad Scale" (FBS) (103)
3. Malingering Detection Tests
4. Actuarial formulas for clinical neuropsychological tests (e.g., WCST, CVLT)

*Caveat: Many of these signs are not unambiguous or have not been thoroughly validated.*

**V. Interview Evidence**

1. Atypical temporal relationship of symptoms to injury
2. Psychological symptoms, or symptoms which are improbable, absurd, overly specific or of unusual frequency or severity (e.g., triple vision)
3. Disparate examinee history or complaints across interviews or examiners
4. Disparate corroboratory interview data versus examinee report

*Caveat: Other explanations are possible for disparate or atypical interview data.*

**VI. Physical Exam Findings**

1. Non-organic sensory findings
2. Non-organic motor findings
3. Pseudoneurologic findings in the absence of anticipated associated pathologic findings
4. Inconsistent exam findings
5. Failure on physical exam procedures designed to specifically assess malingering

*Caveat: As indicated above, non-organic sensory findings may have a psychophysiological basis as may psychogenic movement disorders or other pseudoneurologic presentations.*

disorder factors, rather than "malingering" contributes to exaggerated results in a forensic setting. Ample other evidence indicates that psychiatric or functional disorders can produce response bias or actual performance deficits

related to poor adaptation and maladaptive coping versus malingering (e.g., 32–35). There is also evidence that negative expectancy (e.g., "diagnosis threat"), independent of impairment, can reduce cognitive performance (13, 14).

Based on a critical evaluation of the current state of the art, it appears necessary to caution that malingering: 1) should not be considered dichotomous, as *either / or* (i.e., present or not present, black or white); 2) should not be considered something that clinicians can reliably or validly assess or diagnose with a high degree of probability, even when serious efforts are made; and 3) should not be considered a discrete entity assessed by often used response bias measures. Further, it should not be assumed that response bias measures have a high degree of reliability and validity in predicting valid examination performance on other measures or functional ability in other settings, or that patients take the examination process as seriously as examiners do.

A summary of some of the major limitations and problems with current response bias procedures include (8, 9, 19, 36–40):

- Psychometric research Inadequacies (i.e., basic test construction issues such as reliability and validity; sensitivity and specificity).
- Limited generalizability of analogue research (e.g., unknown differences between simulated and real malingerers).
- Variable Group Membership (wide variability in samples for both simulators and symptom disorder groups).
- Differential Vulnerability to Response Bias (some tests are more obvious or subtle, sensitive or specific).
- Questionable Generalizability of Findings (e.g., from analogue simulation studies to real life situations, from one response bias measure to another, to other tests, to actual symptoms, or across time).
- Absence of Mutual Exclusivity (poor effort can occur in presence of real disorders).
- “Law of the Instrument” bias wherein “malingering” becomes what “malingering” tests measure. Specifically, the definitions of “effort”, and validation studies to examine the construct, are often lacking. Further “effort” cannot be assumed uniform for individuals, individuals within diagnostic groups or for nonlitigating and litigating situations.
- Questionable Specificity: The effects of fatigue, pain, disinterest, non-attended (e.g., computer) administration, mixing cognitive tests and SVT’s in a battery with unknown validity, and other factors on response bias tests, are not understood and have not been addressed.
- Frequently High Misclassification (i.e., false positive or false negative) rates, especially in the very few studies that examined ecological or real world validity (38, 39).
- Incautious use of most current SVT Indexes with regard to diagnosis and decision making may violate APA ethics and “APA Standards for Educational

and Psychological Tests”, given the aforementioned psychometric limitations.

These limitations emphasize: 1) caution with regard to over-interpretation of response bias procedures; and 2) the importance of employing multiple data sources and making thoughtful inferences only after integration of thorough historical information, interview, assessment, behavioral observations, collaborative interview and data sources, and so on.

In order to caution against simplistic and dichotomous conceptualizations with regard to diagnosis, the following table is presented. Notably, Table 64-4 represents just 64 of the possibilities with regard to injury-related presentations. The represented possibilities range from (a) persons with real, uncomplicated disorders with impairments on exam and in functional status and without exaggeration on either (but possible minimization or denial) to (b) persons with complicated, misattributed or non-existent disorders with only exaggerated or feigned impairments on exam and/or in functional status. In an ongoing review of medicolegal report findings that will be submitted for future publication, the authors have examined the frequency of possible diagnostic conclusions in reports from cases in which they have been involved. Findings have consistently indicated that a preponderance of conclusions reflect only a few of these possibilities and reach mostly black or white diagnostic inferences regarding presence or absence of neurologic dysfunction and malingering.

A cautious approach is indicated with regard to estimating the probabilities regarding presence or absence of physical impairment and response bias. For instance, if a person has both actual symptoms and is exaggerating difficulty, inferences must be generated not only about the degree of deliberateness and the degree of physical impairment, but also the degree of awareness of

**TABLE 64-4**  
*Diagnostic Possibilities in Brain Injury Assessment*

BRAIN INJURY IMPAIRMENT	RESIDUAL FUNCTIONAL IMPAIRMENTS	RESIDUAL IMPAIRMENTS ON EXAMINATION
1. Yes	1. Yes & Exaggerated	1. Yes & Not Exaggerated
2. Mixed	2. Yes & Not Exaggerated	2. Yes & Exaggerated
3. Indeterminate	3. No & Exaggerated	3. No & Exaggerated
4. No	4. No & Not Exaggerated	4. No & Not Exaggerated

exaggeration on the part of the subject. Has the person adopted a sick role and talked themselves into believing they cannot perform certain tasks and lack certain abilities (e.g., somatoform disorder), with conscious withholding of effort due to intention of demonstrating what they believe to be true disabilities? Or, are they less conscious and aware, as in a conversion disorder? Or are they completely aware, but coping in a way that may be adaptive? An example of the latter is the case of an aging worker with a chronic history of back failures who has low self-esteem and a poor relationship with his or her employer. This employee may have a belief that another back injury is inevitable and will be cumulatively painful and disabling, will require uncomfortable interactions with others, may result in being fired despite conviction that the company did not make obvious safety precautions to prevent their injury, and that no other job options are realistic.

Table 64-5 presents a summary of major response bias detection strategies and techniques that may indicate that the validity of medical examination and psychological test data should be carefully considered. This table was prepared on the basis of a comprehensive review of existing literature (see 6–15, 17–21, 23–150). Multiple sources were used for most of the indicators. Special attention was given to reviews of specific empirical indicators such as those offered by Nies and Sweet (41) and Trueblood and Schmidt (57), which served as a model for this effort. Notably, this table illustrates the utility of a constellation or profiling approach to response bias detection. This multiaxial conceptual model is presented as a methodological approach for constructing a profile of motivation and response bias, which incorporates a wide array of findings from common instruments and procedures during evaluation. Empirical support exists indicating that each of these indicators has at least some utility in detecting sub-optimal effort or other response bias (e.g., 41, 45, 46).

Importantly, review of original test manuals and studies should be conducted before employing any of these instruments. Also, as noted previously, numerous pitfalls and limitations of each of these procedures, both conceptual and methodological, exist. However, some increasing evidence exists for improved discrimination and increased reliability when multiple measures are employed (54). The proposed conceptual approach is one in which multiple factors are integrated as an optimal method for estimating the degree of effort and the degree to which examination findings are reliable and valid. This conceptual model and procedure (MAP) for estimating motivation economically incorporates currently available instruments and methods and the available published research for direct and indirect measurement of effort and response bias. For review of these instruments and methods, the reader is referred to several good reviews

in textbooks of neuropsychology or the many previous reports and reviews of this literature (e.g., 9, 41, 45, 46, 54, 56, 104, 141, 148, 149).

Most major objective personality measures and many neuropsychological measures have scales or indices that can be calculated, (e.g., Memory Assessment Scales (60) and the Rey Complex Figure Test and Recognition Trial (61)) that provide data on the performance of simulators. The advantages inherent in such procedures include: reduced need for administering and charging for very long tests designed solely for detection of potential motivation problems (especially if negative), and for which numerous generalization difficulties exist; limiting the amount of available time for administering other relevant measures and conducting more comprehensive interview (examinee, collaborative others); potential enhancement of face validity of measures to examinees.

The techniques or strategies suggested in Table 64-5 should not be utilized singly or simple mindedly. They are not intended to support a simple dualistic model that equates response bias or other phenomena (e.g. actual interference effects associated with pain, psychoemotional distress, etc) to malingering and then considers examinee responses as either accurate or malingered. Evidence of response bias on any one test does not necessarily imply absence of impairment or in real world abilities. It cannot be concluded that failure on specific indicators represents inadequate performance or response bias. Rather, the strategies are offered with the following suggestions.

1. Examination responses can be influenced by multiple factors that affect the reliability and validity of examination presentations and performances (e.g., deliberate and nondeliberate effort, psychiatric disorders).
2. The degree to which presentations and performances displayed on examination accurately reflect genuine functional abilities exists on a continuum (versus a dichotomy) and can be estimated by the extent to which indicators of response bias are present.
3. Because the interpretation of findings and diagnostic impressions are dependent upon the reliability and validity of examination results, the reliability and validity of interpretations and impressions is reduced to the extent that indicators of response bias are present.

It should again be emphasized that “failure” on one measure of response bias does not mean that the entire set of complaints is biased or invalid. Ethical guidelines caution against overzealous interpretation of limited test data and, in this regard, with erroneously considering response bias and malingering as synonymous or dichotomous, or neglecting how psychiatric or other factors affect response bias measures. At present, the authors are

**TABLE 64-5**  
**Motivation Assessment Profile—Brain Injury Evaluations (MAP-BI)**

**Performance Patterns on Existing Neuropsychological Tests**

Full Scale IQ	
Low (vs. expected, estimated, etc.)	
Digit Span (Floor Effect)	Age Scale Score < 5
Digit Span: Testing Limits with “Chunking”	Non-improvement with “chunking”
Arithmetic and Orientation scale Performance	“Near-miss” (Ganser errors)
WMS-R Malingering Index: Attention/ Concentration Index versus Memory Index	Attention-Concentration Index Score < General Memory Index(AC-GMI)
Paired Associate learning: Easy vs. Hard item Performance	Hard Items $\geq$ Easy Items
General Neuropsych Deficit Scale (35)	GNDS Score < 44
Speech Sounds Perception Test Performance	>17 errors (Poor)
Seashore Rhythm Test Performance	>8 errors (Poor)
Finger Tapping Test	Unusually low w/o gross motor deficit
Tactual Stimulation Performance	Errors bilaterally vs. laterally
Finger Tip Number Writing – Errors	>5
Finger Agnosia – Errors	>3
Grip Strength	Unusually low w/o gross motor deficit
Category Test Performance	Rare or “spike three” errors; Or > 1 Error on Trials I or II
Wisconsin Card Sorting Test Errors	Discrepant # Perseverative vs. # Category Errors
Recognition memory (RAVLT)	< 6
Recognition memory (CVLT)	< 13
List Learning Serial Order Effects	Abnormal patterns
Warrington Recognition Memory Test (RMT)	Score < 38 (RMW), < 26 (RMF)
Rey Complex Figure Recognition Trial	Atypical Recognition Errors ( $\geq 2$ ); Recognition Failure Errors
Word Stem Priming Task Performance	Poor or unusual performance

**Instruments to Specifically Evaluate Level of Cognitive Effort/Response Bias**

Symptom Validity Testing (SVT)	sig * < 50% chance level responding
Hiscock Forced Choice Procedure (HFCP)	sig < 50% chance level responding, <66 correct
Victoria Symptom Validity Test (VSVT)	sig < 50% chance level responding, <16 on easy and/or hard items
Portland Digit Recognition Test (PDRT)	sig < 50%, chance responding
21-Item Test	<5 on free recall, <3 on free recall, <13 on recognition, <9 on recognition
Test of Memory Malingering (TOMM)	<45 trial 2 or recognition
Forced Choice test of Nonverbal Ability (61)	sig < 50% chance level responding
Dot Counting Test (DCT)	Correct/incorrect responses
Computer Assessment of Response Bias (CARB),	< 89% raises suspicion
Word Memory Test (WMT) IR, DR, Consistency	<89% raises suspicion
Autobiographical Interview (36)	>3 errors
Memorization of 16 Items Test (MSIT)	>8 Omissions, >6 Omissions, <6 Total Correct
Rey Word Recognition List (WRL)	<6 correct, <5 (total correct minus false positives)
Rey Memory for 15 Items Test (MFIT)	<3 complete sets, <9 items (38))
Word Completion Memory Test (WCMT)	R < 9 or Inclusion <15

\*sig = statistically significantly

**Personality Instruments with Built-in Detection Designs**

- Personality Assessment Inventory (PAI) (104)
- Inconsistency (INC), Infrequency (INF), Positive Impression Management (PIM), and Negative Impression Management (NIM) scales.
  - 8 score patterns thought to comprise a “Malingering Index”.
  - >2 patterns malingering suspected
  - >4 patterns likely malingering

<b>Qualitative Variables in Assessing Response Bias</b>	
Time /Response Latency Comparisons Across Similar Tasks	
Inconsistencies across tasks	
Performance on Easy Tasks Presented as Hard	Low scores or unusual errors
Remote Memory Report	Difficulties, especially if < recent memory, or severely impaired in absence of gross amnesia
Personal Information	Very poor personal information in absence of gross amnesia
Comparison Between Test Performance & Behavioral Observations	Discrepancies
Inconsistencies in History and/or Complaints, Performance Comparisons for Inconsistencies Within Testing Session (Quantitative & Qualitative):	Inconsistencies across time, interviewer, etc.
	A. Within Tasks (e.g., Easy vs. Hard Items)
	B. Between Tasks (e.g., Easy vs. Hard)
	C. Across Repetitions of same/parallel tasks (R/O fatigue)
	D. Across similar tasks under different motivational sets
Comparisons Across Testing Sessions (Qualitative, Quantitative)	Poorer/inconsistent performance on re-testing
Symptom Self Report: Complaints	High frequency of complaints; patient complaints > significant others'
<b>Main &amp; Spanswick Indicators (15)</b>	
<ul style="list-style-type: none"> <li>• Failure to comply with reasonable treatment</li> <li>• Report of severe pain with no associated psychological effects</li> <li>• Marked inconsistencies in effects of pain on general activities</li> <li>• Poor work record and history of persistent awards</li> <li>• Previous litigation</li> </ul>	
Symptom Self Report: Early vs. Late Symptom Complaint	
Early Symptoms reported late	
<b>Neuromedical Indicators</b>	
Hoover's test	Test for feigned lower extremity weakness associated with normal crossed hip extensor response
Astasia abasia	"Drunken type" non-organic gait with near-falls but no actual falls to ground
Non-organic sensory impairments	Patchy sensory loss, midline sensory loss, large scotoma in visual field, tunnel vision (Note: usually not, but sometimes, organic)
Non-neurologic upper extremity drift	Long tract involvement results in pronator type drift. Proximal shoulder girdle weakness and malingering typically present with non-pronator drift.
Stenger's Test	Test for malingered hearing loss during audiologic evaluation.
Gait discrepancies when observed versus not observed	If organic should be consistent regardless of whether observed or not.
Gait discrepancies relative to direction of requested ambulation	Gait should present with same impairments in all directions. Malingerers do not as a rule practice a feigned gait in all directions.
Forearm pronation, hand clasping and forearm supination test for digit/finger sensory loss	Malingered finger sensory loss is difficult to maintain in this perceptually confusing, intertwined hand/finger position

TABLE 64-5 (continued)

Pain versus temperature discrepancies	Due to the fact that both sensory modalities run in the spinothalamic tract, they should be found to be commensurately impaired contralateral to the side of the CNS lesion.
Lack of atrophy in a chronically paretic/paralytic limb	Lack of atrophy in a paralyzed/paretic limb suggests the limb is being used or is getting regular electrical stimulation to maintain mass.
Impairment diminishes under influence of sodium amytal, hypnosis or lack of observation	All these observations are most consistent with non-organic presentations including consideration of malingering or conversion disorder.
Incongruence between neuroanatomical imaging and neurologic examination	Lack of any static imaging findings on brain CT or MRI in the presence of a dense motor or sensory deficit suggests non-organicity.
Arm drop test	An aware patient malingering profound alteration in consciousness or significant arm paresis will not let their own hand, when held over their head, drop onto their face.
Presence of ipsilateral findings when implied neuroanatomy would dictate contralateral findings	An examinee claiming severe right brain damage who claims right eye blindness and right-sided weakness and sensory loss.
Tell me "when I'm not touching" responses	An examinee with claimed sensory loss who endorses that he does not feel you touch him when you ask him to tell you "if you do not feel this".
Lack of shoe wear in presence of gait disturbance	An examinee with claimed longer term gait deviation due to orthopedic or neurologic causes should demonstrate commensurate wear on shoes (if worn with any frequency)
Calluses on hands in "totally disabled" examinee	An examinee who is unable to work should not present with signs of ongoing evidence of physical labor
Assistive device "wear and tear" signs	In any examinee using assistive devices for any period of time e.g. cane, crutches, there should be commensurate wear on the device consistent with their claimed impairment and disability.
Mankopf's maneuver	Increase in heart rate commensurate with nociceptive stimulation during exam (there is some controversy on whether this always occurs).
Lack of atrophy in a limb that is claimed to be significantly impaired	If side to side measurements and/or inspection do not bear out atrophy consider other causes aside from one being claimed.
Sudden motor give-away or ratchitiness on manual strength testing	Considered to normally be a sign of incomplete effort or symptom exaggeration.
Weakness on manual muscle testing without commensurate asymmetry of DTRs or muscle bulk.	Suggests simulated muscle weakness if longstanding.
Toe test for simulated low back pain	Flexion of hip and knee with movement only of toes should not produce an increase in low back pain.
Magnuson's test	Have examinee point to area several times over period of examination; inconsistencies suggest increased potential for non-organicity.
Delayed response sign	Pain reaction temporally delayed relative to application of perceived nociceptive stimulus.
Wrist drop test	In an examinee with claimed wrist extensor loss, have them pronate forearm, extend elbow and flex shoulder . . . if on making a fist in this position they also extend wrist then non-organicity should be suspected.
Object drop test	Examinee claims inability to bend down yet does so to pick up a light object "inadvertently" dropped by examiner
Hip adductor test	Test for claimed paralysis of lower extremity, similar to Hoover's test yet looks for crossed adductor response
Disparity between tested range of motion and observed range of motion of any joint	When ROM under testing is significantly disparate (e.g. less) from observed, spontaneous ROM suspect functional contributors
Straight leg raise (SLR) disparities dependent on examinee positioning	Differences in SLR between sitting, standing and/or bending may suggest a functional overlay to low back complaints
Grip strength testing via Dynamometer	<ul style="list-style-type: none"> <li>• Three repetitions at any given setting should not vary more than 20% and/or</li> <li>• Bell shaped curve should be generated if all 5 positions are tested.</li> </ul>
<ul style="list-style-type: none"> <li>• 3 Repetitions</li> <li>• 5 Positions</li> </ul>	

TABLE 64-5 (continued)

Sensory "flip" test	Sensory findings should be the same if testing upper extremity in supination or pronation or lower extremity in internal versus external rotation. Differences may suggest a functional overlay.
Pinch test for low back pain	Pinching the lumbar fat pad should not reproduce pain due to axial structure involvement; if test is positive suspect a functional overlay.

**Important Considerations****Caveats:**

1. *The potential contributions of significant psychiatric, attentional, comprehension, or other disorders that often involve inconsistent presentations should be considered in evaluating inconsistency.*
2. *Unusually poor level of performance may be due to actual interference effects associated with various psychological, sleep or other disturbances, especially heightened anxiety or fear of pain.*
3. *Many disorders do not have unambiguous diagnostic signs*
4. *Many of these indicators are not unambiguous and have not been thoroughly validated.*
5. *Non-organic sensory findings may have a psychophysiological basis as may psychogenic movement disorders or other pseudoneurologic presentations.*
6. *Other explanations are possible for disparate or atypical interview data.*

preparing a paper that documents a group of severe TBI clinical subjects who are not in litigation or receiving compensation where large numbers "fail" response bias measures (i.e., score below recommended cut offs) despite very strong external reinforcement for performing well. In addition, several other researchers have submitted or are preparing papers that demonstrate similar results and/or document a proportion of subjects who fail response bias tests but perform adequately on neuropsychological measures.

A practical approach to considering the numerous indicators of response discussed in this chapter is presented in the flow chart in Figure 64-1. This flowchart is intended to facilitate the integration of these measures in deriving meaningful inferences regarding the presence and extent of response bias. This in turn serves the ultimate purpose of estimating the effect of response biases on performance and impairments noted on self report and examination.

Practitioners should recognize that a great disparity exists between the adversarial legal process where attorneys are advocates for their clients and the IME setting where the doctor must be dispassionate and objective. The danger of attorney "coaching" based on utilization of this material cannot be underestimated. This, of course, would then represent a form of "stealth" threat to the validity of examination data. This threat, or expected consequence of collision between the disparate legal and scientific ethics, has been documented in a publication noting a case of attorney client coaching (146). However, compared to simpler models where only a couple of isolated response bias measures are used, it seems more unlikely that the multiple measures employed in the MAP approach could be understood and manipulated.

Finally, enhancing response bias detection as a means of optimizing interpretability of examination results, critical as it is, should not be considered the final step. Decreasing the potential for response bias is a more efficacious and economic approach to enhancing utility of assessment. The following recommendations for enhancing motivation, assessing response bias, and increasing efficiency, utility and ecological validity of examination procedures are offered.

**RECENT DEVELOPMENTS**

Recent efforts to identify response bias and malingering have been problematic. Malingering, or the act of willful, deliberate, and fraudulent feigning, or gross exaggeration, is only one variant of response bias, and an extreme one. The presence of response bias is much more easily documented than malingering. However, the two are often confounded and used synonymously in professional neuropsychological publications and practice, where response bias measures are frequently referred to, explicitly or implicitly, as "malingering tests". Inferences about malingering, especially in a restrictive health care environment with strong gate keeping pressures, are inherently challenging. In the absence of dependent measures or clinical methods with demonstrated validity for assessment of malingering, inferences about malingering using current measures and procedures necessarily produce fallible judgments with unknown false positive rates.

Two of the major obstacles to developing highly reliability and valid measures of malingering are: the absence of an accepted gold standard, which accounts for the absence of any blinded studies comparing malingerers

Flowchart for Reponse Bias Assessment

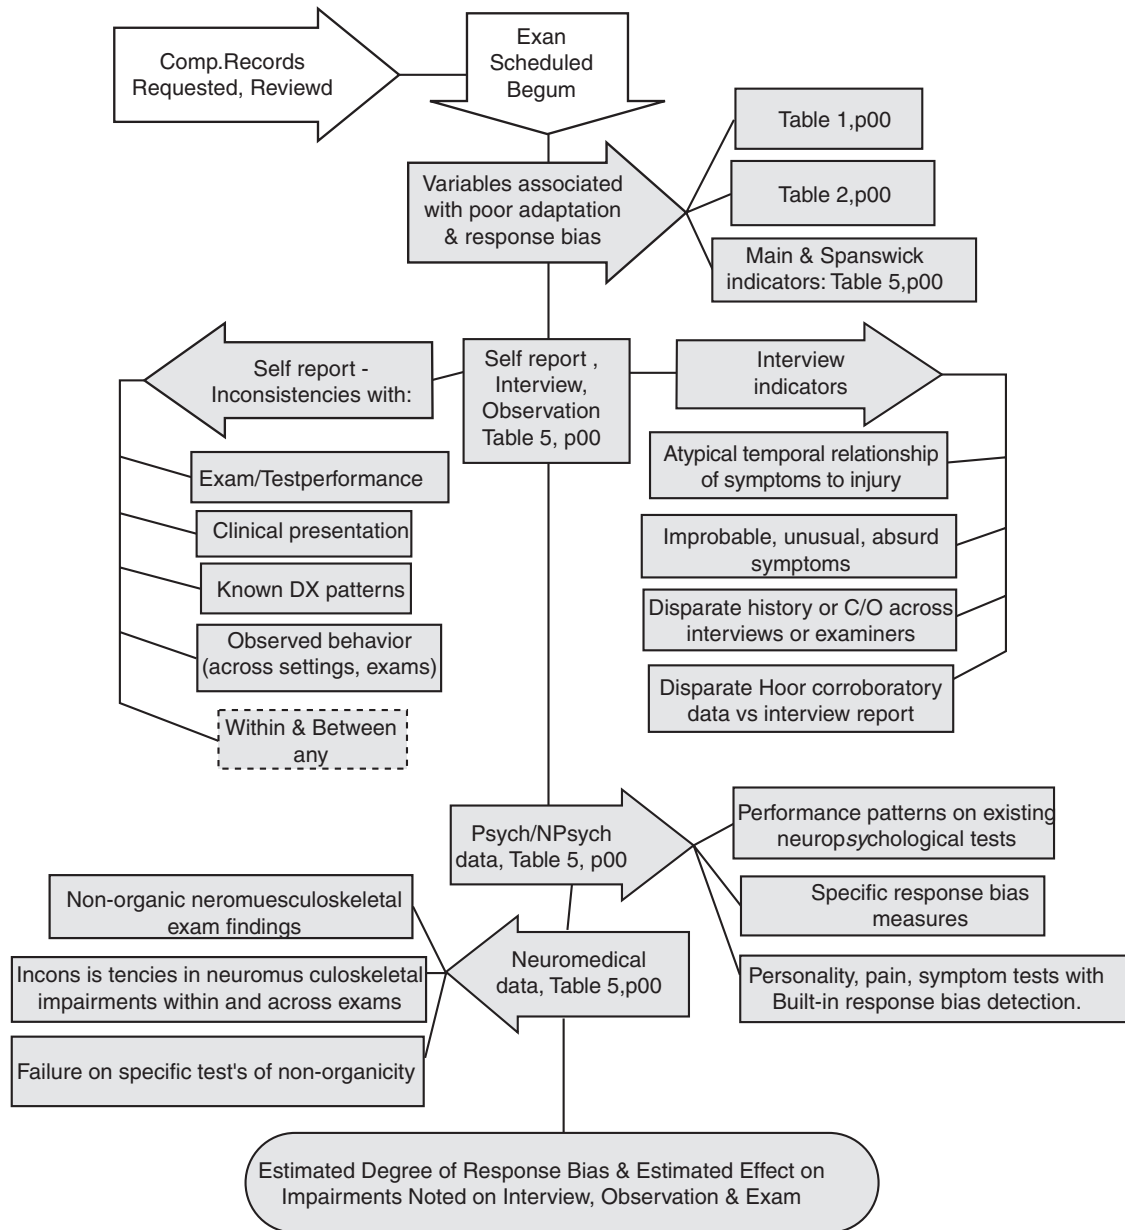

FIGURE 64-1

Flow chart for response bias assessment

and non malingerers; 2) nearly exclusive reliance on simulation studies (i.e., non-injured persons instructed to feign deficits) for establishing reliability and validity (129). In one of the only large group studies that examined the validity of symptom validity instruments for identifying cognitive malingering, the results suggested high false positive rates (38). A research design which attempts to circumvent obstacles relating to simulation studies and absence of a valid gold standard criterion for malingering is one that attempts to employ known

groups. That is, this design examines criterion groups of patients and purported or assumed malingerers and systematically analyzes differences between the groups. This approach may benefit from recent proposals for specifying criteria for malingering (129).

Drawing on previous research, Slick, Sherman and Iverson (151) have proposed diagnostic criteria for malingered neurocognitive dysfunction (MND), defined as volitional exaggeration or fabrication of cognitive dysfunction for the purpose of secondary environmental gain

(e.g., compensation or avoidance). The Slick et al. criteria allow for estimations of three probabilities of MND, including:

- **Definite MND:** presence of (1) substantial external incentive, (2) definite negative response bias on neuropsychological testing, and (3) definite negative response bias is not fully accounted for by psychiatric, neurological or developmental factors.
- **Probable MND:** presence of: (1) substantial external incentive; 2) evidence from neuropsychological testing, excluding definite negative response bias, and one or more types of evidence from self-report, and (3) information or data utilized for criterion #2 are not fully accounted for by psychiatric, neurological or developmental factors.
- **Possible MND:** presence of (1) substantial external incentive; 2) evidence from self-report; 3) information or data utilized for criterion #2 are not fully accountable by psychiatric, neurological, or developmental factors.

Slick et al. (151) urge that inferences regarding malingering be preceded by thorough consideration of differential diagnostic considerations of other types of response bias and psychological, neurologic and developmental contributors, and adoption of a “reasonable doubt” strategy that considers the limitations of assessment methodology, and the cost of false positive errors.

The Slick et al. Proposed Diagnostic criteria for malingering are helpful in delineating the need for multiple indicators for poor effort, and consideration of other, non-SVT factors to be considered in reaching a somewhat less dichotomous diagnosis of definite, probable or possible malingered neurocognitive deficit. However, they nonetheless still suffer from a somewhat limited consideration of factors that can contribute to poor symptom validity test scores, as well as all of the previously noted limitations of available symptom validity measures. Regarding the latter, Ranks (152) recently examined a series of individual cases using detailed analysis of symptom validity measures with the best currently available research support. His presentations, which are being prepared in a manuscript, demonstrate the problems of symptom validity assessment in individual cases using instruments that appear much stronger when examining data from group studies. In findings from a recent investigation by Loring, Lee and Meador (153), the Victoria Symptom Validity Test (VSVT) was found to identify cases of incomplete effort in patients being evaluated for strictly clinical purposes in which no external incentive to perform poorly has been identified. It was also noted that the older patients appeared to be at increased risk for suboptimal performance. Gorissen, Sanz and Schmand (154) investigated schizophrenia patients and

reported that suboptimal performances on symptom validity tests reflected core components of that psychopathology. This suggests that effort is a component of many neurologic disorders and false positives can be expected on tests of effort and motivation, especially in the case of executive impairments.

Evidence from these and other studies (e.g., 152–154) indicate that true base rates for effort test scores (for which there may be a wide range of possible base rates for an individual) have not been established, and that at least some norms from samples that have been offered are unlikely to be representative. Hence, statements from test authors that anyone who is not severely demented can pass such tests appear overly exuberant or misleadingly presumptuous. The search for simple solutions has a long and illustrious history in psychology and medicine where initially positive signs or tests are widely and prematurely and incautiously adopted. Examples such as using the MMPI “conversion V” (58) or the Waddell nonorganic physical signs (23) to purportedly discriminate organic from nonorganic physical etiologies, represent just two examples. In both cases, the professions have shown slow and recalcitrant willingness to abandon these false safety blankets after proving to be invalid indicators. This has been despite the immense potential for negative consequences, and in seeming disregard for core bioethical principles that dictate nonmaleficence (i.e., “First do no harm”).

Sreenivasan, Kirkish and Garrick (155) have recently offered an interesting practical model for the assessment of amplified neuropsychological and psychiatric deficits in civil litigants in cases of MTBI. They proposed a more comprehensive and detailed checklist intended to assist with differentiating between subtle brain dysfunction, symptom amplification, psychological causes for the presence of cognitive and other deficits, or frank malingering. The checklist included examination and rating of patterns for greater consistency with either genuine injury or symptom exaggeration in the following areas:

- I. Neuropsychological testing issues, including: (a) base rates for brain injury, (b) testing consistency with severity of injury and (c) findings on motivational tests;
- II. Congruence of testing data and observed behavior during testing (within and between) with: (a) CNS process; (b) across serial testing; (c) with medical reports; and (d) with occupational and/or school functioning;
- III. Congruence of symptoms or signs with clinical data, including consistency of symptoms/signs with clinical interview (within and between) with: (a) clinical course; (b) past records; (c) physical exam; (d) objective laboratory and test findings; (e) collateral or surveillance data; (f) medication response for natural

history of CNS disease; (g) social, occupational, and/or school functioning;

- IV. Nonclinical factors, including: whether there is: (a) decline in income/business versus pre-injury; (b) pending pre-injury lawsuits; (c) pre-injury work related burn out, job actions, co-worker conflicts and skills problems (d) compensation less than pre-injury income; (e) repeated evaluations with same tests; (f) evaluation context impacting presentation; (g) reasonableness of expectations for recovery;

In addition, it allows for evaluation of the presence or absence of:

- V. Psychiatric and other conditions that may contribute to amplified or atypical symptoms, including: (a) depression/anxiety; (b) personality disorder; (c) conversion/somatization; (d) substance abuse; (e) cumulative concussion; (f) impact of chronic pain; (g) impact of medications; (h) impact of medical comorbidities
- VI. Miscellaneous history, including: (a) prior history of litigation; (b) prior history of lying, malingering; (c) prior criminal activity; (d) prior job track record; (e) prior responses to injury

This model appears to warrant closer consideration, especially with regard to its attention to differential diagnosis and specification of the alternative contributors to failure on symptom validity measures. Future efforts to identify factors predictive of response bias and symptom invalidity should also pay more attention to not only indicators suggesting response bias, but also ones that are inconsistent with response bias and secondary gain, including secondary losses.

### **Recommendations for Enhancing Validity in Impairment and Disability Assessment Findings**

1. Establish rapport and a basic working relationship with patients and examinees. Even in cases of independent evaluations where the referral source and expectation is adversarial, valid data collection requires a collaborative effort. The possibility of dissimulation might be reduced given better rapport (9, 130, 131), understanding of reported symptoms or complaints and communication of that understanding, as well as explanation, feedback and clarification given any suggestion of uncertain motivation. Spend time with patients and try to get to know them as individual persons. We cannot assume that everyone takes our exams and procedures seriously, is as honest or effortful as we would like, or that we will not have to work at getting them interested or invested in doing their best.
2. Ensure that emotional variables affecting motivation are adequately assessed during an interview that is conducted prior to the exam. Specifically, assess the impact of anger or blame and feelings of resentment or victimization (130, 131), as well as the other variables shown in the literature to be associated with poor recovery and adaptation to impairment (6). Assess pain, fatigue or other factors that may actually interfere with optimal performance. Always assess interest/ disinterest in the testing process and any obstacles or impediments to optimal effort and performance. Prepare patients / examinees before beginning testing. Employ understanding, as well as education to help prepare persons to perform to the best of their ability.
3. Make efforts to maximize validity of exam procedures. Where possible, utilize instruments with built-in symptom validity measures. Where possible, utilize comparisons with published patterns and indices indicating sub-optimal test performance for available tests for which there are data for symptom validity indicators (e.g., hand dynamometer; finger tapping; the Wechsler Memory Scale-Revised General Memory vs. Attention/ Concentration index). For example, in addition to comparison of three repeated trials at the same position and comparison of assessment at all five positions, repeat testing with the hand dynamometer allows analysis of consistency of performance patterns across time. Further, measurement of completion time for similar tasks also allows analysis of consistency. Additionally, validity indicators should be developed for existing assessment procedures and symptom validity measures should be built in to newly developed cognitive assessment tests and procedures. Finally, most measures of symptom validity have limitations and caution is advised. Efforts should be made to avoid making strong inferences from instruments for which there are not available data regarding sensitivity and specificity in clinical samples. Instruments with disputed or disproved validity (e.g., Waddell signs) should not be employed or given credibility.
4. Employ shorter symptom validity tests in order to minimize possibility of negative reactions owing to the nature of protracted participation in easy, boring, or atypical tasks. Where possible, employ procedures that both appear more credible and are not well-known. Vary measures and procedures that are employed in order to prevent discrimination of ability measures from symptom validity measures. Publicization of these tests has led to increased recognition by attorneys, clients, support groups, internet groups, and so on. Finally, do not freely share information about symptom validity measures to non-medical professionals. Other professionals adhere to a completely different set of professional

ethics and recent law publications indicate a practice of preparing clients for testing by counseling them with this information (125, 146).

5. Validity of examinations will likely be enhanced when conducted by clinicians who treat persons with brain injury, which also helps to assure more adequate clinical skills for detecting and modifying sub-optimal performance, as well as collection of internalized tracking data to allow validation of previous inferences across time. More experienced brain injury clinicians are more capable of: a) integrating history, interview, corroboratory interview / reports, collateral data, test findings, and personality and emotional status data with more sophisticated clinical observations during examination; (b) adapting more creative modifications of exam procedures and instructions given suspicion of low motivation, to increase motivation and optimize effort; (c) benefiting from the probability that examinees will be more forthcoming and more trusting of an experienced 'doctor'.
6. Remain aware that, in science and medicine, situations are rarely either-or, clear-cut, or one-dimensional. Avoid simplistic conceptual models that are compatible with dichotomous approaches to assessing effort and response bias. Such approaches usually rely on a couple of measures with cut off scores. Cut off scores, by their nature, always entail judgment (150), inherently result in misclassification and impose an artificial dichotomy on essentially continuous variables. "True" cut off scores do not exist. Employ sophisticated, continuous conceptualizations of effort and response bias by using multiple independent measures of estimated effort. Employ a model that conceptualizes motivation and effort as continuous variables that can vary across exam procedures, settings, and occasions. Performance data provides the best information for estimating the degree of effort exerted, and the degree to which test results are reliable and valid.
7. Utilize and devise models that measure the degree of apparent motivation and effort, using multiple data sources, and estimate confidence levels of inferences, given consideration of the multiple factors that contribute to exam findings. Employ similarly sophisticated models for assessing persistent impairments, adaptation to impairments, and disability. Probability statements based on multiple measures are the most appropriate. Integration of contextual information, history, behavioral observations, interview and collaborative data, personality and coping data with multiple measures of effort or performance and current tests exam and qualitative data provides the best information for estimating the degree of effort exerted, and the degree to which test results are reliable and valid.

## CONCLUSION

Evaluation of impairments following brain injury presents a significant challenge with numerous potential obstacles and confounding issues. In addition to frequently subtle but complex deficits, the lack of validated "rating systems" for many residual impairments, and the multiple contributors to impairment and disability, persons with brain injury may present with some bias to report or demonstrate impairment or related disability. Given frequent incentives to distort symptoms during examinations, assessment of examinee motivation is necessary to providing accurate diagnosis. This is prerequisite to provision of appropriate and timely treatment, promotion of optimal recovery, prevention of iatrogenic impairment and disability reinforcement, and appropriate legal compensation and treatment access decision making. In the current chapter, the importance of response bias was reviewed. Response bias assessment procedures relevant to brain injury assessment and treatment were considered and elucidated and appropriate cautions were indicated. Finally, recommendations for enhancing validity in impairment and disability evaluations were offered.

## Decision-Making Capacity After TBI: Clinical Assessment and Ethical Implications

*Sunil Kothari*  
*Kristi Kirschner*

**T**he ability to assess decision-making capacity is one of the “core competencies” of brain injury rehabilitation. Questions about the presence or absence of this capacity lie at the root of many of our recurring clinical and ethical dilemmas. The extent to which a patient can make health care decisions, decide to live without supervision, participate in research, enter into contracts or even engage in sexual activity depends on the nature and extent of their decisional capacity. Unfortunately, many brain injury clinicians feel uncomfortable and ill-prepared to evaluate these abilities. The situation is compounded by the fact that the standard bioethical model of decision-making capacity has limitations when applied to brain injury.

The result is that, “quite frequently”, inadequate attention is paid to assessing decision-making capacity or obtaining legitimate consent in brain injury rehabilitation (1). Even when attempts are made to assess decision-making capacity, there are significant discrepancies between the assessments made by rehabilitation clinicians and those performed by trained experts (2). These difficulties may partly account for the findings of a congressional investigation that brain injury rehabilitation centers often infringed on patients’ autonomy (3). Rehabilitation clinicians do recognize their shortcomings in this area and have ranked as amongst their highest priorities further

education on decision-making capacity as well as the patient’s role in decision making (4).

The objective of this chapter is to enable brain injury clinicians to assess the decision-making capacity of their patients as well as to understand the ethical implications of their findings. Although patients face many types of decisions after a brain injury, we will focus on the capacity to make health care decisions. It is in this realm that questions about decision-making capacity first arise after a brain injury. Moreover, we believe that the model for assessing the capacity to make health care decisions is, with some modification, directly transferable to other contexts (such as deciding to live without supervision, engaging in sexual activity, or entering into contractual relationships).

The chapter is arranged in sections as follows:

- Foundations: balancing autonomy and beneficence
- Decision-making capacity: key principles
- The standard model of assessing decision-making capacity
- Clinical application of the standard model
- The role of neuropsychological testing
- Limitations of the standard model in brain injury
- Choosing an alternate decision maker
- Beyond consent: assent and dissent
- Surrogate decision-making: the special case of withdrawal of care

## FOUNDATIONS: BALANCING AUTONOMY WITH BENEFICENCE

Although our society has long protected the right of individuals to make and act on their own decisions, Anglo-American medicine had been slow to honor this right or even the principle of autonomy underlying it (5). Now, however, autonomy is the foundational value in both bioethics and health care law. The practical consequence of our commitment to this ideal is that patients, and not family members or health care professionals, have the right to make the final decisions regarding their care.

The value of respecting a patient's autonomy is based partly on the presumption that the patient is in the best position to judge what is in her best interest. However, respecting a patient's wishes has value even when she chooses a course of action detrimental to her own welfare. That is, even if a person's choice is not in her best interest, the legal and ethical consensus is that her free exercise of will is more important than preventing any harm that may result to her from the choice made. Of course, the possibility that *others* may be harmed might justify overriding a patient's choice.

If autonomy is so valuable, why shouldn't we honor the choices of all our patients, including those with brain injuries? The answer has to do with the concept of competence. For a patient's choice to be counted as autonomous, and thereby respected, it must be the product of an adequate capacity to reason and choose. But it is precisely this capacity that can be impaired in people with brain injuries. Therefore, the determination as to whether or a not a person's choice is to be honored depends crucially on whether the person is competent to make that decision.

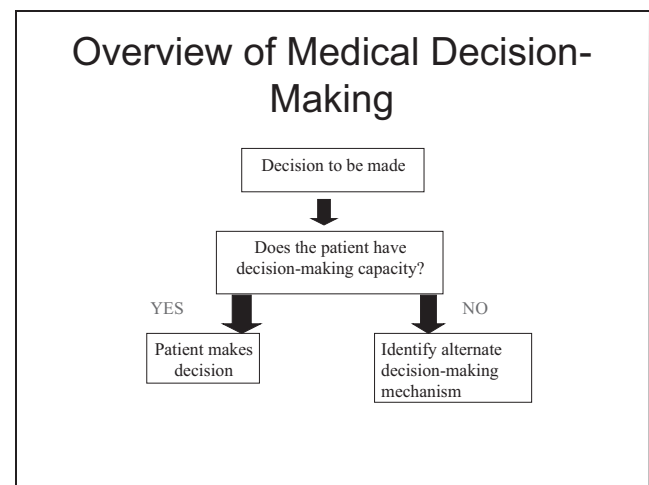

When a person is found to be competent, then the value of autonomy outweighs all other considerations. That is, it is only under extraordinary circumstances that we can override a patient's choice, no matter how much we believe it might harm them. On the other hand, if a person lacks decision-making capacity, then the value of beneficence, which represents a commitment to protecting and even enhancing a person's welfare, is paramount. Although we may still choose to honor the patient's wishes for other reasons, we can now offer a justification (the patient's welfare) for overriding their choices.

Thus, the concern with assessing decision-making capacity is motivated both by a concern with autonomy *and* a concern with beneficence. If a person is competent, we want to make sure that we do not infringe on their ethical and legal right to control their own life. On the other hand, if a person is incompetent, we are obligated to recognize this so that we can prevent or mitigate any harm that may come to them as a result of their choices. This is why it is so important that our assessment of a patient's decision-making capacity be accurate.

## DECISION-MAKING CAPACITY: KEY PRINCIPLES

Whenever a medical decision is to be made, the first step is to determine if the patient has the capacity to make that decision. (Figure 65-1) If so, the patient's wishes must ultimately be honored. If not, an alternate decision maker must be found. Most of this chapter focuses on how to assess whether a patient has decision-making capacity. Near the end however, we will discuss how to identify the appropriate decision maker when a patient is found to lack decision-making capacity.

The model of decision-making capacity that we present represents by far the most widely accepted account, both in bioethics and in the law (6). It should be noted, however, that there is some disagreement about the details of the model, even in the law, where different judicial opinions have occasionally relied on different theories of competence (7). In the text, we have indicated when there are alternatives to the views we present. We start by outlining some general principles which will frame the rest of our discussion. (Figure 65-2) First, it should be noted that, strictly speaking, "competency" is a *legal* category. This means that only a court can find someone incompetent in a particular area. The terms, "decision-making capacity" or "decisional capacity" are used to refer to the *same* set of abilities, as assessed clinically. Therefore, as clinicians, we assess the decision making capacities of our patients, not their competence. Although the legal system does rely heavily on assessments provided by clinicians, the ultimate determination is a judicial one. However, this does not mean that clinicians must rely on the courts every time there is a question about a person's capacity to make decisions; this would overwhelm the legal system. In the vast majority of cases, these assessments can and should be made by clinicians.

**FIGURE 65-1**

Overview of medical decision-making

1. Competency is a *legal* category; decision-making capacity is its clinical correlate.
2. Decision making is a *process*. Assess *how* the decision is made, *not what* is decided.
3. Evaluation should involve *direct observation* of a person's decision making abilities. Avoid inferring from the diagnosis or specific cognitive deficits.
4. Decision-making capacity is *domain specific*. One can be incompetent in some areas (e.g. financial management) but not others (e.g. medical decision making).
5. The decision making abilities required will *vary* with the demands of the situation. Consider how the patient's abilities match up with the demands of the particular decision to be made.
6. The more significant the consequences of a decision, the greater the evidence of competency required ("sliding scale" model).

FIGURE 65-2

## Fundamental principles of competency

Later in the chapter, we will discuss when recourse to the courts might be necessary. For now, the key point is that competence and incompetence are *legal* terms and are most appropriately used to describe judicial determinations. However, because it is common in everyday clinical situations to use the terms "competence" and "decision-making capacity" interchangeably, we will occasionally do the same. Readers should be aware of the distinction, however.

Another key principle is that the focus of an assessment should be on the process by which a decision is made rather than the decision itself. If the process by which a decision is made is sound, then the decision is considered valid, regardless of the clinician's opinion of its merit. Theoretically, the emphasis on the decision making process might lead to a situation in which a particular patient is determined to lack decision-making capacity even while another patient, making the same decision under identical circumstances, is considered competent. This would happen when the process by which one of the patients reached her decision was impaired, while the other's was satisfactory. Further detail on how to assess the decision making process in actual clinical situations will be provided in the next section.

The importance of evaluating the actual decision making process also means that one cannot infer the presence of decision-making capacity from a patient's diagnosis or cognitive deficits. Clearly not everyone with a brain injury or impaired memory lacks decision-making capacity. For this reason, we need to assess patients individually, in the context of the particular decision being made. Ideally, we should observe them as they engage in the process of making the decision that is at issue. This

way we can directly assess their ability to understand, appreciate, and reason with the relevant information (components of decisional capacity that we elaborate on below).

In addition, an assessment of decision-making capacity is distinct from an evaluation of cognitive capacities such as memory, attention, cognitive flexibility, etc. Although these processes affect or even underlie decision-making capacity, deficits in these areas do not automatically preclude the presence of decision-making capacity. Therefore, their evaluation should never supplant (although it can supplement) the direct observation of a person's decision making abilities. This issue will be discussed further in the section on the role of neuropsychological testing.

Decision-making capacity is rarely an all-or-nothing phenomenon; a person may lack the capacity to make certain decisions but not others. In other words, decision-making capacity is domain specific. This is also true of legal determinations of competency. For instance, someone may be found to be incompetent to manage her financial affairs but competent to make medical decisions. In the same way, a clinician may decide that a patient has the capacity to make decisions regarding her place of residence but not about whether to undergo a medical procedure.

Moreover, even *within* a domain, the decision-making capacity required will vary with the particular decision being made. This is because different decisions make different cognitive demands on the patient. Even with regard to medical decision making, patients may be able to make some decisions but not others. For instance, someone may be able to make a simple decision where the risks are low and the benefits high (for instance, to undergo surgery for acute appendicitis) but be unable to make a more complicated decision involving intermediate risks and different categories of outcomes (for instance, trading off a low risk of death for a moderate improvement in functional status). Thus, all assessments of decision-making capacity must be done in the context of the specific decision being made. This principle is well summarized by Grisso and Appelbaum, when they write that ". . . competence is not simply dependent on a person's abilities, but on the *match or mismatch between the patient's abilities and the decision-making demands of the situation that the patient faces.*" (From Ref. 6, p. 23)

Another corollary of the context dependence of assessing decision-making capacity is that the potential consequences of a decision should affect how thoroughly we investigate a patient's abilities. This is known as the "sliding scale" model of assessment. The idea is this: the more significant the consequences of a particular decision, the more evidence we should require that a person has decisional capacity. For example, we would require stronger evidence that a patient has decision-making capacity when she chooses to forgo life sustaining treatment than

when she refuses an antacid to treat gastric reflux. The greater the risk to the patient, the more we need to be certain that the decision represents an autonomous choice.

### THE STANDARD MODEL OF ASSESSING DECISION-MAKING CAPACITY

We have stressed the importance, in assessing decision-making capacity, of contextual features such as the nature, demands, and consequences of the decision being made. We now turn to the specific abilities that constitute decisional capacity. (Figure 65-3) Although the terminology used to describe these skills varies, there is agreement in the bioethical and legal literature about the nature of the abilities themselves. In what follows, we adopt the terminology used by Grisso and Appelbaum (6).

The first and most basic ability required is the ability to *express a choice*. A person who is not able to express (either verbally or behaviorally) a preference lacks decision-making capacity. This would certainly be the case early after a brain injury, before a patient has recovered consciousness. Even after patients have regained the ability to express preferences, however, it is important to recognize that the ability to express a choice is by itself insufficient to establish decision-making capacity. Patients must also possess the other abilities discussed below. The importance of expressing a choice lies in its absence, signaling unequivocal lack of the capacity to make decisions.

A second ability required in order to make decisions is the ability to *understand* relevant information. In the context of medical decision making, this information would include the nature and rationale of the treatment and its risks and benefits as well alternatives to the proposed treatment (as well as their risks and benefits). (Figure 65-4) Of course, this assumes that the clinician herself know what the risks and benefits are; there is considerable

1. The ability to *express a choice*
2. The ability to *understand* information relevant to treatment decision making
3. The ability to *appreciate* the significance of that information for one's own situation, especially concerning one's illness and the probable consequences of one's treatment options
4. The ability to *reason* with relevant information so as to engage in a logical process of weighing treatment options.

Adapted from *Assessing Competence to Consent to Treatment* by Grisso and Applebaum, 1998, Oxford University Press

**FIGURE 65-3**

Components of decision-making capacity

evidence that rehabilitation clinicians have difficulty in estimating patients' risks for activities such as walking, living alone, etc (8).

Of course, simply understanding the information is not enough; one must acknowledge that it is relevant to one's situation. We refer specifically to an *appreciation* of one's condition, with a special emphasis on how the intervention(s) being proposed applies to one's own circumstances. This ability is often impaired in people with brain injuries and manifests itself as decreased insight into any deficits that are present. As a result, a patient may evince complete understanding of the information outlined in Figure 65-4 and yet be unable to relate it meaningfully to her own situation.

In addition to understanding and appreciating the relevant information, patients must also be able to *reason* appropriately. The information must be processed by the patient in a logical and coherent manner. For one, a patient needs to relate the various possible outcomes to their own values. For example, is the value the patient places on physical independence reflected in their thinking and the choices they make? Patients also need to be able to imagine what the consequences of the various options would be. Ideally, patients would be able to go beyond simply verbalizing consequences to being able to describe the potential effects on their life (for instance, to appreciate the impact on their life of possible impotence after prostate surgery). These are just some of the factors that we all consider in making these sorts of decisions.

### CLINICAL APPLICATION OF THE STANDARD MODEL

How does one assess whether or not a person has the required abilities to choose, understand, appreciate and reason? While the evaluation of some of these abilities seems fairly straightforward (e.g. is a person capable of expressing a preference?), the assessment of others seems to be more complicated (e.g. how to assess reasoning ability?). In what follows, we offer suggestions on how clinicians can evaluate a patient's decisional capacity. Our

- Nature and rationale of treatment
- Risks and benefits of treatment (including their likelihood)
- Risks and benefits of the alternatives (including no treatment)

Adapted from *Assessing Competence to Consent to Treatment* by Grisso and Applebaum, 1998, Oxford University Press

**FIGURE 65-4**

Relevant information that patients must understand

focus throughout is on a “bedside” evaluation which can be performed without the aid of more formal tools. However, we should note that such tools are now being developed, including one developed by Grisso and Appelbaum (6). In addition, we address the role of neuropsychological testing in the next section.

As we mentioned earlier, one of the key principles of assessing decisional capacity is that we operationalize our assessment. This means that we should evaluate the abilities described above when a patient is actively involved in the process of making a decision. During this process, we can engage the patient through a series of questions. (Figure 65-5) The point is that we are not inferring the patient’s capacities from either their diagnosis or cognitive deficits (e.g. impaired memory); we are directly examining the abilities in question.

The questions outlined in Figure 65-5 for assessing appreciation, understanding, and expressing a choice are self explanatory. As we mentioned above, assessing the component of reasoning is the least straightforward. The strategy here is to ask the person to “think out loud”. That is, one asks them to retrace for the examiner the process by which they reached their decision. The examiner observes for a logical and coherent thought process. Of special interest are issues such as: how does the person understand and weigh risks (including their likelihood), is the person making a choice consistent with the values that they profess, is the person able to imagine the consequences of the various options, etc.

#### ABILITY TO EXPRESS A CHOICE

“Please tell me what your decision is.”

#### ABILITY TO UNDERSTAND THE RELEVANT INFORMATION

“Can you tell me, in your own words, what you know about:

- Your condition.
- The treatment recommended
- The risks and benefits of this treatment
- The risks and benefits of other options (including no treatment at all).”

#### ABILITY TO APPRECIATE ONE’S OWN SITUATION

“Can you tell me what you believe is wrong with you?”

“Do you believe that you need some sort of treatment?”

#### ABILITY TO REASON WITH THE RELEVANT INFORMATION

“Tell me how you reached your decision”

“What factors did you consider?”

Adapted from *Assessing Competence to Consent to Treatment* by Grisso and Appelbaum, 1998, Oxford University Press

The assessment of a patient’s decision-making capacity is not limited to an evaluation of their abilities to understand, appreciate, and reason. As discussed previously, the context in which these capacities are exercised is crucial. In particular, one needs to understand the specific decisional task the patient is confronting. This is because different tasks make different demands on understanding and reasoning. We should adjust the degree of understanding and reasoning we expect based on the inherent nature and complexity of the decision. For example, certain treatments in acute care medicine may result in a somewhat higher risk of death initially but a better functional outcome for survivors. These outcomes and the resulting necessity to balance values such as death and functional status make greater demands on understanding and reasoning abilities than, for instance, deciding to undergo a minimally risky treatment that should lead to a cure.

In addition to taking into account the complexity of the decision to be made, one should also keep in mind the possible consequences of the decision. This is because, the more significant the consequences, the more evidence of decision-making capacity we should require. For instance, if a patient refuses a low risk, potentially life saving intervention, we would require that they more thoroughly demonstrate evidence of their decision-making capacity than if they refused a high risk intervention with little chance of success. We should adjust the questions that we ask and the answers we deem acceptable based on the likely impact on the patient’s welfare.

Although we have stressed the indispensable role of direct observation of a person’s decision making abilities, there is a role for supplementary information. Specifically, in addition to the assessment outlined in Figure 65-5, one should also solicit information from third parties including caregivers and family members. As a result of the time that they spend with the patient, they often have a richer knowledge of the patient’s decision making abilities than can be gathered from the clinician’s formal assessment. For instance, their observations of how the patient reasons through other decisions or situations will have some bearing on how they deliberate in the present situation. More importantly, there are factors that may be relevant to decision-making capacity that may only be gleaned from direct observation of behavior in other realms.

For instance, as we will discuss below, it is entirely possible that a person could satisfactorily answer the questions asked in a formal assessment, and yet not behave in a way consistent with their answers. This “verbal-behavioral dissociation” is often seen in people with brain injuries but, by its very nature, can easily be missed in the verbally and cognitively biased assessment that we have outlined. Supplementary information in the form of observations by family members and other third parties is crucial in these cases. Of course, one must always

**FIGURE 65-5**

Questions to ask in assessing decision-making abilities

keep in mind the possibility of conflicts of interest between family members and the patient that might affect the information provided.

Finally, a few logistical points should be made about the assessment. First, because cognitive capacities can fluctuate after brain injury, multiple evaluations are often necessary to ensure that a person's best performance is observed. Performing such serial assessments also allows one to establish the consistency of a patient's choices over time. The absence of such consistency (for instance, when a patient changes her decision from day to day) raises serious questions about a patient's decision-making abilities. Moreover, one must also be mindful of any potentially reversible factors that might influence a person's ability to make decisions. Examples would include medication effects and the impact of fatigue. As much as possible, one should attempt to minimize the effects of such factors in the interests of maximizing a patient's performance.

It is also important to ensure that the optimal mode of communication has been established. Communication impairments are ubiquitous in brain injury, ranging from specifically linguistic problems (i.e. aphasia) to higher order impairments (e.g. pragmatic deficits). As a result, it is crucial that adequate communication exists such that there is little doubt that information is being appropriately conveyed to and from the patient. Also, adequate time needs to be spent with the patient to ensure that all the relevant information is provided and that all questions are addressed. Any ancillary means to enhance the disclosure of information should be utilized (e.g. written explanations, visual aids, augmentative communication, etc.).

### THE ROLE OF NEUROPSYCHOLOGICAL TESTING

Neuropsychological testing often plays a significant role in the evaluation of decision-making capacity. We believe, however, that its proper function can be misunderstood. In particular, we are concerned that testing can become a substitute for the direct clinical assessment of decisional capacity, resulting in less accurate and potentially inappropriate conclusions. Neuropsychological testing should play a *supplementary* role in the assessment of decisional capacity; the determination of intact or impaired decision-making capacity should rarely be based solely on the results of such an evaluation. We want to stress that our concerns are limited to *formal testing* only and not assessments performed by neuropsychologists. In fact, by virtue of their training and skills, neuropsychologists are ideally suited to perform the clinical assessment described earlier in the chapter.

It is easy to see why the formal assessment of cognitive deficits is thought to be central to the evaluation of decisional capacity. After all, impairments in decision-making

capacity are a direct result of the neuropsychological sequelae of brain injury. The cognitive, affective, and behavioral domains affected by brain injury form the substrate of most of our everyday tasks, including our ability to make decisions. Since discrete cognitive capacities such as attention, memory, language, etc. underlie the ability to make decisions, it seems only natural that these be formally assessed whenever decisional capacity is in question. However, the desire to base conclusions regarding decision-making capacity purely on formal testing is based on a misunderstanding of the nature of decision making abilities and the ways in which they are affected by cognitive deficits.

Although impairments in decision-making capacity are a *consequence* of neuropsychological deficits (whether cognitive, affective, or volitional), they are not identical with them. The ability to make decisions is best understood by analogy to other abilities in rehabilitation medicine, such as walking. In the case of walking, the inability to walk is the consequence of a complex interaction between various physical deficits (e.g., weakness in different muscle groups, spasticity, deconditioning, residual abilities in other parts of the body, presence of neglect, etc.) as well as the context in which one walks (e.g., level surfaces, carpet, incline, etc.). Although one could theoretically devise a model that incorporates all of these variables to predict whether a particular patient will walk, it is far easier to perform a direct assessment by standing them up and attempting to walk with them. Moreover, given the complexity of walking and its dependence on context, no model will ever be as accurate as direct assessment.

Similarly, the ability to make decisions is the consequence of a complex interaction between various mental capacities (memory, abstract reasoning, attention, etc.) and the context of the decision to be made (whom to vote for, whether to undergo surgery, to engage in sexual activity, etc.). Once again, given the number of variables involved and the complexity of their potential interaction, it would be far easier to directly assess decision-making capacity (as outlined earlier) than attempt to infer its presence or absence from what are, at best, surrogate markers. In addition, the importance of taking the context into account can not be over-emphasized: a particular cognitive deficit might impair the capacity to make one decision but not another.

Because decision-making capacity is not identical with the capacities that underlie it, there is no clear way to determine what pattern of test findings preclude adequate decision making. Even with isolated deficits, there is rarely a one to one correspondence between a deficit and the ability to make a particular decision, much less the ability to make all decisions. For instance, while it is clear that impaired attention can affect most of the components of decisional capacity mentioned above (for instance, understanding or reasoning), it is not clear, except in cases

of extreme impairment, what degree of attentional deficit precludes adequate decision making. We have to return to the direct assessment outlined above (Fig. 65-5) in order to confirm that a patient's inattention is significantly affecting their ability to process information.

The problem is compounded by the fact that, as mentioned above, decision making tasks of differing complexity require different levels of understanding or reasoning abilities. Therefore, a person with impaired attention may have the capacity to make a simple decision but not a more complex one. Once again, we would have to assess the person's abilities directly. Finally, because one can compensate for attentional deficits to a certain extent, the same degree of attentional impairment may result in a patient having decision-making capacity at some times and not others (depending on whether the information is presented in a quiet, distraction-free environment, repeated several times, etc.). There are cases described of patients believed to lack decision-making capacity solely because they had certain deficits on testing (e.g. aphasia), who were found, on a more direct assessment, to actually have decisional capacity (especially when compensatory strategies were employed) (9).

The inability to "read off" a person's decision making status from their cognitive impairments is the primary obstacle to relying *exclusively* on neuropsychological testing; however, there are other limitations as well. It is difficult to test certain capacities that have a direct bearing on decision-making capacity. The best known of these are the so called frontal lobe capacities such as cognitive flexibility, the ability to plan, the ability to consider hypothetical situations, etc. Frontal lobe function can only be incompletely tested at the present time and patients can do well on formal testing even though they have frontal lobe dysfunction directly affecting their decisional capacity (10, 11). This is not as much of an issue when one is directly assessing decision-making capacity because one is directly observing the effects of possible frontal lobe deficits on the patient's reasoning. That is, one can directly observe the patient's ability to consider consequences, recognize and weigh alternatives, assess the ability of a particular decision to realize their goals, etc., all in the context of the decision in question. Once again, direct assessment will usually be superior to a formal assessment of certain neuropsychological domains.

Indeed, we believe that the actual determination of a person's decision-making capacity can often be made independently of a formal neuropsychological evaluation. This is because, as we have outlined above, the components of decision-making capacity (evinced a choice, understanding, appreciation, and reasoning) can be *directly* assessed (Fig. 65-5), without having to evaluate the cognitive capacities that underlie these abilities. While it is true that cognitive functions such as attention or memory form the basis of decision-making capacity, it is *not*

necessary to know how and to what extent they are affected in order to determine whether or not a patient has adequate decision making abilities for a particular situation. Since we are primarily concerned with the *effects* of cognitive deficits on decision-making capacity, we would be better off assessing the decision making abilities directly, rather than inferring them from neuropsychological test results.

In fact, studies that have investigated the correlation between neuropsychological test results and decision-making capacity acknowledge that the clinical assessment of decision-making capacity is the "gold standard" (11, 12). The aim of these studies was to determine whether testing by itself could match the accuracy of direct clinical assessments. Not surprisingly, while neuropsychological test results were correlated with the presence or absence of decision-making capacity, testing by itself was never as accurate as direct clinical assessment (13-16).

Despite its limitations, formal testing does have an important role to play. There are at least two purposes it can serve. First, the presence of deficits on testing can alert us to the possibility that a patient's decision-making capacity may be impaired. For instance, the identification of a short-term memory problem, while not enough to determine that a person lacks decision-making capacity, can prompt a direct assessment to make that determination.

More importantly, neuropsychological testing allows us to determine *why* a person's decision-making capacity may be impaired. The "direct" assessment that we outlined earlier simply allows us to determine whether or not a person has decisional capacity adequate to the task at hand. It rarely allows an identification of the cognitive impairments that underlie a particular patient's difficulties. For example, a person's inability to understand the information provided by a clinician may be caused by inattention or a language deficit. While knowing the cause does not alter the determination that the person lacks decision-making capacity, it does allow the clinician to target interventions to either correct the underlying deficit (e.g. discontinuing a sedating medication) or compensate for it (e.g. provide verbal explanations for someone with alexia).

### LIMITATIONS OF THE PROPOSED MODEL IN BRAIN INJURY

If forced to choose one method of evaluation, the direct assessment of decisional capacity is superior to neuropsychological testing. However, the two approaches complement each other and are best used together. Unfortunately, even this combination is sometimes not enough, especially in the case of brain injury. This is primarily because both direct assessment as well as neuropsychological testing have a strong cognitive bias. That is, they

are heavily weighted towards evaluating the cognitive aspects of decision making while virtually ignoring the affective, volitional, and behavioral domains which are often impaired in people with brain injuries. As is well known, cognitive abilities can often dissociate from these other domains. As a result, someone whose cognitive functions are preserved may be thought to have adequate decision-making capacity when, in reality, deficits in emotion, volition, or behavior may be impairing their ability to make decisions.

The most obvious example is the person who is unable to conform their behavior to their professed beliefs and desires. There are many people with brain injuries who are able to reply appropriately to questions about how they would act in particular situations but are unable to do so when they are actually confronted with them (17). Unfortunately, an assessment that limits itself to purely verbal or written responses (such as in a clinical interview or formal testing) will not be able to identify these problems precisely because they arise only when the patient is performing an action. For instance, in assessing whether someone has the capacity to decide to live on their own, one would ask how the patient would respond to different scenarios (for instance, smelling a gas leak). Even if the patient responded appropriately, one can not automatically assume they will act in the way they described. This might be because they have difficulty with impulse control which circumvents their ability to act in ways they might have intended. Or, the patient may have an amotivational syndrome that affects their ability to act on any of their beliefs or desires. These examples underscore the point made earlier about the importance of supplementing interview-based data with behavioral information obtained both through one's own observations as well as those of others.

Despite its significance in many contexts, the dissociation between cognition and behavior is not quite as relevant for decisions regarding health care. This is because for these decisions the patient rarely has to act; rather, they are passive recipients of others' actions (as in undergoing surgery). Since there is rarely behavior on the patient's part following a health care decision, a cognitively oriented evaluation should be adequate. For those decisions that do have a prominent behavioral component (such as the decision to engage in sexual activity), such an evaluation would have to be supplemented by knowledge of a patients' behavior.

Information about verbal-behavioral dissociations is often relatively easy to collect. Unfortunately, there are other non-cognitive impairments that may be more difficult to detect, thus increasing the chances that someone might be thought to have decisional capacity when, in fact, they don't. The most common of these impairments involve disorders of affect such as moderate to severe depression. Although it is known that depression can

directly affect cognition (for instance, information processing efficiency, short term memory, etc.)(6), these effects should be detectable by a direct assessment such as the one outlined in this chapter (at least in so far as these deficits compromise decision making ability for the decision at hand).

However, disorders of affect can compromise decision making in more subtle, but still significant ways (7). For instance, depression can alter how one values certain outcomes. Consider a severely depressed patient who is faced with a potentially life saving intervention with relatively low risk and minimal discomfort. The patient may have full understanding of the intervention, an appreciation of her medical situation, and adequate reasoning or information processing skills. She may still choose to refuse the intervention because she no longer wishes to live and sees her condition as offering an opportunity to die (18, 19). According to our original model, one would consider this patient to have intact decision-making capacity because she has the requisite cognitive capacities that are the focus of the evaluation. What is impaired is her ability to *value* appropriately; her depression causes her to favor outcomes that she would not have favored prior to the onset of her mood disorder.

The impact of emotions on decision making extends beyond the classical disorders of affect, however. Brain injury can affect emotions in other ways, most notably in the form of the hypoemotionality that can be seen after ventromedial frontal lobe injury (20). According to Damasio, certain frontal lobe injuries can result in an impairment in ". . . assigning different values to different options, . . . [thereby making one's] decision-making landscape hopelessly flat." (from 20, p. 57) He elaborates: ". . . the process of emotion and feeling are indispensable for rationality. At their best, feelings point us in the proper direction, take us to the appropriate place in a decision-making space, where we may put the instruments of logic to good use." (from 20, p.58) In the case of depression, patients still have the capacity to value; however, their valuations are inappropriate and different from what they would have been in the past. In the case of hypoemotionality, however, the capacity to value *any* outcome is impaired, thereby compromising decisional capacity in the way outlined by Damasio.

Impairments of hypo-emotionality are often difficult to identify on standard neuropsychological assessments. Indeed, one patient that Damasio discusses did well on all neuropsychological tests, even those specific for frontal lobe dysfunction. Yet, this patient had profound deficits in making decisions in "real life" situations, attributed to his affective impairments (20). For similar reasons, the assessment of decision-making capacity that we have presented, focused as it is on cognitive skills such as understanding and reasoning, may also fail to identify these sorts of impairments.

Decision making not only involves the ability to value outcomes appropriately but also the ability to respond appropriately to risks. This goes beyond simply understanding the quantitative aspects of risk, which can be impaired in depression (21). It also involves the appropriate emotional reaction to risk (such as being averse to risk unless the potential benefits outweigh the risks involved). Unfortunately, brain injury can also distort risk taking behavior, potentially changing the decisions patients might otherwise have made. For instance, depression after a brain injury can cause people to become more risk averse (22). This might prevent a depressed patient from choosing a moderately risky but highly beneficial medical intervention which they might normally have chosen before they became depressed. Yet, the patient's ability to express a choice, understand, appreciate, and reason would be found to be intact, leading one to conclude that the patient's decision-making capacity was not compromised. Other disorders of affect may cause similar distortions of our perception and response to risks. For instance, anxiety may also cause a state of risk aversion while mania or hypomania can cause one to be risk seeking. Regardless of whether one becomes more or less risk averse, these classical disorders of emotion can affect decision making in a way that would be difficult to detect by either direct assessment or formal testing.

In cases of hypoemotionality, there is evidence that individuals may lose the ability to feel *any* emotional response to the presence of risk. For instance, studies have shown that many patients with frontal lobe injuries do not manifest the normal activation of the sympathetic nervous system when confronted by risk (20, 23). These patients subsequently demonstrated increased risk taking behavior (23). The implications for decision making are clear. In the case of behaviors, not having the appropriate emotional response in the presence of risk will probably lead to increased risk taking with implications for a person's capacity to decide to, for instance, engage in sexual activity. Even for decisions that don't necessarily lead to overt actions on the part of the patient (such as medical decision making), the lack of the affective component of risk perception may lead patients to decide on risky interventions that they might otherwise have avoided. Once again, purely cognitive evaluations such as direct clinical assessments or formal testing will be unable to detect the influence of this type of affective impairment on decision making.

These evaluations will also fail to identify other impairments in decision making that can occur after frontal lobe injury. For instance, there is evidence that patients with ventromedial injuries discount the future excessively and, as a consequence, distort their decision-making by placing undue weight on short term gains or losses at the expense of future gains or losses (23). In the context of medical decision making, this might lead to

a patient deciding against an intervention that might have some temporary discomfort early on but significant benefits in the long-term. Or the reverse might happen: the patient may choose an intervention that provides some short-term gains but may actually be deleterious in the future. It would be difficult to identify this sort of impairment through direct clinical assessment or testing. One would have to rely on behavioral evidence based on one's own observations or reports from others. Unfortunately, this evidence is often not available in the first few months after brain injury since patients have not yet been in contexts where they have had to make many of their own decisions. This type of temporal "myopia" can also affect behavior such that patients might choose short-term pleasure (e.g. not using contraception) over long-term risks (e.g. an unwanted pregnancy).

Finally, there is evidence that frontal lobe injury can result in a lack of sensitivity to behavioral reinforcers (24). This might lead someone to repeat poor decisions because the aversive consequences of that decision are limited in their ability to change the patient's behavior. This sort of deficit is more relevant to decisions involving actions (such as those involving sexual activity) than those that involve health care decisions. When assessing for the presence of this type of deficit, one can often rely on evidence of past behaviors.

In summary, there are a variety of affective or behavioral impairments that can directly affect decision making and yet not be detected by either direct assessment of decisional capacity or formal testing: lack of sensitivity to behavioral reinforcers, temporal myopia and changes in valuation and risk perception (whether caused by classical disorders of affect or hypoemotionality). Of these, only those deficits related to classical disorders of affect (such as depression, anxiety, and mania) are readily accessible to routine clinical examination (whether in the form of interview or formal questionnaires). One should supplement all evaluations of decision making with these assessments to probe for the presence of any significant affective symptomology. If present, more time will need to be spent determining the effects of these affective symptoms on valuation and risk perception. Unfortunately, it is more difficult to assess for the effects of hypoemotionality on valuation and risk perception, the presence of temporal myopia, or the lack of responsiveness to behavioral reinforcers. At the present time, other than finding clues from knowledge of past behaviors and the clinical interview, there is little guidance available on how to directly assess for these deficits.

Even after taking into account volitional, affective, and behavioral issues, there is another situation encountered after brain injury that challenges our traditional methods of assessing decision making. This situation arises when a moderate or severe brain injury seems to cause a fundamental change in the patient's identity.

Family members often comment on these types of changes by statements such as “She’s a different person”, “He’s not the man I married”, or “I’m living with a stranger”. This phenomenon has significant implications for the status of the decisions made by someone with a brain injury.

For instance, consider someone who seems to have full decision-making capacity as outlined above (i.e. no significant deficits in understanding, appreciation, reasoning, or expressing their choices) *and* no significant affective, volitional, or behavioral deficits. However, they now make decisions that they clearly would not have made prior to their injury. For example, what they value and consider important may have changed so that they now spend their money on activities that they would not have before their injury. These sorts of changes are undoubtedly part of the phenomenon that the family describes when they note that the patient is “a different person”. Moreover, families often see the patient’s new choices as *prima facie* evidence that the patient has lost decision-making capacity.

In these situations, the clinician is faced with a difficult situation: someone whose decision-making capacity appears to be intact but who is now choosing courses of action that she may not have chosen prior to the injury. Should the person’s decisions be honored? This is a controversial question which has been most extensively discussed in the context of dementia (25, 26). In someone with a brain injury, our belief is that, as long as the person currently has intact decision-making capacity, their decisions should always be honored. The patient who is being treated is the patient as they are *now*. We feel that it would be unfair to the patient as they are now to sacrifice their autonomy and interests for the sake of their former self.

Finally, although not unique to people with brain injuries, it is important to be aware of any psychodynamic issues that might be affecting a patient’s decision making. We have been struck by how often a person’s decision is determined not by the information at hand (e.g. the risks and benefits of the treatment and its alternatives, etc.) but rather by underlying psychological factors that may or may not be apparent to the patient. Unless explicitly addressed, the examiner will almost always miss the presence and significance of these factors. Yet, these psychological issues often represent the “missing piece of the puzzle” that makes sense of what might appear to be a perplexing decision. This is particularly true when there appears to be a “gap” between the patient’s apparently intact cognitive capacities and the seemingly “irrational” choice they make.

For instance, a young adult may refuse a relatively innocuous medication simply because her family also wants her to take it and she is trying to establish independence from them. Her decision is determined by the conflict with her family and *not* by the indications and

effects of the medication itself. However, the patient may articulate her refusal in terms of her fear of the side effects. Even when reassured about the side effects, she might still maintain her refusal, suggesting to the family and clinician that her decision-making capacity might be impaired. Or, a patient may be very anxious about her symptoms and demand that “everything be done” to evaluate the cause, despite reassurance by the clinician of the benign nature of her condition. Further exploration might reveal that the patient had a family member who became very ill or died after developing similar symptoms.

In both cases, a direct assessment of decisional capacity may fail to reveal any significant deficits. Rather than simply acquiesce, however, clinicians should spend time exploring psychodynamic issues when faced with these dissociations between intact decision-making capacity and seemingly irrational decisions. Recognition of these psychological factors provides an opportunity to address what is really motivating the decision and, hopefully, result in a situation where patients base their decision solely on information that is directly relevant to the treatment.

#### WHEN SOMEONE LACKS DECISION-MAKING CAPACITY: CHOOSING AN ALTERNATE DECISION-MAKER

When it is determined that a patient lacks decision-making capacity for a particular decision, we must rely on alternate methods of making that decision. (Figure 65-1) Most states specify an order which must be followed in identifying another mechanism of decision making. (Figure 65-6) Assuming that the patient does not currently have a guardian, it is important to establish whether or not the patient has retained the capacity to execute a durable power of attorney for health care (DPAHC, which may go by different names in other states). As discussed in further detail below, such a document allows patients to designate another person to make health care decisions for them. Although it might seem odd that a patient who is considered incapacitated from making medical decisions might still retain the capacity to appoint

- Current guardian
- Establish if patient has the capacity to execute a DPAHC
- Advance directive
- Surrogate decision maker (designated by state statute)
- Appoint guardian

**FIGURE 65-6**

Example of alternate healthcare decision-making (Texas) listed in order of priority

a surrogate decision maker, this is clearly in line with the emphasis placed earlier on the context specific nature of decision-making capacity.

What is required to execute a DPAHC is that a patient must *appreciate* why they need someone to make decisions for them, *understand* the nature, benefits, and risks of a DPAHC, its alternatives, and of the person they might designate, and *reason* with this information in a logical and coherent manner. There are patients who either understand or accept that they are unable to make medical decisions and who have strong feelings about who they want to be making decisions in their stead. As long as these patients understand the nature and implications of a DPAHC and alternatives and have logical and appropriate reasons for preferring a particular person, they should be allowed to designate a surrogate decision maker by executing a DPAHC. In fact, in our experience, courts have favored this approach since it represents the “least restrictive” limitation of a patient’s autonomy.

If a patient does not currently have the capacity to execute a DPAHC, one should ascertain whether they had executed one prior to their injury. This would represent one type of an advance directive, known as a proxy directive. The other type of advance directive is known as a decision directive (6, 26). In contrast to the proxy directive, a decision directive does not identify a surrogate decision maker. Rather, it specifies what decisions a patient would want made under particular circumstances. For instance, a person may specify in advance that they do not want to be placed on a ventilator if terminally ill. Thus, a decision directive attempts to anticipate possible scenarios and outlines patients’ wishes should they be unable to express them. The familiar “living will” is one example of a decision directive.

Although very useful in some situations, decision directives have limited applicability in the context of brain injury. The primary reason for this is that very few people have executed advance directives of this sort, especially in the age groups often affected. Even when they exist, decision directives rarely address the situations most often encountered in the rehabilitation setting; rather, they almost always focus on terminal illness. It is true that some states recognize decision directives that apply in cases of permanent unconsciousness or severe disability; however, even these will only apply to a subset of the patients encountered in most rehabilitation settings (26).

More useful in brain injury rehabilitation are proxy directives. Rather than attempt to anticipate the myriad decisions that need to be made, these types of advance directives allow a person to designate a proxy to serve as the decision-maker. As discussed earlier, the Durable Power of Attorney for Health Care (DPAHC) is the legally recognized method for designating a health care proxy. The advantage of such a proxy directive is that it allows the designated decision-maker to make all healthcare

decisions that the patient could have made, unless limited by the patient in the directive. Unfortunately, as with decision directives, proxy advance directives are rarely available in the context of brain injury rehabilitation.

The decision-maker designated by a proxy directive is one example of a surrogate decision-maker. A surrogate decision-maker is one who is morally and/or legally empowered to speak on behalf of another person. In the case of a proxy directive, the surrogate’s authority derives from the fact that the patient explicitly designated them as the proxy. However, there are other methods of choosing a surrogate decision-maker, should the patient not have specified someone in advance. These include a person recognized through state surrogate statutes or a court appointed guardian.

The vast majority of patients do not have either a guardian or an advance directive. To address this situation, many states have adopted statutes that specify, in order of priority, who should serve as the surrogate decision-maker for an incapacitated patient. While the order may vary slightly depending on the individual state statute, the hierarchy usually formalizes the conventionally recognized “next of kin” as the decision-maker. For example, a spouse would precede the adult child, who would precede the parent, who would precede siblings, etc. If no family exists, then even a close friend or clergyman may be recognized as the surrogate decision-maker in some states.

Being familiar with the statute in one’s state is critical. Many surrogate statutes have restrictions on the circumstances under which they are applicable as well as on the types of decisions that surrogates are allowed to make (particularly regarding withholding or withdrawing life-sustaining treatments). In addition, most statutes require a court hearing if another family member challenges the decisions of the surrogate decision-maker recognized by the statute.

If there is no state surrogate statute, most jurisdictions require the appointment of a guardian. A guardian may also be required in states with statutes when the legally recognized decision-maker is being challenged by other family members. Another case in which appeal to the courts may be required is if no one knows the patient or agrees to serve as a surrogate. Other situations that usually require a guardian are the need to make any non-medical decisions (for instance, about financial matters) or when it is obvious that the duration of the patient’s incapacity will be prolonged. Deciding whether to petition for guardianship after a brain injury can be difficult and complex; the reader is referred to several useful reviews of the subject (27, 28).

To summarize, once it is determined that a person lacks decisional capacity, the first step is to identify a surrogate decision-maker. (Fig. 65-1) If the patient lacks the capacity to designate their own surrogate by executing

a DPAHC, one should ascertain whether or not an advance directive exists. If one doesn't (or if it is inapplicable), then the person identified by the relevant state statute is recognized as the decision-maker. If there is no surrogate statute (or if other family members disagree with the decision-maker recognized by a statute), then a guardian will need to be appointed. A guardian will also need to be appointed for all non-healthcare related decisions, since both advance directives as well as state surrogate statutes almost always apply only to healthcare decision-making.

While identifying a surrogate decision-maker is a necessary first step, the clinician also has an ongoing responsibility to ensure that the decisions made by the surrogate are appropriate. This means, first, that the clinician recognizes the limits to the types of decisions the surrogate can make (as specified in the laws of their jurisdiction). In addition, however, the clinician should also focus on the actual decisions made in order to ensure their appropriateness. In other words, the fact that the surrogate is legally empowered to make decisions on behalf of the patient does *not* mean that the surrogate is free to make any decision at all. There are ethical and legal guidelines that constrain the choices that a surrogate can make, and the clinician should be aware of whether these are being followed.

In general, there are two different principles that should guide the decisions made by a surrogate. These are known as the "substituted judgment" standard and the "best interests" standard. In exercising substituted judgment, surrogates are asked to make a decision as they think the patient would have made it. They are asked to put aside their own thoughts and feelings and choose as they believe the patient would have chosen based on their presumed knowledge of the patient's values, beliefs, desires, etc. Although a widely accepted standard, there are certain difficulties encountered in exercising substituted judgment.

First, there is a growing body of evidence documenting the difficulty that surrogates have in accurately predicting patients' wishes in particular situations (29–35). Even when the surrogates felt confident that they knew what their family members would want, these studies revealed a poor correlation between the surrogate's decisions and the patient's actual preferences. Although disturbing, these findings do not necessarily undermine the substituted judgment standard itself.

They do highlight, however, another important issue: what is the evidence for a patient's prior wishes? For instance, was the substituted judgment based on explicit and repeated statements by the patient or a single casual remark? Or does the substituted judgment simply represent an inference based on the patient's past behaviors or presumed values? In general, the most reliable evidence of a patient's wishes are prior statements by

the patient that are explicit and well considered. These statements are especially valid if it is known that the patient had direct or indirect knowledge of the condition in question (through the care of a family member, for instance). In addition, because evidence shows that preferences change over time, more recent statements are especially likely to be representative (36). For all these reasons, it becomes important to ask a surrogate how they came to their decision regarding what the patient would have wanted.

Even when one is confident about the patient's *previous* wishes, however, another, more fundamental problem may arise. Specifically, a person may change their mind after a brain injury. For instance, impairments that may have seemed intolerable to them prior to their injury may now come to be accepted (26). This shift may simply represent the fact that we did not really know what living with certain conditions was like. We all find it difficult, beforehand, to accurately imagine a condition significantly different from our own. In particular, there is a large body of evidence that documents how the able-bodied, including clinicians, significantly underestimate the quality of life possible after a disability, (26, 37–40) even when they live with someone with a severe disability (41).

Another reason that a person's preferences may seem to change after a brain injury is that their fundamental values, beliefs, and desires might, in fact, have been altered by the injury. This change in identity that some patients undergo was discussed earlier. In this context, it raises a fundamental issue: is it even appropriate to appeal to past wishes in making decisions for patients? We alluded to the controversy that surrounds this issue previously; the reader is again referred to several detailed examinations of this issue (25, 26, 34, 35).

Given some of the difficulties in exercising substituted judgment, another criterion is often utilized in evaluating a surrogate's decisions: the "best interest" standard. According to this standard, the criterion for making decisions is to do what is in the best interest of the patient. The primary role for the best interest standard is when the patient's previous wishes are not known. This is often the case in brain injury rehabilitation because few people anticipate having a brain injury, much less discuss with family members in advance what they would want done. In these cases, the decision that is made should be the one that is in the best interests of the patient, regardless of how the surrogate may actually feel about a particular decision.

Although intuitively appealing, the best interest standard faces its own set of difficulties. Specifically, what a person's best interests are and what would advance those interests is often a source of disagreement. One potential danger is that a family member, while well intentioned, may unconsciously project her own beliefs or values into the situation. This can be especially problematic when

seen in the light of the difficulty, discussed above, that we all have in imagining unfamiliar situations. In particular, the tendency of the able-bodied to underestimate the quality of life of the disabled can significantly distort the decisions of surrogates.

Another issue is the proper role of the family or caregivers' interests in decision-making. The rationale for both the substituted judgment and best interest standards is that they place the *patient's* interests first. Certainly, clinicians should be sensitive to any evidence that the family is making decisions based primarily on potential gain to themselves (e.g. financially). Yet, because the family or caregivers are greatly affected by the consequences of any decision made, it seems unreasonable to expect that their interests should have no role in decision-making.

As in many other difficult cases, the exact role that the families' interests play will vary from case to case and, even then, may be a source of reasonable and legitimate disagreement (34, 35). For instance, the placement of a patient in a nursing facility solely so that the family can have use of the patient's home is clearly wrong. On the other hand, it seems understandable when the same decision is made because the family member is a single, working parent unable to provide 24 hour care. It is important to acknowledge that these issues are not merely personal but also ones that have public policy and social implications. The lack of readily available social support systems, financial remuneration for caregivers, and viable community-based living alternatives for persons with brain injuries adds layers of complexity to any surrogate decision-making process.

In conclusion, after identifying the appropriate surrogate decision-maker, the clinician still has an ongoing responsibility to evaluate the decisions made to ensure that they represent what the patient herself would have wanted or, at least, are in the patient's best interests. If the clinician feels that the decisions made by a surrogate are not appropriate, every effort should be made to address and resolve this issue in discussions with the surrogate and other involved parties. Ethics committee consultations and/or consultation with legal counsel may also be needed to mediate conflicts and ensure adequate protection for vulnerable patients. If an ethics committee mechanism is used, it is desirable to ensure that persons who are knowledgeable about life with brain injury be included in the process. If these measures don't resolve the concerns, then appeal to the legal system may be necessary.

### BEYOND CONSENT: ASSENT AND DISSENT IN BRAIN INJURY REHABILITATION

While accurate, the process depicted in Figure 65-1 omits a crucial moral dimension of our approach to patients whose decision-making capacity is at question: the content

and quality of the conversations and interactions that precede the final decision. This is especially clear if we approach the process from the point of view of patients who decline or "dissent" from our recommendations. While it is true that we must ultimately honor the wishes of those patients who possess decision-making capacity, we are also morally obliged to engage them in conversation intended to understand their perspective and persuade them to re-consider their choice. Likewise, for patients who lack decisional capacity, it is still morally important that we attempt to secure their agreement or "assent" to the decisions that are made. In both cases, our commitment to our patients' welfare obliges us to make a significant effort, short of manipulation or coercion, to persuade them of the treatment plan. Although consent is the central concept in approaching decision-making capacity after brain injury, clinicians also need to be aware of the moral significance of assent and dissent (42).

By "assent", we refer to securing the agreement of a patient who does not have the decisional capacity to provide full informed consent. The concept of assent was first developed in the field of pediatrics, where it was recognized that children, although unable to give full consent, should still play some role in the decision making that surrounds their care. In fact, it has been urged that clinicians always attempt to secure the assent of children for treatment decisions, even though the parents have both the ethical and legal authority to make the actual decisions (43).

We believe that the concept of assent is also relevant to brain injury rehabilitation and that we should always make an attempt to secure the assent of decisionally incapacitated patients. This reflects a basic respect for and acknowledgement of the patient, despite the impairments in their decision-making. At a more practical level, a patient's assent is likely to increase patient compliance, especially with those treatments that require their active participation. Of course, there are situations in which assent is not relevant, such as in the minimally conscious patient. And there will be situations in which, in spite of the best efforts of the treatment team, patients may still refuse to give their assent to the treatment plan.

In these situations, it is generally acceptable to proceed with treatment, at least in the inpatient setting, especially if not proceeding leads to significant harm to the patient. Clearly, this only applies to those decisions where the patient is a passive recipient of treatment (for instance, receiving medications). If the treatment involves the active participation of the patient (such as engaging in physical therapy), forcing treatment is usually impossible and often morally repugnant. Addressing these issues in the outpatient setting is more complex and other legal considerations might apply (for instance, by virtue of the fact that the patient is no longer in a health care facility) and legal consultation may need to be obtained.

## SURROGATE DECISION-MAKING: THE SPECIAL CASE OF WITHDRAWAL OR WITHHOLDING LIFE-SUSTAINING TREATMENT FOR PERSONS WITH BRAIN INJURY

Surrogate decision making in the context of withdrawal of care raises issues that are not found for other health care decisions. Prior to the 1970's, disputes regarding the use of life-sustaining technologies were rare; indeed, in many cases these technologies were non-existent. With the growth and increased availability of technologies such as ventilators and gastrostomy tubes, questions about how and when to apply these technologies became commonplace (and, in fact, account for the impetus behind the growth in bioethics as a discipline). Patients with brain injuries were often front and center in such discussions. No case probably symbolizes the beginning of this era more than that of Karen Ann Quinlan.

Philosophers, theologians, ethicists, and health care professionals have disagreed over the years about whether there is a moral difference between withholding life-sustaining treatment (i.e. not initiating the life saving treatment) and withdrawing life-sustaining treatment, or taking away the treatment that is believed to be sustaining life (44). In general, there has been more recent consensus in the United States that they are morally equivalent acts (45, 46). In fact some would argue that to withhold the initiation of life-sustaining treatment because of a fear that a withdrawal decision may arise is dangerous, unwise, and not in the best interest of the patient. Sometimes (and brain injury is often one of these cases) only through the initiation of life-sustaining treatment can better prognostic information be clarified thus allowing a more considered decision about the on-going role of life-sustaining treatment if needed.

In the next section, we will briefly review some of the salient and often very public legal cases regarding persons with brain injuries in which questions of withdrawal of life-sustaining treatment arose. These cases have been chosen as we believe they help to illustrate some of the common law guidelines, cultural mores, and evolving moral discussions in this always complex, and often contentious, area of decision-making.

### Karen Ann Quinlan

In 1975, Karen Ann Quinlan, at the age of 21, sustained cardiac arrest and anoxic brain injury, resulting in permanent vegetative state (PVS). (We will use this phraseology to delineate a condition in which the patient lacks awareness of their environment and recovery is highly unlikely). In 1976, her father sought legal guardianship with specific authority to direct the withdrawal of her mechanical ventilation (47). The Supreme Court of

New Jersey granted him guardianship as requested and indicated that he could exercise on her behalf her right to privacy (i.e., to be free of unwanted medical treatment). In essence, if Mr. Quinlan and her family believed that Ms. Quinlan would not want to have her life supported by a ventilator, they could choose to have the ventilator withdrawn. The Court further stated that this decision was clearly based upon her *poor medical prognosis*—i.e. her state of PVS, believing that the “overwhelming majority of [society] would, we think, in similar circumstances, exercise such a choice in the same way for themselves or for those closest to them.”(47)

### Nancy Beth Cruzan

In 1983, Nancy Beth Cruzan was in a motor vehicle crash. She was also judged to be in a permanent vegetative state, and was fed via a gastrostomy tube. In 1986, her parents, acting as her guardians, initiated proceedings “to terminate her artificial nutrition and hydration.” Their request was based upon her poor medical prognosis for improvement as well as statements that she had made to a friend that “if sick or injured she would not wish to continue her life unless she could live at least halfway normally.” In essence, this case weighed 2 aspects of the due process clause of the 14th amendment to the Constitution: States are prohibited from “depriving any person of life, liberty, or property without due process of law.”(48) In other words, the first aspect was her *liberty right* to be free of unwanted medical treatment and the second was her *right to life*. The argument of the appellants (Nancy Cruzan's parents) was rejected by the Supreme Court of Missouri as not meeting the State's standard of “clear and convincing evidence”<sup>1</sup> of the incompetent person's wishes.

This case was reviewed by the U.S. Supreme Court in 1990 (49). The U.S. Supreme Court upheld a state's right to decide the standard of proof required before life-sustaining treatment can be withdrawn (most though not all have chosen the clear and convincing standard of proof). The Court also specifically commented on the role of surrogate decision-makers in the process, noting the difficulty that surrogates might have in executing decisions:

Close family members may have a strong feeling—a feeling not at all ignoble or unworthy, but not entirely disinterested, either—that they do not wish to witness the continuation of the life of a loved one which they regard as hopeless, meaningless, and even degrading. But

<sup>1</sup> Clear and convincing standard of proof has been defined as “proof sufficient to persuade the trier of fact that the patient held a firm and settled commitment to the termination of life supports under the circumstances like those presented” *In re Westchester County Medical Center on behalf of O'Connor*, 72 N.Y. 2d 517, 531, N.E. 2d 606, 613 (1988).

there is no automatic assurance that the view of close family members will necessarily be the same as the patient's would have been had she been confronted with the prospect of her situation while competent. Furthermore, "the State may also properly decline to make judgments about the "quality" of a particular individual's life and simply assert an unqualified interest in the preservation of human life to be weighed against the constitutionally protected interests of the individual" (49).

### Michael Martin

In 1987, Michael Martin sustained a head injury, leaving him with extensive cognitive and physical impairments. (50) He had a colostomy and a gastrostomy for nutrition and hydration. He was unable to take food orally. Mr. Martin lived in a nursing home, and communicated with head nods and gestures. In 1992, while being treated for a bowel obstruction, Mary Martin, his wife and guardian, contacted the hospital's bioethics committee to determine whether Mr. Martin's nutrition and hydration could be withdrawn. Based upon prior conversations, Mr. Martin was reported to say to his wife that he would rather die than be dependent on people or machines. In casual conversations on 2 occasions with co-workers he said he would not want to live if he were in a "vegetative state." The hospital ethic's committee issued a statement that withdrawal of treatment was both medically and ethically appropriate, but that it must be authorized by the court before the hospital would assist in withdrawal of treatment.

In contrast to Karen Ann Quinlan and Nancy Beth Cruzan, Michael Martin was *not* in a permanent vegetative state. Though he could understand short, simple questions, the medical experts all agreed that he lacked decisional capacity. Furthermore, Mr. Martin's sister contested Mary Martin's request and asked that she be removed as his guardian and conservator. Though Mary Martin was upheld as the guardian and conservator, the Michigan Supreme Court reversed the Court of Appeals decision in favor of withdrawal of medical treatment, concluding that there was not clear and convincing evidence that withdrawal of food and fluid is what Mr. Martin would want in his *current* condition: "To end the life a patient who still derives meaning and enjoyment from life or to condemn persons to lives from which they cry out for release is nothing short of barbaric. If we are to err, however, we must err in preserving life." (from 50 at 401–2).

Michael Martin's case is particularly interesting because he was neither terminally ill nor in a permanent vegetative state, which have been referred to as "condition-based thresholds" that some argue must be present before a non-treatment decision can be made. Though he had made some compelling statements about not wanting to live on machines or if in a vegetative state, he seemed content and did not indicate after his brain injury a desire to die. The Michigan Supreme Court ruled that to be clear

and convincing, the statements previously made needed to be a "serious, well thought out, consistent decision to refuse treatment under these exact circumstances, or circumstances highly similar to the current" (50).

### Robert Wendland

Robert Wendland, like Michael Martin had an extensive brain injury (in 1993 from a drunk driving accident) but was clearly not in a vegetative state. He was conscious but unable to talk. He was fed and given water through a gastrostomy tube and needed assistance with his activities of daily living. He lived in a nursing home in California. In 1995 his wife and conservator, Rose Wendland, petitioned the court for permission to withdraw his nutrition and hydration based upon statements that Mr. Wendland had made while competent that led her to believe he would not want to be sustained in his current state.

Like the prior cases, there was no written advance directive. The request was challenged by Mr. Wendland's mother and sister who brought suit to remove Rose Wendland as his conservator (51). Two critical issues emerged in this case: the threshold issue (and notably, for the first time, the language of "minimally conscious state" was being applied in court to describe the neurological state of the patient), and 2. the clear and convincing evidence standard was again challenged. Mr. Wendland died before the case could be decided by the California Supreme Court, but given the importance of the case they chose to issue a ruling clarifying and confirming that a "clear and convincing" evidence standard was necessary.

The case sparked a great deal of interest and a large number of amicus curiae briefs on both sides. Substantial support in favor of allowing Rose Wendland to withdraw Mr. Wendland's nutrition and hydration and thus lower the standard of evidence from clear and convincing to a preponderance of the evidence included the California Medical Association, the American Civil Liberties Union, and 41 bioethicists (52). Those opposed included a number of disability activists organizations including Not Dead Yet, ADAPT, the ARC, Brain Injury Association, Inc., the Disability Rights Center, The National Council on Independent Living, and the National Spinal Injury Association.<sup>2</sup>

<sup>2</sup> Not Dead Yet is a national grassroots organization of people with disabilities formed in 1996 to advocate against legalization of physician assisted suicide and euthanasia. ADAPT is composed of people with disabilities whose purpose is to advocate for the civil rights of people with disabilities to live in their homes and communities. The ARC is devoted to the welfare of persons with mental retardation and their families, and was instrumental in framing the ADA. The Disability Rights Center was established in 1978 to enable people with disabilities to live in society and secure their human and civil rights. The National Council on Independent Living is the oldest cross-disability grassroots organization run by and for people with disabilities.

### Terri Schiavo

In 1990, at the age of 26, Terri Schiavo sustained a cardiac arrest resulting in anoxic brain injury. In May of 1998, Michael Schiavo, Terri's husband and guardian, filed a petition in Florida to remove her gastrostomy tube. In support of the petition, Ms. Schiavo's husband presented testimony about statements Ms. Schiavo made before her arrest that he believed indicated she would not want to live in her current state (like the other cases reviewed, she did not have a written advance directive). Ms. Schiavo's parents, the Schindlers, who opposed the petition, objected to this testimony and also sought to have Mr. Schiavo removed as her guardian. In contrast to Nancy Beth Cruzan, Ms. Schiavo's neurological diagnosis of permanent vegetative state has been the subject of dispute, with medical experts on both sides disagreeing about her diagnosis and prognosis for improvement with further rehabilitation efforts (53). Specifically, the court placed the burden on the Schindlers to "establish that new treatment offers sufficient promise of increased cognitive function in Mrs. Schiavo's cerebral cortex—significantly improving the quality of Mrs. Schiavo's life—so that she herself would elect to undergo this treatment and would reverse the prior decision to withdraw life-prolonging procedures." The Second District Court of Appeals of Florida determined that there was not sufficient evidence presented to question her diagnosis of vegetative state or her poor prognosis for improvement (54). The appellate court also addressed the issue of family involvement in such decisions:

But in the end, this case is not about the aspirations that loving parents have for their children. It is about Teresa Schiavo's right to make her own decision, independent of her parents and independent of her husband. In circumstances such as these, when families cannot agree, the law has opened the doors of the circuit courts to permit trial judges to serve as surrogates or proxies to make decisions about life-prolonging procedures. It is the trial judge's duty not to make the decision that the judge would make for himself or herself or for a loved one. Instead, the trial judge must make a decision that the clear and convincing evidence show the ward would have made for herself (54).

After multiple appeals, legislative maneuvering, and much public dissension, Ms. Schiavo's nutrition and hydration was withdrawn and she died 13 days later on March 31, 2005 in a Florida hospice.

### SUMMARY

There are no simple guidelines for decision-making regarding the withdrawal and/or withholding of life sustaining treatment for persons with brain injury. The only

case of the five presented above that was reviewed by the U.S. Supreme Court, and thus has clear federal jurisdiction, is that of Nancy Beth Cruzan. The other cases were tried in the various states of New Jersey, Michigan, California and Florida, and are thus subject to the laws of each state. As each State is likely to have specific laws governing such decisions, it is imperative to be well-versed in state law and to consider consultation with legal counsel and ethics committees in the decision-making process. Many people will also find guidance from spiritual advisers or religious leaders to be very helpful and these resources should always be offered. Nonetheless, there are some generalizations and guidelines that we feel might be helpful in negotiating this difficult terrain:

1. It is important to know whether the person with a brain injury ever executed an advance directive. Are there written statements regarding the person's wishes for care and medical treatment? Did the person stipulate who they trusted to make decisions on his/her behalf if incompetent? Such directives have great moral and legal authority in this country, and in most instances are considered sufficient to satisfy evidence of "clear and convincing evidence" of a person's wishes. That is not to say, though, that an advance directive should be considered absolute and binding (26, 55). Specifically, while competency is required to make an advance directive, it is not necessarily a requirement for negating one. Thus, if a person with brain injury is able to reliably indicate that they no longer wish for their advance directive to be followed, then (in general) it should not be followed. (There are rare exceptions. For example, the Declaration for Mental Health Treatment in Illinois allows a person to sign an advance directive indicating they wish treatment including hospitalization, medication, electroconvulsive therapy, etc. if they have a mental condition requiring such treatment in the future, *even if they would refuse it at the time*) (56).
2. One of the critical questions in considering the withdrawal of life sustaining treatments involving persons with brain injury is: when is life with disability worse than death? These decisions inherently involve quality of life determinations by third parties, often invoking considerations of concepts of pain and suffering, the meaning of human life and personhood, concepts of "dignity," and economic considerations. While there is growing consensus among the legal, medical and bioethics communities that withdrawing life sustaining treatment is permissible when a person has permanent vegetative state in the US, there are still substantial minority voices that oppose this practice. There is also not a clear social consensus regarding whether withdrawal or withholding of treatment is

permissible in the absence of an advance directive when a person is not permanently unconscious; i.e., is minimally conscious or otherwise has severe brain injury.

3. It is imperative to establish a careful neurological diagnosis and provide the most accurate prognostic information possible. It is unlikely that a single, brief bedside neurological examination can establish with a high degree of certainty a diagnosis such as permanent vegetative state (PVS), and indeed, there is substantial evidence to show that an erroneous diagnosis of PVS is not an infrequent occurrence. (57, 58)
4. Given the complexities of brain injury, it is extremely important that health care providers with extensive experience with this condition (and in particular the rehabilitation phase) be involved in evaluating patients and providing information to families. For example, speech language therapists can help ferret out problems with communication that are due to sensory or motor impairments and not due to unconsciousness. Information about how people with brain injury (in general) adjust and experience their lives is also critical information, yet often missing from discussions of prognosis. While the experiences of a group cannot allow us to predict the experience of a single individual, it does provide a more complete, balanced and holistic view than a list of likely impairments.
5. Try to present information to families and surrogates in as balanced (i.e., neutral) a fashion as possible and avoid value-laden terminology. For example, the Glasgow Outcome Scale categories are highly value-laden, and thus potentially problematic. Only level five is considered a "good recovery," with moderate disability, severe disability, PVS, and death constituting the other four categories. These categories also are very broad and focus on the level of disability and not the level of handicap or life satisfaction, both of which are critically important to one's adjustment to brain injury (40).
6. Do not assume that all families feel equipped to provide care for their family member with a brain injury. In the U.S., it is not uncommon that families are expected to assume the responsibility for being caregivers—often at great personal expense, being asked to sacrifice jobs, other family responsibilities, and financial resources to meet the person's needs. It may be important to provide permission to the family member *not* to assume this role and to explore with families alternatives to support the person with brain injury in getting his/her needs met.

## Life Care Planning After TBI: Clinical and Forensic Issues

*Roger O. Weed  
Debra E. Berens*

### INTRODUCTION

This chapter presents an overview of the tenets, methodologies, topics, and issues to be considered when evaluating the future medical, or life care, needs of the patient with acquired brain injury (ABI). Commonly known as a life care plan, the plan can be relatively short, with very little “medical” needs, or very complex and detailed, with multiple medical and rehabilitation needs outlined. For example, a patient may or may not have experienced a loss of consciousness, yet still exhibit clinical signs and symptoms suggesting long-term follow-up that affect vocational and social functioning but require little or no physician or medical needs (1,2). Although information relating to a wide range of brain injury conditions is included in this chapter, most details will be geared toward the patient who has multiple future care needs that justify an assessment for life care plan development.

A generally accepted and working definition for life care plan is:

*A life care plan* is a dynamic document based upon published standards of practice, comprehensive assessment, data analysis and research, which provides an organized concise plan for current and future needs with associated costs, for individuals who have experienced catastrophic injury or have chronic health care needs.

*Source:* Combined definition of the University of Florida and Intelicus annual life care planning conference and the American Academy of Nurse Life Care Planners (now known as the International Academy of Life Care Planners) presented at the Forensic Section meeting, National Association of Rehabilitation Professionals in the Private Sector (NARPPS) annual conference, Colorado Springs, CO, and agreed upon April 3, 1998 (3).

As a “dynamic document,” medication changes and other updates can be expected over time. As will be seen below, however, life care plans, when completed according to established procedures, are a reliable document.

### HISTORY

Life care planning first appeared in the legal publication, *Damages in Tort Action* (4), which established the guidelines for determining damages in civil litigation cases. By 1985, the life care plan was introduced to the health care industry in *A Guide to Rehabilitation* (5). One of the first rehabilitation professional training programs was organized by Dr. Paul Deutsch and offered on September 16–17, 1986, in Hilton Head, SC, where more than 100 rehabilitation professionals from throughout the United States, including one of this chapter’s authors, assembled

to begin the process of setting standards for development of life care plans.

In the fall of 1992, five rehabilitation professionals—Richard Bonfiglio, MD; Paul Deutsch, Ph.D.; Julie Kitchen, CDMS; Susan Riddick, RN; and Roger Weed, Ph.D.—met to discuss issues associated with the life care planning industry. Concerned that fragmentation and poor standardization would result in an overall decline of the industry, the group developed a concentrated training program representing the various aspects of life care planning (3).

After designing the program, a management company (Rehabilitation Training Institute) was contracted to set up training programs throughout the United States. Before the announcements were fully distributed, the first of the organized tracks was filled. It appeared obvious that there was a number of rehabilitation professionals interested in pursuing advanced education related to life care planning, and several participants requested official recognition for their educational efforts. Dr. Horace Sawyer of the University of Florida agreed to pursue an official certificate of completion through the University of Florida's Continuing Education Department. As a result, a private/public partnership between the Rehabilitation Training Institute and the University of Florida was formed and named Intelicus. The five founders donated the program content to Intelicus. Some even continue today as faculty, although they no longer have control over program content or management. Over the years, these courses have been adjusted to focus on the roles and responsibilities that more specifically identify with life care planners based on research and participant comments. Most recently, the Intelicus life care planning training program was purchased by MediPro Seminars, LLC, to continue to offer life care planning advanced training, as well as the annual international life care planning conference. (See [www.mediproseminars.com](http://www.mediproseminars.com).)

Although the certificate from the University of Florida added value to obtaining education specific to this specialty practice, it did not provide the assurance of ethical practice or the professional identity desired by people who had invested thousands of dollars and many hours of their time in the training process. Ultimately, the Commission on Disability Examiner Certification (now known as the Commission on Health Care Certification, or CHCC) based in Midlothian, Virginia, and directed by V. Robert May, Rh.D., assumed the responsibility in leading the way to certification. Because of his efforts, the first national certification in life care planning (i.e., Certified Life Care Planner) was offered in 1996. Currently, several organizations have approval of the certification Board to provide training leading to certification and/or continuing education training for certification maintenance. Also, in the 1990s, the International Academy of

Life Care Planners was formed (previously known as the American Academy of Nurse Life Care Planners), and in 2002, the *Journal of Life Care Planning* and the Foundation for Life Care Planning Research were launched. Life Care Planning Summits also have been held bi-annually since 2000 to discuss and reach consensus on many topics of importance to ethical life care planning practice.

Over the years, life care plans have been expanding into a variety of fields including but not limited to managed care, workers' compensation, civil litigation, mediation, reserve setting for insurance companies, estate trust fund planning, gerontology care, and federal vaccine injury fund cases, all of which include individuals with brain injury in the patient population (6–11).

The range of future care needs can differ significantly depending on a mild, moderate, or severe brain injury. Individuals with mild brain injury, for instance, may not require a comprehensive life care plan and may be less likely to need all of the care commonly considered for a life care plan. Nevertheless, there may be value in utilizing the standardized approach in these cases to assure a comprehensive evaluation is done. For details with regard to definitions and functional deficits for individuals with mild acquired brain injury, the reader is referred to Goldberg's chapter on Post-Concussive Disorders found elsewhere in this book.

Patients with mild or moderate brain injury can have few, if any, physical problems. Therefore, the physician or medical team may not be an integral part of the future care planning. Instead, the case manager, neuropsychologist, vocational expert and, perhaps, the family or other support system, will be the most relevant participants in the life care planning process. However, it is not uncommon for an individual with mild to moderate head injury to also have musculoskeletal problems including fractures, facial damage (which may or may not be repairable), seizures, and other physiological deficits (12). On the other hand, patients with more severe brain injury often have multiple and obvious physical impairments as well as more severe cognitive deficits and require multiple physicians, life-long medical care, and multiple supply, medication and equipment needs. Obviously, an effective life care plan will include items for all treatable deficits that are related to or a result of the ABI.

In order to assure that the rehabilitation consultant addresses all appropriate issues for earning capacity analysis, it is helpful to utilize a standard methodology such as RAPEL (2, 3, 8, 9, 13). RAPEL is a mnemonic to help ensure the relevant "damages" of a case are evaluated. Adapted for pediatric cases, PEEDS-RAPEL<sup>®</sup> expands the RAPEL method and analyzes relevant data specific to the child with a disability, i.e., P (parental/family occupations), E (educational attainment), E (evaluation results), D (developmental stage), and S (synthesis). For further discussion

on PEEDS-RAPEL<sup>®</sup> for pediatric case evaluation, the reader is referred to Neulicht & Berens (14).

Although all sections of RAPEL will be discussed in this chapter, only one part, the Rehabilitation plan, is directly related to the life care plan.

### RAPEL APPROACH

When developing a reasonable opinion for forensic cases, it is expected that the rehabilitation consultant follow a standardized assessment approach to provide the appropriate information for the patient, patient's family, attorney, and economist. Certain specific requirements are necessary in order to satisfy all of these issue and although methods for determining the cost for future care as well as vocational and hedonic damages have been published

(6, 15, 16), it appeared that a comprehensive "common sense" approach encompassing both needs was lacking. The RAPEL method, representing five primary issues relating to future care needs and earnings capacity analysis (see Table 66-1), was designed to address rehabilitation needs and provide a "road map" of care, as well as generate a "bottom line" figure based on future care needs and earnings capacity analysis for persons with a catastrophic injury, including ABI.

The first of the RAPEL topics is as follows:

**R = Rehabilitation Plan.** The patient's vocational and functional limitations, strengths, emotional functioning, and cognitive capabilities are assessed utilizing information gathered from treating professionals or other experts listed in this chapter. This may include additional future testing, counseling, training fees, rehabilitation technology, job analysis, job coaching, placement, and

**TABLE 66-1**

*The RAPEL Method: A Common Sense Approach To Future Care and Earnings Capacity Analysis*

<b>Rehabilitation plan</b>	Determine the rehabilitation plan based on the patient's vocational and functional limitations, vocational strengths, emotional functioning, and cognitive capabilities. This may include testing, counseling, training fees, rehab technology, job analysis, job coaching, placement, and other needs for increasing employment potential. Also consider reasonable accommodation. A life care plan is appropriate for catastrophic injuries.
<b>Access to the labor market</b>	Determine the patient's access to the labor market. Methods include skilltrait ( <a href="http://www.skilltrait.com">www.skilltrait.com</a> ) or various other computer programs, transferability of skills (or worker trait) analysis, disability statistics, and experience. This may also represent the patient's loss of choice and is particularly relevant if earnings potential is based on very few positions.
<b>Placeability</b>	This represents the likelihood that the patient could be successfully placed in a job. This is where the "rubber meets the road". Consider the employment statistics for people with disabilities, employment data for the specific medical condition (if available), economic situation of the community (may include a labor market survey), availability (not just existence) of jobs in chosen occupations. Note that the patient's attitude, personality, and other factors will influence the ultimate outcome.
<b>Earnings capacity</b>	Based on the above, what is the pre-incident capacity to earn compared to the post-incident capacity to earn. Methods include analysis of the specific job titles or class of jobs that a person could have engaged in pre- vs. post-incident, the ability to be educated (sometimes useful for people with acquired brain injury), family history for pediatric injuries, and computer analysis based on the individual's worker traits. Special consideration applies to children, women with limited or no work history, people who choose to work below their capacity (e.g., highly educated who are farmers), and military trained.
<b>Labor force participation</b>	This represents the patient's work life expectancy. Determine the amount of time that is lost, if any, from the labor force as a result of the disability. Issues include longer time to find employment, part-time vs. full-time employment, medical treatment or follow up, earlier retirement, etc. Display data using specific dates or percentages. For example, an average of four hours a day may represent a 50% loss.

Reprinted with permission from Ref. 17.

other needs for improving the patient's potential for employment. Future medical care is also addressed here and typically is displayed in a life care plan for individuals with a catastrophic injury.

One commonly observed problem for forensic cases is the lack of specific data to conscientiously determine a complete lifetime cost. Many professionals who write reports expect that a re-evaluation will take place in one to two years, at which time additional recommendations will be made. However, in personal injury litigation, it is important to determine, as much as possible at the time of plan development, all of the issues that are expected to be addressed throughout the patient's lifetime. Generally, it is recommended that the rehabilitation consultant meet or communicate with the patient's treatment team (if able) or other appropriate experts associated with the case to discuss the case in detail, rather than rely upon written reports or other records. Extensive rehabilitation plans may best be addressed through a detailed assessment of lifetime needs; i.e., the life care plan. The life care plan is a published format designed to outline appropriate future care details (3, 4, 6, 9, 10).

### ELEMENTS OF THE LIFE CARE PLAN

First, it is important to understand that a variety of formats have been developed to display patient needs. In the original texts and books, the topics listed below were suggested and are still used today. The important aspect is to assure that all topics below are considered, as appropriate, in effective life care planning.

1. *Projected Evaluations.* Intended to describe non-physician evaluations that will occur on a periodic basis. These may include evaluations in physical therapy, speech therapy, recreational therapy, occupational therapy, music therapy, dietary assessment, audiology, vision screening, swallow studies, and others. The information displays specific recommendations, frequency over lifetime, and expected costs.
2. *Projected Therapeutic Modalities.* After projected evaluations have been completed, recommendations for ongoing treatment will be offered. With patients who have a catastrophic brain injury, it is common to include physical therapy, speech therapy, occupational therapy, family education, counseling, etc. This page identifies which non-physician treatment is recommended, over a specific period of time, at what frequency, and what cost.
3. *Diagnostic Testing/Educational Assessment.* Generally speaking, people with a catastrophic brain injury will undergo a variety of diagnostic testing, including neuropsychological, psychological, vocational evaluation, and, in the case of children, psycho-educational testing. Often evaluations will occur at specific points in a patient's life which would be identified by listing the years at which the evaluation would take place. For example, a child might be tested psychologically at ages that coincide with certain developmental stages or specific educational milestones. Such milestones may be the beginning of school, onset of puberty, beginning of high school, and entering employment or transitioning to adulthood. Consideration also should be given to additional evaluations that may be indicated as the patient ages, such as between age 50–60.
4. *Wheelchair Needs.* This page includes the type and configuration of wheelchairs the patient requires. For example, people who are tetraplegic often require a power wheelchair that reclines or tilts in space. The individual accesses and controls the wheelchair in a variety of ways, including joystick, sip and puff, head tilting, voice control, and others. The specifications will allow the life care planner to research costs from a variety of vendors (18). Some patients with hemiparesis may prefer a scooter for mobility assistance and some with less severe brain injuries may be ambulatory for short distances but need a light-weight manual wheelchair for longer distances.
5. *Wheelchair Accessories and Maintenance.* Each wheelchair requires certain accessories such as cushions for skin care, lap tables, carry bags, and other potential custom features. In addition, the wheelchair, depending on amount of use, requires maintenance. Maintenance can be very expensive for power wheelchairs, like the iBOT™, or inexpensive for wheelchairs which are used only for back-up purposes and are lightly used.
6. *Aids for Independent Function.* Many individuals with a brain injury have restricted ability to use their bodies and can make use of certain items for independence. A common example is the environmental control unit (ECU) or system that allows the patient to turn lights on and off, open and close doors, start and stop computers, turn on/off televisions, radios, fans, etc. Some less expensive adaptive aides may include reachers which will allow an individual to grasp items on a shelf or on the floor without having to stand up or bend over.
7. *Orthotics and Prosthetics.* With regard to significant brain injury, many patients will require braces or ankle/foot orthosis (AFO) to help with contractures, decrease spasticity, etc. Sometimes these braces, when custom designed, are costly and, over an individual's lifetime, can add up to a significant amount of money. Prosthetics generally are needed for individuals with one or more amputations. Prostheses

also require accessories (e.g., socks, liners, cosmetic covers, etc.) and will need replacement and ongoing maintenance over the patient's lifetime. The cost for all of these items, as well as applicable maintenance and replacement schedules, will be included on this page.

8. *Home Furnishing and Accessories.* Often a patient living at home will have need for a specialty bed and skin care mattress or powered lift and recline, portable ramps for accessibility, patient lift systems, etc. This section will require a specific inventory of the patient's needs at home or in their place of residence.
9. *Drug and Supply Needs.* This page includes prescription and non-prescription medication and supplies as related to or a result of the brain injury. As an example, a patient who is in a persistent vegetative state will likely need catheters or adult diapers, skin care products, and medications for various injury related problems or complications.
10. *Home Care/Facility Care.* Philosophically, it is more desirable to have a patient live in the least restrictive setting possible. This alternative also is a way to reduce complications from diseases from other patients that are common in a facility setting, as well as to improve the emotional status of the patient. However, this may not be the most cost effective alternative nor, in some cases, the most medically appropriate. Facility care, generally, is not as responsive to an individual as a custom-designed home care program; however, some individuals have no capability of living at home, or their needs exceed those which are available in a home environment. In this situation, facilities for individuals with serious behavioral disorder or those in persistent vegetative state as a result of acquired brain injury may be the most appropriate. There also may be need for specialty programs such as yearly summer camps, especially for children and adolescents. The level of in-home care also should be identified. For example, some individuals need only occasional home care or a time specific amount each day (i.e., 4 hours per day) while other patients need 24-hour, high-tech, nursing care.
11. *Future Medical Care: Routine.* Probably the most common routine medical care for individuals with acquired brain injury is provided by a physiatrist. The frequency of visits will depend on the medications, complications and severity of the injury. A person on antiseizure medication may be seen several times per year to evaluate the blood level and efficacy of the drug. Routine medical care also may include annual evaluations by the various specialty(ies) that may be appropriate for the severity of the brain injury. For instance, in dual diagnosis cases where the individual has both a brain injury and a spinal cord injury, the patient may need a routine annual evaluation by psychiatry, urology, dermatology, orthopedics, neurology, and others, as well as X-rays and lab work or diagnostic tests (e.g., urodynamics). This page summarizes those needs.
12. *Transportation.* Transportation needs vary substantially from patient to patient. Some individuals need little or no modification to their vehicles and may only require mileage reimbursement for injury-related appointments. Others may have a need for adding hand controls to their present vehicle. Yet other individuals may need a custom-designed van with lift and wheelchair tie-downs and rely on a driver for all driving activities or be able to drive with highly sophisticated technology such as the Digi Drive system (19).
13. *Health and Strength Maintenance.* This page, titled Recreation and Leisure Time Activities in the original literature, is designed to identify specialty recreation needs, adaptive games, and devices that will allow patients to be as active as possible and engage in health improving therapeutic action. Activity is very important to the physical and emotional well-being of a patient and such activities are often adjunctive to, and less expensive than, hiring a physical or occupational therapist. Specialty sports-related wheelchairs (such as basketball, tennis, and other custom-designed chairs) should not go on this page, but instead should be placed on the Wheelchair page. For more information on Health and Strength Maintenance, see *Support for Recreation and Leisure Time Activities in Life Care Plans* (20).
14. *Architectural Renovations.* If the patient is to be cared for at home, significant and comprehensive architectural renovations often will be required depending on the extent of the injury and the patient's functional limitations. For example, a patient who uses a wheelchair for mobility will need ramps (preferably at two entries into the home), hallways may need to be widened, the kitchen may require modification, fire or smoke detection will be needed, specialized floor coverings may be installed, bathrooms may be enlarged, equipment and attendant rooms may be added, and an emergency exit out of or near the bedroom may be added. Hablutzel and McMahon (21) published architectural renovation standards based on the Americans with Disability Act for those who wish to read more about this area.
15. *Potential Complications.* Costs of Potential Complications are not included in the total cost of the life care plan, presumably because effective life care planning will reduce potential complications as it provides the structure for quality care. On the other hand, it is important for people to understand what common

complications are involved with a particular disability (i.e., acquired brain injury). In the case of people with significant ABI, they are at higher risk to re-injure themselves due to poor balance or judgment and lack of safety awareness. Also, individuals with severe brain injury or who are in a persistent vegetative state often have skin breakdown, cardiovascular difficulty, pulmonary diseases, etc. Individuals on long-term Dilantin anti-seizure medication often have gum disease or other dental problems. Poor psychological adjustment to the person's disability often is the direct result of poor environment, poor care, or inability to engage in meaningful activities (22).

16. *Future Medical Care/Surgical Intervention or Aggressive Treatment.* In some situations the patient will have known needs for aggressive care. Commonly known problems for people with a brain injury include plastic surgery, dental restoration, time-limited rehabilitation programs, and short-term inpatient brain injury "tune-ups" (episodic one to four week rehabilitation programs). To be placed on this page, it is expected that these services are more probable than not to occur and occasional or time-limited treatment.
17. *Orthopedic Equipment Needs.* Some patients will need specific orthopedic equipment, such as body support equipment, walkers, or standing table. This is frequently termed "durable medical equipment."
18. *Vocational/Educational Plan.* This page was not included in the original life care planning literature and was later added to specifically address future vocational and educational or training needs. The professional involved in developing the life care plan may not be responsible for addressing this portion of the patient's future care if he/she is not qualified to assess these issues. Additionally, other qualified professionals may choose to complete a narrative report and a specific rehabilitation plan that focuses on vocational issues in a separate document. It is the authors' opinion that this page should be included in the life care plan in the same way that allied health recommendations are included, since overlap or "falling between the cracks" can otherwise result. This page obviously should include recommendations for vocationally-related items such as job coaching, supported employment, vocational counseling, tuition/fees, books and supplies for training programs, rehabilitation technology, and/or specialized educational programs, as well as the cost of each item.

### The Life Care Planning Team

In many ways, developing a comprehensive life care plan is much like completing a puzzle and making sure all the

pieces fit together to complete the picture (11). The following individuals and professionals commonly have a role to play in the life care planning process and may or may not be involved in any given case. (Note: in forensic cases when developing a defense plan, the treating team, patient and others may not be available to the life care planner.)

- **Patient** (i.e., the person with the disability). Assuming that the patient is accessible (i.e., legally permitted) and capable of appropriate interaction, interview and listen to him or her. Legally permitted in this context refers to the potential that defense experts in some states do not always have the "right" to interview patients and, therefore, do not have access to meet or talk with them. In cases where the patient is interviewed, it is the authors' experience that during the interview, patients often will demonstrate deficits or discuss their problems in reasonable detail. For cases where an interview does not occur, one possible alternative is to have the attorney ask standard interview questions via deposition. A videotaped "Day in the Life" of the patient also is helpful to review. An important point to make is that defense "consultants" are not disclosed and, therefore, will not interview patients. It is also recommended that the patient interview take place in the person's residence (home or facility). In the authors' opinion, patients are less inconvenienced and more comfortable in their normal setting. Secondly, for patients with numerous supplies, medications and equipment requirements, this procedure maximizes the potential for a comprehensive assessment of needs, including a review of potential architectural needs.
- **Family members/caregivers.** Similar to the patient interview, life care planners commonly interview and listen to the family (if legally permitted) involved in the patient's care. It is not uncommon for patients with a brain injury to be unable to describe in adequate detail the difficulties that they experience, and the family can help to "paint the picture." In addition, family support often is very important to ultimate outcome.
- **Medical evaluation.** Medical evaluation(s) with appropriate medical specialists should include an assessment of the patient's functional limitations, expected future medical treatment including referral to other specialties, a review of medications, supplies, and/or durable medical equipment, as well as related topics (see Table 66-2 for suggested questions).
- **Physiatrist.** Many patients with mild to moderate brain injury will have few, if any, long term *medical* needs. However, for major injuries, a physiatrist who specializes in long term brain injury rehabilitation can be designated the team leader for many of the

**TABLE 66-2**  
**Example Questions for Physicians: Life Care Plan Only**

1. Future Care (Distinguish what is reasonable and appropriate vs. medically necessary vs. desirable.)
  - How long will the patient need follow-up?
  - When will the patient reach maximum medical improvement?
  - How long and how often will treatment be needed? (Include frequency and duration, e.g., every six months for 2 years then once per year thereafter, etc.)
  - What treatment is expected? (Follow-up visits, routine evaluations, etc.)
  - How much will each visit cost?
  - Are X-rays or lab work needed? If so, how often and how much will each cost?
  - Do you anticipate any further surgeries or aggressive medical treatment; e.g., several years from now due to complications? If so, what, when, and how much will each cost?
2. Possible Complications  
What complications are possible/expected? (Traumatic arthritis, contractures, adverse reactions to medications, seizures, spasticity, earlier onset of aging-related dementia, maladaptive behaviors, additional injury due to reduced physical skills or poor judgement, etc.)
3. Recommended Medical Follow-up By Other Specialties
  - Orthopedist?
  - Neurology?
  - Physiatrist?
  - Cosmetic Surgeon?
  - Dermatology?
  - Psychology/Neuropsychology?
  - Occupational Therapist, Physical Therapist, Speech Therapy, Dietary, Recreation Therapy?
  - Other?

If you recommend any of the above, do you have an opinion regarding what treatment will be needed, how often it will be needed, and expected costs?

Partially adapted and reprinted with permission from Ref. 17.

specialties listed below, and a team may be assembled which includes physicians who address specific areas, such as plastic surgery, pulmonology, orthopedics, etc. As cited in Weed (3), in general, the physiatrist will be the best physician to establish a medical foundation for a life care plan (23, 24). As noted by Zasler (24), "All too often physicians may not be fully versed in life care planning. It is therefore critical that life care planners communicate in an appropriate and timely manner to assure that their role in a particular case is understood" (p. 57). One way to assure that future care information is properly solicited is to utilize the example questions checklist in this chapter. For physicians, if recommending a life care plan for a patient, or if meeting with an already assigned life care planner for one of his/her patients, it is recommended that the person conducting the life care planning assessment be asked if he/she is board certified as a life care planner (specifically if they are a CLCP). The goal of this questioning is to increase the likelihood that the life care plan is developed according to existing standards.

- **Neuropsychologist.** The neuropsychologist can play an invaluable role in evaluating the long-term effects of the brain injury on the patient's ability to

function (25). It is within the role of the life care planner to refer a patient for a neuropsychological evaluation in cases where there is documented or suspected brain injury/impairment (26). A specialized list of questions to help the life care planner prepare a life care plan, including address future vocational/educational issues, has been developed to assure that the appropriate questions are asked during the evaluation (see Table 66-3). Asking the right questions is important because many neuropsychological evaluations do not seem to be geared toward identifying long-term future care needs or rehabilitation strategies to maximize the patient's ability to function in society or participate in gainful work.

- **Occupational therapist.** The occupational therapist may be an appropriate referral for an assessment for seating and positioning, adaptive aids, safety in the residence, and other vocationally-related issues (27). For some patients, activities of daily living training, including household safety, would be included.
- **Speech and language pathologist** (may also be called Communication Disorders Specialist). The qualified speech and language pathologist is instrumental in assessing augmentative communications for patients with more severe communications disorder, as well

**TABLE 66-3**  
**Neuropsychologist Questions**  
(with credit to Robert Fraser, Ph.D.)

In addition to the standard evaluation report, add the following as appropriate.

1. Please describe, in lay terms, the damage to the brain.
2. Please describe the effects of the accident on the patient's ability to function.
3. Please provide an opinion to the following topics:
  - a. Intelligence level? (include pre- vs. post-incident if able)
  - b. Personality style with regard to the workplace and home?
  - c. Stamina level?
  - d. Functional limitations and assets?
  - e. Ability for education/training?
  - f. Vocational implications - style of learning?
  - g. Level of insight into present functioning?
  - h. Ability to compensate for deficits?
  - i. Ability to initiate action?
  - j. Memory impairments (short-term, long-term, auditory, visual, etc.)?
  - k. Ability to identify and correct errors?
  - l. Recommendations for compensation strategies?
  - m. Need for companion or attendant care?
4. What is the proposed treatment plan?
  - a. Counseling? (individual and family)
  - b. Cognitive therapy?
  - c. Re-evaluations?
  - d. Referral to others? (e.g., physicians)
  - e. Other?
5. How much and how long? (Include the cost per session or hour and re-evaluations.)

Reprinted with permission from Ref. 17.

as assessing receptive/expressive speech and language abilities, and identifying cognitive remediation professionals (28).

- **Physical therapist.** A physical therapist is often the most appropriate referral to determine the patient's true physical capabilities by compiling a functional capacity assessment that is more detailed than most physicians can report (29). For example, Ergos™ equipment has become quite sophisticated, as has Lido™, Cybex™, and other equipment designed to identify the individual's physical and functional capabilities.
- **Educational consultant.** For the school-aged patient, an educational consultant can be very important to maximize the patient's educational potential. Under the federal Individuals with Disabilities Education Act (IDEA), the public school system is responsible for providing specialized services to eligible school-age children with disabilities through age 21, if appropriate. Additionally, each state offers early intervention programs for children from birth to age 3. However, many of these school-aged children are poorly served for a variety of reasons. One may be that the child has not been adequately assessed in order to identify deficits that would meet the criteria for specialized education. Another is that the

child may meet the eligibility requirements but the school's funding is inadequate and the school fails to provide appropriate support. Another potential for dispute may be the school's contention that therapy is required for "medical" purposes rather than "educational" and the school, therefore, will not provide the services. Educational consultants who are familiar with the rules often can negotiate the appropriate education protocol which would then be included in the life care plan.

- **Vocational evaluator** (if there is work potential). A vocational evaluator can establish standardized protocols for assessing the patient's vocational capabilities, including aptitudes, interests, temperaments, and other related information (25). For the patient with a brain injury, a "real work" situational assessment or on-the-job evaluation may be more appropriate than formal timed or time-limited testing. The evaluator should have at least a Master's degree and experience working with individuals with a brain injury. A Certified Vocational Evaluator (CVE) is the recommended specialty for this assessment.
- **Rehabilitation counselor.** A rehabilitation counselor with a Master's degree or higher from an accredited rehabilitation counselor training program should be involved to assist in arranging for

a job analysis, labor market surveys, vocational guidance and counseling, selective job placement, and/or supported employment, and is often the true coordinator of services (25, 30). Indeed, for purposes of this chapter, the rehabilitation consultant for the patient with a mild to moderate brain injury is likely the prime candidate to take the information generated by the specialties listed above and develop it into a rehabilitation plan and earnings capacity analysis. A Certified Rehabilitation Counselor (CRC) is recommended, although a CVE (see above) may also have the expertise to provide this service.

- **Economist.** In most situations, the life care planner or expert witness, in forensic cases, will work with an economist. The economist will rely upon the base costs in the life care plan to project the cost of care throughout the patient's life expectancy (16). This specialized industry is sophisticated and complex. The rehabilitation professional who does not have an education in economic forecasting is sometimes requested to project life care plan costs in personal injury litigation cases, and it is the authors' opinion that this is a dangerous practice in most instances. It is important to know, for example, what the different rates of inflation are for medical and non-medical care, as well as discounts to present value methodologies. In most cases, the economist will be necessary as they are well-versed and educated in inflation rules and investment strategies. On the other hand, there are a few states that endorse the "Alaska Rule" which assumes that inflation and reasonable investment rates are essentially equal and "wash out" each other such that an economist may not be needed in those cases. In summary, it is strongly recommended that the life care planner defer to an economist or other trained and qualified professional for the ultimate cost of the life care plan, unless he or she has specific training in this specialized area.

As a general rule, in order for an economist to project the cost of care, certain details must be included. In the authors' experience, many health care providers offer opinions that a patient will require follow-up services for "a long time;" however, it is not possible to identify specific costs for patient needs when the time frame is not quantified. In order to obtain a "bottom line" cost for the care plan, the professional must obtain the following information:

- expected type and amount of treatment (frequency)
- date to start treatment
- date to stop treatment
- base cost of treatment (in today's dollars)

See Table 66-4 for an example entry that contains the minimum required data to calculate future costs.

**TABLE 66-4**  
*Example Minimum Information Needed for Economist to Project Costs*

Psychological Evaluation 6/2005 at a cost of \$600.  
Expect counseling to start 7/2005, one time per week, one hour session each for 26 weeks at a cost of \$100 per hour.

Expect group counseling one time per week for 2 years, beginning 1/2006 at a cost of \$40 per session.

Expect medical follow-up four times per year by psychiatrist at a cost of \$150 for the initial visit, then \$75 each visit until 1/2007.

Medication prescribed is Prozac, one 20 mg. per day, from 7/2005-1/2007, at a cost of \$53.86 for 30 pills.

Occasionally, identifying the frequency and duration of activities can be very complex. Pediatric brain injury cases often will include needs for periodic speech, occupational, and physical therapy which may begin and end at specific developmental periods in the child's life (27-29). Although these therapies may be provided through the school system while the child is in school, private or medically based therapies often are indicated to address the child's needs outside the education setting for the following reasons: (1) to augment school-based services, (2) to address the child's needs at home and in the community, (3) to prevent or reduce medical complications, and 4) to provide continuation of therapies throughout the summer to assure maintenance and carry over of skills into the next developmental stage. By knowing what services are provided by the school system, the life care planner can better determine what additional services the child needs outside the school environment to achieve short and long-term goals (31). For instance, occupational therapy may be needed for activities of daily living for a six-year-old child and then be discontinued throughout school years until the child is ready to enter the work world at which time an occupational therapist may rejoin the treatment team in order to furnish assistive devices for work-related activity. A challenge for life care planning is that sometimes treatment team professionals fail to consider the life-time needs of a patient, since they are most often involved in care lasting only one to two years.

To continue with an explanation of the RAPEL method previously described:

**A = Access to Labor Market.** In many cases involving individuals with ABI, the patient may very well be able to return to a job that is custom-designed around his/her disability or with an employer who is interested in hiring an employee with mild to moderate cognitive deficits. However, the patient may not have access to the

same number or level of vocational choices as he or she did prior to the injury. In essence, it may be that the patient would appear to have no particular loss of earnings capacity, but at the same time be at high risk for losing a job and then having a significant problem locating alternate suitable employment. Access to labor market can be determined through the services of a qualified rehabilitation consultant and is beyond the scope of this chapter.

**P = Placeability.** Placeability represents the likelihood that the patient will be successfully placed in a job with or without rehabilitation or rehabilitation consultant assistance. One may need to conduct a labor market survey, job analysis, or, in pediatric cases, rely upon statistical data to opine about ultimate placeability as an adult. In some situations, the economic condition of the community also may be a factor. It is important that the rehabilitation consultant recognize that the patient's personality, cognitive limitations, and other factors certainly influence the ultimate outcome. For adults, the rehabilitation consultant generally should include an opinion about jobs that are available (actual openings) in addition to jobs that exist but are not currently available to the patient.

**E = Earnings Capacity.** Based on the rehabilitation or life care plan, access to the labor market, and placeability factors, the patient may or may not be employable in the labor market. If employment is likely, an estimate of the earnings potential is included as a mitigating factor in determining damages. In addition, identifying the pre-incident earnings capacity is a necessary element of determining what is included in the life care plan since jurisdiction "rules" will determine certain needs. For example, if the life care plan is being prepared for a patient related to a vaccine injury fund case, then general living costs (housing, food, transportation, etc.) will be part of the plan, whereas these costs generally are not included in personal injury cases.

**L = Labor Force Participation.** This category represents an opinion about the patient's expected work life expectancy or amount of time expected to be in the work force. Usually an individual who has a reduced life expectancy also will be expected to have a reduced work life expectancy. At the other end of the spectrum, the patient's participation in the labor force may be unchanged after the brain injury. Or, an individual may have the capacity to work six hours per day rather than eight hours per day, which represents a 25% loss of normal work life expectancy. Other patients may require a longer period of time to find a job or have longer time off between jobs as a result of the ABI and this could have an impact on their worklife expectancy. Further, some patients, pre-injury, may have demonstrated consistent extra income by working overtime hours or at a second job and this situation should be considered in the analysis as well.

In summary, the RAPEL method identifies the minimum data needed for determining damages in personal injury litigation and provides the data needed for economists to arrive at a bottom line figure.

## GENERAL LIFE CARE PLANNING PROCEDURES

As a first step, the life care planner must request and receive all medical records and consultations (9, 18, 32, 33). If the individual is involved in litigation, depositions of health care professionals often are available and useful to review as related to damages and/or future care needs. If information is unclear, confirmation of diagnosis is essential. As previously noted, if the patient resides at home, it is recommended that the interview take place in the residence rather than in an office or other location so that a complete inspection of the individual's needs can be done. It is unlikely that the patient and/or family member(s) will remember all of the drugs and supplies, and an on-site inventory is the most effective way to determine the patient's current needs. In addition to an inventory of medications, supplies, and equipment during the initial interview, information is obtained with respect to the patient's pre-incident medical and social history, family history, current physical and emotional status (including limitations), medical treatment, socioeconomic status, employment history, and long-term plans. A thorough assessment usually requires several hours to complete.

Subsequent to the review of medical records and patient/family interview, the life care planner begins the process of identifying long-term care issues and options, including considerations for aging (32). If the care planner is retained by the plaintiff, the treatment team is usually consulted and is encouraged to take an active role in development of the life care plan. In fact, if the life care planner has access to relevant treatment members and fails to communicate with them, a serious breach of professional responsibility is likely. However, it is recognized that there are cases where it is not permissible to contact treatment team members. (For additional information on this topic see 34). The life care planner acts to coordinate and communicate information to and from all members of the treatment team, patient and family. Generally, the life care planner will be the author of the document, although many people, including the patient, provide opinions and recommendations. The life care plan will identify the source of each recommendation(s), frequency, and treatment areas consistent with appropriate and reasonable care. The life care planner needs to have enough knowledge about the disability to participate in the planning process by knowing which questions to ask, who to invite to participate, how to fill in gaps of information,

and when participants' contributions are unreasonable (either excessive or deficient).

Similarly, the clinician on whom the life care planner relies needs to be competent and confident in their opinions with regard to future needs as the reliability and validity of the life care plan rests on the foundation of each individual entry. The physician or health care provider must know the patient's particular situation and the literature with regard to probable needs. For example, does a person with a brain injury really need EEGs every year to life and is there reasonable support or foundation for the recommendation? Obviously, there is a shared responsibility between the health care clinician and life care planner and the life care planner must be acutely familiar with the patient and his/her disability to know if the clinician is offering recommendations that are reasonable and resemble an accepted standard of care. For example, one of the authors met with the treating physician for a patient with tetraplegia. After a few recommendations were elicited, it was obvious the doctor was not well-versed about the long-term implications of spinal cord injury as related to future care needs. It was eventually revealed that the physician had treated only one tetraplegic patient in his career, and he happily supported the author's recommendation to refer the patient to a specialty spinal center to obtain the required information. In addition, it is the physician's or health care professional's responsibility to make sure the life care planner is qualified with which to collaborate on development of the life care plan. One way for the clinician to be sure of the life care planner's qualifications is to ask if the life care planner has completed specific training and/or achieved certification in this specialty profession (i.e., Certified Life Care Planner/CLCP).

Once an initial life care plan is developed based on adequate foundation for the entries, investigation into resources, cost research, and availability of services begins. The process of identifying resources can be a long and arduous task, involving research and personal contact with community and national resources, catalogs, and Internet databases. Upon a complete and thorough investigation, the life care plan is usually presented and reviewed by the patient/family (if clinically appropriate) and perhaps the treatment team. The plan can provide the patient, family, and treatment providers the opportunity to coordinate and execute effective care options with a clear understanding of the financial resources necessary for providing the service(s). Caveat: In the event the author of the life care plan has solicited and received written recommendations from the medical/therapeutic providers, or a consultation has been properly documented in the file, it may not be necessary to specifically send the life care plan back to the provider(s) for review. However, it is the authors' experience that having the physician or physicians who participated in development

of the plan to review and sign off or endorse the medically-based recommendations as being a reasonable plan of care can be helpful and important for case documentation.

## CLINICAL AND FORENSIC ISSUES

1. The rehabilitation expert is expected to provide an opinion in personal injury cases about what is "more probable than not" within rehabilitation certainty, as represented by the standards of the profession (7, 9, 35, 36). If a patient *might* need additional plastic surgery, then this does not represent what is more probable than not and cost for such items should not be included in the plan totals. It should not make a difference as to whether the expert is retained by the plaintiff or the defense since qualified professionals should arrive at similar conclusions if the data is appropriately analyzed (37). However, there may be occasions where there are philosophical differences or, perhaps, an attorney has provided information that is biased, and it is within the rehabilitation consultant's ethics to attempt, to the best of his or her ability, to fairly and objectively develop a plan which would accurately represent the patient's needs in order to help *resolve* litigation.
2. Replacement schedules for equipment can be dependent on a variety of conditions<sup>38</sup>. When possible, the source which supplied the product (assuming the patient already has it) should be contacted to obtain an opinion based on the individual patient. Contact with manufacturers also may be an acceptable source, although in the authors' experience, replacement schedules as promoted by the manufacturer may be less often than what it is in practical terms. Factors to consider include age, activity level, anticipated amount of use, patient's weight, and quality of product. For example, a younger individual who requires the use of a wheelchair may be very active, participate in wheelchair sports, live in a rural area that is "hard" on wheelchairs, etc., and each of these factors must be considered. Another example may be that of a patient who is 70 years of age, very sedentary, and never leaves the residential facility where he/she lives. Replacement schedules based on the above examples obviously differ for the reasons stated. An overview of basic guidelines to consider when determining replacement schedules can be reviewed in Amsterdam's chapter (38).
3. Items included in the life care plan should represent what is considered reasonable quality of care and presumes fewer complications than would otherwise be expected. The life care plan should identify potential complications based on research, patient's

history of complications, records reviewed, or expert opinion. For example, as discussed earlier in this chapter, people with ABI commonly have a higher risk of re-injury due to poor judgment and/or physical skills, among other factors. However, unless one can identify the nature of the re-injury, severity, frequency or duration, or the likelihood that re-injury has a better than 50% probability of occurrence, costs should not be included in the plan totals.

4. The life care plan generally should not include needs that are not directly related to the patient's disability. (Note: There are occasions where this rule does not apply, such as family trusts and vaccine injury fund cases). For example, a person with pre-existing diabetes would not have the cost of medication, glucose monitor, or physician visits related to diabetes included in the plan. Assuming that damages related to earnings capacity is a part of the case, costs associated with normal living expenses also would be excluded. For example, the cost of an individual's vehicle would be deducted from the cost of a handicapped van so that the plan would only include those costs associated with the need to modify the van as a result of the injury. The additional costs associated with van maintenance (only for those parts that have been modified, i.e., wheelchair lift, hand controls or other driving modifications, swivel seats, etc.), mileage to injury-related medical/therapy appointments, and increased insurance as a result of insuring a more costly, modified van would be included. Routine maintenance, fuel, etc. would not be included in the plan as the patient would have been expected to incur those costs associated with owning a regular vehicle had the injury not occurred (although an allowance for increased mileage may be added as appropriate). Similarly, the cost of home modifications as a result of the injury are reasonable to include in the plan, but the entire cost of a house is not (again, for the reason that the patient would have been expected to live somewhere had the injury not occurred). In the event the existing home is not modifiable, the value of the existing home, or the average value of a comparable home in the local community should be deducted from the value of purchasing or building an accessible home. Another example is that individuals who reside in a facility usually receive food and housing as part of the per diem cost. If a part of the patient's damages includes earning capacity, then the economist should be instructed to deduct the average yearly cost of food and housing that the patient would have expected to incur even without the injury. For patients who receive nutrition via enteral feeding, the average yearly cost of regular food should be deducted from the cost of their liquid nutrition. However, the life care planner must be cognizant of the nature of the case which may dictate what is properly included and accepted in the life care plan. As noted previously, special rules apply to litigation cases such as federal vaccine injury fund, Federal Employees Liability Act (FELA), or one of many other jurisdictions that may have special requirements.
5. For a child with a brain injury who attends public school, an individually designed educational program that includes occupational therapy, physical therapy, speech/language therapy, vision therapy, special education, and/or other resource services is available through the school at no additional cost to the family. Typically no cost for these school-based services should be included in the life care plan. However, what is defined as "educationally related" vs. "medically related" can form the basis for conflict and may determine what or whether the child receives school-based services. As suggested previously in this chapter, it may be wise to include the services of an educational consultant or expert in the life care plan to help negotiate the best school-based program. In some rare situations, a private specialty school may clinically be the best option for the patient, in which event the costs for the private specialty school will be included in the life care plan.
6. Personal injury cases in some states have collateral source rules which mean that certain patient needs, if covered by another entity, should not be a part of the life care plan. Although the life care planner must take this issue into account, the retaining attorney would know when this rule applies and should inform the expert.
7. The method for obtaining recommendations from treating professionals or other experts can take many forms. For life care planners who are retained by the plaintiff, direct contact with the treatment team is recommended. An in-person meeting with the physiatrist, for example, can assure that the life care planner has the full attention of the physician. Phone contact may also be a reasonable option, especially where distance and/or scheduling issues dictate alternate means of communication other than face-to-face. It is recommended that the life care planner take notes during such communications, then send the written notes back to the physician so that he/she can review, sign and return them to the life care planner for documentation, along with any corrections or refinements that are indicated. Another method is to send the entire life care plan to the physician(s) for review, endorsement, and signature. A third approach is to submit a letter with specific questions on which the physician can hand-write recommendations or can dictate responses typed on the doctor's letterhead. The important

factor is that written documentation verifies the medical foundation for life care plan entries.

8. For patients who require attendant care, the life care planner is expected to research agency costs (typically minimum of three sources). Some experts assert that privately hired attendants are less expensive. However, the life care planner needs to be certain that the family infrastructure for private hiring is in place. Second, the costs associated with private hire are not as low as it may seem on the surface. Costs for advertising, interviewing, hiring, bonding, background checks, training costs, back-up provision, insurance, payroll expenses, taxes, etc. are in addition to the hourly rate paid to the private caregiver (see Kitchen & Brown, 39, for additional details).
9. The concept of “medically necessary” is one which the physician and allied health professionals are familiar. In the authors’ experience, a common tenet in personal injury cases is that the injured party has a “right” to be made whole (reasonably). So, what may be “medically necessary” in Medicare may not meet the same threshold in personal injury litigation. The reader should discuss this issue with the referral source to refine the definition and be sure all necessary items are included in the plan.
10. *Qualified* life care planners are trained to conduct their assessments in the same manner (i.e., following the same methodology and procedures) regardless of who pays the bill. One test is to inquire about the percentage of plaintiff vs. defense cases on which the professional has worked. Some life care planners are noted for providing close to 100% defense work, while others are close to 100% plaintiff work. One can easily assume there is a reason. It is recognized that there is no “law” that requires life care planners to be licensed or certified (unlike physicians) and that there are some who are considered very good but who also are not certified. However, it is the authors’ opinion that certification in life care planning at least assures that the planner has knowledge about standards and procedures. As with most certifications, no competence can be assured, but minimum knowledge has been demonstrated in the testing process. Incidentally, unlike most rehabilitation related certifications, there was no “grandfathering” in the CLCP certification so all individuals who sit for the exam from the first administration in 1996 forward, has had to achieve a passing score on the test to become certified.
11. Life expectancy can be a significant factor for life care planning and controversy exists over who is qualified to render a life expectancy opinion. It is clear that a life care plan is designed to provide the needs for the patient’s life expectancy; however, for some children who are severely or significantly

impaired, they will not live to be an adult. In these and other cases of individuals with a reduced life expectancy, the age of life expectancy becomes a critical point in assessing a patient’s future. Typically, the life care planner will rely on a physician or medical expert to render the life expectancy opinion (23, 40, 41) and the life care plan needs will be adjusted accordingly. However, there are life expectancy experts who are not physicians or medical specialists who have been involved in research and have successfully been qualified in court to opine about how long a person will live (42-45). Obviously, this topic can be a battleground in forensic cases since each year that a person lives costs more. In some cases, an expert for the plaintiff may claim that a child would live to age 60 and the defense expert may opine to age 20, resulting in millions of dollars in differences. Also, in a few jurisdictions, a normal life expectancy table may be specifically required. The theory is that the defendant who is responsible for an injury that shortens one’s life should not receive “credit” for the reduction and would therefore be required to pay for damages to a normal life expectancy.

12. The Health Insurance Portability and Accountability Act of 1996 (HIPAA) will have an effect on how health care providers, life care planners, insurance companies, law firms, etc. interact with regard to medical information pertaining to an individual with a disability. The authors are beginning to see some of its effects in their own practices and some challenges that are being created as a result. Although details are beyond the scope of this chapter, many life care planners will need to sign business associate agreements with law firms and/or insurance companies and additional safeguards for “protected health information” will be required. Some life care planners have reported more difficulty interfacing with physicians and medical providers to access their patient’s medical information and research their health care needs even with a properly signed and executed information release form. As a recent example, one of the authors researched a patient’s medication costs to include in the life care plan and, as part of routine practice, asked the patient’s pharmacist for a printout of the medications and supplies. Rather than complying as had been done numerous times in the past, the pharmacist informed the life care planner that the request and information release form signed by the patient had to be sent to an outside “HIPAA compliance vendor” for review and authorization before the pharmacy would release the information. Implications of this are that the new procedure could potentially add weeks onto the research portion of the plan and

would delay obtaining the patient's actual medication history. In other instances, pharmacies have required that the patient/family personally pick up the medication history rather than send it directly to the life care planner.

## BASIC ETHICAL ISSUES

The efficacy and value of the life care plan is dependent in large part on the ethics of the person developing the plan<sup>46, 47, 48</sup>. Several common issues arise in this domain which deserve brief mention (Weed & Berens, 49, reprinted here with permission).

### Professional Preparation

The qualifications of professional rehabilitation practitioners depend on experience and academic preparation. It is imperative that one's credentials be represented accurately, and that current licensure and/or credentialing be maintained. Life care planning practitioners are held to the ethical standards of their professional discipline(s). Therefore, the life care planner should belong to a relevant organization that has ethics and/or should be certified as a life care planner (see the International Academy of Life Care Planners at [www.IALCP.com](http://www.IALCP.com) and the Commission on Health Care Certification at [www.CHCC1.com](http://www.CHCC1.com)).

### Who Is the Patient? (A.K.A. Client)

Common within the field of rehabilitation service delivery and for purposes of this chapter, the patient is the person with a disability. The life care planner is expected to provide objective, independent opinions, limited to his or her field of expertise, and demonstrate no conflict of interest. It is important that their contract for services clarifies the responsibilities and duties of the life care planner. Ultimately, the goal is to develop a document that provides for the needs of the patient over his/her lifetime in a manner that preserves quality of life, reduces potential complications, and also provides quality, appropriate, efficient and cost-effective services.

### Informed Consent

In most cases, patient consent is required for the review of confidential medical records, for patient interviews, and communication with providers of goods and services. The patient or their legal representative must understand and consent to these services. He or she is free to withdraw consent from any or all portions of services at any time. In some cases, the life care planner may act as a consultant to an insurance company or attorney, in which case, different rules may apply since direct contact may

be limited or non-existent. The life care planner must know which rules apply in the cases on which they provide services.

### Confidentiality

Protection of patient confidentiality must be maintained at all times, within legal and ethical parameters. Case managers and life care planners may release records of their work with proper authorization from the patient or his/her legal representative. Written summaries and recommendations should be addressed to the referral source who can then be responsible for distribution of copies to insurers, the patient, and service providers. Special care should be taken with the use of computerized files, electronic mail, and facsimile transmission of information in order to protect confidentiality.

### Written Reports

In personal injury litigation, it is not uncommon for the life care planner to decline to provide written opinions, probably at the request of the attorney who retained their services. Obviously, written reports represent the most common way of expressing opinions and making recommendations in all rehabilitation industries. Failure to do so in litigation related cases is inviting criticism of the life care planning process as a whole. It is the authors' opinion that the life care planner have some form of written documentation in their file.

### Use Existing Standards

Again, in personal injury litigation, certain trends are developing with regard to how life care plans are compiled. In the past, some rehabilitation consultants have chosen to use their own "private logic" when outlining future care needs. Under the Daubert<sup>50</sup> ruling (1993), it is important for the expert to develop opinions subject to published and peer reviewed methods, procedures and standards. One publication that focuses exclusively on this topic is the *Journal of Life Care Planning*, 2002, 1(1) (available through Elliott & Fitzpatrick, [www.elliottfitzpatrick.com](http://www.elliottfitzpatrick.com)). Another resource for consensus on life care planning issues is the 2000 Life Care Planning Summit Proceedings<sup>51</sup>.

## CONCLUSIONS

In general, determining lifetime future care needs for a patient with ABI can be a challenge. Oftentimes, deficits are subtle and require significant expertise to identify not only what the deficits are but strategies to assist the patient with becoming as functional and independent as possible over his/her lifetime. These cases can require a

remarkable amount of information gathering, records review, and diligent coordination among rehabilitation professionals as well as research of necessary items and services. If the evaluation is thorough, a life care plan with a reasonable estimate of financial damages can be attained and will assist in resolving the case so the patient can “get on with his or her life” (i.e., have the services in the life care plan implemented).

**CASE STUDY\***

**Rehabilitation Plan and Vocational Worksheet Using Rapel Method and Approved by Psychiatrist and Others Involved in Client's Treatment**

Re: Losta Newron  
 Address: XXXX, Chicago, IL  
 Date of Report: 5/6/03  
 Date of Birth: 4/11/99  
 Date of Injury: 11/11/01

**Description of Injury**

Apparently, the patient was pulling on a chain when the counter to which the chain was attached fell on her. The mother states the counter weighed between 200-300 pounds and required two men to pull it off. Reportedly, the patient was unconscious and had blood coming from her ears, mouth and nose. She was diagnosed with severe closed head injury with multiple skull fractures and facial lacerations. She had a very good recovery based on the initial extent of injuries. However, several life long sequelae were expected and are outlined in the life care plan below.

**Rehabilitation Plan** (see Life Care Plan)

*Potential Complications*

Potential complications include, but are not limited to:

1. Seizure disorder.
2. Risk of re-injury due to reduced judgment, intelligence, physical skills, and visual perception.

<i>Anticipated Length of Rehabilitation Program:</i>		Through childhood and potentially lifetime.	
RECOMMENDATION	DATES	FREQUENCY	EXPECTED COST
Comprehensive neuropsychological evaluation	2004 (age 5) through 2017	Once in 2004, then yearly through 2010 (age 11), 2013, 2017 (age 18)	\$600 (2004) then \$1,000 each
Psychological	2003–2005		\$90–110 per hour
a. Individual or couples therapy for parents		Expect once per week for 6–8 mos.	
b. Family and individual client counseling	Begin 2005	Once per week for one year, twice per week from age 12 to 14, twice per week from age 16 to 18, once per week from age 18 to 21	\$90–110 per hour
Psychiatric evaluation	2003–2017	Yearly	\$75–100 each
Occupational therapy	To 2004 (age 5)	Once or twice per week	\$100 each visit
Physical therapy evaluation	Est. September 2003	Once only (also see comprehensive eval.)	\$100
Neurological evaluation	2003–2010	Yearly	\$80 each (does not include EEG or CT scans or other diagnostic studies, if needed)
Ophthalmologic evaluation for strabismus related to ABI	June 2003 to life expectancy	Yearly	\$35–55 each (does not include dilation or corrective lenses, if necessary)
Speech/language evaluation	2003 and 2004 at age 5 (included in comprehensive evaluation)	Once in 2003, 2004	\$100 (2003) 2004 cost included in comp. eval.

\*For purposes of this chapter, the below case study is in an abbreviated form.

RECOMMENDATION	DATES	FREQUENCY	EXPECTED COST
Comprehensive team evaluation (include medical, P.T., O.T., speech/language, etc.)	2004 (age 5)	Once only	\$1,800
Special education Option 1: Private school for children with disabilities. Also consider summer education or camp. Option 2: Public school system covered by the Individuals with Disabilities Education Act (IDEA). Include 13 years of learning disability consulting, 3 days per week for school year and summer school.	2003–2017	36 weeks per year (40 weeks per year if summer school)	\$10,000 per school year (recommended for maximum outcome)  4 weeks @ \$350–\$1,000 per week (summer) \$0 for public school.  \$40/hour learning disability consulting 36 weeks per year regular school or 40 weeks per year with summer school
Neurobehavior development consultant	2003–2017	3 contacts with school and patient per year to enhance educational achievement	Expect 2 hr per occasion at \$100/hr (total 6 hr per year)
Health and strength maintenance (including pool therapy, walking, and recreational activities to encourage motor coordination, perceptual training and strengthening)	2003 through entrance into school, 2004 (age 5)		No additional expected cost.
Driving evaluation	2014 (age 15)	1 X only	\$400
Vocational a. Pre-vocational evaluation	2015 (age 16)	Once only	\$600
b. Vocational evaluation	2017 (age 18)	Once only	\$600
c. Vocational counseling, guidance, placement assistance, and follow-up. (Note: Costs for job coaching and supported employment, which may be appropriate, are not included.)	2016–2019	150 hours over three years	\$65/hour
d. Post-high school education or vocational-technical training			Unknown

*Note:* This plan does not include costs associated with the patient's case management services nor her reduced ability to work outside of the home.
