Evered and colleagues (48) examined the incidence and potential influences of emotional and personality problems in 129 patients with a history of MTBI and a presumed post-concussive disorder. The majority of patients (63.5%) met criteria for either Axis I and/or Axis II disorders, which is a rate of psychopathology that is higher than in the general public. The most common Axis II (i.e., personality) disorders were compulsive, histrionic, narcissistic, and dependent. This study clearly indicates that psychological problems, relating to personality and/or acute psychopathology, are prominent in patients with the presumed post-concussive disorder.

Greiffenstein and Baker (270) studied a unique sample of 23 patients involved in MTBI litigation (or disability evaluations) who had completed the MMPI prior to their injuries. They found that the majority of pre-injury MMPI profiles were abnormal in this group, with particular elevations on scales relating to physical symptoms, somatization, depression, and problems with thinking (i.e., Hs, D, Hy, and Sc scales; 83% to 87% of the sample had elevated scores on these scales). All 23 individuals had at least one elevated scale pre-injury, and 21 had two or more elevated scales pre-injury. Unexpectedly, when compared to their post-injury MMPI-2 profiles, their mean scores on the clinical scales pre-injury were actually *higher* than their mean scores post-injury. The highest mean scores post-injury were again the Hs, D, Hy, and Sc clinical scales (i.e., 74% to 100% of the sample with elevated scores on these scales). These findings suggest a very high prevalence of pre-injury psychopathology in this sample. However, the authors caution that there may have been a potential selection bias in this study towards sampling of patients (a) who were already abnormal, and (b) being worked up for past psychogenic contributions to medical complaints.

Although poorly understood, there is little doubt that personality characteristics influence the development and maintenance of the post-concussive disorder. These characteristics represent a large psychological component to the disorder. Other social-psychological factors, such as the nocebo effect, expectations, misattribution, the "good-old-days" bias, and diagnosis threat will be described in the next section.

### Social-Psychological Factors

Without question, social-psychological factors can have an enormous impact on the development and maintenance of the post-concussive disorder. There have been a small number of fascinating studies in this area illustrating the importance of these factors.

*Expectations and the Nocebo Effect.* Approximately 15 years ago, Mittenberg and colleagues discussed “expectations” as a partial explanation to account for elevated symptom reporting in patients who sustained MTBIs (74). Symptom reporting was examined in 223 community volunteers and 100 patients referred for neuropsychological assessment following a brain injury. The injured patients were asked to report the presence or absence of current symptoms and symptoms pre-injury. Community volunteers reported current symptoms and the symptoms they would *expect* to experience after sustaining a brain injury. Two important results emerged: (a) the number of symptoms reported by patients post-injury was the same as the number of symptoms healthy controls would *expect* to experience after a brain injury, and (b) patients with brain injuries consistently *underestimated* the normal prevalence of PCS-like symptoms in their retrospective accounts (i.e., their pre-injury symptoms) compared with the base rate of PCS symptoms reported by normal controls (i.e., their current symptoms). To explain these findings, Mittenberg and colleagues proposed that for some people the presence of PCS symptoms following MTBI may be due to “the anticipation, widely held by individuals who have had no opportunity to observe or experience post-concussive symptoms, that PCS will occur following mild head injury” (p. 202). Following an injury, a patient may “reattribute benign emotional, physiological, and memory symptoms to their head injury” (p. 203) and disregard or inaccurately recall their pre-injury symptom experience. For example, an individual may attribute a headache post-accident to the injury rather than due to a stressful day at work (271). This explanation has been termed *expectation as etiology*. Other researchers have reported similar, although not identical, results (271, 272).

People might “expect” to experience certain symptoms and problems, and this expectation might partially underlie symptom reporting following an MTBI. However, Gunstad and Suhr (271) emphasized the importance of appreciating a more generalized expectation of negative outcome regardless of the event (e.g., accident, injury, illness, or disease), consistent with the “nocebo effect.” The nocebo effect was introduced more than 40 years ago (273, 274) and research and discussion in this area has been ongoing (e.g., 275–281). The nocebo effect is the causation of sickness by the expectations of sickness and by associated emotional states. That is, the

sickness is, essentially, caused by expectation of sickness (282).

The nocebo effect in general, and expectations regarding symptoms and problems associated with MTBI in particular, likely represent significant psychological factors in the perception and reporting of symptoms in some patients. People’s retrospective perception of their past functioning also can influence their perception of their current functioning. For example, a person might falsely perceive a bigger difference than is actually the case between their past and present functioning due to overestimating past abilities or under-estimating past problems. This has been termed the “good-old-days bias.”

*“Good-Old-Days” Bias.* Researchers have reported that patients with back injuries, general trauma victims, as well as patients with head injury, overestimate the actual degree of change that has taken place post-injury by retrospectively recalling fewer pre-injury symptoms than the base rate of symptoms in controls (74, 271, 283–285). The *good-old-days* bias is a general response bias to view oneself as healthier in the past regardless of the presence or absence of brain injury and/or the experience of another negative event (e.g., an illness). The good-old-days bias seems to occur following a negative event (271, 284). As noted by Gunstad and Suhr (271), the “experience of any negative event, be it accident or illness, head injury or non-head-injury, may be required for one to focus on the past as ‘better’ than one’s current state, for one to think about the ‘good old days’ prior to the negative event” (p. 330).

The tendency of people to recall past symptoms and functioning more favorably than is actually the case is further complicated by involvement in personal injury litigation. Researchers have reported that plaintiffs tend to exhibit a *response bias* in symptom recall compared to non-litigants. That is, personal injury claimants free from head trauma tend to report a lower pre-accident prevalence of cognitive, mental, and emotional symptoms in their daily lives compared to non-litigants (e.g., 286, 287). Specifically, in a preliminary study, Lees-Haley and colleagues reported that personal injury claimants reported “better” past levels of functioning in life in general, self-esteem, concentration, and memory than general medical patients who were asked to provide retrospective ratings. The personal injury litigants also reported less depression, anxiety, irritability, and fatigue (287). These findings were replicated in a large-scale, multi-site study (286). In addition, personal injury litigants rated their premorbid work or school status, marriage, and relationships with their children as better than controls. This response bias, combined with an expectation of certain symptoms following MTBI, can have a potent impact on symptom reporting.

*Stereotype Threat and Diagnosis Threat.* Psychological factors also are relevant to understanding neuropsychological

test performance in people who are symptomatic long after an MTBI. For many years, researchers have been interested in the concept of *stereotype threat* to help explain performance differences between certain groups (e.g., 288–295). Research in this area is growing quickly (e.g., 296–301). The term *stereotype threat* was introduced by Steele (294) who defined this phenomenon as the “social-psychological threat that arises when one is in a situation or doing something for which a negative stereotype about one’s group applies. This predicament threatens one with being negatively stereotyped, with being judged or treated stereotypically, or with the prospect of conforming to the stereotype” (294, p. 614).

Stereotype threat, as a theory and psychological factor, suggests that an individual’s performance on a particular task can be negatively affected by the threat of an inferior and/or negative stereotype, such as men are superior to women in mathematics (288, 302). The adverse affect on performance is believed to be related to anxiety and/or a reduction of effort caused by the person’s negative expectations (294, 303). Research has supported the influence of stereotype threat as a partial explanation for why (a) women perform more poorly than men on mathematics tests (293, 295, 298), (b) African Americans perform more poorly on selected items from the Graduate Record Examination than Caucasians (288), and (c) Caucasians perform more poorly than Asians on mathematics tests (289). Similarly, stereotype threat is also thought to partially explain (d) the presence of memory and cognitive decline in aging (291, 296, 297), and (e) differences in intellectual performance in students stereotyped as intellectually inferior versus superior (300).

Suhr and Gunstad (302, 304) have conducted two innovative studies relating to stereotype threat with university students who suffered past MTBIs. Suhr and Gunstad (304) hypothesized that in people with MTBI, “calling attention to a personal history of head injury and its potential effects on cognition might lead to worse cognitive performance than that seen in individuals with similar head injury history, but who do not have attention called to either the head injury history or the possible consequences of head injury” (p. 450). This hypothesis was called *diagnosis threat*. Suhr and Gunstad (304) examined the effect of diagnosis threat on cognitive performance in 36 undergraduate students with a self-reported history of MTBI. Participants were assigned either to a diagnosis threat condition or a neutral condition. All participants completed a brief neuropsychological test battery. Prior to participation, subjects in the diagnosis threat condition were provided with information highlighting their “diagnosis” of head injury and the expected cognitive deficits associated with head injury.

Participants in the diagnosis threat condition performed worse on measures of intellectual ability, immediate memory, and delayed memory, but not on measures

of attention and psychomotor speed. Participants in the diagnosis threat condition rated themselves as putting forth less effort during testing, rated the tasks as more difficult, and felt they performed less well than participants in the neutral condition. In a follow-up replication study examining 53 undergraduate students with a history of self-reported MTBI, Suhr and Gunstad (302) reported that participants in the diagnosis threat condition performed worse on measures of memory, attention/working memory, and psychomotor speed. Contrary to the stereotype threat hypothesis however, differences in cognitive functioning between groups was not related to effort or anxiety.

The magnitude of the effect of diagnosis threat on neuropsychological test performance is not trivial. In fact, it’s alarming. The results from the Suhr and Gunstad (302, 304) studies are presented with the results from several meta-analytic studies in Figure 23-1. Quite remarkably, the psychological effect of “diagnosis threat” has a large, adverse effect on neuropsychological test performance. Notice that the adverse effect of an MTBI on neuropsychological test performance, when measured beyond the acute recovery period, is very small and virtually undetectable in group studies. In contrast, the adverse effect of diagnosis threat, in university students, is comparable to the adverse effects of depression and litigation on neuropsychological test performance.

### **Litigation Stress, Exaggeration, and Malingering**

Weissman (305) described aspects of litigation stress in the quote below. What is apparent from this quote is Weissman’s belief that litigation produces negative effects on the plaintiff’s mental state through multiple pathways, including greater susceptibility to stressors, attitude changes, motivational changes, and biases in self-reported problems.

Involvement in litigation renders plaintiffs susceptible to stressors and to influences that may lead to increased impairment, biased reportage, and retarded recovery. Underlying personality patterns play a critical role in defining and shaping reactions to trauma, to the stress of litigation, and to treatment interventions. Protracted litigation creates conditions that promote mnemonic and attitudinal distortions, as well as conscious and unconscious motivations for secondary gain. (Ref. 305, p. 67).

Plaintiffs with acquired brain injuries or psychological problems find themselves in a very different health care environment compared to injured or emotionally distressed people not in litigation. For example, individuals other than the injured person have a vested interest in the assessment and rehabilitation of the plaintiff. As well, others have a vested interest in doubting the veracity of

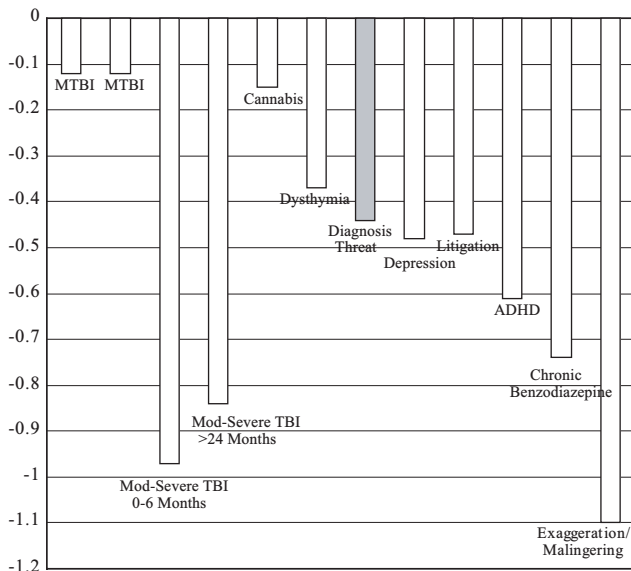

FIGURE 23-1

#### Effect sizes on overall neuropsychological functioning

*Note:* Effect sizes typically are expressed in pooled, weighted standard deviation units. However, across studies, there are some minor variations in the methods of calculation. By convention, effect sizes of .2 are considered small, .5 medium, and .8 large. This is from a statistical, not necessarily clinical, perspective. For this figure, the overall effect on cognitive or neuropsychological functioning is reported. The effect sizes are displayed in a negative direction to visually illustrate the “negative” or “adverse” effect on cognitive functioning. Effect sizes less than .3 should be considered very small and difficult to detect in individual patients because the patient and control groups largely overlap. First MTBI, moderate-severe TBI 0–6 months, >24 months, all in Schretlen & Shapiro (5), 39 studies,  $N = 1,716$  TBI,  $N = 1,164$  controls; second MTBI (338), 11 studies,  $N = 314$  MTBI,  $N = 308$  controls; Cannabis (339), long-term regular use, 11 studies,  $N = 623$  users,  $N = 409$  non or minimal users; Dysthymia, Depression, & Bipolar Disorder (340), 3 comparisons for dysthymia, 97 comparisons for depression, and 15 comparisons for bipolar disorder; Diagnosis Threat (302, 304), 2 studies, 23 comparisons; Litigation/financial incentives (55), 17 studies,  $N = 2,353$  total; ADHD (341), based on Full Scale IQ, 123 studies; Chronic benzodiazepine use (342), 13 studies,  $N = 384$ , 61 comparisons; Exaggeration/malingering (316), 32 studies published between 1985 and 1998, 41 independent comparisons

the patient’s health problems. The effect of these vested interests can be seen in the skepticism frequently attached to diagnoses of post-concussive disorder, post-traumatic stress disorder, or major depression; outside the context of litigation, these diagnoses are accepted with less skepticism.

One result of these vested interests and skepticism is that plaintiffs with alleged post-concussive disorder or psychological problems will be subjected to more intensive, frequent, and possibly hostile assessment of their

health problems. Thus, an individual seeking relief for symptoms while in litigation will experience a very different health care environment than will the person seeking such relief outside the context of litigation. In fact, there might even be pressures to avoid effective treatments and remain off work in order to illustrate the damages resulting from the cause of action. Undoubtedly, protracted litigation can be very stressful, and a plaintiff who was once significantly injured but who has largely recovered might feel *entitled* to the compensation anticipated by his lawyer, thus feeling *justified* in his decision to grossly exaggerate his current disability.

Exaggeration and/or malingering is believed to be a serious problem in disability evaluations and personal injury litigation relating to MTBI and the post-concussive disorder (306, 307). Hundreds of studies and reviews relating to the detection of exaggerated symptoms, poor effort during neuropsychological testing, and malingering have been published in the past 15 years. It is virtually impossible for clinicians to keep up with the research in this area. Fortunately, there are many good reviews of this literature (e.g., 308–318). Specific guidelines and recommendations for identifying malingering in a neuropsychological evaluation have been available for several years (319), and have recently been published for pain-related disability evaluations (320).

Malingering is the intentional production of false or greatly exaggerated symptoms for the purpose of attaining some identifiable external reward (41). It is important, however, to differentiate malingering from symptom exaggeration (which as discussed below, may have many possible explanations), the latter being embellishment of a symptom or sign that has a true physiological or psychological basis. In the presence of litigation, an individual may exaggerate symptoms. The person might exaggerate memory problems, concentration difficulty, depression, anxiety, pain, dizziness, sleep disturbance, or personality change. During neuropsychological testing, a person who is malingering (or for that matter exaggerating) is more likely to deliberately under-perform by consciously making errors, by not putting forth full effort, and/or by amplifying/fabricating complaints.

Resnick (321) described three types of malingering, labeled “pure malingering,” “partial malingering,” and “false imputation.” Pure malingering is characterized by a complete fabrication of symptoms. Partial malingering is defined by exaggerating actual symptoms or by reporting past symptoms as if they are continuing. False imputation refers to the deliberate misattribution of actual symptoms to the compensable event. Appreciating these types is important because mental health and legal professionals might have a simplistic view of malingering (i.e., only “pure malingering” is considered malingering).

Many lawyers and health care professionals adopt a rather extreme position regarding malingering. They

assume that malingering represents total fabrication (fraud). An example would be the person who pretends to not be able to walk who is videotaped walking. Less blatant malingering is conceptualized differently, such as “exaggeration.” Exaggeration is seen as common in personal injury litigation, and part of the function of the adversarial system is to illustrate to the trier of fact that exaggeration is present. Some professionals are tempted to believe that if a person has a well-documented psychiatric condition or visible brain damage on MRI that the person could not be malingering. However, it would be naïve to assume that a person with a psychiatric problem or the lingering effects of a traumatic brain injury could not malingering. That would be tantamount to concluding that people with these conditions are not capable of engaging in goal-directed behavior (e.g., exaggeration of symptoms to influence their litigation).

To conclude that a person might be malingering, the clinician must make an inference regarding a person’s underlying motivation or reasons for providing poor effort during neuropsychological testing, exaggerating symptoms or problems, and/or fabricating symptoms and problems. As seen in Figure 23-2, there are many possible underlying motivations for exaggeration (singly or in combination). The “cry for help” euphemism implies that the person has serious psychological or psychiatric problems and is desperately seeking recognition of, and attention for, these problems. There is a long history of conceptualizing exaggeration as a cry for help in psychology and neuropsychology, whereas in psychiatry and general medicine clinicians are inclined to attribute exaggeration to “psychological factors,” “psychiatric problems,” or “non-organic factors.” Second, in personal injury litigation, a person often feels angry about being injured and by perceived mistreatment from an insurance company. Some people feel justified in aggressively pursuing their litigation and feel entitled to generous compensation. Through a series of independent evaluations they might feel the need to exaggerate their symptoms or problems in order to be taken seriously, or to communicate how bad off they were in the past. There might be a number of secondary benefits relating to exaggerating one’s problems, such as attention from family and friends, or avoidance of unpleasant activities. Third, some people with depression have an extremely negative view of themselves, the world, and their future. This negativistic thinking can manifest in exaggeration of symptoms and problems. Some people have a personality style that is prone to dramatizing and exaggerating their problems. Fourth, a person might deliberately exaggerate because he has a deep-seated psychological need to be perceived as sick and disabled. The motivation is not the litigation, per se, but to be seen and treated as a sick and disabled person. Under these circumstances, the person would be diagnosed with a factitious disorder. Finally, a person

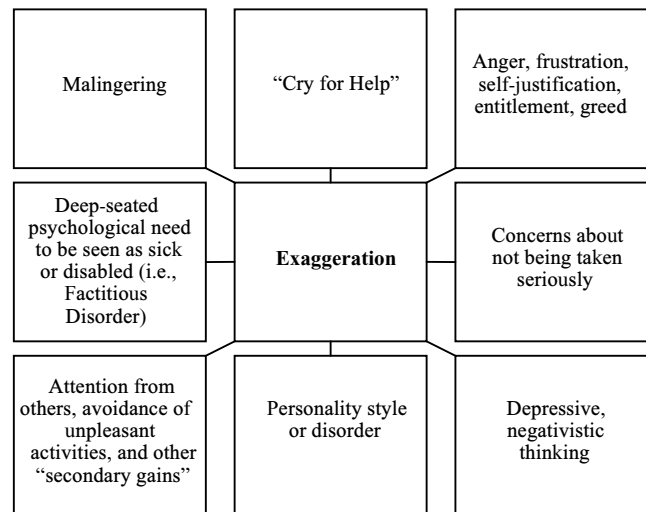

FIGURE 23-2

Possible reasons or motives for exaggeration

might deliberately exaggerate and/or under-perform during testing because he is trying to influence the outcome of his evaluations in order to influence the outcome of his litigation. This latter behavior is what we consider malingering.

In our experience, exaggeration is very common in people believed to have a persistent post-concussive disorder who are being evaluated in relation to a Worker’s Compensation claim, disability evaluation, or personal injury litigation. Malingering is much less common than exaggeration, and it would be a mistake to assume, without careful deliberation, that the exaggeration reflects malingering.

## CONCLUSIONS

There is no universally agreed upon etiology, pathophysiology, definition, or diagnostic criteria for the post-concussive disorder. Even the name of the syndrome/disorder varies in the literature (e.g., post-concussion syndrome, post-concussion disorder, and post-concussional disorder, to name a few). The disorder is assumed to be a direct and/or indirect consequence of an injury to the head or brain. However, a mild injury to the head or brain is not necessary (and often not sufficient) to produce the constellation of symptoms and problems that comprise this disorder. The symptoms and problems typically conceptualized as comprising the post-concussive disorder are non-specific; they can follow a mild injury to the brain or they can arise from other conditions, singly or in combination, such as chronic headaches, chronic bodily pain, depression, or post-traumatic stress disorder. These symptoms are also common in healthy, community-dwelling adults.

Following a mild traumatic brain injury, there is no doubt that most people experience a constellation of symptoms such as headaches, dizziness, fatigue, balance problems, sleep disturbance, difficulty thinking (e.g., concentration or memory), and/or emotional changes (e.g., irritability). These symptoms largely reflect the neurophysiology of concussion, which has been conceptualized as a multilayered neurometabolic cascade. The pathophysiology of this injury is largely reversible. However, under some circumstances people can have (a) macroscopic lesions, and/or (b) fairly widespread cellular damage or dysfunction (see the chapter by Iverson and colleagues in this book for a review).

Of course, not everyone experiences all symptoms, or symptoms to the same degree, but a core set of symptoms is commonly experienced. As a rule, these symptoms are at their worst in the first few days post-injury and they tend to get progressively better thereafter. This is illustrated in Figure 23-3. The data presented in Figure 23-3 represent a typical and common finding in the sport concussion literature and in clinical practice with concussed athletes. Athletes tend to report very high levels of symptoms and problems in the first few days post-injury, with relatively rapid resolution and recovery. Professional athletes seem to recover the fastest (322–325), followed by university athletes (30), and high school athletes (31, 326). This pattern reflects the reversible nature of the pathophysiology of mild concussions.

Trauma patients typically take longer to return to their baseline functioning. This is not surprising given that athletes tend to be young, healthy, highly motivated people with incentives to recover quickly and fully, and disincentives for having lingering problems. This creates a

FIGURE 23-3

Total post-concussion symptom scores in concussed high school football players

Note: Total Post-Concussion Scale scores (mean and error lines equal one standard deviation) for 47 concussed high school football players tested preseason, within 4 days of injury ( $M = 1.7$ ,  $SD = .9$ ), within 8 days of injury ( $M = 5.5$ ,  $SD = 1.4$ ), and within 21 days of injury ( $M = 11.4$ ,  $SD = 3.6$ )

very different psychological perspective on the injury. In contrast, trauma patients often are older, less healthy, and they get injured under unexpected circumstances such as motor vehicle accidents, assaults, or work-place accidents. MTBIs sustained under these circumstances can be psychologically traumatic, and they can also occur in tandem with other physical injuries. A trauma patient might have significant personality characteristics, life stressors or circumstances, and/or pre-existing mental health or medical problems that complicate the expected recovery from an MTBI. A person with poor coping skills and vulnerable personality characteristics who has co-occurring depression, chronic pain, PTSD, or a combination of problems is virtually guaranteed to endorse many “post-concussion-like” symptoms even if he or she has fully recovered from the injury. It is very easy to misdiagnose a person with a co-morbid condition as having a persistent post-concussive disorder (which carries the assumption of brain damage or dysfunction as the etiology of the symptoms).

Without a doubt, an MTBI is *not necessary* for producing the constellation of symptoms and problems that comprise the persistent post-concussive disorder. The disorder is not specific to an injury to the head, brain, or both. Therefore, this disorder should be considered a diagnosis of exclusion. The clinician should carefully study the history and progression of the symptoms and problems, and systematically attempt to rule out the most obvious differential diagnoses or competing explanations for the symptoms (see Table 23-5 and Figure 23-4). Once identified, the differential diagnosis should be treated.

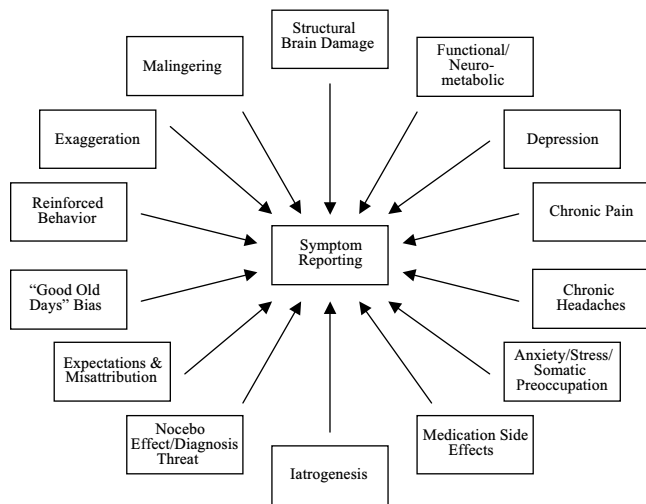

In our view, it is very unlikely that the post-concussive disorder simply reflects a neurological problem arising from a mild traumatic brain injury. The *initial* pathophysiology is, without question, neurological. From the beginning, however, there is great variability in how people respond psychologically to being injured and to experiencing symptoms and problems. Injured adults are psychologically-susceptible to the nocebo effect (expecting a negative outcome following a negative event) and misattribution of symptoms, and health care providers can inadvertently reinforce these factors. Some people are very psychologically vulnerable to developing chronic problems following an injury to their head, brain, body, or “psyche,” and the post-concussive disorder can be caused and maintained by factors that are entirely unrelated to permanent brain damage or dysfunction. In fact, in our view, the majority of people who appear to have the disorder (resulting from putative brain damage or dysfunction) actually have something else, such as depression or a combination of factors illustrated in Figure 23-4 (of course, a combination of factors might be the etiology for a post-concussive disorder).

People who sustain MTBIs characterized by structural damage on day-of-injury CT are, obviously, at

Adapted with modifications from Iverson (4). The first four patterns represent the natural history of recovery from MTBI, in decreasing order of frequency. “Recovery” means few or no symptoms that are due to the biological effects of the original injury. The vast majority of concussed athletes and healthy adults with minor concussions in everyday life are represented by #1 (with very small numbers falling in patterns 2–11). The vast majority of trauma patients with *uncomplicated* MTBIs and no significant premorbid problems or comorbidities are represented by #1–3, with small numbers represented by pattern #4. The persistent post-concussive disorder is best illustrated by numbers 4–7 (psychological factors play a large role in maintaining symptom reporting). Numbers 8–11 represent patterns that frequently occur when a person is misdiagnosed with a persistent post-concussive disorder

**FIGURE 23-4**

Possible factors influencing symptom reporting acutely, post-acutely, and long after a mild traumatic brain injury

increased risk for permanent brain damage (i.e., those with “complicated” MTBIs). However, most of these patients do not develop a persistent post-concussive disorder. When they do, it is likely that several factors depicted in Figure 23-4 are operative (including permanent brain damage). The antiquated notion of a binary distinction between “organic and psychological” contributes to the long-standing disagreements and polarized perspectives relating to the post-concussive disorder. As is increasingly being demonstrated in diverse fields of

research, the “psychological” is often a link between biology and behavior. Do some people who appear to have the persistent post-concussive disorder have identifiable abnormalities on structural or functional neuroimaging? Of course they do. Does that mean that the abnormalities are the *predominant* underlying cause of the disorder? Of course not (but they might be major or minor contributors to the symptom presentation). Adopting a biopsychosocial perspective is the only reasonable way to have a comprehensive, unbiased understanding of this disorder.

In clinical and forensic practice, diagnosing someone with a persistent post-concussive disorder implies directly or indirectly that the person has “brain damage.” This is a relief to a small number of patients seeking an explanation for their perceived problems. For many patients, however, it can have serious iatrogenic implications. The diagnosis can cause them to worry, dwell, and become focused on the belief that their brain is damaged. The diagnosis can be counter-therapeutic, reinforcing the misattribution of all symptoms to brain damage and leading to a sense of hopelessness regarding treatment and future improvement. According to the ICD-10 diagnostic criteria for the syndrome, one of the cardinal features is a preoccupation with symptoms and fear of brain damage with hypochondriacal concern and adoption of a sick role.

In our experience, the post-concussive disorder is over-diagnosed and frequently misdiagnosed. By over-diagnosed, we mean that there is often an assumption that a symptomatic person with a remote MTBI is suffering from brain damage that largely underlies the perceived

and reported symptoms. This assumption of brain damage carries a very negative prognosis and tends to inhibit attempts at treatment. Although it might be true in some patients, for most people the original injury to the brain has *mostly* resolved and the disorder represents, in large part, an entrenched psychological disorder. By misdiagnosed, we mean that the person is actually suffering from something else, such as chronic pain, depression, or PTSD, which is misdiagnosed or co-diagnosed.

Of course, it is also possible that the diagnosis of post-concussive disorder can be missed. We have seen cases in the first three months post-injury where the treating clinician has diagnosed depression or PTSD when it seemed more likely that the patient was suffering from symptoms and problems arising predominately from the biological and psychological consequences of his or her MTBI.

So, what is the post-concussive disorder? The literature to date does not allow us to determine whether it is a single disorder, a spectrum disorder, or a group of disorders. The literature does not allow us to determine the degree to which abnormal brain physiology underlies some or all of the symptoms and problems associated with the disorder. There is no way to reliably differentiate the post-concussive disorder from depression, and it is possible that the disorder is a depression-spectrum disorder. In its “true” form, the post-concussive disorder arises as a direct *and* indirect consequence of mild injury to the brain (assuming it is not frankly misdiagnosed sometime long after an MTBI). When it manifests early and is maintained chronically the condition is almost always biopsychosocial. The “biological,” the “psychological,” and the “social” are all potentially treatable<sup>7</sup>. In our view, it is a mistake to conceptualize patients with the post-concussive disorder as if they are simply less “serious” versions of patients with severe traumatic brain injuries. These are distinct patient populations with distinct treatment and rehabilitation needs.

Ideally, clinicians and researchers should try to prevent the development of, or treat, the post-concussive disorder. There is evidence that early intervention, as simple as education and reassurance, is helpful for reducing the number and severity of symptoms experienced in the initial weeks and months post-injury (see the chapter by Iverson et al. for a review). This education, reassurance, and problem-solving should occur in the first two weeks post-injury.

When patients appear to have a *persistent* post-concussive disorder, differential treatment often flows from

<sup>7</sup> Unfortunately, when treatment is offered it typically does not involve a broad-spectrum biopsychosocial approach, with an emphasis on identifying and addressing the diverse factors that underlie the ongoing symptoms and problems. Without this approach, the treatment is likely to be unsuccessful. Ineffective treatment contributes to the belief that the post-concussive disorder is “permanent.”

differential diagnosis. Given the clear overlap between the symptoms of depression and post-concussive disorder, some researchers have recommended treatment with antidepressants (327–330) or cognitive behavior therapy (331, 332). Medications and psychotherapy would be an obvious choice, of course, if depression is simply mimicking the post-concussive disorder. Those recommending cognitive behavior therapy have set forth a treatment protocol that is based on those principles but is tailored toward the post-concussive disorder and belief systems relating to symptoms and brain damage.

We believe that the post-concussive disorder is *treatable* in the majority of patients. The first step is to identify whether a person really has it, or whether his or her symptoms and problems are more appropriately attributable to something else (thus, differential diagnosis leading to differential treatment). If the person is believed to be suffering from a post-concussive disorder, then general mental health and specific “symptomatic” treatment is indicated. Symptomatic treatment involves treating depression and anxiety, improving sleep, reducing stress, facilitating adaptive coping, helping the patient problem-solve life stressors, increasing exercise, and promoting a resumption to a more active and normal lifestyle.

Our research group (GLI) is in the process of piloting a new psychological treatment program for patients with persistent post-concussive disorder. This program arises from Contextual Behavior Therapy and Acceptance & Commitment Therapy (ACT; 333, 334). This approach has been successfully used with several clinical populations (e.g., depression, anxiety, stress, and substance abuse), as well as very difficult patients with chronic pain (335–337). Acceptance and Commitment Therapy is based on the idea that psychological suffering is usually caused by experiential avoidance, cognitive entanglement (i.e., “cognitive fusion”), and the resulting failure to take needed behavioral steps that are consistent with core values. This treatment approach takes the view that simply trying to change problematic thoughts and feelings as a means of coping might be relatively unhelpful. In contrast, powerful alternatives are available, including acceptance, mindfulness<sup>8</sup>, cognitive defusion (learning to see thoughts as thoughts), value clarification, and committed values-based action. The treatment program includes components of traditional cognitive-behavioral therapy, and it includes psychoeducation

<sup>8</sup> Mindfulness-based Cognitive Therapy, based largely on the work of Jon Kabat Zinn, includes simple breathing meditations and yoga stretches to help patients become more aware of the present moment, including getting in touch with moment-to-moment changes in the mind and the body. This therapy also includes basic education about depression, anxiety, and stress, and several exercises from cognitive therapy that show the links between thinking and feeling. The approach is closely linked to the Eastern insight meditation tradition that has been taught for two thousand years.

relating to the social-psychological factors that influence the perception and attribution of symptoms (e.g., nocebo effect, misattribution, and the “good-old-days” bias, as depicted in Figure 23-4).

To date, most attention in the literature has been devoted to describing characteristics or predictors of the post-concussive disorder, or debating its existence or etiology. It is our hope that researchers increasingly will turn their attention to treatment designed to reduce patient's suffering and improve their real-world functioning.

**APPENDIX A**  
**British Columbia Post-Concussion Symptom Inventory (BC-PSI)**

**BC-PSI**

Name: \_\_\_\_\_

Date: \_\_\_\_\_

The following is a list of symptoms that you may have experienced. Please rate each symptom or problem in regards to how often it happens and how bad it is. Consider your experience with these symptoms or problems over the past two weeks, including today.

**HOW OFTEN**

**HOW BAD**

*(Frequency)*

- 0 = Not at all
- 1 = 1-2 times
- 2 = Several times
- 3 = Often
- 4 = Very often
- 5 = Constantly

*(Intensity)*

- 0 = Not at all
- 1 = Very mild problem
- 2 = Mild Problem
- 3 = Moderate problem
- 4 = Severe problem
- 5 = Very severe problem

**SYMPTOMS & LIFE PROBLEMS**

**HOW OFTEN**

**HOW BAD**

- |                              |       |       |
|------------------------------|-------|-------|
| 1. Headaches                 | _____ | _____ |
| 2. Dizziness/light-headed    | _____ | _____ |

**APPENDIX B**  
**Scoring Template for the BC-PSI**

**SYMPTOM CLASSIFICATION**

<b>SYMPTOM/PROBLEM</b>	<b>PRODUCT</b>	<b>ITEM SCORE</b>	<b>NONE</b>	<b>MILD</b>	<b>MODERATE</b>
Headaches					
Dizziness/light-headed					
Nausea/feeling sick					
Fatigue					
Extra sensitive to noises					
Irritable					
Sad					
Nervous or tense					
Temper problems					
Poor concentration					
Memory problems					
Difficulty reading					
Poor sleep					
Total Score	—		—	—	—

**Step 1:** Multiply the frequency rating by the severity rating and enter value in the “Product” column (e.g., 2 x 3 = 6).  
**Step 2:** Convert product score to “Item Score” based on the following: Product = 0–1, Item score = 0; Product = 2–3, Item Score = 1; Product = 4–6, Item Score = 2; Product = 8–12, Item Score = 3; Product = 15+, Item Score = 4. Enter the Item scores into the grid. **Step 3:** Sum the Item Scores for the Total Score. **Step 4:** Place an “X” in the appropriate classification range for each symptom based on the following “Item Score” criteria: 0 = None, 1–2 = Mild, and 3+ = Moderate or greater. Total Scores: 0 = “Low”, 1 – 9 = “Normal”, 10 – 14 = “Unusually High”, and 15+ = “Extremely High” relative to *healthy adults*.

## Sport-Related Concussion

*Michael W. Collins*  
*Grant L. Iverson*  
*Michael Gaetz*  
*Mark R. Lovell*

**C**oncussion is a common injury in sport (1–11). Moreover, these injuries might be more prevalent than initially thought because some concussions may go unrecognized (12). Injuries without loss of consciousness (LOC) occur most frequently; in fact, approximately 90% of concussions in sport occur without LOC (13–15). Because most concussions lack the dramatic on-field nature of those with LOC, they are typically more difficult to detect and might be under-diagnosed by sports medicine practitioners (16). The importance of accurate diagnosis, management, and return-to-play decisions extends from the elite ranks of professional athletes to the child or adolescent athlete. This chapter, designed to be a comprehensive overview, is divided into the following eight sections: (a) definition of concussion, (b) pathophysiology, (c) injury severity markers (signs), (d) symptoms, (e) structural and functional neuroimaging, (f) neuropsychological outcome, (g) cumulative effects, (h) recovery time and return to play decision-making, and (i) conclusions.

### DEFINITION OF CONCUSSION

There has not been a universally-accepted definition of concussion. Traditionally, the most widely accepted definition has been that proposed by the Committee on

Head Injury Nomenclature of Neurological Surgeons in 1966 (17). That committee defined concussion as: “a clinical syndrome characterized by the immediate and transient post-traumatic impairment of neural function such as alteration of consciousness, disturbance of vision or equilibrium, etc., due to brain stem dysfunction.”

More recently, many clinicians and researchers currently use the definition of concussion described by the American Academy of Neurology (AAN): “Concussion is a trauma-induced alteration in mental status that may or may not include a loss of consciousness” (18, p. 582). This definition was prompted by the belief of the AAN definition authors that previous definitions may be too limiting because the injury is not restricted to the brain stem and may involve other brain structures (e.g., cortical areas). This definition also served to emphasize the fact that concussion may occur with or without a loss of consciousness.

In 2001, and most recently in 2004, an International Symposium on Concussion in Sport was held where concussion experts from around the world met to discuss specific issues related to the injury. One major outcome of these symposia was the adoption of a global definition of concussion that improved upon previous definitions. The current definition is as follows: “Sports concussion is defined as a complex pathophysiological process affecting the brain, induced by traumatic biomechanical forces”

(19, p. 196). In addition to this definition, the features listed below were outlined.

1. "Concussion may be caused either by a direct blow to the head, face, neck, or elsewhere on the body with an "impulsive" force transmitted to the head.
2. Concussion typically results in the rapid onset of short-lived impairment of neurological function that resolves spontaneously.
3. Concussion may result in neuropathological changes, but the acute clinical symptoms largely reflect a functional disturbance rather than structural injury.
4. Concussion results in a graded set of clinical syndromes that may or may not involve loss of consciousness. Resolution of the clinical and cognitive symptoms typically follows a sequential course.
5. Concussion is typically associated with grossly normal structural neuroimaging studies." (19, p. 196)

### PATHOPHYSIOLOGY

The pathoanatomy and pathophysiology of mild traumatic brain injury (MTBI) is reviewed, in detail, in the mild traumatic brain injury chapter in this book. In that chapter, it was described that brain injuries produced by acceleration/deceleration forces occur along a continuum of severity dependent upon the mechanical forces that caused them (20, 21). Concussion in athletes is typically produced by acceleration/deceleration forces (e.g., helmet to helmet contact in North American football or helmet to ice contact in ice hockey). Concussion can be considered an injury at the mild end of the MTBI continuum with LOC (when it occurs) and posttraumatic amnesia being considerably more brief in duration, and with low levels of axonal stretch. This limited axonal stretching can initiate a pathophysiologic process that leads to very limited cell death (largely dependent on the morphology of the cell) but in the vast majority of cells leads to a reversible series of metabolic events.

Giza and Hovda (22) describe the complex interwoven cellular and vascular changes that occur following concussion as a multilayered neurometabolic cascade. The primary mechanisms include ionic shifts, abnormal energy metabolism, diminished cerebral blood flow, and impaired neurotransmission. A brief summary of this process, derived from several sources (22, 23), is provided below.

Stretching of an axon results in an indiscriminate release of neurotransmitters and uncontrolled ionic fluxes. When ionic gradients are disrupted, cells respond by activating ion pumps in an attempt to restore the normal membrane potential. Pump activation increases glucose utilization. This contributes to dramatic increases in the local cerebral metabolic rate for glucose. This

hypermetabolism occurs in tandem with decreased cerebral blood flow, which contributes to the disparity between glucose supply and demand. There also appears to be impaired oxidative metabolism and diminished mitochondrial function, resulting in the over-utilization of anaerobic energy pathways and elevated lactate as a by-product. Moreover, intracellular magnesium levels appear to decrease significantly and remain depressed for several days following injury. This is important because magnesium is essential for the generation of adenosine-triphosphate (ATP – energy production). Magnesium is also essential for the initiation of protein synthesis and the maintenance of the cellular membrane potential. A sustained influx of  $Ca^{2+}$  can result in mitochondrial accumulations of this ion contributing to metabolic dysfunction and energy failure. High intracellular  $Ca^{2+}$  levels, combined with stretch injury, can initiate an irreversible process of destruction of microtubules within axons.

Fortunately, the brain undergoes a dynamic restorative process in the initial days to weeks following a concussion. From a commonsense perspective, the ionic shifts, abnormal energy metabolism, diminished cerebral blood flow, and impaired neurotransmission believed to be associated with concussions in sports reinforces the importance of immediate rest following injury. Although not established empirically, it seems reasonable to assume that vigorous exercise or hard physical contact might exacerbate the pathophysiology described above.

### INJURY SEVERITY MARKERS (SIGNS)

Appropriate acute care and management of the concussed athlete begins with a detailed and accurate assessment of the severity of the injury. As with any serious injury, the first priority is always to evaluate the athlete's level of consciousness and ABCs (airway, breathing, and circulation). The attending medical staff must always be prepared with an emergency action plan in the event that the evacuation of a critically head-or neck-injured athlete is necessary. This plan should be familiar to all staff, be well delineated, and frequently rehearsed.

#### Loss of Consciousness

Upon ruling out more severe injury via neurological and clinical examination, the acute evaluation continues with the assessment of concussion. First, the clinician should establish whether a loss of consciousness (LOC) has occurred. By definition, LOC represents a state of brief coma in which the eyes are typically closed and the athlete is unresponsive to external stimuli. LOC is relatively uncommon and reportedly occurs in less than 10% of concussive injuries in most (13–15), but not all (24) studies. Moreover, prolonged LOC (>1–2 minutes) in sport-related

concussion occurs much less frequently. Athletes with LOC are typically unresponsive for only a brief period of time, sometimes only one to two seconds. This may at times make LOC difficult to identify because the response of medical personnel to injured athletes is beyond this time window.

Although many of the concussion grading and management scales rely heavily upon the presence or absence and duration of loss of consciousness, research on the relation between LOC and outcome is mixed. Large scale studies with trauma patients have not revealed a relation between LOC and neuropsychological outcome (e.g., 25, 26). Some researchers examining athletes with concussions have reported an association between LOC and immediate or short-term outcome (e.g., 24, 27, 28), while others have not (e.g., 29, 30).

### Confusion

A more common form of mental status change following concussion involves confusion and amnesia. Confusion (i.e., disorientation), by definition, represents impaired awareness and orientation to surroundings, though memory systems are not necessarily directly affected. An athlete with post-injury confusion will typically appear stunned, dazed, or “glassy-eyed” on the sideline or playing field. Confusion is often manifested in athletes who do not remove themselves from play in the form of difficulty with appropriate play-calling, failure to correctly execute their positional assignment during play, or difficulty in communicating game information to teammates or coaches. Teammates are often the first to recognize that an athlete has been injured when the athlete shows these behaviors and has difficulty maintaining the flow of the game. On the sidelines, confused athletes may answer questions slowly or inappropriately, ask “what is going on” or “what happened,” and may repeat himself or herself during evaluation. Some may be temporarily disoriented to time or place, and even, very rarely, to people they know well (e.g., not knowing coaches or teammates). To properly assess the presence of confusion, medical personnel can ask the athlete simple orientation questions such as the date, and names of the stadium, city, and opposing team. Please see Table 24-1 for a list of orientation questions extracted from the University of Pittsburgh Medical Center’s Concussion Card.

### Amnesia

Amnesia is emerging as perhaps the most important sign to carefully assess following concussion (after more serious injuries have been ruled out). Amnesia due to concussion may present as retrograde amnesia (difficulty with memory of events prior to the injury) or post-traumatic/ anterograde amnesia (difficulty with memory for events

following the injury). Both forms of amnesia should be assessed thoroughly. Athletes who present with one or both types of amnesia may initially have difficulty recalling large spans of time before the injury, after the injury, or both. These larger periods of amnesia typically shrink as the injury becomes less acute. The presence and duration of amnesia, disorientation, or mental status disturbance has been associated with immediate outcome or slower recovery (24, 28, 29, 31, 32) in many, but not all studies (e.g., 30).

Post-traumatic amnesia and anterograde amnesia are synonymous terms that represent the duration of time between the head trauma (for example, an ice hockey player’s forehead striking the boards) and the point at which the athlete reports a return of normal continuous memory functioning (e.g., remembering the athletic trainer asking the athlete orientation questions in the locker room). One method for assessing post-traumatic confusion and amnesia is provided in Table 24-1 (UPMC Concussion Card Mental Status Testing).

At times, especially during a sideline assessment, confusion and post-traumatic amnesia may be difficult to disentangle. It is important to remember that confusion is not necessarily associated with a loss of memory, whereas

**TABLE 24-1**

*University of Pittsburgh Medical Centers’  
Sideline Concussion Card: Acute (sideline  
or on-field) Mental Status Testing*

**On-Field Cognitive Testing**

Orientation (ask the athlete the following questions)

- What stadium is this?
- What city is this?
- Who is the opposing team?
- What month is it?
- What day is it?

*Post-Traumatic Amnesia (ask the athlete to repeat the following words)*

- Girl, dog, green

*Retrograde Amnesia (ask the athlete the following questions)*

- What happened in the prior quarter or half?
- What do you remember just prior to the hit?
- What was the score of the game prior to the hit?
- Do you remember the hit?

*Concentration (ask the athlete to do the following)*

- Repeat the days of the week backward, starting with today
- Repeat these numbers backward (63) (419)

*Word list memory*

- Ask the athlete to repeat the three words from earlier (girl, dog, green)

amnesia is only present with a loss of memory. This memory loss may span only a few seconds or minutes. It sometimes can span several hours, but rarely exceeds a day. A practitioner may be unable to differentiate confusion and amnesia until the athlete's confusion has resolved. Only then can memories surrounding the injury actually be discussed. Once the athlete is more lucid, the practitioner may gain additional insight into any existing post-traumatic amnesia by asking the athlete to recall the events that occurred immediately following the trauma (e.g., rising from the ground, walking/skating to sideline, memory for any part of the game played or observed after the injury, memory for the score of the contest, memory of the ride home, and so on). Post-traumatic amnesia is inferred by failure to remember events following the injury.

Retrograde amnesia is defined as the inability to recall events before the head trauma. Commonly used questions to assess retrograde amnesia are presented in Table 24-1. Medical personnel may ask for the athlete's memory of the actual injury (e.g., seeing a linebacker charge toward him with his helmet down, then falling backward and striking the back of his head to the ground). Then, additional questions can probe events that are increasingly remote from the injury (e.g., the score at the beginning of the first quarter, coming onto the field for stretching exercises, and getting dressed in the locker room). The length of retrograde amnesia will typically "shrink" over time. As recovery occurs, the period of retrograde amnesia may shrink from several minutes to a few seconds (in rare cases an athlete will have retrograde amnesia for hours or days). The presence and duration of retrograde amnesia has been associated with worse initial presentation and with slower recovery (27–29, 31).

## SYMPTOMS

The initial signs and symptoms of concussion vary from athlete to athlete, depending on the biomechanical forces

involved, specifically-affected brain areas, athletes' prior history of injury, and other factors. A summary of common on-field signs and symptoms of concussion is presented in Table 24-2. It is important to note that an athlete may present with as few as one symptom of injury or potentially a constellation of symptoms.

Headaches and dizziness are the most commonly reported symptoms of injury (9, 13). Moreover, headaches lasting more than three hours post injury (27), those present at seven days post injury (32), or those that are migraine-like (33) have been associated with slow recovery. However, the absence of headache does not rule out a concussion, highlighting the importance of a thorough assessment of all symptoms. Assessment of post-concussion headache may be complicated by the presence of musculoskeletal headaches and other pre-existing headache syndromes (e.g., migraine disorder or frequent stress headaches).

Most frequently, a "concussion headache" is described as a sensation of pressure in the skull that may be localized to one region of the head or may be generalized in nature. In some athletes (particularly athletes with a history of migraine), the headache may take the form of a vascular headache, may be unilateral, and is often described as throbbing or pulsating. The headache may not develop immediately after injury and may develop in the minutes, or even hours, following injury. Therefore, it is important to question the potentially concussed athlete regarding the development of symptoms beyond the first few minutes after injury. Post-concussion headache is often worsened with physical exertion. Thus, if the athlete complains of worsening headache during exertional testing or return to play, post-concussion headache should be suspected and conservative management is indicated. While headache following a concussion usually does not constitute a medical emergency, a severe or progressively severe headache, particularly when accompanied by vomiting or rapidly declining mental status, may signal a life-threatening situation such as a subdural hematoma or

**TABLE 24-2**

*University of Pittsburgh Medical Center's Sideline Concussion Card: Signs and Symptoms of Concussion*

SIGNS OBSERVED BY STAFF	SYMPTOMS REPORTED BY ATHLETE
Loses consciousness	Feeling "foggy" or groggy
Forgets events prior to play (retrograde)	Change in sleep pattern (appears later)
Forgets events after hit (post-traumatic)	Feeling Fatigued
Appears to be dazed or stunned	Headache
Is confused about assignment	Nausea
Forgets plays	Balance problems or dizziness
Is unsure of game, score, or opponent	Double or fuzzy/blurry vision
Moves clumsily	Sensitivity to light or noise
Answers questions slowly	Feeling sluggish or slowed down
Shows behavior or personality change	Concentration or memory problems

intracranial bleed. This should prompt immediate transport to hospital and a CT scan of the brain.

In addition to headaches, many other symptoms may emerge as a result of concussive injury. For example, athletes will commonly experience blurred vision, changes in peripheral vision, or other visual disturbance. Moreover, an athlete may report increased fatigue, “feeling a step slow,” or feeling sluggish. Fatigue is especially prominent in concussed athletes in the days following injury and this symptom may be as prominent as headache. Also, athletes may report cognitive changes, including problems with attention, concentration, short-term memory, learning, and multitasking. These symptoms sometimes become more noticeable after the athlete has returned to school or work.

Another frequently reported symptom which has gained recent research attention is a reported sensation of feeling “foggy” following concussion (34). In this study, a sample of concussed high school students who endorsed feeling “foggy” on a symptom inventory were compared to concussed high school athletes who did not endorse a sense of “fogginess.” At one-week post injury, the foggy group demonstrated significantly slower reaction times, attenuated memory performance, and slower processing speed via computerized neurocognitive testing. In addition, the “foggy” athletes also endorsed a significantly higher number of other post-concussion symptoms when compared to the group who did not endorse fogginess.

Another commonly reported or observed symptom is that of emotional changes. Most often, athletes will report increased irritability, or having a “shorter fuse.” However, other emotional changes may occur such as sadness/ depression, nervousness/ anxiety, or even (much less commonly) silliness or euphoria. Affect may be described by the athlete or parent as flattened or labile. Emotional changes may be very brief (e.g., a linebacker bursts into tears for 30 seconds on the sideline) or may be prolonged in the case of a more significant injury (athlete reports persistent depression).

### STRUCTURAL AND FUNCTIONAL NEUROIMAGING

Given that concussion is largely a metabolic and not a structural injury, traditional neuroimaging techniques such as CT or MRI are almost always unremarkable following a single concussion. Despite this fact, these techniques are useful for ruling out more serious pathology (e.g., cerebral bleed or skull fracture) that occasionally occur in sports-related head injuries. Athletes most likely to show abnormalities on structural neuroimaging are boxers. This is not particularly surprising because historically damage could be seen with the naked eye at

autopsy (35). Studies on professional boxers, active and retired, have revealed the greatest number of CT abnormalities estimated to be between 25–50% (36–39). In these boxers, a cavum septum pellucidum was considered a CT sign of traumatic encephalopathy (40). CT abnormalities were correlated with the number of bouts fought (41) and were estimated to be less frequently observed in amateur boxers [between 0 and 20% had abnormalities (42–44)]. In addition to boxing, Sortland and Tysvaer (45) reported that approximately 33% of a sample of retired Norwegian international soccer players had widening of the lateral ventricles suggesting some form of generalized cerebral atrophy.

Magnetic resonance imaging (MRI) studies on boxers show a similar pattern of results as those using CT with the exception that MRI was able to detect subdural hematoma, white matter changes, and focal contusion not detected using CT (38, 46). MRI studies on young or amateur boxers consistently showed no change as a result of participation in their sport (42, 47, 48).

Recently, functional MRI (fMRI) and blood oxygen level dependent (BOLD) activity has been used to learn about the functional changes that can occur following concussion. One study compared symptomatic concussed athletes to a university student sample using a working memory task. Concussed athletes had areas of decreased activation compared to controls, such as the mid-dorsolateral prefrontal cortex. In addition, there was activation of regions beyond those of the control subjects in both temporal and parietal lobes (49). A prospective study on a small number of concussed athletes revealed differences from baseline brain activity using a number of cognitive tasks. Specifically, there was an increase in regions that were activated compared to baseline with greater signal intensity in these areas compared to baseline. Concussion induced differences in neural functioning were observed in the absence of behavioral deficits (50). These two small fMRI studies differed in methodology (between versus within subject designs) and in some of the results provided. There were two similarities: (a) Concussed athletes had a greater number of brain regions activated following concussion than did non-injured controls or the same athletes at baseline. This finding is consistent with recruitment of brain areas beyond those normally expected following concussion. (b) Both studies showed areas with greater levels of activation following concussion, however, Chen et al. reported a reduction in frontal lobe activity associated with working memory.

There are also few positron emission tomography (PET) and single photon emission computerized tomography (SPECT) studies on concussed athletes. The limited data on concussion in athletes suggests a pattern of frontal hypoactivation following injury. In amateur boxers, rCBF values were reported to be within the normal range while professional boxers had flow values that were

below normal (51), especially in frontocentral regions (52). Other studies have revealed hypoperfusion in boxers (53). In general, there are differences in subjects and methodologies across studies that likely contribute to some of the discrepant findings. Nonetheless, there is some consistency across studies on blood flow following concussion suggesting hypoperfusion in the frontal lobes.

The electroencephalogram (EEG) has also been used to study concussion in athletes. Standard clinical EEG assessments revealed abnormalities associated with several years of involvement in boxing and soccer (e.g., 54–56). More recently, preliminary evidence for amplitude reductions across all standard frequency bands, especially during standing postures, were reported in 12 recently concussed athletes who were asymptomatic at the time of assessment (57). Similar reductions in gamma band activity were observed during a movement paradigm requiring a 50% maximal voluntary contraction (58).

In addition to EEG, there are a growing number of cognitive event-related potential (ERP) studies on concussed athletes. Although preliminary, the results suggest that these techniques may be of considerable benefit for the assessment of a single concussive event. One of the ERPs used in these studies was the N2/P3 or P300 response, a series of averaged EEG responses time-locked to a stimulus, with positive or negative peaks associated with different cognitive processes. P3 peak amplitude is believed to index allocation of attention (59, 60), while latency is related to stimulus evaluation and categorization time (61), transfer of information to consciousness and memory systems (60), and stimulus saliency (62).

Studies that used an auditory P3 paradigm have yielded mixed results. In one of these studies, five boxers were examined before and after a fight. Although several of the peaks showed no change in latency or amplitude, decreased amplitude was observed for the N2b peak (which precedes the P3 response) following the fights (63). Another study on amateur boxers reported no differences for auditory P3 latency or amplitude (64). In contrast, visual N2/P3 studies have yielded more consistent findings (65). In concussed athletes that were symptomatic, significant reductions in visual P3 amplitude were reported compared to recently concussed but asymptomatic athletes and never concussed athletes (66, 67). In addition, longer visual P3 peak latencies were correlated with self-reported attention and memory deficits in athletes with three or more concussions (68).

ERPs that precede movement have also been used experimentally to assess concussion in athletes. One of these studies showed negative results (68). Others have reported preliminary evidence for amplitude reductions using small numbers of concussed athletes in using a postural paradigm (69) and a movement paradigm requiring a 50% maximal voluntary contraction (58). Therefore, the electrophysiologic studies to date, while

experimental and preliminary, have revealed differences in brain function for some athletes with suspected cumulative effects, those who are symptomatic, and those with residual brain dysfunction beyond that indicated by self-reported symptoms.

## NEUROPSYCHOLOGICAL OUTCOME

Many athletes with concussions have neurocognitive decrements as measured by traditional paper-pencil and computerized neuropsychological tests in the initial hours, days and potentially weeks post injury (15, 16, 24, 30, 70–76). In terms of group data, it has become a fairly robust finding that athletes tend to recover in terms of perceived symptoms and neuropsychological test performance within 2–14 days (1, 14, 15, 24, 77, 78).

In an NCAA prospective cohort study (14), 1,631 football players from 15 colleges completed preseason baseline testing during the 3 year study. Players with concussions ( $n = 94$ ) and noninjured controls ( $n = 56$ ) underwent assessment of symptoms, cognitive functioning, and postural stability immediately, 3 hours, and 1, 2, 3, 5, 7, and 90 days after injury. Concussed athletes' balance problems resolved within 3–5 days, self-reported postconcussion symptoms gradually resolved by day 7, and neurocognitive functioning improved within 5–7 days. By seven days post injury, 91% of athletes returned to personal baseline levels of symptom reporting.

Collins, Lovell, and Iverson recently have analyzed the results from a three-year, prospective, naturalistic, cohort study of high school football players. Participants were 2,141 high school athletes from Western Pennsylvania. During this 3-year study, 136 concussions were recorded and these athletes were carefully followed, clinically, until they were cleared to return to competition. The recovery rates were as follows: 1 week = 45%, 2 weeks = 73%, 3 weeks = 82%, 4 weeks = 91%, and 5 weeks = 97%. Thus, individual variability exists with recovery from sports concussion, especially in high school athletes, and the duration of symptoms can persist well beyond two weeks post injury.

Results from a six-year, prospective, National Football League concussion study have been published in a series of eight articles (9, 28, 78–83). A total of 887 concussions were recorded in 650 players during the study period. The time taken to return to play was as follows: (1) day of injury = 56.0%, (2) 1–6 days = 35.9%, (3) 7–14 days = 6.5%, and (4) more than 14 days = 1.6% (28). Those athletes who returned to play in the same game had fewer and briefer signs and symptoms of concussion, and they did not appear to have significantly increased risk for a second injury either in the same game or during the season (83).

A subset of concussed NFL players underwent baseline neuropsychological evaluations and then completed

a second evaluation ( $N = 95$ ) within a few days following their concussion ( $M = 1.4$  days,  $SD = 1.3$ ; (79)). The players did not show a single statistically significant decrement on any neuropsychological test when seen in the first few days post injury. These results, of course, are inconsistent with studies in both collegiate and high school athletes, where neurocognitive decrements are more pronounced. These results might reflect a selection bias (NFL athletes exhibit more rapid recovery, perhaps due to genetics/biological hardiness), or that age, and developmental factors may play a role in recovery from concussion. In fact, results from a recent study suggested that high school athletes might have slower recovery from concussive injury when compared to a matched collegiate sample (84).

In regards to cumulative effects, NFL athletes with a history of three or more concussions did not perform more poorly on neuropsychological testing than those with fewer than three (78). This finding, too, appears somewhat inconsistent with studies involving amateur athletes. Researchers have reported that three or more concussions in high school and university athletes are associated with small but measurable cumulative effects (34, 68, 85), and increased risk for future concussions (86, 87).

### CUMULATIVE EFFECTS

Athletes, their families, coaches, athletic trainers, and sports medicine professionals are concerned about possible lingering effects, or permanent brain damage, resulting from multiple concussions. The literature on cumulative effects will be reviewed in detail in this section. When considering repeated subconcussive and concussive blows to the head, the most obvious athlete group to study is boxers. Few would debate that a *career* in boxing can result in obvious changes to the structure and function of the brain (38, 88–92). However, this may not be the case with amateur boxers. Professional boxing differs from amateur boxing in a number of ways: amateur boxers are typically not the elite in their weight-class, use headgear and larger gloves, and have fewer rounds per fight. Therefore, it is not surprising to observe differences between amateur and professional boxers, for example, on measures such as whole brain regional cerebral blood flow (rCBF) (51, 52).

Taken as a whole, studies on *amateur* boxers have offered mixed results regarding changes in brain structure and function. Significant changes in cerebral perfusion have been reported in amateur boxers compared to non-boxing athletic controls (53). On the other hand, a series of studies by Haglund and colleagues that compared high and low match amateur boxers versus athlete and non-athlete controls reported no differences on a mini-mental status

examination or platelet MAO activity (93), magnetic resonance imaging (MRI) or computed tomography (CT) (42), neuropsychologic testing (64), or auditory evoked or event-related potentials, with only slight or moderate electroencephalographic (EEG) deviations between high match boxers and athletic controls (94). Similarly, Porter (95) observed no statistical change in a group of 19 amateur boxers over a period of nine years using neuropsychologic testing compared to non-boxing athletic controls.<sup>1</sup>

The literature on subconcussive blows to the head in other sports is also mixed. Some studies reported neuropsychological decrements (75) or temporary adverse effects immediately following repeatedly heading a soccer ball during practice (96). Other studies such as those associated with heading the soccer ball, tournament boxing,<sup>2</sup> or springboard diving generally suggest no statistically significant neuropsychological (6, 97–100) or balance effects (101).

Although the evidence regarding subconcussive effects is somewhat unclear, there is some evidence that a history of three or more concussions is associated with changes in cognitive neurophysiology (68), subjective symptoms (68, 102), and neuropsychological test performance (102). Furthermore, athletes with three or more concussions may be at increased risk of sustaining a future concussion (86), have worse on-field presentations of their next concussion (85), are more likely to have slowed recovery (86), and have greater acute changes in memory performance (102).

The literature regarding the persistent effects of two previous concussions is mixed. In regards to possible long-term effects, some researchers have reported significant findings (16, 103), others have not (68), and others reported equivocal results (e.g., 104). Further, no differences were observed on neuropsychological testing or symptom reporting for those with one versus two concussions (105). In a large-scale study, athletes with one or two previous concussions did not differ on neuropsychological testing or symptom reporting from athletes with no previous concussion on baseline, preseason testing (106). There is, however, preliminary evidence that athletes with two previous concussions have slower recovery times (86).

The studies indicating little or no change associated with subconcussive effects in boxers should be considered preliminary because they examine change over a short time frame (up to nine years) and do not take into account the possibility of long-term effects. This is important

<sup>1</sup> Sixty-six percent of the controls in this study were involved in some form of football with 28% reporting concussions.

<sup>2</sup> The study on boxers did not include those whose bout was stopped by the referee or those with epitaxis; boxers in these groups had increased simplex and choice reaction times compared to controls.

because the symptoms associated with chronic traumatic encephalopathy in boxers often show up later in life (107, 108). Similarly, the findings to date on three or more concussions should be considered preliminary – much additional research is needed because the aforementioned studies all have significant limitations in terms of methodology, generalizability, or both.

### Pathophysiology of Cumulative Effects

Given that there is general agreement regarding the existence of some form of cumulative effects in some athletes, the question can be asked: What is the pathophysiologic basis of these injuries? Specifically, are the changes based in the functioning of previously injured neurons, genetic differences related to the susceptibility to cumulative effects, or some other form of measurable permanent change?

Researchers have reported that axons of cultured human neurons have a remarkable capacity for stretch with no primary axotomy observed with strains below 65% of the length of the axon. In addition, axons exhibit the behavior of “delayed elasticity”. In other words, stretch causes a temporary deformation that gradually returns to the original orientation and morphology even though internal axonal damage was sustained (109). Once stretched, a pathophysiologic process begins that can lead to further structural change and metabolic dysfunction. First, strain on the axonal membrane causes an abnormal influx of  $\text{Na}^+$  through mechanosensitive sodium channels, a reversal of the  $\text{Na}^+$ - $\text{Ca}^{2+}$  exchangers, and activation of voltage gated  $\text{Ca}^{2+}$  channels (110). This in turn causes selective proteolysis or a breakdown of  $\text{Na}^+$  channels and progressively increasing levels of intra-axonal  $\text{Ca}^{2+}$  (111). It is the massive influx of  $\text{Ca}^{2+}$  that leads to damage to the axonal cytoskeleton and initiates the formation of axonal swellings.

Using an animal optic nerve stretch model, it was determined that stretch below four mm did not cause any morphological change in axons, a stretch of five mm produced changes in visual evoked potentials that were significantly different from controls, with six mm stretch causing morphological change including retraction balls and axonal swellings (112). Therefore, there appears to be a progression following a single injury from no apparent change in structure or function, to functional change, to structural change in the axon based on the extent of stretch. However, researchers have reported that repetitive mild injuries using similar or *lower* levels of force than those used to produce single mild injuries caused a greater number of structural and functional changes. For example, when comparing animals that received two mild injuries (using lower levels of force) to those that sustained a single mild injury, the number of foci with injured axons in the frontal lobes was significantly

greater in the two injury group (113). In another study, two consecutive mild brain injuries three days apart produced a similar biochemical pattern as found in severe TBI while those separated by five days appeared as two distinct mild injuries (114). This study points out the possibility of a “critical window” where subsequent mild re-injury can lead to significant pathophysiological change. Further, repeated mild injuries have been shown to cause sublethal but significant biochemical markers of cellular injury and the production of neurites with a beaded and damaged appearance. In this study, it was noted that cells undergoing repeated injury resembled those that sustained a single injury produced with greater magnitudes of stretch (115).

Human studies on the pathophysiology of repeated mild injury are limited to case studies, usually in retired athletes with suspected permanent and significant brain damage (i.e., “chronic traumatic brain injury,” “dementia pugilistica,” or “punch-drunk syndrome”), a distinct clinical entity from Parkinsonism (116). Former athletes, usually boxers, with this serious condition often have slurred speech, ataxic gait, memory impairment, personality changes, and Parkinsonism. An autopsy on two boxers with repetitive brain injury related to participation in contact sport revealed neuronal cytoskeletal changes (117).

The preliminary evidence on cumulative effects has led some to ask whether athletes are at risk for developing dementia due to participation in their sport (118) and whether there is a genetic basis for cumulative effects (89)? These questions have evolved mostly from the sport of boxing. One of the more comprehensive studies on this topic assessed brain damage in 30 boxers with varying age and experience. All three boxers who exhibited evidence of severe brain damage or dysfunction had at least one copy of the APOE  $\epsilon 4$  allele. This is compared with 50% of those with moderate damage, 25% of those with mild damage, and 18% of those with normal examinations. In addition, it was reported that there may be neuroprotective features associated with having the APOE  $\epsilon 2$  allele (107). Kutner and colleagues reported that as a group, older players who had the APOE  $\epsilon 4$  allele performed worse on cognitive testing than did all other players including those of the same age and younger players with the APOE  $\epsilon 4$  allele (119).

Beyond studies on the genetic make-up of athletes, there is preliminary evidence that neuronal DNA itself can be altered following mild injuries in animals. Following MTBI in rats, cells with condensed nuclei, chromatin, and shrunken and round cell bodies were observed. On occasion these cells contained what appeared to be apoptotic cell bodies (120). Regarding cumulative effects, increased vulnerability of stretched neurons to a secondary insult (e.g., physical or biochemical) was associated with the production of reactive oxygen species (ROS) that were

produced even when the stretch was sub-lethal. For example, the combination of mitochondrial ROS (superoxide) and nitric oxide (NO) into peroxynitrite leads to protein nitration, DNA degradation, and cell death. The DNA fragmentation seen in these cells was not considered apoptotic but was attributable to damage by reactive nitrogen species (121).

### Second Impact Syndrome

Second impact syndrome is related to an *extraordinarily rare* cascade of events in which an athlete experiences a catastrophic brain injury following a seemingly mild concussion. In theory, sustaining a second brain injury during a period of increased vulnerability with unresolved metabolic dysfunction has been linked to second impact syndrome. The pathophysiologic basis for second impact syndrome is thought to be cerebrovascular congestion or a loss of cerebrovascular autoregulation leading to considerable brain swelling and edema (122, 123). It has been reported that relatively few athletes, approximately 35 or more in the years between 1980 and 1993, have succumbed to this syndrome (122). When it occurs, morbidity is 100% and mortality is reported to occur in up to 50% of cases (122). To date, most cases of second impact syndrome have been reported in children (e.g., 124) or adolescents (125, 126). Recent animal modeling has indicated that a single mTBI revealed transient and minimal impairment on a composite neuroscore test and minimal breach of the blood brain barrier. If a second mild injury was inflicted within 24-hours of the first injury, a marked breakdown of the blood brain barrier occurred leading to swelling and edema (127). This change in blood brain barrier integrity following a second concussive injury occurring shortly after the first may be a possible mechanism for the rapid swelling and edema formation that occurs in humans.

### RECOVERY TIME AND RETURN TO PLAY DECISION-MAKING

Though significant individual variability exists in recovery from concussion, most group studies have indicated that a single concussion typically resolves in less than two weeks for most athletes (1, 14, 15, 24, 31, 77, 78). Current clinical experience and research has suggested that proper management of concussion should lead to a good prognosis in the vast majority of athletes. Most sports medicine researchers and professionals agree that returning an athlete to contact sport participation prior to complete recovery might increase the risk of poor outcome. Thus, the most important step a practitioner can take toward a positive prognosis is proper assessment and

management of concussion in the acute and follow-up stages of injury.

### Concussion Grading Scales

Traditionally, return to play decisions were based partially on concussion grading scales that served to classify individual injuries according to severity and offer return to play guidelines. During the past thirty years, over twenty concussion management guidelines have been published with the intent of providing guidance and direction for the sports-medicine practitioner in making complex return to play decisions. The authors of each of these guidelines also provided an accompanying grading scale designed to reflect and characterize the severity of the injury. Although these guidelines have very likely resulted in improved care of the athlete, these multiple directives also created significant confusion and sparked almost continuous debate. A historical review of all past and current concussion guidelines is beyond the scope of this chapter, however, brief review of four of the more popular guidelines is provided in Table 24-3.

Cantu originally proposed his grading scale and management guidelines based on clinical experience (128). However, Cantu was careful to emphasize that these guidelines were intended to supplement rather than replace clinical judgment. The original Cantu guidelines allowed return to play the day of injury if the athlete was symptom free both at rest and following physical exertion. For athletes who experienced any loss of consciousness (e.g., grade 3 concussion), a restriction of contact for one month was recommended. Athletes who had suffered a Grade 2 concussion were allowed to return to play in two weeks, if asymptomatic for a period of 7 days.

The Colorado Guidelines (125) were published in 1991 following the death of a high school athlete due to presumed Second Impact Syndrome and were drafted under the auspices of the Colorado Medical Society. These guidelines allowed for same day return to play if symptoms cleared within 20 minutes of injury. For Grade 3 concussion, these guidelines recommended immediate transport to a hospital for further evaluation. These guidelines were later revised under the sponsorship of the American Academy of Neurology (18). The AAN guidelines allowed return to competition the same day of injury if the athlete's signs and symptoms cleared within 15 minutes of injury. Grade 2 concussion was managed in a manner similar to the Colorado Guidelines, with return to competition within one week, if asymptomatic.

More recently, Cantu has amended his guidelines to emphasize the duration of post-traumatic symptoms in grading the severity of the concussion and making return to play decisions (129). Grade 1 concussion was redefined by an absence of loss of consciousness, and post-concussion

**TABLE 24-3**  
**Recent Concussion Grading Scales**

GUIDELINE	GRADE 1	GRADE 2	GRADE 3
Cantu (133)	1. No loss of consciousness 2. Posttraumatic amnesia last less than 30 minutes	1. Loss of consciousness lasts longer than 5 minutes OR 2. Posttraumatic amnesia lasts longer than 30 minutes	1. Loss of consciousness lasts longer than 5 minutes OR 2. Posttraumatic amnesia lasts longer than 24 hours
Colorado (125)	1. Confusion without amnesia 2. No loss of consciousness	1. Confusion with amnesia 2. No loss of consciousness	1. Loss of consciousness (of any duration)
AAN (18)	1. Transient confusion 2. No loss of consciousness 3. Concussion symptoms mental status changes resolve in less than 5 minutes	1. Transient confusion 2. No loss of consciousness 3. Concussion symptoms or mental status change lasts longer than 15 minutes	1. Loss of consciousness (brief or prolonged)
Cantu (129)	1. No loss of consciousness  OR 2. Posttraumatic amnesia or signs/symptoms lasts longer than 30 minutes	1. Loss of consciousness lasts less than 1 minute  OR 2. Posttraumatic amnesia lasts longer than 30 minutes but less than 24 hours	1. Loss of consciousness lasts more than 1 minute  OR 2. Posttraumatic amnesia lasts longer than 24 hours OR 3. Post-concussion signs or symptoms last longer than 7 days

signs or symptoms lasting less than 30 minutes. Same day return to competition was allowed only if the athlete was completely asymptomatic following the injury.

The above mentioned management guidelines reached their peak popularity during the 1980's and 1990's. However, in the late 1990's, sports medicine practitioners and organizations began to question the scientific basis of these guidelines (130). This trend prompted the American Orthopaedic Society for Sports Medicine (AOSSM) to sponsor a workshop with the purpose of re-evaluating current guidelines and establishing practical alternatives (131). Although the AOSSM guidelines did not differ substantially from prior guidelines, this workshop started a trend away from the use of a numeric grading systems for determination of return to play following concussion (e.g., as developed by the Cantu, Colorado, and AAN guidelines). The AOSSM guidelines stressed more individualized management of injury, rather than applying general standards and protocols.

### Current Return to Play Criteria

Currently, prevailing standards of care require an athlete to satisfy three conditions before returning to play. From the perspective of a sports medicine physician, the athlete should be asymptomatic at rest and during non-contact

exertion before return to play is indicated. Once asymptomatic at rest, the athlete is then progressed through increasing non-contact physical exertion, until he/she has demonstrated asymptomatic status with heavy non-contact physical exertion and non-contact sport-specific training. In addition, the athlete should demonstrate full recovery of cognitive function exhibited by his/her performance on a neuropsychological testing battery (if available).

### Asymptomatic Status at Rest

Separately or in conjunction with administration of a neurocognitive test battery, the athlete should complete a symptom inventory (such as the Postconcussion Scale, see Table 24-4) or symptom interview both on the sideline (may be brief) and serially throughout recovery. Before progressing to any significant level of physical exertion, the athlete should report being asymptomatic at rest for at least 24 hours. If the athlete's report of asymptomatic status is suspected to be false, a careful discussion of the importance of reporting all symptoms should be initiated with the athlete. If there are others who present for evaluation with the athlete (e.g., parents, athletic trainers, or teammates), asking these third party informants about the athlete's previous or current symptom complaints might be helpful.

### Asymptomatic Status with Physical Exertion

Once an athlete demonstrates asymptomatic status at rest, he or she should begin a graduated return to physical exertion prior to contact participation, because post-concussion difficulties might evolve with increased cerebral blood flow. The Vienna group and the Prague group have encouraged a graduated protocol (19, 132). Briefly, the protocol involves an athlete successfully moving through the following exertional steps in 24-hour periods: (1) light aerobic exercise (walking, stationary biking), (2) sport-specific training (ice skating in hockey, running in soccer- typically moderately exertional), and (3) non-contact training drills (usually heavily exertional). If the athlete's previously resolved post-concussion symptoms return at any point during the graded return to physical exertion, the athlete should return to the previous exertion level at which they were last asymptomatic.

### Intact Neurocognitive Function (either compared to baseline or normative data)

Neurocognitive recovery can be considered achieved when the athlete's performance either returns to baseline levels or, in the absence of baseline, is consistent with premorbid

estimates of functioning when the test data are compared to normative values (clinicians should utilize test batteries that have readily available athlete-specific norms).

Pre-season or baseline neuropsychological assessment can be very helpful for comparing post-injury functioning to "normal" functioning for the injured athlete. Some practitioners prefer to complete serial follow-up using computerized neuropsychological testing in order to gain insight into the extent and type of cognitive impairment created by the injury. The first test is often performed while the athlete remains symptomatic, then completed again once the athlete is asymptomatic to gauge progress and ensure a return to baseline or premorbid expectations of cognitive functioning. Other practitioners prefer to test the athlete when he/she is asymptomatic at rest and with heavy non-contact exertion, and prior to returning the athlete to any type of contact participation. This may maximize the chances that neuropsychological testing will only need to be performed once at follow-up.

Once the athlete is symptom free at rest and with physical exertion, as well as within expected levels on cognitive testing (if available), he/she may return to full-contact training, then to competition. Again, if any symptoms emerge with return to contact participation, the athlete should return to non-contact physical exertion.

## CONCLUSIONS

This chapter was intended to be a comprehensive overview of concussion in sport, dealing with topics such as definitions, on-field/sideline presentation, pathophysiology, structural and functional imaging, neuropsychological outcome, cumulative effects, and return to play decision making. The pathophysiology of concussion has been conceptualized as a multilayered neurometabolic cascade (e.g., 22). The primary mechanisms include ionic shifts, abnormal energy metabolism, diminished cerebral blood flow, and impaired neurotransmission. Fortunately, the brain undergoes a dynamic restorative process in the initial days to weeks following a concussion. From a commonsense perspective, the ionic shifts, abnormal energy metabolism, diminished cerebral blood flow, and impaired neurotransmission believed to be associated with concussions in sports reinforces the importance of immediate rest following injury. Although not established empirically, it seems reasonable to assume that vigorous exercise or hard physical contact might exacerbate the pathophysiology described above.

Many athletes with concussions have neurocognitive decrements as measured by traditional paper-pencil and computerized neuropsychological tests in the initial hours, days, and potentially weeks post injury. In terms of group data, it has become a fairly robust finding that athletes tend to recover in terms of perceived symptoms and neuropsychological test performance within 2–14 days. However, individual variability exists in recovery rates, especially in high school athletes, and the duration of symptoms can persist well beyond two weeks post injury.

Researchers have reported that three or more concussions in high school and university athletes are associated with small but measurable cumulative effects, and increased risk for future concussions. The literature on subconcussive blows to the head, or the long-term effects of one or two previous concussions, is mixed. In general, there is insufficient evidence at this time to conclude that subconcussive blows or 1–2 previous concussions results in adverse long-term effects in the average athlete.

Ideally, athletes should satisfy three conditions before returning to play. The athlete should be asymptomatic at rest and during non-contact exertion. Once asymptomatic at rest, the athlete is then progressed through increasing non-contact physical exertion, until he/she has demonstrated asymptomatic status with heavy non-contact physical exertion and non-contact sport-specific training. In addition, the athlete should demonstrate full recovery of neurocognitive function exhibited by his/her performance on a neuropsychological testing battery (if available).

The management of sports-related concussion has evolved rapidly over the past decade and has been based on an explosion of laboratory and clinical research.

Current prevailing models of assessing readiness for return to play following injury have been increasingly based on research studies rather than on panels of experts, which represented the zeitgeist in the 1980's and 1990's. Contemporary models of care have recognized the complexity of the recovery process following concussion and are beginning to consider the unique contribution of factors such as the athlete's age, developmental history, and past injury status in determining outcome. This recognition of the interplay between multiple variables is leading to the development of a much more sophisticated understanding of the recovery process; we anticipate that this will continue in the near future. Given the current trend towards research-based models of clinical care, we anticipate that concussion management will continue to grow and develop as our capacity for completing large-scale clinical research projects increases and we are able to meld this information with other advances in the neurosciences such as structural and functional neuroimaging and electrophysiological techniques.

## Assessment and Rehabilitative Management of Individuals with Disorders of Consciousness

*Joseph T. Giacino  
Douglas I. Katz  
Nicholas Schiff*

**T**here has been a resurgence of interest and scientific inquiry concerning disorders of consciousness (DOC) over the last decade. American and

European initiatives have led to the development of guidelines for assessment, prognosis and rehabilitation of individuals in coma and the vegetative state (VS) (1–3) and have contributed to the formulation of neurobehavioral criteria for the minimally conscious state (MCS) (4). These initiatives, coupled with the development of improved behavioral and neuroimaging assessment procedures, have fostered increasing consensus regarding conceptual and empirical approaches to understanding DOC.

This chapter will review and critique the major developments in this area that have influenced the clinical management of DOC. Following a review of the diagnostic criteria associated with coma, VS and MCS, new insights garnered from functional neuroimaging studies into the pathophysiology of these disorders will be discussed. Behavioral and radiologic assessment techniques developed specifically for this population will be discussed in relation to diagnostic and prognostic utility. Medical, environmental and neuromodulatory interventions designed to facilitate recovery of cognition will be reviewed and discussed relative to efficacy. Clinical predictors of outcome will be outlined, with particular attention to differences

between individuals diagnosed with VS and MCS and general recommendations for clinical management will be outlined. Finally, ethical issues will be defined and future directions for research proposed.

### DEFINITIONS AND DIAGNOSTIC CRITERIA

Numerous terms have been offered to characterize states of altered consciousness, many of which have not been operationalized (see table 25-1). Not surprisingly, estimates of misdiagnosis among disorders of consciousness range from 15% to 43% (5–7). In recognition of this problem, a multi-disciplinary group was assembled in 1995 through the auspices of the Aspen Neurobehavioral Conference to formulate a consensus statement regarding the diagnostic and prognostic criteria for coma, VS and MCS. The recommendations of the Aspen Group were subsequently endorsed by the American Academy of Physical Medicine and Rehabilitation, the American Association of Neurologic Surgeons, the American Congress of Rehabilitation Medicine, the Brain Injury Association of America, and the Child Neurology Society. The definition and diagnostic criteria for MCS, crafted by the Aspen Group, was published in 2002 in *Neurology*, the official journal of the American Academy of Neurology (4).

TABLE 25-1

**Terms Used to Refer to Disorders of Consciousness**

Akinetic mutism	Minimally responsive state
Apallic syndrome	Permanent vegetative state
Coma	Persistent vegetative state
Coma vigil	Post coma unawareness
Cognitive death	Prolonged coma
Decerebrate state	Prolonged post-traumatic unconsciousness
Low level	Vegetative state
Minimally conscious state	

**Coma**

Coma is a state of pathologic unconsciousness in which the eyes remain closed and the patient cannot be aroused (8). It is most often the result of severe, diffuse bi-hemispheric lesions of the cortex or underlying white matter, bilateral thalamic damage or paramedian tegmental lesions. The clinical criteria for diagnosing coma were described by Plum and Posner in 1982 (9) and remain well accepted. The defining feature of coma is the complete loss of spontaneous or stimulus-induced arousal. The eyes remain continuously closed despite the application of noxious stimuli and there are no sleep/wake cycles on EEG. On examination, there is no evidence of purposeful motor activity, no response to command and no indication of receptive or expressive language ability. Coma is a self-limiting state that typically resolves within two to four weeks in those who survive the initial injury.

**Vegetative State (VS)**

The vegetative state has been mired in controversy since it was first introduced by Jennett and Plum (10) more than 30 years ago. The term itself is controversial because it is considered to be pejorative by the lay public, and because clinicians have not been able to agree on the prognostic parameters associated with this diagnosis. VS is a condition in which awareness of self and environment is presumed to be absent and there is an inability to interact with others, although the capacity for spontaneous or stimulus-induced arousal is preserved (11). VS typically follows a period of coma but may also arise from developmental malformations or may represent the culmination of progressive degenerative or metabolic disorders. The neuropathologic substrate is usually determined by the cause of injury. Diffuse axonal injury is the most common finding in post-traumatic VS. Vascular causes of VS are often associated with paramedian thalamic damage and diffuse laminar cortical necrosis is frequently noted following anoxic brain injury. The diagnosis of VS is made when there is no evidence of sustained or reproducible, purposeful behavioral responses to visual, auditory, tactile or

noxious stimuli, and no evidence of language comprehension or expression. Unlike coma, intermittent periods of wakefulness (i.e. eye opening) occur in VS and represent functional restoration of the reticular system.

The term *persistent VS* (PVS) remains controversial, in part, because it has been used inconsistently in the medical literature. The most current practice parameter on PVS published in 1995 by the American Academy of Neurology (1) stipulates that PVS can be diagnosed after one month following either traumatic or non-traumatic brain injury. After reviewing the published literature on PVS, the AAN introduced a new term, *permanent VS*, suggesting that this term be applied three months after non-traumatic brain injury, and after twelve months following traumatic injury. The distinction between persistent and permanent VS is intended to establish the point after which recovery of consciousness is highly improbable.

According to the AAN practice parameter, PVS is a diagnostic term and does not imply irreversibility. In view of the inconsistent application of PVS and the high rate of recovery of consciousness that occurs between three and twelve months post-injury in individuals who remain in VS longer than one month (12, 13), the Aspen Group recommended that the term PVS be abandoned. Instead, they proposed that when the diagnosis of VS is made, it should routinely be accompanied by a description of the injury and the length of time since onset as both of these factors provide prognostic information (14).

**Minimally Conscious State (MCS)**

MCS is a condition of severely altered consciousness in which there is minimal but definite behavioral evidence of self or environmental awareness (4). MCS usually represents a transitional state reflecting improvement in consciousness from coma or VS, or progressive decline as in neurodegenerative disease (e.g., Alzheimer's disease). The natural history and long term outcome have not been fully characterized, however, at least ten papers have been published on MCS since this condition was defined in 2002. The neuropathologic substrate of post-traumatic MCS was recently investigated in a post-mortem analysis completed by Jennett and colleagues (15) who found that the typical lesion profile consists of grade 2 or 3 diffuse axonal injury with multi-focal cortical contusions, sometimes accompanied by thalamic involvement. In comparison to patients diagnosed with VS, thalamic lesions were notably less prevalent in MCS (50%) relative to VS (80%). Based on these findings, MCS appears to be characterized by greater sparing of cortico-thalamic connections which may account for why patients in MCS retain some capacity for cognitive processing.

The diagnosis of MCS is based on clearly discernible evidence of one or more of the following behaviors: 1) simple command-following, 2) intelligible verbalization,

3) recognizable verbal or gestural “yes/no” responses (without regard to accuracy) or 4) movements or emotional responses that are triggered by relevant environmental stimuli and cannot be attributed to reflexive activity. Examples of the fourth criterion include a) smiling or crying following exposure to emotional (e.g., family photographs) but not neutral stimuli (e.g., photographs of objects), b) vocalizations or gestures that occur in direct response to specific linguistic prompts, c) accurate reaching toward objects placed within the immediate visual field, d) manipulation of objects placed in the hand and e) sustained visual fixation or pursuit eye movements.

In making the diagnosis of MCS, it is important to consider the frequency and complexity of the behavior observed. When there is evidence of rudimentary cognition only (e.g., inconsistent visual tracking), the diagnosis of MCS requires serial reassessment. At the opposite end of the MCS spectrum, patients who demonstrate consistent evidence of complex cognitively-mediated behavior (e.g., command following) fall at the upper limit of MCS.

Within the diagnostic category of MCS, there is a subgroup of patients whose behavior is difficult to characterize, both from a practical as well as theoretical standpoint. Some MCS patients infrequently initiate behavior or respond to environmental prompts, but on occasion, exhibit behaviors that infer complex cognitive processing (e.g., follow countermanding or go-no go commands). It is not unusual for these individuals to show marked fluctuations in behavioral responsiveness across examinations. We recently evaluated an individual who was able to provide reliable responses to a series of yes/no questions during the initial examination. On follow up examination conducted 24 hours later, responses to the same questions were inconsistent and unreliable. There is little agreement as to whether patients who infrequently engage in complex responses should be included in the MCS category. It is often difficult to determine whether the low rate of behavioral responsiveness observed in these individuals is primarily due to sensory limitations, motor dysfunction, abulia or fluctuations in level of consciousness.

### Emergence from MCS

Emergence from MCS is signaled by the recovery of interactive communication or functional object use. In contradistinction to MCS, emergence from MCS requires *reliable and consistent* evidence of either communication or object use. Communication may occur through verbal responses, gestural means or augmentative devices. “Functional object use” requires discrimination among items presented (e.g., comb brought to head and toothbrush to mouth). Aphasia and apraxia must be ruled out as contributing or causative factors in patients who don’t meet the criteria for reliable communication ability or functional object use.

The last ten years have witnessed movement toward achieving universally agreed upon terminology for disorders of consciousness. This is an essential step in assuring accurate diagnosis and promoting well-informed treatment decisions. Unless there is a common frame of reference to guide research and clinical practice, the difficulties inherent in evaluating and treating disorders of consciousness will prove insurmountable.

## PATHOPHYSIOLOGY AND NEUROIMAGING

### Neuropathology of VS and MCS

Traumatic and non-traumatic VS have distinct and identifiable pathologies. Adams et al. (16) studied 49 patients remaining in VS for at least one month until death and found that non-traumatic injuries included severe bilateral thalamic damage in all instances and, in the majority of cases, were associated with diffuse cortical damage. In contrast, traumatic etiologies associated with VS showed grade 2 and 3 diffuse axonal injuries and severe thalamic degeneration in almost all of patients who survived for 3 months before death. These pathological studies confirm the intuition that the chronic vegetative state is characterized by overwhelming cerebral damage. An important conclusion that is often overlooked is that the most consistent and severe pathologies arising from both types of injuries are in subcortical structures, particularly the thalamus. The cerebral cortex is generally spared in traumatic VS, with only about 10% of patients showing diffuse ischemic neocortical injury patterns; brainstem damage is uncommon in chronic VS patients emphasizing that VS is primarily a disorder of cerebral integration at the thalamocortical level.

No comprehensive study has evaluated specific anatomic pathologies associated with MCS. Jennett and colleagues (17) reported 65 autopsies of patients with traumatic brain injury leading either to VS or severe disability and found wide variation in underlying neuroanatomical substrates. This study included 12 patients with histories consistent with MCS at the time of death. Of note, two of the MCS patients demonstrated only focal brain injuries, without DAI or focal thalamic infarction (a consistent finding in approximately half of the severely disabled patients). Further work to determine the pathological correlates of MCS is required.

### Functional Neuroimaging Studies

Several new brain imaging techniques are providing important insight into the mechanisms of neurological disorders of consciousness. Functional MRI (fMRI) and functional positron emission tomography ( $^{15}\text{O}$ -PET) studies respectively correlate changes in blood oxygen level and cerebral blood flow with neuronal activation.

Precise correlational studies of single-unit and multi-unit neuronal recordings from brain regions simultaneously studied using fMRI techniques indicate that fMRI signal activations are tightly correlated with neuronal population activity (18). These findings support the use of both fMRI and  $^{15}\text{O}$ -PET activations as a proxy for neuronal activation *per se*. Brain metabolism can also be quantified in neuroimaging studies using fluorodeoxyglucose positron emission tomography (FDG-PET) imaging, a measure of cerebral glucose metabolic rates. FDG-PET studies in patients with Parkinson's disease have correlated regional glucose metabolism with neuronal firing rates in cerebral structures (19). Direct measurements of cerebral metabolism and neuronal activity demonstrate a rough equivalence of metabolic rate and mean firing rate of population of neurons (20). Combined with traditional structural MRI imaging and EEG (or magnetoencephalography, MEG, recordings obtained from measurements of the brain magnetic field) these techniques offer an integrative view of the damaged brain.

*Pet Studies* The clinical judgment of unconsciousness in PVS was first supported in imaging studies by fluorodeoxyglucose positron emission tomography (FDG-PET) studies that revealed overall cerebral metabolism to be reduced by 50% or more below normal levels in PVS patients (21–24). More recently, Schiff and colleagues used functional brain imaging techniques including fluoro-deoxyglucose-positron-emission tomography (FDG-PET), magnetoencephalography (MEG) and magnetic resonance imaging (MRI) were combined with clinical assessments (25, 26). These studies identified novel evidence of the modular organization of brain systems in three patients who retained small islands of cerebral metabolic activity that correlated with clinically identified behavioral fragments. In one case, a 42 year old male diagnosed with post-traumatic VS of seven years duration, repeatedly displayed selective emotional responses following exposure to specific environmental events. He exhibited pronounced eye and mouth-opening, pupillary dilatation and groaning when touched or presented with loud noise, giving the appearance of grave distress. Conversely, when exposed to soft music or his mother's soothing voice, he showed signs of sympathetic and behavioral relaxation. PET data indicated that the patient's global resting metabolic rate was approximately 30% of normal, however, the right putamen, caudate, orbitofrontal cortex, lateral and superior temporal cortex showed elevated metabolism up to nearly 50% of normal levels. When correlated with the behavioral findings, the PET results appeared to reflect partial preservation of the neural network responsible for receptive prosody.

Several investigators have employed  $^{15}\text{O}$ -PET imaging techniques to the evaluate PVS patients. Laureys and colleagues have identified a marked loss of distributed

network processing in the vegetative state (27–29). In their studies, elementary auditory and somatosensory stimuli were presented to PVS patients and normal control subjects and compared to baseline resting conditions in  $^{15}\text{O}$ -PET subtraction paradigms; PVS patients demonstrated a loss of brain activations outside of primary sensory cortices for both types of stimuli. Cortical regions identified as 'hierarchically higher-order' multi-modal association areas active in the normal control subjects did not activate in the PVS patients. Laureys et al.'s findings are consistent with evidence of early sensory processing in PVS patients as measured by evoked potential studies and add important additional information about the integrity of cerebral information processing in PVS. Menon and colleagues (30) described a 26 year old woman in a persistent vegetative state (PVS) four months following an attack of acute disseminated encephalomyelitis that functionally impaired both cortical and subcortical (brainstem and thalamic) structures. Right occipital-temporal regions in this patient demonstrated selective activation of the right fusiform gyrus and extrastriate visual association areas with visual stimulation. These results were obtained in response to presentation of familiar faces and scrambled images. No other evidence of cortical processing was reported but the patient became increasingly responsive at 6 months and minimally expressive at 8 months into the course of her illness. Menon et al. interpreted this activity measured at four months as indicating a recovery of minimal awareness. However, such selective identification of relatively complex information processing may not alone index recovery of cognitive function or even potential for recovery (25, 31).

Only a few studies have addressed patterns of brain activation in MCS patients. Boly et al. (32) used the same  $^{15}\text{O}$ -radiolabeled PET paradigms for auditory stimuli tested in PVS patients to examine responses in MCS compared to healthy control subjects. Both MCS and normal subjects showed activation of the bilateral superior temporal gyri (Brodmann areas 41, 42 and 22) compared to earlier studies in the PVS patients where activation was limited to bilateral Brodmann areas 41 and 42 (33). Laureys et al. showed more widespread activation of  $^{15}\text{O}$ -radiolabeled PET responses for auditory stimuli with emotional valence (i.e., infant cries and patient's own name) than that for meaningless noise in an MCS patient (34).

*fMRI Studies* Schiff et al. (35) presented fMRI studies of two MCS patients, one related to TBI and the other to a spontaneous intracranial hemorrhage who remained in MCS for more than 18 months. When these patients were passively exposed to audiotaped narratives provided by family members, widespread activation of the language network was observed on fMRI. However, an important dissociation was observed in MCS patients compared to normal controls., When the narratives were time-reversed

so that the semantic content was no longer discernible, there was a marked reduction in the extent and magnitude of activation of language structures, unlike the normal controls who showed a slight increase in activation (see figure 25-1). For both patients studied, FDG-PET revealed marked reduction of resting metabolic rates to near VS levels. The low resting metabolic activity suggests that the MCS patients may suffer a severe deficit of ‘baseline’ brain activity proposed by Gusnard and colleagues (36) to account for high resting cerebral metabolic rates in the normal human brain. This suggests that patients in MCS may not be able to recruit “top-down” monitoring functions necessary for processing ambiguous or complex environmental information. It is important to note that although functional brain imaging may eventually provide useful correlates of the differences in MCS and PVS evident at the bedside, at present these studies cannot be used to advance diagnostic or prognostic distinctions.

Bekinschtein, Miklison, Sigman & Manes (37) recently reported evidence of emotion processing in an MCS patient who suffered a severe traumatic brain injury using functional magnetic resonance imaging (fMRI). When they played a recording of the patient’s mother’s

voice, functional MRI demonstrated activation of the amygdala and the insula, subcortical structures related to emotion. Functional connectivity between the secondary auditory cortex and temporal and prefrontal cortices suggested some potential for higher order integrative processes necessary for conscious auditory perception in MCS patients.

## CLINICAL ASSESSMENT

Prior to the last decade, procedures for evaluating individuals with disorders of consciousness were limited to the Glasgow Coma Scale (38) MRI and EEG studies. These procedures continue to be useful during the acute stage of recovery but represent relatively gross indicators of cerebral dysfunction. Specialized behavioral and neuroradiologic protocols have recently been developed in an attempt to provide a more specific means of monitoring recovery across the subacute and post-acute periods and to improve outcome prediction.

### Bedside Examination

There are no standardized evaluation procedures for the clinical bedside examination of patients with impaired consciousness. Most clinicians rely on systematic evaluations of arousal and behavioral responses to various forms of stimulation. Nevertheless, frequent errors in diagnosis occur, (5, 6) either because of a misinterpretation of responses or examinations that are inadequate to detect minimal, inconsistent responsiveness.

The bedside neurological examination of patients with impaired consciousness should focus on two general areas, assessment of the integrity of the central nervous system, particularly brainstem pathways (e.g. pupillary responses, ocular movements, oculovestibular reflexes, breathing patterns) and the presence of higher level cortical functions (e.g. purposeful, voluntary behaviors). The examiner’s task is to systematically elicit and distinguish behaviors that are reflexive or automatic, reliant on spinal or subcortical pathways, from those that are cortically-mediated and represent some level or awareness or purposeful intent.

Cognitive awareness or conscious intent may be difficult to interpret when responses are extremely inconsistent or simple. There is an inverse relationship between the dimensions of *complexity* and *consistency* when judging whether particular behaviors imply consciousness. When a behavior is more complex, such as a verbalization, fewer instances of the response are sufficient to demonstrate consciousness. When a behavior is less complex, such as a finger movement, more frequent occurrences are necessary to establish a link to stimulus awareness or conscious intention. For this reason, single bedside examinations are often inadequate to conclusively establish level of

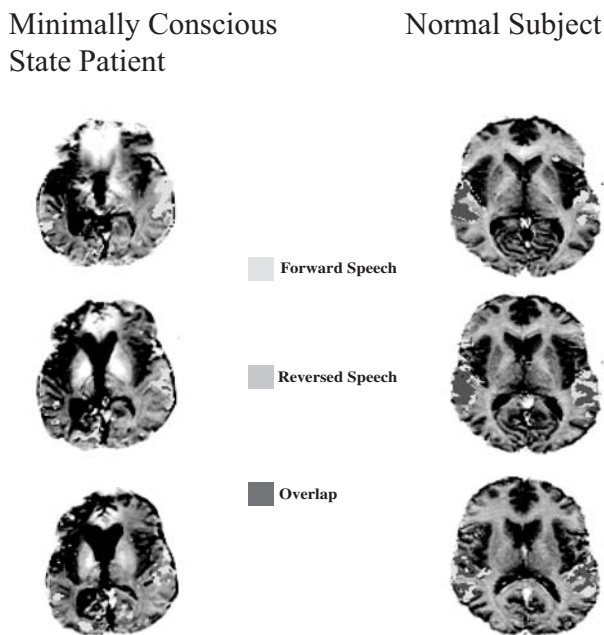

FIGURE 25-1

Images from fMRI studies of MCS patients and normal subjects. MCS patient shows widespread network activation for forward presentation of spoken narratives (yellow color), but time-reversed narratives produce only small regional activation of primary auditory cortex (red colored areas showing overlap for both stimulus types). In contrast, the normal subjects activate the entire network roughly equally for both stimulus conditions as seen in predominance of red colored regions for the normal subject

**TABLE 25-2**  
***A Systematic Approach to the Examination of Patients with Impaired Consciousness Includes the Following Steps***

1. Brainstem integrity and other subcortical evaluation
  - Pupillary response, blink reflex to visual threat
  - Ocular movements, gaze deviations
  - Oculovestibular reflexes (oculocephalic (“doll’s eyes”) maneuvers, calorics)
  - Corneal response
  - Gag reflex
  - Breathing pattern
  - Decerebrate postures
  - Other posturing, reflexes and tone
2. Cortical functioning
  - a. Observation of spontaneous activity
    - Purposeful, complex movements (involving cortically mediated isolated motor control) vs. posturing (decorticate or decerebrate) or reflex or stereotyped, patterned (subcortically mediated) movements
    - Spontaneous vocalizations or verbalizations
    - Eye movements (signs of fixation or tracking vs. nonspecific roving or no movement)
  - b. Responses to stimulation or environment
    - Tracking or fixation to stimuli (try salient stimuli such as familiar pictures, faces, mirror)
    - Verbal stimulation (e.g. patient’s name, commands, social greetings):  
 Begin with simple commands sampling a variety of areas under different neural control, favoring those areas of potentially preserved movement.
      - Eye commands – e.g. ‘look up’, ‘blink twice’;
      - Limb commands – e.g. ‘make a fist’, ‘show 2 fingers’, ‘raise your arm’;
      - Oral commands – e.g. ‘open mouth,’ ‘stick out tongue’;
      - Axial or whole body commands – e.g. ‘turn your head,’ ‘lean forward’).
      - Ask patient to ‘stop moving’ or ‘hold still’ to distinguish from spontaneous repetitive movements.
    - Noxious stimulation
      - Look for localization or purposeful defensive maneuvers vs. reflexive or generalized, stereotyped movements or facial expressions.
    - Response in contingent relationship to environment or other stimuli
      - Look for intentional reach for or manipulation of objects on or around the patient (e.g. pulling at tubes, clothing, items placed in the hand)
      - Look for changes in facial expression contingent on stimuli such as familiar voices, particular conversation, pictures, music, etc.
      - Look for attempts at purposeful mobility in bed, chair, and even ambulation
      - Gestural behaviors indicating tentative communication (e.g. yes/no signals)
    - Confounding factors affecting arousal (e.g., centrally acting medications, concurrent illness, subclinical seizures);
    - The potential influence of aphasia, apraxia and other higher cortical disorders that may affect ability to respond to commands.

unconsciousness. Repeated assessments and use of standardized evaluations (see below) may be necessary for diagnostic accuracy. Table 25-2 presents a systematic approach to the neurological examination of patients with impaired consciousness.

There are several common problems that can lead to inaccurate diagnosis of consciousness in patients with impaired consciousness. These include:

- Attributing purposeful intent for responses that are reflexive or generalized to any form of stimulation;
- Inadequate evaluation to detect conscious behavior – e.g. insufficient sampling time, inadequate arousal, inappropriate choice of stimuli;

- Over- or underconsideration of family or other’s observations of purposeful behavior (i.e., failure to recognize that family may be first to observe signs of consciousness or to overattribute purposeful intent);
- Simple, cortically mediated behaviors of uncertain cognitive significance; e.g. simple isolated limb movements;

The examiner should use strategies to account for some of these confounds and maximize the chance of detecting signs of conscious behavior. The clinician should:

1. *Assure optimal arousal.* There should be an adequate warm-up period, with verbal and tactile stimulation

to promote wakefulness. Deep pressure stimulation is often effective. Positioning is important and patients are usually more wakeful sitting up. The time of day, the patient's sleep-wake cycles and fatigue from activities preceding the neurological examination all have to be considered. Sedating medications should be avoided and treatable medical conditions should be addressed.

2. *Assure optimal environmental conditions.* Avoid distractions, provide adequate lighting, remove physical restrictions to movement and position stimuli to the patient's best advantage.
3. *Consider stimulus duration and rate.* Use a long enough presentation time and interstimulus interval to allow time for the patient to respond and to minimize perseveration. Recognize that as the interval between stimulus and response increases, the chance that a spurious response is mistakenly attributed to a stimulus also increases. Watch for signs of response fatigue.
4. *Avoid unnecessary complexity in command-following trials.* Use simple declarative language, one request at a time.
5. *Consider the patient's motor repertoire in choosing commands.* Use commands that incorporate motor responses that appear to be within the patient's capabilities, such as spontaneously observed movements.
6. *Distinguish purposeful from reflexive behavior.* When attempting to elicit movements to command, avoid responses that may represent common reflexive behaviors; e.g. squeeze hands, blink eyes.
7. *Evaluate a variety of potential responses and employ a range of different stimuli.* Attempt to elicit responses to a few different types of command – e.g. a limb command and an eye command. Look for other forms of purposeful behavior; e.g. manipulation of an object placed in the patient's hand; social handshake; purposeful resistance to unpleasant stimulation.
8. *Assure adequate examination time and perform serial reassessments.* Quick bedside evaluations, such as typical morning rounds, are often not adequate in detecting responses in patients with DOC. Repeated reassessments are necessary to establish response consistency, validity of examination findings and accuracy of the diagnosis.
9. *Pay attention to observations of others.* Families, nurses, therapists, who are more familiar or spend more time with the patient, often observe behaviors associated with consciousness before they are observed by the physician. The physician's assessment should incorporate these observations.

### Standardized Rating Scales

During the 1990's, advances in trauma care led to an increase in the number of survivors of severe brain injury.

Consequently, neurorehabilitation programs experienced an increase in the number of admissions involving patients with prolonged DOC. In light of these changes, neurorehabilitation specialists recognized the need for reliable assessment instruments that could detect subtle but potentially important clinical changes after the acute period of recovery. This resulted in a proliferation of standardized neurobehavioral assessment scales designed to gauge level of consciousness in unresponsive or poorly responsive patients. These instruments were intended to provide a comprehensive overview of neurobehavioral functions and, at the same time, to detect subtle changes in response frequency and complexity. The JFK Coma Recovery Scale (CRS) (39), the Western Neuro Sensory Stimulation Profile (WNSSP) (40), the Coma/Near Coma Scale (CNC) (41), the Sensory Modality Assessment Rehabilitation Technique (SMART) (42) and the Wessex Head Injury Matrix (43) represent examples of such measures. Although the validity and reliability of these instruments have been shown to be adequate (39–44), other important psychometric characteristics and their diagnostic and prognostic utility have not been well-studied.

The CRS was recently revised in an effort to improve differential diagnostic accuracy between VS and MCS (45). Interrater and test-retest reliability were found to be high for CRS-R total scores. Total scores were also significantly correlated with the Disability Rating Scale, providing evidence for concurrent validity. Analysis of internal consistency revealed moderate intercorrelations between the total CRS-R score and individual subscale scores suggesting that the scale is a reasonably homogeneous measure of neurobehavioral function. There was also no evidence of ceiling or floor effects based on the distribution of scores. Regarding its clinical utility, the CRS-R reliably distinguished features of VS and MCS in a group of 80 patients with DOC, and identified 10 cases that were misdiagnosed as VS. Based on these findings, the CRS-R appears to meet minimal standards for measurement and evaluation tools designed for use in interdisciplinary medical rehabilitation.

### Individualized Behavioral Assessment

The rigorous attention to methodologic consistency afforded by standardized measures does not allow case-specific questions to be addressed. For example, standardized procedures may not be able to differentiate between random movement and low frequency movement to command because the investigational technique is fixed and the number of observations restricted. For example, finger movement that occurs on two of four trials immediately after the command to "move your fingers" raises the possibility of verbal comprehension. However, if finger movement fails to occur during the next 20 trials administered, the probability that the two

earlier responses represented evidence of verbal comprehension is diminished. Conversely, a patient may move his or her fingers following command on 10 consecutive trials but, if the same finger movement precedes the command, or persists well after the last command is administered, it is less likely that this response is an indication of verbal comprehension. To address this problem, DiPasquale and Whyte (46) developed an approach termed, "Individualized Quantitative Behavioral Assessment (IQBA)." IQBA applies principles of single subject research design to assess the cognitive and behavioral capacities of individuals with marked limitations in responsiveness. In this technique, clinical questions are individually tailored, stimuli and response criteria are operationally-defined and behavioral frequencies are analyzed statistically to determine whether the behavior of interest exceeds the rate predicted by chance. This approach has been successfully employed to investigate command-following, visual function, communication ability, emotional responses and drug efficacy (47).

Standardized and individualized procedures should be viewed as complementary as they serve different purposes. Standardized methods are designed to provide a broad overview of the integrity of sensory, motor and cognitive processes. When viewed *in toto*, these findings can help establish diagnosis, prognosis and lesion locus, and may inform the optimal approach to treatment. The inherent flexibility offered by the individualized approach provides an opportunity to control case-specific influences on behavior which contribute to diagnostic inaccuracy and erroneous judgements concerning consciousness.

### TREATMENT INTERVENTIONS AND EFFECTIVENESS

The primary goal in treating individuals with disorders of consciousness is to restore basic functional competence. The degree to which this goal can be achieved is dependent upon multiple factors including arousal level, sensorimotor functions, communication ability, initiation and drive mechanisms and executive control processes. Treatment strategies, therefore, are usually designed to improve or augment one or more of these areas. Unfortunately, no treatment has definitively been shown to alter the natural course of recovery from coma, VS or MCS. This may be due, in part, to the lack of prospective, randomized controlled clinical trials (RCTs). RCTs represent the gold standard for testing treatment effectiveness, but are particularly difficult to organize because they require large sample sizes, tight control over exposure to related treatments and an extended period of follow up. Not surprisingly, most of the published research on treatment efficacy consists of uncontrolled case studies and case series.

### Types of Treatment

Interventions available for individuals with disorders of consciousness can be grouped into three broad categories. Treatments that rely on *sensory stimulation (SS)* provide systematic exposure to a variety of environmental stimuli. The intent of SS is to improve arousal level and increase the frequency of purposeful behavior. Included within this category are environmental exposure strategies and structured sensory stimulation programs. *Physical management* strategies employ traditional rehabilitation techniques to promote physical health and prevent secondary complications. Interventions such as range of motion exercises, positioning schedules, bowel and bladder training, spasticity management and prevention of heterotopic ossification fall within this category. *Neuro-modulation* protocols are designed to promote recovery by directly altering the neurophysiologic substrate presumed to be responsible for mediating consciousness. Pharmacologic interventions and deep brain stimulation represent examples of neuromodulatory approaches. Table 25-3 provides an overview of the treatments described above.

### Treatment Efficacy

Treatment decisions should be guided by the strength of empirical evidence available for a particular intervention. A direct consequence of the lack of prospective RCTs on treatments for disorders of consciousness is that most existing efficacy studies have significant methodologic limitations that limit their interpretability and clinical application.

Research designs are often flawed and difficult to compare across studies. Diagnostic criteria are non-uniform, subject characteristics are inadequately reported, outcome measures are psychometrically weak or too insensitive to detect subtle but prognostically important changes over time and there is significant variation in the frequency and duration of the treatments employed. Nevertheless, the literature does provide some empirical information concerning the interventions used with this population.

*Sensory Stimulation* In a recently completed evidence-based review, Giacino (48) found that the majority of published studies of SS represent class III and IV evidence (49) which is primarily comprised of case studies and retrospective data analyses (50–53). No class I prospective randomized controlled trials (RCT) were identified. A class II RCT, completed by Johnson, Roethig-Johnston and Richards, (54) provided multimodal SS to 14 patients in coma or VS within 24 hours of injury. Biochemical and physiologic markers were monitored before and after SS. On average, the treatment group received SS for 8 days and the placebo group was treated for 4 days. The authors reported that there was a significant stimulation effect

**TABLE 25-3**  
**Overview of Treatment Interventions Utilized in Disorders of Consciousness**

TYPE OF INTERVENTION	RATIONALE	METHOD	INTENDED OUTCOME	EFFICACY STUDIES
<b>Sensory Stimulation</b>				
Environmental Exposure	Sensory enrichment prevents failure to thrive and loss of preserved functions	Exposure to naturally-occurring environmental stimuli/events (e.g. TV, music, group activities)	Activation of basic perceptual processes (e.g. visual scanning, sound localization)	No published studies
Structured Sensory Stimulation	Information processing efficiency is dependent upon proper calibration of stimulus intensity and response threshold	Administration of multi-modal sensory stimuli (e.g. auditory, visual, tactile, olfactory) titrated to existing sensory thresholds	Improve breadth and reliability of behavioral response repertoire	Hall, et al. (50) Wilson, et al. (51) Pierce, et al. (52) Wood, et al. (53) Johnson, et al. (54)
<b>Physical Management</b>				
	Health maintenance and physical re-conditioning maximize the likelihood and rate of recovery of spared neurologic functions	Implementation of range of motion exercises, positioning protocols, bowel/bladder schedules, skin care regimens, etc.	Prevention of aspiration, contractures, decubiti, malnourishment, heterotopic ossification, infection	Mackay, et al. (55) Timmons, et al. (57) Tanheco & Kaplan (58) Weber (59)
<b>Neuromodulation</b>				
Pharmacologic	Specific chemical agents may potentiate damaged neurotransmitter systems responsible for mediating attention and intention	Administration of cholinergic, dopaminergic, noradrenergic and serotonergic agonist medications	Improve arousal (i.e. wakefulness), alertness (i.e. vigilance) and intention (i.e. behavioral initiation)	Reinhard, et al. (61) Powell, et al. (62) Passler & Riggs (63) Meythaler, et al (64) Zafonte, et al. (65)
Deep Brain Stimulation	Electrophysiologic stimulation of the brain stem reticular system produces physiologic and behavioral changes associated with arousal	Chronic electrical stimulation of mesodiencephalic structures	Amelioration of arousal and/or cognitive deficits (e.g. neglect, memory disturbance) associated with disruption of thalamocortical circuits	Kanno, et al. (71) Tsubokawa, et al. (72) Schiff, et al. (73)

noted between groups at 6 days post-injury on only one of six biochemical markers. No difference was noted in biochemical or physiologic measures between survivors and deceased subjects. Of the remaining class III and IV studies (50–53), none were masked, approximately 50% provided inadequate subject and treatment descriptions and most lacked information necessary to determine the equivalence of the comparison group. In view of the dearth of methodologically sound studies involving SS, definitive conclusions regarding the effectiveness of this type of intervention cannot be drawn. Consequently, it is incumbent upon clinicians to clearly elucidate to family members, the high degree of clinical uncertainty associated with this form of treatment. To date, there have not been any published reports of harm associated with the use of SS.

*Physical Management* Despite the universal acceptance and widespread use of physical management strategies employed to facilitate recovery of consciousness and function, no prospective RCTs have been conducted to date. Mackay, et al. (55) completed a retrospective study to assess the effectiveness of an organized inpatient rehabilitation protocol on length of stay and cognitive outcome. Retrospective chart reviews were completed on 38 individuals with severe TBI (initial GCS of 3 to 8) consecutively discharged from an inpatient rehabilitation facility. Seventeen individuals received an aggressive, formal program of multi-disciplinary rehabilitation during the acute hospitalization. Treatment methods were designed to promote physical recovery and prevent complications. The 21 remaining individuals did not receive any formal rehabilitative treatment. There were no statistically significant

differences between the two groups on injury severity, brain stem reflexes, associated injuries or level of function on admission. Outcome data indicated that duration of coma and length of rehabilitation were approximately 66% shorter, discharge ratings on the Levels of Cognitive Functioning scale (LCFS) (56) were significantly higher and the percentage of home discharges was greater in the group that received the structured rehabilitation program. The generalizability of these findings is limited as they are based on a retrospective chart review and the authors provided only a cursory description of the treatment intervention.

Timmons, Gasquoine and Scibak (57) evaluated the degree of functional improvement noted in 47 patients who received interventions designed to promote health maintenance. All patients were admitted to rehabilitation at LCFS levels II to III within six months of injury. Since none of the patients reportedly showed functional communication, all were presumably in VS or MCS. Treatment consisted of interventions aimed at improving "physiologic integrity" and preventing complications. Procedures were administered by nursing staff and included hygiene procedures, positioning protocols, range of movement, pulmonary care and multisensory stimulation. By 12 months post-injury, 83% of the level III patients demonstrated functional improvement as compared to 31% of level II patients. Overall, 44% of the sample had regained functional communication, mobility or were able to use an upper extremity to perform activities of daily living. The authors suggested that amount of treatment influenced outcome since patients who did not improve received fewer hours of treatment than those who did (15 vs. 25 hours per week). This relationship did not appear to be related to length of time post-injury, however, the authors did not consider spontaneous recovery as a possible cause of the improvements noted.

Two additional case study reports describe functional improvement following introduction of physical management strategies. Tanheco and Kaplan (58) reported significant improvements in communication and self-care abilities in a 31 year-old woman with a six year history of eyes-closed coma resulting from a motor vehicle accident. The patient was admitted from a nursing home for inpatient rehabilitation after family members reportedly observed eye-opening, accurate head nods and occasional verbalizations. On admission, the patient was severely contracted with multiple decubiti, speech intelligibility was 10% to 25% and communication was compromised by vocal cord paralysis and limb contractures. Range of motion, stretching, serial casting and surgical releases were performed to facilitate motor function while breath control and single syllable vocabulary exercises were implemented to increase communication ability. An exercise regimen was begun to increase strength and

endurance. After approximately six months of treatment, the patient was discharged home. By fourteen months, she was able to self-feed and groom with set up and could dress and transfer with moderate assistance. She was able to communicate bowel and bladder needs and rarely experienced incontinence. The decubiti healed and active range of movement improved enough to allow her to use her right upper extremity for pointing. This case is of interest given the late re-emergence of consciousness and degree of functional recovery that occurred after physically-based rehabilitation strategies were initiated.

Weber (59) monitored EEG responses in 3 patients (2 TBI, 1 anoxic) with GCS scores of eight or below during the first week post-injury in a neurologic intensive care unit. The treatment condition involved two 30 minute sessions of sensorimotor facilitation consisting of passive ranging, quick stretch exercises and joint traction. This was followed by proprioceptive and thermal stimulation accompanied by verbal requests for movement. Each patient served as their own control and received two 30-minute non-treatment sessions in an A-B-A-B design. EEG recordings were obtained before and after exposure to the treatment or non-treatment conditions. Data analyses revealed differential EEG responses by treatment condition. There were significant voltage fluctuations in the bandwidth of the damaged hemisphere that were associated with the patient's "awake" state. Significant voltage changes were not noted in the damaged hemisphere during the non-treatment condition. EEG tracings also suggested normalization of sleep following treatment exposure in all three patients. Unfortunately, follow up data was not collected so it is not known whether the reactive EEG changes presaged a favorable outcome.

*Neuromodulation* Neuromodulatory approaches to treatment of disorders of consciousness seek to alter the neurophysiologic disturbances that accompany severe brain injury. Pharmacologic intervention is the most widely used form of neuromodulation. Drug therapy has been utilized to improve arousal, promote behavioral initiation and persistence, stimulate speech and reduce agitation. The "workhorse" agents used in rehabilitation of individuals with disturbances in consciousness generally fall into three medication classes- psychostimulants, dopamine agonists and tricyclic anti-depressants. There is some evidence that stimulants and dopamine agonists are effective for improving arousal (i.e., wakefulness) and basic attentional functions (60). Significant improvements in behavioral initiation and response persistence have been noted following administration of amitriptyline (61), bromocriptine (62, 63) and amantadine (64, 65). Recovery of spontaneous speech (66, 67) and increases in verbal fluency (62) have also been tied to the use of bromocriptine in individuals diagnosed with MCS.

There are few controlled medication trials in patients with disorders of consciousness. Meythaler and colleagues (64) recently conducted one of the few prospective, randomized, controlled trials completed to date. These investigators administered amantadine hydrochloride (100 mg, bid) or placebo to 35 patients who were one to six weeks post-injury and had Disability Rating Scale scores between 15 and 22. A crossover design was used in which half the group received amantadine first, followed by placebo, while the other half received placebo first, followed by amantadine. Results indicated that cognitive and functional improvement was more rapid during the on-drug phase, regardless of whether subjects received AH or placebo first. At three and six month follow-up, there was no significant difference in DRS scores between treatment groups. Two important methodologic problems challenge the authors' conclusions, however. The group that received amantadine first was less severely disabled prior to treatment than the placebo group and may have achieved more favorable outcomes independent of treatment. Second, because a crossover design was used early in the course of recovery, the group that received amantadine first had improved substantially at the point of crossover, limiting their opportunity to improve to the same extent as the comparison group during the second phase of treatment. By the time the group treated with amantadine first reached crossover, the range of possible improvement on the DRS had narrowed from 15 points (during the active drug phase) to 5 points (during the placebo phase).

In a multicenter observational study of 124 patients with TBI, of all stimulants and dopaminergic agents administered, only amantadine was associated with better outcome (DRS scores) at 4 months post-injury (77). A subanalysis of those who received amantadine indicated that significant improvement in DRS scores occurred just after amantadine was initiated, suggesting that the medication influenced the improvement in functioning.

Passler and Riggs (63) investigated the effectiveness of another dopaminergic agent, bromocriptine (2.5 mg, bid), in improving functional outcome in a series of five patients in VS. In this study, bromocriptine was used in association with multidisciplinary rehabilitation interventions. The authors reported that physical and cognitive recovery at 12 months post-injury was greater in the bromocriptine-treated patients, relative to a group of historical controls. The strength of this study is limited by the small sample size, questionable comparability of the historical control group and failure to adequately address the influence of spontaneous recovery on outcome. It should be noted that a number of studies have reported adverse behavioral and cognitive side effects associated with the use of dopaminergic agents, including agitation, perseveration (68) and exacerbation of neglect (69).

Deep brain stimulation (DBS) is a neurosurgical procedure in which electrical pulses are delivered through

electrodes implanted in brain stem or thalamic structures. This technique is derived from experimental findings in animals showing behavioral and EEG arousal responses in response to stimulation of the reticular system (70). One of the earliest clinical reports of DBS was described by Kanno and colleagues (71) and involved patients diagnosed with vegetative state. Clinical improvements were reported in three of the four patients treated and all four demonstrated improvements in EEG within two weeks of treatment. Improvements were noted in eye-opening, emotional expressiveness, verbal command-following and communication ability during the course of the trial. Tsubokawa and others (72) administered DBS to eight patients (TBI = 4, vascular = 3, anoxia = 1) who were reportedly in a vegetative state for more than six months. Stimulation was applied to sites in the mesencephalic reticular formation and non-specific thalamic nuclei. Behavioral changes associated with increased arousal, including opening of the eyes and mouth, vocalization and movement of the extremities, were observed in response to the stimulation. The behavioral changes coincided with desynchronization of the EEG and marked increases in regional cerebral blood flow and cerebral metabolic rates of oxygen and glucose. The authors noted that two of the eight patients recovered consciousness after 12 months post-injury.

Both of the DBS studies described above are compromised by significant methodologic flaws limiting their clinical applicability. Crude assessment and outcome measures were employed in both studies making it difficult to determine the accuracy of the patients' diagnoses as well as the nature and extent of the changes reported. Because neither study utilized a no-treatment control group, spontaneous recovery cannot be excluded to explain the improvement noted in some of the cases reported.

Schiff, Rezai and Plum (73) have recently proposed a re-designed protocol for DBS that focuses on activation of specific cortical fields via stimulation of carefully selected thalamic targets. In this approach, specific subdivisions of the intralaminar nuclei of the thalamus are stimulated to facilitate activation of damaged but still viable thalamocortical networks. This protocol is recommended for use with patients in MCS versus those in VS, given the that the former are more likely to have greater sparing of thalamocortical and corticocortical pathways relative to the latter, suggesting they may be better able to harness the stimulation effects.

There is a clear need for additional clinical trials of interventions designed to speed the pace of recovery from severe brain injury and improve functional outcome. Because relatively few rehabilitation centers offer services for patients with DOC, this can only be accomplished through multicenter collaborative studies. In the last year, a study of the effectiveness of amantadine hydrochloride, funded by the National Institute on Disability and Rehabilitation Research, was launched. This study involves

eight rehabilitation centers in the U.S. and one in Germany. The primary aims are to determine if amantadine improves functional outcome during inpatient rehabilitation beyond the effects of a placebo, and whether amantadine-induced improvements persist following drug washout.

## PROGNOSIS

Prognosis for patients with DOC has been analyzed with respect to three main outcome areas: recovery of consciousness, functional recovery and mortality. Outcome of VS and MCS are considered separately below. Most of the available information concerns patients in VS since MCS has only recently been operationally defined.

### Outcome Following VS

Over 10 years ago, the Multi-Society Task Force on PVS (11) analyzed all available reports on outcome of VS and summarized prognosis for recovery of consciousness and functional recovery, based on the Glasgow Outcome Scale (74). The report included data on 434 adults and 106 children with traumatic brain injury, and 169 adults and 45 children with nontraumatic brain injury – primarily anoxic brain injury and stroke. Prognosis for recovery was substantially better for victims of traumatic brain injury than those who sustained nontraumatic injury. Of adults with traumatic brain injury who were unconscious at least 1 month, 33% recovered consciousness by 3 months post-injury, 46% by 6 months and 52% by 1 year. Approximately 35% of patients with TBI who were still unconscious at 3 months, regained consciousness by one year; if still unconscious for 6 months, 16% regained consciousness by 1 year. Of those adults with nontraumatic brain injuries unconscious for 1 month, only 11% recovered consciousness by 3 months and 15% by six months. No person with nontraumatic injury regained consciousness after 6 months post-injury.

Prognosis in children was only slightly more favorable. For those children with TBI who were unconscious at 1 month, 51% regained consciousness by 6 months and up to 62% of children with TBI recovered consciousness at one year after injury. After nontraumatic injury, recovery of consciousness occurred mainly within the first 3 months (11%), but a very small percentage (2%) regained consciousness between 6 and 12 months. Table 25-4 shows a summary of these outcome data.

The Task Force concluded that prognosis for recovery of consciousness was very poor 12 months after traumatic injuries and 3 months after nontraumatic brain injury for both adults and children. They suggested the term *permanent vegetative state* for patients who were still unconscious beyond these intervals after injury. Although unlikely, the chance of recovering consciousness is not absolutely lost. There are several reports of

**TABLE 25-4**  
**Prognosis and Functional Outcome According to the Glasgow Outcome Scale at 1 Year After Prolonged Unconsciousness in Adults with Traumatic Brain Injury (TBI) or Nontraumatic Brain Injury (nonTBI)**

	TBI	NON-TBI
Unconscious at least 1 month:		
Death	33%	53%
VS	15%	32%
SD	28%	11%
MD	17%	3%
GR	7%	1%
Unconscious at least 3 months:		
Death	35%	46%
VS	30%	47%
SD	19%	6%
MD/GR	16%	1%
Unconscious at least 6 months:		
Death	32%	28%
VS	52%	72%
SD	12%	0%
MD/GR	4%	0%

(From: Multi-Society Task Force on PVS, 1994) (VS = vegetative state; SD = severe disability; MD = moderate disability; GR = good recovery).

later recovery of consciousness (11, 75) Childs and Mercer (75) pointed out that there is insufficient evidence in the Task Force study or any other studies to predict the incidence of late improvement. In fact, using the limited number of cases followed beyond 12 months in the Task Force report, they recalculated that the incidence of regaining consciousness after 12 months in that limited series of patients was 14%.

The Task Force report described functional outcome using the Glasgow Outcome Scale. By 12 months post-injury, more than one-half of the patients were *severely disabled*, nearly one-third were *moderately disabled* and a little more than an eighth achieved a *good recovery* level. Functional outcome was worse after nontraumatic injury; nearly three-quarters of those who regained consciousness were severely disabled at 12 months. Outcome for children was somewhat better at 12 months: one-half were severely disabled while most of the remainder achieved a good recovery. Older adults (>40 years old) tended towards a worse functional outcome, rarely improving beyond the level of severe disability.

According to the Task Force report, mortality is relatively high for patients in VS at least 1 month (82% at 3 years, and 95% at five years (11). Life expectancy improves the longer a patient in VS survives and younger patients have a greater chance for survival (76).

Although the Task Force analysis provides some general guidelines and probabilities for outcome after prolonged unconsciousness, outcome prediction for individuals with prolonged unconsciousness is difficult at best. A recent multicenter study of 124 patients with severely impaired consciousness (VS or MCS) of 1 month or more after TBI, examined a number of demographic, injury severity, functional and neuroimaging variables to predict outcome. Of all the variables tested, time from injury to initial rehabilitation evaluation, initial functional level in a rehabilitation facility and the rate of early functional recovery were highly predictive of both recovery of consciousness and functional outcome at 4 months post-injury (77).

Electrophysiologic studies may provide some information in determining prognosis after prolonged unconsciousness. Somatosensory evoked potential studies are useful in predicting permanent vegetative state after anoxic brain injury. Absence of the N20 potential in the presence of the earlier N14 potential is a very poor prognostic sign for recovery of consciousness (78). In general, the absence of cortical potentials indicates worse prognosis early in the course of recovery. The presence of the later cortical potentials does not necessarily carry a favorable prognosis. Cognitive event related potentials can provide additional prognostic information over SSEPs alone (79). A recent study by Fischer and others (80) demonstrated that if the cognitive evoked potential was present in patients with prolonged coma, the patient did not remain in a vegetative state. In that study, the best predictors for regaining wakefulness, though not necessarily consciousness, after coma of various etiologies were the presence of a pupillary reflex, followed by the presence of late auditory evoked potentials (N100) and middle-latency evoked potentials.

Structural neuroimaging (CT and MRI) is not very helpful in prognosticating outcome of impaired unconsciousness but there are some correlates with worse outcome. Kamplf and colleagues (81) found that location of brain lesions after trauma was a better predictor of recovery from prolonged unconsciousness than Glasgow Coma Scale scores, age and papillary abnormalities. Patients who did not recover consciousness by 12 months had a significantly higher frequency of corpus callosum, corona radiata and dorsolateral brainstem lesions than those that did regain consciousness. These locations are not specific for unconsciousness but are correlates of more severe grades of diffuse axonal injury (82).

### Outcome Following MCS

Functional outcome appears to be substantially better for patients in MCS than those in VS when evaluated during a similar time post-injury. In a small series of patients with impaired consciousness followed for 4 months, Rappaport (41) reported improvement in 25% of a small group of patients with impaired consciousness noting that only

those in MCS (referred to as “near-coma”) improved; none in VS improved in the follow-up period.

Although few prognostic studies of MCS have been completed, there is strong consensus that outcome from MCS following traumatic brain injury is highly variable, ranging from good recovery to severe disability on the Glasgow Outcome Scale (GOS) (74). The timeframe for establishing when MCS can be considered permanent is unclear as few empirical studies have addressed this particular subgroup.

Studies comparing functional outcome between individuals diagnosed with VS and MCS suggest that individuals in MCS show more rapid improvement, a longer period of recovery and significantly less functional disability at twelve months (77, 83, 84). Figure 25-2 depicts the results of a study conducted by Giacino & Kalmer (83) that investigated functional outcome on the Disability Rating Scale (DRS) (85) across the first year post-injury in patients diagnosed with VS or MCS. The VS and MCS groups were stratified further according to etiology of injury (i.e., traumatic or non-traumatic). Although both diagnostic groups presented with similar levels of disability at one month post-injury, outcome was significantly more favorable by twelve months in the MCS group, particularly after TBI. The differences in outcome became progressively more apparent at 3, 6 and 12 months post-injury. The probability of a more favorable outcome (moderate or no disability) by one year was much greater for the MCS group (38%) than the VS group (2%) and only occurred in those patients with TBI.

Giacino and Kalmar’s findings have recently been replicated and extended by Lammi and colleagues (84) who followed 18 patients in traumatic MCS for two to five years after discharge from an inpatient brain injury

FIGURE 25-2

From “The vegetative and minimally conscious states: A comparison of clinical features and functional outcome,” by J.T. Giacino and K. Kalmar, 1997, *Journal of Head Trauma Rehabilitation*, 12(4), p. 42. Copyright 1997 by Aspen Publishers, Inc. Reprinted with permission

rehabilitation program located in Australia. The authors found that 15% of their sample had partial disability or less at follow-up while 20% fell in the extremely severe to vegetative category. In comparison, Giacino and Kalmar reported that 23% of their sample had no more than partial disability at 12 months with 17% classified as extremely severe to vegetative. In both samples, the most common outcome was moderate disability which occurred in approximately 50% of patients. Of particular importance, Lammi et al. also noted that duration of MCS was not correlated with DRS outcome and that 50% of their sample had regained independence in activities of daily living at follow-up. Both of these studies suggest a clear separation between MCS and VS in course of recovery and eventual functional outcome. Mortality following MCS appears to be similar to that of VS indicating that the presence of consciousness is not the critical factor predicting survival (86). Additional data concerning mortality after severe TBI is provided in the chapter by Shavelle, et al. in this volume.

### RECOMMENDATIONS FOR A RATIONAL APPROACH TO CLINICAL MANAGEMENT

In the absence of empirically-established standards of care for clinical management of individuals with disorders of consciousness, clinicians should adhere to a core set of basic tenets to guide evaluation and treatment of patients with DOC. In that spirit, the following recommendations are proposed, not as a prescriptive mandate, but rather, as a self-study reference for brain injury rehabilitation programs that offer services to this population.

#### Assessment Strategies

Carefully-defined *inclusion criteria* should be developed for patients with DOC seeking admission to rehabilitation programs. This population has unique needs that may not be easily accommodated by traditional rehabilitative interventions. Specialized training is essential for staff members responsible for providing assessment and treatment services as few academic programs directly address the care of patients with DOC. Diagnosis, cause of injury, length of time post-onset, degree of medical stability, age, level of disability and adequacy of support system are factors that should be considered in admission decisions as each one can influence outcome. Creation of a local database is useful for monitoring these variables and may help identify admission and discharge trends, gauge program effectiveness and facilitate longitudinal research.

A *comprehensive neuromedical work up* should be obtained on admission. This should include a complete review of the history, comprehensive physical examination, neurologic assessment, neuroimaging studies (if recent scans are unavailable), nutritional assessment and

review of current medications. Undetected or co-existing medical conditions such as post-traumatic epilepsy, hydrocephalus, late subdural hematoma, neuroendocrine dysfunction, nutritional deficiency, occult infection and drug toxicity must be excluded as potential causes of under-arousal and under-responsiveness (4).

A *well-defined assessment protocol* should be developed to monitor changes in neurologic, cognitive, physical and functional status. Standardized measures of neurobehavioral responsiveness (39–42, 44) and functional disability (85) should be utilized and supplemented with individualized assessment techniques (46), as needed. When conducting medication trials, outcome goals should be operationally-defined and objective measures employed to track progress. In most cases, patients should be serially reevaluated during the first three months post-injury to detect fluctuations in level of responsiveness. After the three month mark, assessment frequency should be determined by the patient's rate of change. Follow-up examinations should be completed at 12 months whenever possible as significant change is unlikely after this point.

There are no universally accepted *criteria for determining when rehabilitative treatment should be discontinued*. It is incumbent upon individual programs to determine local decision-making criteria to assure consistency across patients. There are four clinical factors that should be considered in the decision to discontinue treatment (48). The first two, cause of injury and length of time post-onset, represent important determinants of outcome, particularly when they are utilized in combination. As discussed earlier, the probability of recovering from VS after three months is significantly higher following traumatic versus non-traumatic brain injury (11, 83, 84). The patient's current level of neurobehavioral responsiveness is a third factor that should be taken into account as this reflects the extent of spared neural circuitry available to process sensoriperceptual input and mediate behavioral output. Response profiles dominated by reflexive brain stem activity offer little opportunity to promote higher-order cognitive processing given the loss of cortical connectivity. The fourth factor, rate of recovery, is perhaps the most important variable. Prior studies suggest that evidence of ongoing change is a favorable predictor of functional outcome, even in patient's who have not yet regained signs of consciousness (39, 77). The specific weight that should be assigned to each factor has not yet been elucidated. Additional research is needed before algorithms can be developed to guide treatment discontinuation decisions. This task should be viewed as an important objective in brain injury rehabilitation.

#### Treatment Strategies

Physical management interventions (e.g., range of motion, positioning, hygiene, etc.) should be considered a standard

component of the rehabilitation regimen of patients with disorders of consciousness. While it is unknown whether these interventions can facilitate the pace or degree of neurophysiologic recovery, there are strong rational indications for their use, and little evidence that they are ineffective or unsafe. Steps should be taken to ensure that comfort is maintained and pain alleviated, particularly when intrusive medical and rehabilitative procedures are performed. Other interventions such as sensory stimulation and medication trials should be considered treatment *options* and should be construed as supplementary to the basic rehabilitative strategies described above.

Special emphasis should be placed on utilizing behavioral and pharmacologic strategies to promote arousal and facilitate neurogenic drive. Preserved cognitive function may be masked by deficiencies in these areas. Alternative or augmentative communication systems should be implemented in individuals diagnosed with MCS because sensory and neuromuscular impairments often accompany disturbances in consciousness (5, 6). Assisted communication systems should not be incorporated into long-term care plans until there has been an adequate period of assessment in which response consistency and reliability have been demonstrated.

Finally, a formal protocol for providing family/surrogate education and training should be developed. An explicit mechanism for allowing ongoing communication between caretakers and the rehabilitation team across the span of treatment is a pre-requisite for effective treatment. At a minimum, family conferences should be held shortly after admission and prior to discharge. The initial conference should include discussion of the preliminary assessment findings, particularly those that pertain to functional capacity and prognosis for further recovery. The treatment objectives recommended by the clinical team should be presented and integrated with the goals stipulated by the caretakers. Specific treatment methods should be outlined and accompanied by information regarding the efficacy of the proposed interventions and the anticipated outcome in each targeted area. A second meeting should be held prior to discharge to confirm or modify the initial diagnostic and prognostic impressions, clarify recommendations for clinical management and to establish a plan for follow-up assessment, as indicated.

### ETHICAL CONSIDERATIONS

Neurorehabilitation specialists often encounter difficult ethical issues related to the clinical management of patients with DOC. While most clinicians have not received formal training in bioethics, it is important to have some awareness of the type of ethical questions that are likely to arise during the course of treatment. Comprehensive review of these issues is beyond the scope of this chapter but it is

useful to summarize some of the questions clinicians can expect to be confronted with during acute and post-acute care of these patients. For additional discussion of ethical considerations, interested readers are referred to the chapter by Kothari, et al. in this text and the recent special issue of *Neurorehabilitation* on scientific advances and ethical dilemmas concerning life-sustaining treatments in VS (87).

- Is it appropriate to allocate resources to the treatment of patients with chronic disorders of consciousness at the same level as patient's who are fully conscious?
- At what point should rehabilitative treatment be considered futile?
- What services should be provided after VS and MCS are deemed permanent?
- Is it appropriate to withdraw artificial nutrition and hydration in non-terminal patients in permanent VS and MCS?
- Should artificial hydration and nutrition be discontinued in patients in VS and MCS before criteria for permanence are met?
- Should patients with disorders of consciousness be permitted to participate in clinical trials?

### CONCLUSIONS AND FUTURE DIRECTIONS

Disorders of consciousness are arguably the most enigmatic conditions encountered in medical rehabilitation. Although progress has been made over the last decade in developing more reliable assessment methods, the psychometric integrity and clinical utility of these measures remain highly variable. Similarly, remarkably little is known about the neurophysiologic substrate underlying these disorders. These problems have been sustained, in part, by clinical nihilism – the belief that little effort should be invested in these patients because they cannot be helped. Recent initiatives to establish standards of care for evaluation and clinical management have begun to take hold and are expected to progress more rapidly in view of new insights gained from novel neurodiagnostic technologies.

At present, there are no treatment interventions that have been demonstrated to be effective in facilitating recovery of consciousness. Additional research is needed to 1) clarify the natural history of recovery from VS and MCS, 2) identify predictors of recovery of consciousness and cognition, 3) elucidate the pathophysiology underlying specific disorders and 4) develop treatments capable of altering outcome in patients with DOC. To accomplish these goals, it will be necessary to establish collaborative partnerships across rehabilitation centers and across disciplines. In the current healthcare climate, few rehabilitation centers can recruit patient samples large enough to carry out adequately powered clinical trials. Moreover, most centers do not have

ready access to neuroscientists, biophysicists, neurosurgeons, neurologists and bioethicists, all of whom contribute uniquely to the study of patients with DOC.

## Post-Traumatic Seizures and Epilepsy

**Stuart A. Yablon**  
**Victor G. Dostrow**

### INTRODUCTION

Traumatic brain injuries (TBI) remain a leading cause of neurologic disability and death in the population of the United States and westernized nations. While the incidence of hospitalization for mild TBI in the United States has declined (1), the number of patients hospitalized for TBI remains significant, approximately 100/100,000 per year (1). Among the survivors of TBI, a sizable number remain with important medical and neurological sequelae, including seizures.

The relationship between TBI and subsequent development of post-traumatic seizure (PTS) disorders, including incidence, risk factors for initial occurrence and recurrence, and management, comprise the central themes of this review. Most cited studies address PTS among adults. Issues pertinent to diagnostic and therapeutic management of PTS in the patient with severe traumatic brain injury (TBI) are emphasized.

### CLASSIFICATION OF POST-TRAUMATIC SEIZURES AND EPILEPSY

It is useful to review terms employed in the discussion of post-traumatic seizure disorders. These are defined in the Practice Parameter on the Antiepileptic Drug Treatment of Post-traumatic Seizures by the Brain Injury Special

Interest Group of the American Academy of Physical Medicine and Rehabilitation (2) (Table 1), and the Guidelines for Epidemiologic Studies on Epilepsy, by the Commission on Epilepsy and Prognosis of the International League Against Epilepsy (3). An *epileptic seizure* is a clinical manifestation presumed to result from an abnormal and excessive discharge of a set of neurons in the brain. The clinical manifestation consists of sudden and transitory abnormal phenomena, which may include alterations of consciousness, motor, sensory, autonomic, or psychic events, perceived by the patient or an observer (3). *Epilepsy* is a condition characterized by recurrent (two or more) epileptic seizures, unprovoked by any immediate identified cause (3).

*Post-traumatic epilepsy* (PTE) is a disorder characterized by recurrent late seizure episodes, not attributable to another obvious cause, in patients with TBI (2). Although PTE has commonly designated single or multiple seizures, including early seizures, the term should be reserved for recurrent, late PTS. Since most studies regarding seizures among patients with TBI do not address recurrence, the term post-traumatic seizures (rather than epilepsy) is preferred, since it encompasses both single and recurrent episodes. Thus, a *post-traumatic seizure* (PTS) refers to a single or recurrent seizure episode occurring after TBI (2). Post-traumatic seizures have been further classified into early (< 1 week after TBI) and late (>1 week after TBI) categories, primarily due to prevailing

opinion that they represent similar manifestations of different pathophysiologic processes (4). Classification of early seizures as those occurring within the first seven days after TBI has sparked some controversy (5), particularly with regard to long-term AED treatment decisions. There is little data to suggest that seizures that occur at day 8 or 14 have recurrence characteristics that justify classification as late seizures, and underlying mechanisms of seizure appearance are more likely to reflect acute pathophysiologic processes rather than those of chronic epilepsy.

The exclusion of "other obvious causes" is especially relevant to this patient population. Seizures occurring among patients with TBI may be the result of precipitants unrelated to mechanisms currently linked with post-traumatic epileptogenesis. Seizure precipitants have been defined as any endogenous or exogenous factor that promotes the occurrence of epileptic seizures (6). Examples of seizure precipitants among patients with TBI include hydrocephalus (7), sepsis (8), hypoxia (9), metabolic abnormalities (10) and mass-occupying lesions, including hemorrhage (11, 12). Among epileptic patients, more than 60% cite precipitants among recurrent seizures they experience. (6)

Drugs (13, 14), including alcohol (15, 16), prescribed psychotropic agents (14, 17–22), and recreational/illicit drugs (13, 23) warrant particular scrutiny as seizure precipitants among patients with TBI. In one study, for example, 19% of patients with severe TBI developed seizures attributed to tricyclic antidepressants (22). Antidepressants other than tricyclic agents are also implicated with seizure occurrence, including immediate (21) and sustained-release formulations of bupropion (17). While SSRIs are considered to have lower proconvulsant activity than other common antidepressants (24–26), several uncontrolled case studies of epileptic patients with depression have reported that SSRI administration increased seizure frequency (27, 28). Certain antipsychotic drugs, including newer atypical antipsychotic agents, particularly clozapine, may induce EEG abnormalities and seizures (18). Antibiotics, particularly imipenem (29) and quinolone agents (30), have been associated with seizures. Seizure risk is generally elevated among critically ill patients (31), however, and proper dose adjustment for renal clearance may mitigate much of the risk attributed to antibiotic administration (31, 32). Bromocriptine and amantadine, dopamine receptor agonists used to treat impaired arousal after TBI, have been implicated as seizure precipitants (33), although this association presently appears to be largely anecdotal. Recreational/illicit stimulants with well-known seizure-inducing properties include cocaine; however, few are probably aware that caffeine at high doses may also induce epileptic seizures (34). Amphetamine and related drugs rarely induce epileptic seizures at therapeutic doses (34). Moreover, methylphenidate and dextroamphetamine do

not appear to be associated with increased seizure risk among patients with TBI (33, 35).

Seizures and seizure disorders are classified according to their clinical and electroencephalographic characteristics, as developed by the Commission on Classification and Terminology of the International League Against Epilepsy (36, 37). Seizures have been divided into two categories, based primarily on pattern of onset. These include partial or focal seizures, and generalized seizures. Patients with nonpenetrating TBI frequently have sustained multiple foci of cerebral injury (38–40), and may manifest more than one type of seizure (4).

Generalized seizures denote those that are bilaterally symmetrical in origin without local onset (36). The most commonly recognized example is the grand mal, or tonic-clonic (GTC) seizure. Generalized-onset or secondarily generalized seizures (SGS) are reported in approximately half of the patients with PTS (41) and appear more frequently in patients with nonpenetrating TBI (42), and among children (43).

Partial or focal seizures originate in a localized area of one cerebral hemisphere. Partial seizures are further classified according to whether consciousness is maintained (simple partial [SPS]) or impaired (complex partial [CPS]) during the seizure. Characteristics of both vary, depending on the location of the seizure activity within the brain. Twelve percent of cases of CPS in the general population may be attributable to TBI (44). Partial-onset seizures are observed in slightly more than half of all patients with PTS, and appear more frequently in adults (4), and patients with early seizures (4, 42, 45), focal lesions on CT (46), penetrating TBI (PTBI) (42, 47), and nonpenetrating TBI of greater severity (46). Studies that incorporate videoelectroencephalography (VEEG) are more likely to detect subtle clinical signs that may indicate partial-onset PTS (48, 49).

The Working Group on Status Epilepticus (50) defines *status epilepticus* (SE) as more than 30 minutes of (1) continuous seizure activity or (2) two or more sequential seizures without full recovery of consciousness between seizures (50). More recent publications define SE as seizures that persist for shorter durations, (52, 51), based upon estimates of the duration necessary to cause injury to central nervous system neurons (51). This definition differs from those of other terms describing multiple seizure episodes, including serial seizures and acute repetitive seizures. *Serial seizures* are two or more seizures occurring over a relatively brief period (i.e., minutes to many hours), but with the patient regaining consciousness between the seizures (51). *Acute repetitive seizures* are clusters of seizures that appear to increase in frequency or severity over a short time. Acute repetitive seizures may become SE, but the frequency of this occurrence is unclear (53). Clinical manifestations of SE vary, and may include clinically obvious tonic-clonic movements, or small amplitude

twitching movements of the eyes, face, or extremities (51). Some patients have no observable repetitive motor activity, and the detection of SE requires EEG. Further discussion regarding status epilepticus after TBI follows later in this review.

Nonepileptic seizures, (NES) often called pseudo-seizures or psychogenic seizures, are terms used for episodic behavioral events which superficially resemble epileptic attacks but which are not associated with paroxysmal activity within the brain (54). NES may be psychogenic, or may include non-epileptic events such as syncopal episodes and cardiac events. NES are not uncommon in neurologic settings (55), and may coexist with epileptic seizures in patients with epilepsy (55, 56). The differentiation between nonepileptic and epileptic seizures cannot be made on the basis of clinical characteristics alone. Electroencephalographic monitoring (particularly with video) (56) is often helpful in establishing a diagnosis. Postictal prolactin (PRL) measurement (57) may provide additional diagnostic information if significant elevations are observed, suggesting that an epileptic seizure has occurred within one hour (58). The utility of this test to discriminate between epileptic seizures and NES has been questioned, however, as a subset of patients with video-electroencephalography (VEEG)-documented psychogenic NES have also been reported to experience an increase in PRL, particularly if the sample is obtained within 10–20 minutes of a suspected NES (58).

While recognized to occur among patients with TBI, relatively few studies address post-traumatic NES. Hudak et al reported that one-third of patients with moderate-to-severe TBI undergoing VEEG for diagnosis of epilepsy were found to have psychogenic NES (48). When non-diagnostic VEEG studies were excluded, patients with NES comprised 40% of the TBI sample (48). Barry et al. described the characteristics of 16 patients thought to have PTS, who actually had NES, as confirmed on VEEG monitoring. Patients with NES were characterized by injuries of much milder severity, although the disability associated with the NES was pronounced. The patients usually had manifestations of other conversion disorders as well, and psychiatric histories that predate the TBI (59).

Epilepsy has been classified into different epileptic syndromes, with two general divisions employed (3, 37). One division separates epilepsies characterized by generalized seizures from syndromes characterized by seizures of focal onset, termed localization-related epilepsies. The other division separates epilepsies of known etiology (secondary or symptomatic) from those that are idiopathic (primary) and those that are cryptogenic (seizures or epilepsy in which no known risk factor has been identified). Symptomatic epilepsies and syndromes are considered the consequence of a known or suspected disorder of the central nervous system, such as TBI (3, 37). Recurrent late post-traumatic seizures, or post-traumatic epilepsy,

are a common and important type of remote symptomatic epilepsy (3), accounting for 20% of all symptomatic epilepsy in the general population (60). Symptomatic (or secondary) epilepsies comprise syndromes of great individual variability, based mainly on seizure type and anatomic localization.

### MANIFESTATIONS OF POST-TRAUMATIC SEIZURES AND EPILEPSY

Seizures may present with a variety of manifestations, including cognitive, behavioral and affective changes that may not be attributed to an underlying epileptic disorder (61, 62). Patients with severe TBI may exhibit cognitive, behavioral, and affective sequelae that potentially confound attribution of episodic behavioral changes to an underlying epileptic disorder (48). The varied semiology of seizures that originate in the frontal or temporal lobes, and their associated ictal or postictal alteration of consciousness, justify their consideration in the differential diagnosis of any TBI patient with episodic (especially stereotypic) changes in mental status. Given the propensity of TBI contusion localization to the frontal and temporal lobes (40, 63), it is not surprising that these regions are the most frequent sites of origin for VEEG-verified partial-onset PTE (48). Presumed or pathologically-confirmed post-traumatic seizure foci, however, have been described in all major lobes of the brain (38, 48, 63–65).

Patients with frontal lobe epilepsy may exhibit complex, semipurposful, complex motor automatisms such as kicking, screaming, and thrashing episodes (62). Frontal lobe interictal and postictal manifestations also include cognitive or affective symptoms, such as confusion, anger, hostility, and hallucinations (66, 67). Complex partial seizures of temporal lobe origin may also present with emotional symptoms such as fear or panic, followed by periods of postictal confusion and amnesia (37). Seizure-related aggression, however, is rare (68, 69). It is usually associated with postictal confusion, particularly while the patient is being restrained (69, 70). Conversely, reports of aggression are more frequent among epileptic patients, particularly with younger age, male gender, psychopathology, and prior brain injury (71), but aggression episodes are typically unrelated to seizure type, frequency, or age of onset (72). Conventional interictal scalp EEG are of limited diagnostic assistance in such cases. Electrographic manifestations of seizure activity in the orbitofrontal and mesial temporal regions of the brain may be difficult to recognize, and can be misleading (62) by showing no abnormality (37) at all. Table 26-1 shows the characteristics of localization-related epilepsies based upon the involved lobe of the brain (37, 67, 73–79).

**TABLE 26-1**  
**Characteristics of Localization-Related (partial-onset) Epilepsies**

SITE OF ORIGIN	MANIFESTATIONS
<b>Frontal</b>	<p><b>Seizure types:</b> SPS, CPS, SGS, combinations; SE is frequent complication. Seizures often occur several times a day, and frequently during sleep.</p> <p><b>Features:</b> Features strongly suggestive of frontal lobe epilepsies include: 1) Generally short seizures; 2) CPS often with minimal/no postictal confusion; 3) rapid secondary generalization; 4) prominent tonic/postural motor manifestations; 5) complex gestural automatisms at onset (frequent); 6) falling with bilateral discharge (frequent).</p>
<b>Cingulate</b>	<p><b>Features:</b> CPS with complex gestural automatisms at onset; autonomic signs (common); changes in mood and affect (common); psychic/emotional auras, including fear and anger (frequent).</p>
<b>Orbitofrontal</b>	<p><b>Features:</b> CPS with initial sudden, complex, bizarre motor and gestural automatisms that may be bilateral and mixed with staring, olfactory hallucinations/illusions and autonomic signs; psychoemotional auras are rare.</p>
<b>Dorsolateral</b>	<p><b>Features:</b> Tonic (common) or clonic (less common) with versive eye and head movements and speech arrest. <i>Dorsolateral premotor cortex</i>-onset usually without aura, with tonic head/neck/eye movement or "pseudoabsence" (very brief lapse of consciousness &lt;10 sec duration); <i>Pre-frontal/Frontopolar</i>-psychic auras, visual illusions, or initial loss of consciousness followed by head and eye movements.</p>
<b>Motor Cortex</b>	<p><b>Features:</b> SPS (most common) with manifestations reflecting the side and topography of the area involved: <i>Lower prerolandic area</i>-speech arrest, vocalization or dysphasia, contralateral tonic-clonic movements of the face, or swallowing. Generalization is frequent. <i>Rolandic area</i>-SPS without "march" (jacksonian seizures), particularly beginning in contralateral upper extremity. <i>Paracentral lobule</i>-tonic movements of the ipsilateral foot and contralateral leg, postictal paralysis (frequent).</p>
<b>Supplementary Motor Cortex</b>	<p><b>Features:</b> Postural, focal tonic seizures, with vocalization, speech arrest, and fencing postures; usually no aura; may have autonomic symptoms.</p>
<b>Temporal</b>	<p><b>Seizure types:</b> SPS, SGS, CPS, combinations.</p> <p><b>Features:</b> Features strongly suggestive of temporal lobe epilepsies include: 1) SPS typically characterized by autonomic and/or psychic symptoms and certain sensory phenomena (e.g. olfactory and auditory), epigastric, often rising, sensation (most common); 2) CPS with onset of motor arrest or stare followed by oro-alimentary automatism (often), other automatisms frequently follow. Aura is common. Seizure duration typically &gt;1 min, with postictal confusion/amnesia, and gradual recovery (common); 3) Interictal scalp EEG with no abnormality, slight or marked asymmetry of background activity, or temporal spikes, sharp waves, not always confined to the temporal region. Ictal scalp EEG onset may not precisely correlate with clinical onset.</p>
<b>Mesiobasal / Limbic</b>	<p><b>Features:</b> CPS with visceromotor and behavioral symptoms, including rising epigastric discomfort, nausea, marked autonomic signs, and other symptoms, including belching, pallor, fullness/flushing of the face, respiratory changes, pupillary dilatation, fear, panic, and olfactory-gustatory hallucinations. Auditory symptoms do not occur. Interictal scalp EEG may be normal.</p>
<b>Lateral</b>	<p><b>Features:</b> SPS with auditory hallucinations or illusions or dreamy states, visual misperceptions; or language disorders (dominant hemisphere). May progress to CPS with propagation to mesial temporal or extratemporal structures. The scalp EEG may show unilateral, bilateral midtemporal or posterior temporal spikes.</p>
<b>Occipital</b>	<p><b>Seizure types:</b> SPS, SGS, CPS. CPS may occur with spread beyond the occipital lobe.</p> <p><b>Features:</b> Usually visual manifestations, appearing in the visual field contralateral to the discharge (unless generalization occurs). Nonvisual symptoms have been reported, but most often reflect spread to other lobes.</p> <p><i>Positive phenomena:</i> Visual hallucinations (most common), including sparks, flashes. Visual illusions have been reported, but probably reflect non-dominant parietal lobe involvement.</p>

**TABLE 26-1**  
(continued)

SITE OF ORIGIN	MANIFESTATIONS
<b>Parietal</b>	<p><i>Negative phenomena:</i> Ictal amaurosis, fleeting scotoma, hemianopsia. (well-recognized but less common).</p> <p><b>Seizure types:</b> SPS (most common), SGS (especially with paracentral lobule), CPS.</p> <p><b>Features:</b> Predominantly sensory with many characteristics, also some rotatory or postural motor phenomena may occur.</p> <p><i>Positive phenomena:</i> Most common: (tingling, electric shock-like sensations, desire/sensation of movement in body part) usually involving hand, arm and/or face contralateral to seizure focus. Less common: intraabdominal sensation of sinking/nausea, particularly with inferior and lateral parietal lobe involvement. Rare: pain, visual phenomena occurring as formed hallucinations.</p> <p><i>Negative phenomena:</i> numbness (common), disturbance in body image (a feeling that a body part is absent, asomatognosia [loss of awareness of a part or a half of the body, particularly with nondominant hemisphere involvement]), severe vertigo or spatial disorientation (inferior parietal lobe), receptive or conductive languages disturbances (dominant parietal lobe), lateralized genital sensation (paracentral parietal lobe).</p>
<b>Insula</b>	<p><b>Seizure type:</b> SPS</p> <p><b>Features:</b> Throat/laryngeal discomfort, paresthesias on contralateral (typical) side of body, dysarthria/aphonia, hypersalivation.</p>

### Ictal versus Postictal Focal Neurological Deficits

The presence of focal motor, sensory or language deficit of new-onset should alert the clinician to the possibility of a recent unwitnessed PTS. Todd's phenomenon/a are terms given to a heterogeneous group of focal signs of neurologic dysfunction that may follow a partial (9) or generalized tonic-clonic seizure (80). Todd's phenomena are recognized postictal manifestations of PTS (81). These do not reflect permanent structural damage, but rather represent transient *postictal* disruption of function that typically resolves within 24 to 48 hours (9). Todd's phenomena should be differentiated from ictal paralysis, a "negative" *ictal* epileptic manifestation, (82).

### Unclassified Phenomena (not considered to be post-traumatic seizures)

Transient behavioral changes, reminiscent of CPS (83–85), have been noted among TBI patients without concurrent seizures. In most reports, patients manifest interictal discharges on EEG, without the hypersynchronous EEG activity and stereotyped behaviors which characterize partial seizures and localization-related epilepsies (84, 85). When described among patients with TBI, these are usually reported among individuals with mild injury severity (84, 85). In these reports, many patients respond favorably to AEDs such as carbamazepine (CBZ) (85).

The resemblance of the behaviors to some CPS of temporal or frontal lobe origin, and favorable response to AEDs, tends to confuse clinical diagnosis. At present, the description of these behavioral abnormalities should not be considered diagnostic for epileptic seizures.

### INCIDENCE OF POST-TRAUMATIC SEIZURES

Traumatic brain injuries are an important cause of epilepsy, accounting for 20% of symptomatic epilepsy observed in the general population, and 5% of all epilepsy (60). TBI is the leading cause of epilepsy in young adults (86). Many studies addressing the relationship between TBI and epilepsy derive from observations of veterans sustaining PTBI in battle (47, 87–99). Studies in civilian settings (4, 39, 41, 43, 46, 100–129) generally appeared later and reflect a larger patient population with nonpenetrating TBI, as opposed to PTBI. The observed results vary, reflecting differences in inclusion and exclusion criteria, methods for evaluation and description of seizure phenomena, attention to confounding variables, duration of follow up, and patient population studied (130). Nevertheless, these studies provide useful information regarding the incidence, risk factors, and natural history of PTS/PTE.

In summary, the overall incidence of late seizures in hospitalized patients following nonpenetrating TBI is

approximately 4–7%, varying with the injury and patient characteristics (4, 102). Late seizures are observed less frequently among children (43, 102, 122). The incidence of PTS among patients with nonpenetrating TBI observed in the rehabilitation setting appears substantially higher than that reported in other civilian settings (103, 107, 108, 113, 118, 125, 127, 131), approximately 17%. This is probably a reflection of the increased severity of injury and concurrence of multiple risk factors encountered among inpatients in these settings (103, 113). In contrast, the incidence of seizures among adults after mild TBI is slightly greater than that observed in the general population (101, 102). PTS will be observed in approximately 35–65% of patients with PTBI (47, 88, 91, 92, 113). Discussion regarding the influence of specific risk factors upon the incidence of PTS follows later in this chapter.

The incidence of early seizures is approximately 5% (4, 132) among all nonpenetrating TBI patients, and is higher in young children (4, 42, 43, 102, 104), among whom the incidence is approximately 10% (43, 102). However, continuous EEG monitoring of patients with severe TBI in the intensive care unit suggests that the incidence of early convulsive and nonconvulsive EPTS may be considerably higher than initially believed, approximately 22% (49). Immediate seizures, which make up 50–80% of EPTS (4, 42, 93, 122, 133), are particularly frequent among children with severe TBI (43, 102). EPTS are occasionally observed among children with mild TBI (4, 43), but are comparatively much less frequent among adults with mild TBI. Early seizures among these adults warrant investigation for an underlying intracranial hemorrhage. In a study of >4000 adults with mild TBI, an intracranial hemorrhage was found in almost half of the patients with EPTS (123).

The incidence of early seizures is approximately 10% (43, 102) among young children (4, 42, 43, 102). Immediate seizures, which make up 50–80% of EPTS (4, 42, 93, 122, 133), are particularly frequent among children with severe TBI (43, 102). Late seizures are observed less frequently among children (43, 104, 122) than adults.

## NATURAL HISTORY OF POST-TRAUMATIC SEIZURES AND EPILEPSY

### Onset

Approximately one-half to two-thirds of patients who suffer PTS will experience seizure onset within the first 12 months, and 75–80% by the end of the second year following injury (41, 46, 47, 92, 96, 97, 109). After five years, adults with mild TBI do not appear to have a significantly increased risk relative to the general population (101). However, patients with moderate or severe TBI and PTBI remain at increased risk after this postinjury duration (42, 46, 47, 101).

### Recurrence

It is increasingly evident that seizure recurrence is a critical factor in determination of subsequent disability, and quality of life (135, 134). Greater seizure frequency significantly correlates with lower employment rates, which in one study ranged from 57% among patients seizure-free for 3 months, to 30% in patients with daily seizures. As seizure frequency increased, health care costs increased and measures of QOL declined (135).

Limited data exist regarding PTS recurrence. Earlier studies reported that about one-half of patients will experience a single PTS without recurrence (110, 122), and another quarter will suffer a total of 2–3 seizures (122). These reports addressed recurrence following early seizures. Recent studies addressing LPTS recurrence, however, suggests a more ominous prognosis (136, 137). Semah et al investigated the relationship between prognosis for seizure recurrence and the etiology of epilepsy. Among 50 patients with remote symptomatic epilepsy with history or radiographic evidence of TBI, only 30% of those with partial epilepsy experienced seizure free durations of >1y without recurrence (137). Haltiner and colleagues followed 63 adults with moderate or severe TBI, who developed LPTS during the course of participation in a randomized, placebo-controlled study of the effectiveness of phenytoin prophylaxis for prevention of LPTS (138). The cumulative incidence of recurrent late seizures was 86% by 2 years. However, 52% experienced at least 5 late seizures, and 37% had 10 or more late seizures within 2 years of the first late seizure (136).

Pohlmann-Eden (41) published results of a PTE study population derived from a tertiary referral epilepsy clinic. Fifty-seven patients with PTE were compared with 50 age and sex-matched control patients with severe TBI. Of all PTE patients, 35% became seizure-free (no seizures within the last 3 years), 3.5% without any treatment. Twenty-one percent experienced more than 1 seizure per week. The most important risk factors for poor seizure control were missile injuries, “combined seizure patterns,” high seizure frequency, AED non-compliance and alcohol abuse (41).

In summary, recent evidence suggests that while patients with EPTS will experience a late seizure in 20–30% of cases, seizure onset after the first week is associated with a much higher likelihood of seizure recurrence (97, 136). Seizure frequency within the first year after injury may be predictive of future recurrence, particularly with PTBI (47). Persistent PTS may be more common in partial seizures, and less common in generalized seizures (47, 137). IPTS are generally believed to carry no increased risk of recurrence (4, 139). On the other hand, between one-fifth to one-third of patients with LPTS will experience frequent recurrences, apparently refractory to conventional AED therapy (41, 131, 136). Some of these patients may be helped with surgical intervention (38, 64, 140). TBI neuroimaging characteristics may be of value

in predicting the appearance (113) and intractability (141) of PTE. Finally, few studies explicitly address rates of PTE remission, that is, disappearance of seizures (142). Early studies, derived mostly from PTBI populations, describe remission rates that range from 25–40%. Higher overall remission rates are reported in studies conducted after the development of effective AEDs (142).

### Complications and Consequences of PTS

Potentially significant complications accompany seizures in the patient with TBI. Indeed, occurrence or recurrence of seizures is an important cause of non-elective rehospitalization (143) and death (144) among patients with severe TBI. Among patients with newly-diagnosed (145) or chronic remote symptomatic epilepsy, persistent seizures are associated with increased mortality, particularly among individuals with status epilepticus or generalized convulsions (146). Several studies have examined the sequelae of PTS (147–150). An appreciation of these potential consequences is useful when evaluating risk/benefit relationships for decisions regarding AED therapy.

#### *Cognitive and Behavioral Function*

As introduced earlier, manifestations of PTS include cognitive and behavioral dysfunction. Evidence of cognitive impairment may occur or persist during the interictal state, however, when the epileptic patient is not actively manifesting seizures (151–153). Similarly, persistent behavioral abnormalities and a significantly higher incidence of psychiatric-related hospitalizations have been noted among patients with PTS when compared with non-epileptic controls with PTBI (154). Mazzini et al (125) found that disinhibited behavior, irritability, and aggressive behavior were significantly more frequent and severe among rehabilitation inpatients with PTE, when compared with TBI patients without seizures.

#### *Influence on Neurological Recovery*

Animal studies suggest the existence of a complex relationship between post-traumatic seizures and neurological recovery (155). Specifically, depending on the severity of the seizure induced and time of presentation, seizures may inhibit, improve, or not affect functional recovery. In studies conducted with rodents, if “mild” subclinical kindled seizures occur early after brain damage, no delay is noted in somatosensory recovery. This suggests that brief infrequent PTS occurring during the early post-traumatic period did not adversely affect functional recovery. However, if more severe and widespread seizures are kindled within a 6-day critical period after brain lesion, a permanent impairment of functional recovery results. When these same seizures occur after this

critical period, recovery of function proceeds unimpeded. It is important to note that contrasting results have been found using models of brain injury other than kindling models (155).

#### *Outcome*

Recurrent PTS may exert an adverse impact upon functional status among adults (156) and children (105) with TBI, independent of that attributable to the severity of injury. Among patients with PTBI in the Vietnam Head Injury Study, PTS were one of seven impairments which independently and cumulatively predicted employment status (156). PTS and increasing brain volume loss have been noted to exert independent and profound effects on cognitive performance among patients with restricted frontal lobe lesions due to PTBI (157).

However, studies among patients with nonpenetrating TBI less clearly discriminate the influence of seizures on functional prognosis (103, 104) and cognition (158) from those of injury. Haltiner (159) examined the relationship of LPTS to neuropsychological performance and aspects of psychosocial functioning. While patients with LPTS demonstrated greater impairment than those without seizures, after adjusting for injury severity, there were no significant differences in outcome at 1 year as a function of seizures. The authors concluded that poorer outcomes encountered among patients with PTS at 1 year postinjury reflect the severity of injury and not the effects of LPTS *per se*. Asikainen noted that patients with PTS had poorer outcome as measured by the Glasgow Outcome Scale (GOS), a gross global outcome measure, but no significant differences in employment outcome when compared with nonepileptic patients with TBI (104). Mazzini (125) also found that PTS correlated with significantly poorer outcome, as measured by the GOS, disability rating scale, functional independence measure, and subscales of the neurobehavioral rating scale at one year after severe TBI. In contrast, early seizures appear to have little influence on outcome (132, 160).

#### *Status Epilepticus*

Status epilepticus is the most clinically significant manifestation of PTS, and carries the greatest risk of adverse outcome. It may cause additional neurologic injury, potentially occurring within 10 minutes of seizure onset, according to some reports (161). One study employing continuous EEG monitoring suggests that early nonconvulsive SE may not be rare, occurring perhaps in as many as 6% of patients with severe TBI despite “therapeutic” levels of AED prophylaxis (49). Moreover, status epilepticus among patients early after TBI is associated with a very high mortality risk (49). Fortunately, *convulsive* SE remains an infrequent manifestation of PTS (122).

Additionally, SE is usually attributable to another cause, such as antiepileptic drug (AED) withdrawal, acute systemic or neurologic injury, such as anoxic encephalopathy or stroke (162), sepsis, metabolic derangements, or a combination of these conditions (8). Status epilepticus is more likely to be encountered as a PTS manifestation in children, (163). Deaths associated with SE are usually attributable to the disorder which precipitated it (164, 165).

### *Mortality*

Mortality among patients with PTS remains consistently elevated in most reports (147, 149, 150, 166). However, the contribution of PTS to this increased mortality is unclear. Walker noted that men with PTS have a death rate somewhat exceeding that of comparable normal men. However, information supplied by relatives suggested that causes of death were not specific for men with TBI, and seemed to reflect those found in elderly people (149). In another related series of studies, deaths among PTBI patients with PTS appeared due to the sequelae of injury and unrelated to seizures. These patients approached the actuarial mortality norm for their peers after only 3 years (133, 148).

Sudden unexpected death in epilepsy (SUDEP) accounts for 18% of all deaths among patients treated in major epilepsy centers (167). Walczak and colleagues noted that occurrence of tonic-clonic seizures, treatment with more than two AEDs, and full-scale IQ less than 70 are independent risk factors for SUDEP. Tonic-clonic seizure frequency may be a risk factor, but only in women. The presence of cerebral structural lesions was not found to be a risk factor for SUDEP (167), and this phenomenon has not been described among patients with PTE.

In summary, sequelae associated with isolated LPTS are comparable to those found in any seizure. Isolated or infrequent late seizure episodes are generally associated with relatively little risk. Increasing frequency and severity of seizure disorders, including status epilepticus, carry greater associated risks of increased morbidity or mortality, and worsened cognitive and functional prognosis.

## **POST-TRAUMATIC EPILEPTOGENESIS**

### **Epileptogenesis**

Epileptogenesis refers to the dynamic process underlying the appearance and natural history of epilepsy (9). For decades, physicians treating patients with TBI have sought to prevent the appearance of PTS by interrupting the process of the development of seizures through the prophylactic administration of AEDs. However, the pathophysiologic mechanisms involved in acquired epileptogenesis are not well understood, though they

clearly involve multiple pathways at the molecular and cellular level, as well as changes in neural networks that result in the appearance of spontaneous seizures (168). This limited understanding of the pathophysiology of acquired epileptogenesis has probably influenced the failures encountered with clinical trials of AED prophylaxis (169), discussed later in this chapter. Propelled by insights into the molecular genetics of epilepsy (170), the topic of acquired epileptogenesis is attracting increasing scientific investigation.

Aside from careful observations derived from clinical, electrographic, and neuroimaging studies among human subjects (171), much of what is known or postulated regarding acquired epileptogenesis has been derived from studying pathological specimens from surgical patients with epilepsy, as well as a large number of animal models of epilepsy (168, 171–174). These animal epilepsy models simulate human epilepsy, and provide a system for studying mechanisms that account for the characteristics of acquired epilepsy in humans (168). Such characteristics include the presence of a “latent” period between time of injury and recurrent seizure onset (171), as demonstrated in the kindling model of epilepsy, or the propensity for seizure occurrence with specific characteristics of TBI (175), as found in patients with hemorrhagic contusions and modeled in the ferric chloride model. Indeed, the presence of an unambiguous stimulus (TBI) for later appearance of epilepsy in patients with clearly identified risk factors has prompted great interest in post-traumatic epilepsy and epileptogenesis as an archetypal model for remote symptomatic epilepsy (176). The development of relevant animal models is important, as selection of AEDs for development for marketing worldwide are primarily based on results of preclinical animal model studies (169, 177). A number of these models suggest that many AEDs have antiepileptogenic potential (168). The theoretical and clinical implications of such models in the treatment of epilepsy, including post-traumatic epilepsy and epileptogenesis, have been reviewed elsewhere (155, 168, 171, 175, 177, 178). In the discussion that follows, animal models of epilepsy with historic relevance to post-traumatic epileptogenesis are followed by a review of more recent studies addressing this issue.

### **Ferric Chloride Model**

Initially described by Willmore in 1978, the iron or ferric chloride model is the first considered to reflect mechanisms responsible for post-traumatic epilepsy in humans. Specifically, it is felt to model pathophysiologic processes resulting from a cortical contusion / focal neocortical injury. It is of theoretical interest because cortical deposits of hemosiderin may be important in the development of recurrent PTS (179). Patients with cerebral injuries

characterized by contact of blood and cortical tissue manifest an increased incidence of PTS (180). Contusion or cortical laceration causes extravasation of red blood cells, with hemolysis and deposition of hemoglobin. Willmore demonstrated that recurrent focal epileptiform discharges could result from cortical injection of ferrous or ferric chloride (179). It is felt that the iron salts and hemoglobin in neural tissue may contribute to epileptogenesis by initiating lipid peroxidation, damaging cell membranes and inhibiting neuronal Na-K ATPase (174).

### Kindling Models

The kindling model of epilepsy is arguably the most recognized animal model of epileptogenesis (173, 181). When initially described (182), brief trains of weak electrical stimulation were applied to susceptible areas of rodent brains, until a seizure was observed. When continued over a prolonged period of time, progressively less stimulation was required to induce the seizures, and spontaneous seizures eventually appeared. Once established, this enhanced sensitivity to electrical stimulation appears to be permanent for the life of the animal. Here, epileptogenesis is triggered by the kindling paradigm. The relevance of kindling to remote symptomatic epilepsy derives from the hypothesis that other stimuli, such as subclinical seizures or structural brain lesions, may trigger epileptogenesis (183).

Agents that retard or abort the kindling process are considered "antiepileptogenic," whereas those that merely suppress or block seizures in fully "kindled" animals are "anticonvulsant." Such studies have demonstrated that PHT (184) and CBZ (185, 186) have anticonvulsant effects but lack antiepileptogenic action. By contrast, studies that examined the effects of GABAergic drugs, including VPA, DZP, and PB, on kindling have shown that they demonstrate antiepileptogenic properties (168, 184, 187, 188). Among the newer AEDs, TGB and LEV show antiepileptogenic action (168) in kindling models. In contrast, TPM (168) and LTG show limited antiepileptogenic activity in kindling (189, 190, 191) and rodent status epilepticus models (192). Retardation of kindled seizures appears to outlast the period of exposure to antiepileptogenic drugs, suggesting that they were not simply masking seizure expression.

Several notable limitations exist with the kindling model. For example, the original kindling studies were performed on rats. Subsequently this phenomenon was demonstrated in rabbits, cats, and later, genetically-seizure-predisposed primates (184). Since neuroanatomical structural differences between species imply functional differences, it is not surprising that animal kindling models demonstrate significant phylogenetic variability in expression (193). Further, despite the efficacy of some compounds on the kindling model, none of them has had

an indisputable antiepileptogenic action in animal models with spontaneous seizures (176) or in humans (168). Also, no disease-modifying effects have been described (192). Thus, the extent of this model's relevance to investigations of human PTE is considered controversial (181).

### Recent Studies of Post-traumatic Epileptogenesis

#### *Fluid Percussion Injury Model of Post-traumatic Epilepsy*

In 2004, D'Ambrosio and colleagues described the results of a series of experiments that demonstrate, perhaps for the first time, reproduction of post-traumatic epilepsy induced by a single episode of lateral fluid percussion injury (194), a clinically-relevant model of nonpenetrating TBI (195). Prior studies of experimental TBI (including those incorporating fluid-percussion experimental injury [196]) describe acute seizures (197), and hippocampal hyperexcitability to electrical stimulation (196, 198) or exposure to proconvulsant agents (199). However, spontaneous chronic seizures, the hallmark of epilepsy, has not been described (194). Moreover, while neocortical epileptic foci commonly develop in humans following TBI (38), changes in neocortical excitability have not been studied in rat models of nonpenetrating TBI, which have focused on the hippocampus (194). To date, investigation of neocortical pathophysiology in PTE has been limited to two approaches: the first involves studying neocortical islands isolated by undercuts from the surrounding grey matter, and the second involves chronic neocortical implantation of ferrous chloride (179, 194). Both models bear limited resemblance to the human post-traumatic condition, however, as they lack its unique focal and diffuse mechanical and hemorrhagic components (194). These limitations, in turn, potentially influence the relevance of these models to mechanisms of human post-traumatic epileptogenesis and subsequent therapies that can be translated to human PTE (194).

The study's main findings demonstrate that a single episode of fluid percussion injury is sufficient to cause PTE in the rat. The characteristics of PTE appeared comparable to those of human PTE, as seizure manifestations emerged after a latent period, and were partial in onset after a focal injury. Moreover, epileptiform activity is first detected in the neocortex at the site of injury, which electrophysiologic studies demonstrate is chronically hyperexcitable after fluid percussion injury. Finally, post-mortem pathological examination reveals that intense glial reactivity is observed at the site of injury. In summary, the clinical, electrophysiological, and structural changes of severe lateral fluid percussion injury appear to

parallel changes seen after neocortical injury in human PTE (194).

### *Synaptic Plasticity*

During recent years, a large (and increasing) number of studies demonstrate the ability of the brain to adapt to injury with changes in functional, and structural reorganization (198, 201, 202). These reorganizational changes, termed plasticity, may serve an adaptive role in development and recovery (200, 203), or a maladaptive role when they contribute to disorders such as epilepsy (203–206). Pathological studies of TBI reveal that compensatory collateral axonal sprouting occurs following brain injury (207) and may be a mechanism of importance in functional neurological recovery (200, 208). Under certain circumstances, however, collateral sprouting may give rise to the development of seizure foci (209) or the spread of epilepsy from a primary focus to synaptically-related brain regions (206). Additional excitatory synaptic contacts on cell somata could produce a marked increase in cell excitability, particularly if the new excitatory synapses replaced inhibitory ones (209). If the induced alterations in connectivity increase excitability, neural pathways could become progressively susceptible to epileptic events, and may contribute to the subsequent development of seizures (210).

While sprouting and subsequent formation of new synaptic connections has been proposed as a post-traumatic epileptogenic mechanism, it is not likely to be the only pathway to neuronal hyperexcitability (178). Postinjury development of neuronal hyperexcitability may be the result of three general types of plastic change: a) alterations in intrinsic membrane properties, b) changes in synaptic connectivity, and c) modifications of receptors and receptor subunits (178, 211). Direct axonal injury may render surviving neurons more excitable through alterations in intrinsic membrane properties. Loss of afferents can induce sprouting of axons, leading to hyperexcitability by increasing recurrent cortical pathways (178).

If the aforementioned models are important mechanisms common to both “adaptive plasticity” after TBI and “maladaptive plasticity” in PTS, potentially significant implications follow. Specifically, AEDs whose potential effects are exerted by preventing the development of compensatory excitatory neural pathways, i.e. a seizure focus, may concurrently retard neurological recovery through a similar mechanism of action (212). Moreover, since PTS occur among a minority of all patients with TBI, including severe TBI, AED therapy broadly directed against subclinical seizure activity among all TBI patients during recovery may be more detrimental to neurological and functional outcome than either seizures alone or initiation of AED therapy after seizure onset.

## **“ASYMPTOMATIC” MANAGEMENT OF POST-TRAUMATIC SEIZURES & EPILEPSY: PREVENTION, PROPHYLAXIS & PRACTICE GUIDELINES**

The term prophylaxis has been defined as “specific measures taken to prevent disease in an individual . . .” (213). In the context of PTS, the term applies to AED treatment administered to patients who have not manifested seizures. Several justifications can be proposed for prophylaxis of PTS. First, AEDs might prevent PTS at a time when they potentially pose the greatest risk of secondary injury, such as seizure-induced elevations in intracranial pressure (214). Second, seizure prevention may help avoid loss of employment, loss of driving privileges, or accidental injury (214). Third, there may exist concern over the medicolegal implications of negligent treatment if PTS appear. Finally, there exists the possibility that administration of AEDs may alter or arrest epileptogenesis. Thus far, however, animal and human studies fail to provide evidence that AED therapy prevents the development of the post-traumatic seizure focus (168), or alters the course of seizure recurrence aside from suppression of the seizure focus (177).

### **Identification of the “High-Risk” Patient**

Methods have been proposed to improve identification of those patients at risk for PTS development, and therefore those most to gain from its prevention or potential recurrence. These include assessment of the clinical characteristics of the patient, the injury, as well as information yielded by neuroimaging and electrophysiologic assessment techniques (Table 26-2).

#### *Patient Characteristics*

Age, history of alcohol abuse, and family history represent the patient characteristics most frequently cited as factors influencing subsequent seizure risk. Patients with histories of alcohol abuse, particularly chronic alcoholism, demonstrate an increased risk of early (132) and late seizure development (93, 115, 117, 121, 122, 124, 216, 220) and recurrence (41) following TBI. Few data exist regarding PTS risk associated with low levels of alcohol use, either before or after TBI. Patient age appears to exert a strong influence on PTS risk (43, 102, 104, 122). Children demonstrate markedly lower risk for LPTS, and considerably higher risk for IPTS and EPTS, when compared with adult patients with comparable injury severity. Some studies suggest that age at onset of injury (64) or seizures (221) may influence susceptibility to seizures later in life.

Some authors note a modestly increased incidence of PTS among patients with nonpenetrating TBI and a family history of seizures (4, 93, 116, 216). This has not

**TABLE 26-2**

Intracranial hemorrhage	43, 113, 117, 125, 218, 219
Injury severity	4, 47, 93, 97, 101, 102, 125, 219
Focal hypoperfusion	125
<b>Other</b>	
Early post-traumatic seizures	4, 47, 113, 115, 219

been consistently observed (47, 98, 222), suggesting that the influence of a family history of seizures appears weak when compared to the effects of extensive cerebral trauma (47). However, Diaz-Arrastia and colleagues recently noted that inheritance of the apolipoprotein (APOE) εε allele was significantly associated with development of late seizures, but not poorer outcome, after moderate and severe TBI (217). If such findings are replicated, genetic influence may ultimately be shown to have an important role in post-traumatic epileptogenesis.

### *Injury Characteristics*

Certain injury characteristics demonstrate an increased likelihood of resulting in recurrent, late PTS. Virtually uniform agreement exists regarding observations of markedly increased seizure risk among patients with PTBI (41, 47, 88, 90, 91–93, 97). Blood appears to demonstrate an extremely irritating effect on cortical neurons, as demonstrated by increased seizure incidence among TBI patients with intracranial bleeding, (4, 41, 43, 47, 102, 112, 116, 117, 121, 124, 218, 219) particularly with subdural hematoma (113, 219). Increased extent of PTBI (47, 92, 166); and severity of nonpenetrating TBI (41, 43, 91, 100, 126, 128), as evidenced by prolonged duration of post-traumatic amnesia (4, 41, 93, 102, 112, 114, 127), prolonged duration to follow commands (219), lower GCS (4, 101, 102, 219) or impairment of consciousness (114, 117, 124, 127), are prominently associated with increased seizure risk.

General agreement exists regarding observations of increased PTS risk in patients with TBI characterized by focal neurologic deficits (4, 41, 47, 91, 95, 97, 108, 109, 117, 124), depressed skull fractures (4, 93, 94, 112, 129), cerebral contusions (39, 46, 100, 104, 109, 110, 115, 218), and retained bone or metal fragments (88, 89, 93, 97). Lesion location may affect incidence (46, 93, 95–100, 157, 219, 223), type (64), and possibly frequency (223) and treatment response (38) of PTS. The concurrent presence of multiple risk factors is consistently associated with increased seizure risk (4, 91, 117, 122, 124).

Late PTS rarely occur after mild TBI (101). Among adults, trivial blows to the head almost never result in seizures, but may occur in the presence of preexisting (224) or concurrent (123) brain lesions. In a recent multicenter study, 8% of patients with GCS scores in the mild range (13–15) developed late post-traumatic seizures within 24 months; all had CT-scan evidence of contusion or intracranial hemorrhage (113). Despite their rarity, PTS and even recurrent PTS *do* occur after mild TBI, but their presence in the adult patient should prompt an investigation for a precipitating cause, such as an intracranial mass lesion. Moreover, frequent LPTS after mild TBI should also prompt careful evaluation for NES (59).

### *Electroencephalography (EEG)*

The utility of the interictal EEG as an objective predictor of subsequent PTS appears limited (115, 126, 225, 226). It is frequently abnormal in patients with TBI, both with and without PTS (46, 218, 227, 228), reflecting the severity of brain damage sustained (46, 226). Sleep-deprivation activation procedures similarly do not appear to differentiate between patients with and without PTS (229). The rare change of focal slow wave activity to focal spike discharges, particularly during the first month postinjury (100), or persistence of focal spike or sharp wave discharges may be suggestive of increased seizure risk (121, 225, 228). However, such discharges may be observed on the EEG of non-epileptic patients (218, 230). Conversely, a normal EEG may precede PTS onset (225–227, 231), though this finding is more frequently associated with a favorable prognosis (121, 218). EEG findings should be evaluated in context with other clinical risk factors when assessing the likelihood of PTS onset.

The EEG provides valuable information in focus localization, seizure persistence, and severity prognostication once PTS have been observed (89, 225, 232). In addition, the EEG may identify the presence of nonconvulsive seizures among patients with impaired consciousness, particularly early after severe TBI (49). The utility of the EEG in predicting PTS recurrence following a seizure-free period has not been established.

In the neurorehabilitation setting, we believe that the EEG is potentially helpful when considering the continuation of AED therapy in patients with a history of EPTS.

### AED Prophylaxis Clinical Trials and Guidelines

Encouraged by animal studies suggesting that anticonvulsants may prevent the development of epileptic foci in animals, a number of studies have been published addressing the efficacy of AED prophylaxis in TBI. These studies have been extensively reviewed elsewhere (233), and their relevant findings and conclusions summarized here. These clinical trials and literature reviews have also served as a basis for practice management guidelines addressing AED prophylaxis of early and late seizures (2, 234).

Retrospective studies and nonrandomized open trials involving human subjects appeared first in the scientific literature (92, 115, 121, 133, 235–240) with generally favorable results (236–240). Decidedly unimpressive results were observed among prospective investigations (124, 138, 218, 220, 241–245) of chronic prophylaxis for late PTS. Indeed, published randomized, controlled prospective investigations almost uniformly fail to substantiate evidence of efficacy for CBZ (218), PHT (138, 241, 242, 244, 245), PB (124), or VPA prophylaxis (243) of late PTS. In four of these trials, the incidence of PTS was actually higher among the PHT-treated groups (138, 241, 244). Meta-analyses of these trials indicate that AED prophylaxis is not accompanied by a reduction in LPTS, (168, 242, 246–248), mortality, or neurological disability (246, 248).

In contrast, AED prophylaxis consistently reduces the incidence of early PTS (138, 218, 220, 249). As in some of the studies cited previously, however, there is no clinical evidence that AED prophylaxis of early seizures reduces the occurrence of LPTS, or has any effect on death or neurological disability (248). Most published trials lack sufficient numbers of patients with PTBI to conclude whether AED prophylaxis exerts a favorable or adverse influence on seizure incidence in this high-risk subset of TBI patients (250).

While disappointing, treatment failure among trials conducted thus far should not imply that future trials are similarly destined to fail. Different approaches are currently under investigation (251). These include: 1) the use of available AEDs that have not been previously studied for prophylaxis of PTE, such as MgSO<sub>4</sub>; 2) different timing of administration (e.g. <12h postinjury) with presently-available AEDs (251); and 3) development and investigation of future AED's, preferably with demonstrated efficacy in a relevant animal model of human PTE.

Table 26-3 summarizes the practice management guidelines of four medical societies that have published guidelines pertinent to AED prophylaxis of PTS (2, 5, 234, 250). These include the Brain Injury Special Interest Group of the American Academy of Physical Medicine and Rehabilitation (BI-SIG) (2), the American Academy of Neurology (AAN) (5), the Brain Trauma Foundation ([BTF] in conjunction with the Joint Section on Neurotrauma and Critical Care) (234), and the Penetrating TBI Committee (250). The guidelines of the BI-SIG, AAN, and BTF are all very similar, and primarily address non-penetrating TBI in adults (2, 5). The guidelines of the Penetrating TBI Committee specifically

**TABLE 26-3**  
*Practice Management Guidelines for AED Prophylaxis of PTS*

PATIENT POPULATION	SEIZURE TYPE	RECOMMENDATION	DEGREE OF CERTAINTY (252)
<b>Nonpenetrating TBI (High-risk)</b>	Late PTS (without EPTS)	Not recommended	Standard (2, 23) "Level B" (5)
<b>Penetrating TBI</b>	Late PTS (without EPTS)	Not recommended (2, 250) (No specific opinion for PTBI [5, 234])	Option (2, 250)
<b>Penetrating TBI or high-risk nonpenetrating TBI</b>	Early PTS	May be used	"Level A" (5) Option (2, 234)

Degree of Certainty-strength of recommendations: **Standards** refer to generally accepted principles for patient management that reflect a high degree of clinical certainty (i.e., based on class I evidence or, when circumstances preclude randomized clinical trials, overwhelming evidence from class II studies that directly addresses the question at hand or from decision analysis that directly addresses all the issues). **Guidelines** refer to recommendations for patient management that may identify a particular strategy or range of management strategies and that reflect moderate clinical certainty (i.e., based on class II evidence that directly addresses the issue, decision analysis that directly addresses the issue, or strong consensus of class III evidence). **Options** refer to strategies for patient management for which there is unclear clinical certainty (i.e., based on inconclusive or conflicting evidence or opinion) (252).

address prophylaxis with penetrating TBI, and conclude that AED prophylaxis for LPTS appears unjustified (250).

### MANAGEMENT OF POST-TRAUMATIC SEIZURES AND EPILEPSY

It is beyond the practical scope of this review to critically examine the breadth of literature pertinent to the treatment of all patients with epilepsy, and the reader is referred to textbooks that serve this role (253, 254). Nevertheless, treatment issues that are particularly germane to patients with TBI and recurrent PTS will be briefly reviewed. In the discussion that follows, the authors' clinical experience will be incorporated into the literature review extrapolated from other epileptic populations when addressing symptomatic management of patients with PTS/PTE.

#### Diagnosis

An initial step in the management of suspected seizures is establishing whether or not a seizure disorder indeed exists (61). In light of the social, economic, and medical implications that accompany the diagnosis of an epileptic disorder, errors need to be avoided. In many cases, a diagnosis can be reliably made from clinical observations of seizure phenomena, particularly those noted by experienced staff in the hospital setting. Classification of the observed seizures is similarly important, as categorization can have significant prognostic and therapeutic implications.

There are situations, however, where the diverse or subtle clinical presentations of PTS complicate diagnosis. As noted earlier, epileptic manifestations (particularly those of CPS) may not be recognized in patients with significant cognitive and behavioral dysfunction. Alternatively, nonepileptic phenomena such as NES, myoclonus, or syncopal episodes may be mistaken for PTS. Clinical observations alone may thus be insufficient to render or rule out a diagnosis of PTS, prompting the use of other diagnostic options (48).

The EEG is the single most informative laboratory test for the diagnosis of epileptic disorders (255–257) and should be obtained in any patient with suspected PTS. The EEG may assist in assessing the likelihood of an underlying epileptic condition when correlated with the clinical diagnosis (258), or in localization of the seizure focus (255). Although interictal epileptiform activity is apparent in only approximately 50% of single awake recordings in adults with epilepsy, this proportion rises to approximately 80–85% if sleep is included. Two recordings obtained while the patient is awake will demonstrate epileptiform activity in 85% of individuals with epilepsy, and this rises to 92% of persons within four recordings (255). In patients who manifest only generalized seizures,

interictal discharges are bilateral, symmetrical and synchronous, generally of greatest amplitude over the frontal regions but sometimes located posteriorly. In patients with partial seizures, discharge topography will more or less closely correspond to that of the focus from which seizures arise. These focal interictal discharges may spread, producing secondarily generalized spike-and-slow-wave activity. If the generalization is rapid, the focal onset may be difficult to detect (255).

There exist limitations in the diagnostic sensitivity of the standard interictal EEG, however, and absence of EEG abnormalities does not exclude the presence of a seizure disorder (255). Postictal PRL measurement may be useful in some of these patients, as significant elevations in serum PRL levels reliably occur within 20–40 minutes following GTC seizures (259) and many CPS (259). PRL elevations are typically not observed after SPS (260), CPS of frontal lobe origin (261), or after 30 minutes in most patients with NES (57, 58, 260). Significant PRL elevation occurring after a possible PTS episode may help confirm clinical suspicion of an underlying epileptic disorder (262). Given the significant diurnal variation in serum PRL levels, however, it is often prudent to obtain a baseline value for comparison, drawn at the same time of day as the postictal specimen, within a few days.

When initial standard evaluations fail to resolve the clinical diagnosis, long-term EEG monitoring techniques, including ambulatory EEG monitoring (263, 264) and/or inpatient VEEG telemetry (255, 265) are effective and clinically valuable (48). Ambulatory EEG monitoring offers an intermediate-level option for recording while the patient conducts normal activities at home, work, or school (9, 263, 264). It is most useful for investigating the patient in a natural environment; for example, to test the claim that a patient has seizures at home which are not observed in hospital (255). A patient or observer log is maintained to identify the times and descriptions of behavioral episodes suspected of representing seizure activity (9). Ambulatory monitoring has been transformed by the recent development of recorders using solid-state memory or removable miniature digital discs (255). Ambulatory monitoring is usually performed without simultaneous video registration, however, and thus EEG telemetry with video monitoring provides the best opportunity to obtain an artifact-free ictal EEG while observing and evaluating associated clinical behavior (265). Concurrent computerized automatic seizure detection often identifies important events, particularly at night, that are not reported by the patient or nursing staff. Definitive diagnosis requires recorded examples of all seizure types experienced by the patient (255). Conversely, an absence of discharges during prolonged monitoring, particularly in a patient with frequent

seizures, may serve to cast doubt on the diagnosis of epilepsy (255).

Hudak et al. recently described the utility of prolonged VEEG monitoring in the clinical management of paroxysmal behaviors in TBI survivors (48). In this retrospective record review, 127 patients with a documented history of moderate-to-severe brain injury preceding onset of frequent, disabling paroxysmal behaviors were evaluated in an epilepsy monitoring unit for management of medically intractable epilepsy. VEEG monitoring was conducted for an average of 4.6 days. AED administration was suspended during the assessment period. Monitoring was successful in establishing a diagnosis in 82% of the cases referred. Sixty-two percent of the evaluated patients had focal seizures, 6% had generalized seizures and 33% had psychogenic NES. The authors concluded that VEEG is a useful procedure in the evaluation of TBI survivors with paroxysmal behaviors suggestive of epilepsy, and that the yield of diagnoses that may alter treatment is substantial (48).

### Treatment and Selection of the AED

While broad agreement exists regarding the appropriateness of AED treatment among patients who manifest two or more seizures, considerable debate remains concerning the benefits of treatment in reducing recurrence risk following a first seizure (266, 267). Overall, about 33 percent of patients with a first unprovoked seizure can be expected to have a second within the subsequent three to five years. This risk varies considerably, however, depending on clinical characteristics of the patient (268). Increased risk is observed among patients with remote symptomatic epilepsy (268, 269, 270). Approximately 44–48% percent of patients with a first remote symptomatic seizure will experience a second seizure in the next three to five years (268, 269). Of the patients with a second seizure, almost 87% will experience a third seizure at five years (268). Seizures occurring immediately following an acute precipitant or injury to the brain carry a lower risk of recurrence than a late seizure (271).

Treatment after first seizure has been advocated, though few randomized clinical trials have been conducted to establish the efficacy of this practice. One randomized multicenter clinical trial concluded that treatment of the first seizure with antiepileptic drugs leads to a significant reduction of relapse risk. The authors added, however, that the decision to start treatment in a patient with a first seizure must balance that patients risk of relapse, the benefits of avoiding the consequences of a second seizure, and the risk of AED toxicity (272).

Once a decision has been reached that pharmacological treatment of a patient with PTS is indicated, a primary goal is to attain control of seizures with one medication (9, 273). The decision of which specific agent to

use will reflect the type of post-traumatic seizure, the route and frequency of drug administration, as well as the anticipated and realized adverse effects. Among patients with symptomatic localization-related epilepsy (273), including patients with TBI who manifest seizures of partial onset, extended release CBZ remains a commonly preferred drug (233, 273, 274). Patients with tonic-clonic seizures of generalized, secondarily generalized, or multifocal onset respond well to VPA (273–275). CBZ (275) and PHT (275, 276) are also effective anticonvulsants for GTC seizures. While generally effective for seizure control of tonic-clonic seizures (9, 276), the utility of PB is severely limited by prominent adverse effects on cognition and behavior (277), and is rarely used in current practice (278).

Anecdotal evidence suggests that neurologists and physiatrists increasingly employ newer “second generation” AEDs in symptomatic management of selected patients with PTE. Unfortunately, there currently exists little scientific data, specific to PTE, that support (or refute) the benefits of this practice. For example, a recent PUBMED literature search (September 2004), cross-referencing the terms “post-traumatic seizures” or “post-traumatic epilepsy” with key words of the newer AEDs, including “lamotrigine”, “topiramate”, “oxcarbazepine”, “levetiracetam”, or “tiagabine”, failed to yield a single reference. Presently, extrapolation from scientific literature derived from other patient populations, particularly those with remote symptomatic epilepsy, and evolving clinical experience are all that exist to guide clinical practice with newer AEDs for patients with PTE.

Fortunately, two expert consensus panels recently address the use of the newer AEDs as initial monotherapy (273, 279), including patients with symptomatic localization-related epilepsy (SLRE) and symptomatic generalized epilepsy (SGE)(273). The Quality Standards and the Therapeutics and Technology Assessment Subcommittees of the American Academy of Neurology published a practice parameter summarizing an evidence-based assessment regarding the efficacy, tolerability, and safety of seven new AEDs in the management of new onset partial or generalized epilepsy, including GBP, LTG, TPM, TGB, OXC, LEV and ZNS (279). They found evidence that GBP, LTG, TPM, and OXC are effective as monotherapy in newly diagnosed adolescents and adults with either partial or mixed seizure disorders, but not generalized epilepsy syndromes. No specific guidelines were provided regarding AED use in remote symptomatic epilepsy or PTE (279). Karczeski et al. employed an “expert consensus method” to survey epilepsy specialists (273) regarding AED preference in specific clinical scenarios. The survey revealed a preference for CBZ as the initial AED for management of symptomatic epilepsies. Besides CBZ, PHT, OXC and LTG were also cited as initial first line agents for SLRE manifested by simple partial seizures or complex

partial seizures. For management of SLRE with secondarily generalized seizures, PHT, OXC, LTG, and VPA were identified as initial first line AEDs (273). A limitation of this consensus statement (273) is that it does not address the place of ZNS or LEV in the clinical armamentarium, as these agents were not in wide use at the time the survey data were obtained.

### Adverse Effects of AED Therapy

Antiepileptic drugs commonly employed in the treatment of PTS may be associated with significant idiosyncratic and dose-related adverse drug reactions (279, 280, 281), requiring their discontinuation or substitution in as many as 20–30% of patients (282, 283). These include hematologic, dermatologic, hepatic, neurologic, endocrinologic, urologic, and teratogenic adverse effects (279, 284, 285). Transient or persistent leukopenia and thrombocytopenia may be observed in patients taking PHT and CBZ, though idiosyncratic aplastic anemia is extremely rare. Rashes are occasionally encountered with many AEDs and severe dermatologic reactions more rarely noted with LTG and PHT (279, 280). Hirsutism and gingival hyperplasia may be problematic in patients treated with PHT (280). Weight gain has been associated with VPA and GBP treatment, and weight loss reported with ZNS and TPM (275, 279). Mild and transient elevations of hepatic enzymes, up to two to three times normal in some cases, are reported to occur in patients receiving PHT, CBZ, and VPA, (286). Frequent and rigorous routine laboratory monitoring regimens, however, aside from baseline determination of hematologic and hepatic function or closer observation of noted abnormalities, are unjustified for most AEDs (with the notable exception of FBM). These typically do not provide meaningful protection from rare and potentially life-threatening manifestations (287, 288). Appropriate counseling for the patient, family, and/or caregivers regarding potential complications and symptoms that might herald an adverse event is far more useful and important (288).

Cognitive effects of AEDs warrant particular attention in the patient with TBI. Newer AEDs demonstrate superior cognitive adverse effect profiles and tolerability when compared with older agents (302, 303, 304). In contrast, older AEDs, particularly PB, PHT and CBZ, significantly impair memory performance in double-blind crossover trials among healthy adults (289). Patients with severe TBI already have significant cognitive impairment. Antiepileptic drugs may exert independent and additional adverse cognitive effects on the patient with TBI who is receiving chronic therapy (290). Among patients with severe TBI participating in the landmark prophylaxis trial of Temkin et al. (138), a significantly greater proportion (78%) of individuals treated with PHT demonstrated cognitive impairment sufficient to preclude testing at one

month postinjury. This was observed in only 47% of corresponding patients treated with placebo (290).

Among older established AEDs, most studies demonstrate no comparative advantage in cognitive adverse effect profile between CBZ, PHT, or VPA, though few include subjects with TBI (291–294). Smith (294) found no significant difference on cognitive testing results among patients randomized to withdrawal from PHT and CBZ prophylaxis. Only 13 of the 82 studied patients sustained severe TBI, however, with the remainder receiving prophylaxis following craniotomy or mild/moderate TBI. There remains considerable evidence suggesting that PHT provides a relatively unfavorable cognitive side effect profile among patients with severe TBI (290, 291). Patients randomized to receive 6 months of VPA for prophylaxis of LPTS following severe TBI demonstrated no evidence of adverse cognitive effects when compared with those receiving 1 week of PHT (291). In contrast, an earlier study among comparably injured patients receiving PHT prophylaxis yielded unequivocal evidence of cognitive impairment among AED-treated patients (290).

While attention regarding adverse drug effects frequently focuses upon observable phenomena, such as lethargy, the influence of AED therapy upon the course of postinjury neurologic recovery also warrants consideration (295). Specifically, certain drugs, including AEDs, clearly impair recovery after brain injury in laboratory animals (296–298). Schallert et al. (298) demonstrated that diazepam administered to rats within 12 hours of neocortical damage delayed recovery indefinitely, whereas delayed administration of diazepam resulted in only transient reinstatement of neurologic deficit (298). Brailowsky observed that PHT increased the severity of cannula-induced cortical hemiplegia in rats, though motor impairment was not seen when administered to the animals after their hemiplegic syndrome had cleared (296). These findings suggest that AED administration with diazepam or PHT during certain critical periods following brain injury may exert a deleterious effect upon subsequent neurologic recovery.

In summary, dose-related and idiosyncratic adverse effects occur among a substantial subset of treated patients, particularly with older AEDs. Cognitive adverse effects may be particularly problematic, particularly with the older established agents, impacting upon long-term tolerability. The cited studies serve as a reminder that decisions regarding chronic AED treatment, and particularly prophylaxis, cannot be considered solely on the merits of effectiveness in seizure prevention. Rather, consideration must also be given to potentially significant adverse effects and toxicities of the AED regimen.

### AED Substitution

Neurosurgeons and neurologists have preferred PHT for prophylaxis (299, 300) and symptomatic AED treatment,

primarily because of its availability in parenteral forms that can be administered in the acute setting, where seizures are more likely to occur. Since the publication of prophylaxis guidelines (2, 5, 234), however, we have observed a clear trend towards less frequent use of AED prophylaxis. In addition, among patients receiving symptomatic AED treatment, PB use is rare, with PHT remaining the most commonly observed for use in acute care settings AED for initial symptomatic management. These patients are commonly maintained on the chosen AED until a satisfactory seizure-free duration has passed. AED substitution has previously been usually reserved for failure of seizure control or the manifestation of significant drug reactions (9). As mentioned earlier, selection of a newer AED as initial monotherapy is likely to improve tolerability, particularly with cognitive adverse effects, while maintaining comparable efficacy. For similar reasons, many neurorehabilitation specialists consider substitution of PHT monotherapy for other less cognitively-impairing medications, such as LTG, as clinical circumstances allow.

When substituting an AED for another drug, clinically effective levels of the latter AED should be attained prior to discontinuation of the former drug (9). Among the newer AEDs, serum levels are not commonly obtained, although these are available at reference laboratories. Once appropriate and effective doses of the new drug are achieved, a gradual taper of the former drug ensues. At one time, CBZ was the most common AED employed for substitution instead of PHT in our center. More recently, however, we use LTG as slow add-on therapy (usually added to PHT), followed by gradual withdrawal of PHT after maintenance of seizure control and effective doses of LTG (approximately 4–500mg /day). Our preference for LTG derives from a clearly favorable cognitive adverse effect profile, particularly when compared with either PHT or CBZ (301). Among patients requiring more rapid additional seizure control, LTG is not a therapeutic option, due to the increased danger of serious rash or Stevens-Johnson syndrome (305) associated with rapid dose increases. Instead, we employ VPA, as it is effective for both generalized and partial seizures (275), it demonstrates generally favorable tolerability among patients with TBI (291), and it is available in parenteral and once-daily oral formulations. VPA may also be a practical choice among patients with PTE that are also demonstrating post-traumatic mood lability and irritability. We are aware of colleagues that favor LEV as a preferred AED for substitution among patients with TBI, citing its ability to be rapidly titrated to effective dose range (306) as well as its tolerability. However, anecdotal reports of a lack of persistent antiepileptic effect, and documented psychiatric adverse effects (307), may limit the utility of this agent in some patients.

### **Duration of AED therapy**

No clinical studies specifically address the duration of AED therapy for patients with recurrent LPTS. In general, it is reasonable to consider AED withdrawal from patients with epilepsy after a 2-year period free of seizures (308). Reported rates of relapse vary considerably, and reflect the type of seizure disorder being treated (9). The risk of seizure recurrence under a policy of slow AED withdrawal is still substantial when compared with a policy of continued treatment, particularly during the first year of withdrawal (309). Increased risk of recurrence has been reported among patients with a history of more frequent seizures, treatment with more than one AED, a history of GTC seizures (309), and abnormal or epileptiform discharges on pre-withdrawal EEGs (308, 310). Among patients for whom the risk of relapse after discontinuation appears low, the psychosocial benefits of discontinuation may be considerable (311). There is no consensus regarding the ideal period over which AEDs should be withdrawn in patients with recurrent seizures, although conservative recommendations advise a period of 12 months (9, 312). Worsening of seizures following PHT (313, 314) or CBZ (314) discontinuation is believed to reflect the loss of therapeutic drug effect rather than a withdrawal phenomenon. In contrast, withdrawal exacerbation of seizures is prominent with barbiturates (315) and benzodiazepines (316), and does not indicate that the drug was necessary for maintenance of seizure control (9).

### **Surgical Treatment of Post-traumatic Seizures**

Recent studies are providing valuable insight into the natural course of history regarding post-traumatic seizure recurrence (136). These studies identify a subset of patients remaining refractory to treatment, even with multiple AEDs. The definition of “refractory” is debatable, and there is evidence that adding a 2nd or 3rd AED may facilitate seizure remission in about one-fifth of patients that remain with seizures while taking a single AED (317). Nevertheless, for those patients who continue to experience frequent seizures despite various AED monotherapy or polytherapy combinations, surgical treatment options are increasingly available, particularly in recent years (318).

### **Surgical Resection of Epileptic Focus**

Advances in neuroimaging technology, coupled with results of recent landmark studies, have prompted a dramatic shift toward surgical treatment for certain types of medically-refractory epilepsy (217, 319). There is now growing sentiment among epilepsy specialists that surgical treatment for refractory epilepsy is seriously underutilized (319, 320). In the first randomized study comparing surgical and medical treatment for temporal lobe epilepsy,

58 percent of surgically treated patients were free of disabling seizures at one year, versus only 8 percent of those assigned to receive medical treatment (321). Significant improvements in outcome were observed in measures of quality of life as well as a trend with respect to social functioning (321). The Multicenter Study of Epilepsy Surgery similarly reported that resective surgery significantly reduced seizure recurrence after medial temporal (77% 1-year remission) and neocortical resection (56% 1-year remission) (322). In light of such findings, the American Academy of Neurology, in association with the American Epilepsy Society and the American Association of Neurological Surgeons, published a practice parameter supporting the benefits of anteromesial temporal lobe resection for disabling complex partial seizures. It further recommended referral of patients with these seizures to an epilepsy surgery center (319).

### *Surgical Excision of the Post-traumatic Seizure Focus*

Surgical excision of the seizure focus also provides an important treatment option for carefully selected patients with refractory PTE. Favorable responses, including seizure freedom have been described among selected patients with PTE treated with resective surgery (38, 140, 323). Patients with unilateral post-traumatic frontal lesions who undergo complete resection of perilesional encephalomalacia /gliosis and adjacent electrophysiologically abnormal tissue respond particularly well to surgery (324, 325). The cumulative experience described in published studies, however, also highlight the challenges accompanying accurate identification of the seizure focus in patients with severe TBI, who often demonstrate bilateral and multifocal injury (38, 64). Marks described 25 patients with PTE treated in their tertiary epilepsy center, 21 of whom were treated surgically. Seventeen of these patients were felt to have mesial temporal lobe epilepsy, and another 8 patients were judged to have neocortical epilepsy. Of the 21 patients treated with surgery, only 9 (43%) had favorable outcomes, characteristically those with well-circumscribed hippocampal or neocortical focal lesions (64). Schuh and associates reported on 102 patients who underwent anterior temporal lobectomy. A history of TBI, alone or in combination with other factors, was significantly correlated with continued seizures after surgery (326).

### *Vagus Nerve Stimulation (VNS)*

Vagus nerve stimulation (VNS) is an alternative to pharmacologic treatment of seizures in patients who have failed conventional pharmacotherapy, either due to lack of efficacy or adverse effects (327). The mechanism of action of VNS is not yet clear (328).

VNS is approved by the FDA for adjunctive treatment of intractable partial seizures in patients over

12 years old. Based on controlled, randomized trials, approximately 30% of these patients can be expected to have at least a 50% decrease in overall seizure frequency (329, 330). Efficacy in LPTS has not been specifically studied. Persistence of benefits has been demonstrated (331). While this technique is indeed invasive, no intracranial surgery is required, and surgical morbidity and mortality are limited. Adverse effects include hoarseness, cough and dysesthetic sensations in the throat (330).

While numbers of patients treated with this technique are limited compared to AED therapy, in 1999, the American Academy of Neurology Therapeutics and Technology Subcommittee classified VNS as safe and effective for intractable partial seizures, based on sufficient Class I evidence (332). At present, VNS is considered to be an appropriate therapy for patients with medically refractory epileptic seizures who are not optimal candidates for resective epilepsy surgery (327).

A potential advantage to the use of VNS in the context of LPTS is the relative absence of cognitive adverse effects. However the role of this technology in the treatment of epilepsy in the context of TBI remains to be delineated.

### **Consultation and Referral**

Guidelines for the appropriate level of primary and specialty care of patients with seizures, including recommendations for referral to specialty centers, have been published (333). In summary, the first step for individuals experiencing an initial seizure or seizures is to consult their primary-care physician in their own community. The primary physician may then choose to begin a treatment program or refer the individual to a general neurologist for consultation. In any case, if seizures continue to occur after three months, a referral to a general neurologist is indicated. When the seizures are controlled, many patients appropriately return to the care of their primary physicians, with follow-up to the neurologist as needed. If seizure control is not achieved at the end of the first year of treatment, referral to a center that offers comprehensive diagnostic and treatment services to patients with intractable seizures is indicated (326).

### **CONCLUDING STATEMENTS**

In light of the evidence previously discussed, our management approach for LPTS is presented. Patients with acute TBI who are transferred to the neurorehabilitation hospital setting receiving an AED for prophylaxis, and without reported early seizures, are gradually tapered from AEDs early in their hospital course. As mentioned previously, routine chronic AED prophylaxis of LPTS is

unjustified, and with few exceptions\* no AED therapy is provided unless late seizures are reported (2, 5). AED prophylaxis withdrawal in the hospital setting facilitates monitoring for the potentially varied manifestations of seizures. Since seizures tend to occur in the earlier postinjury period, this also helps insure the presence of trained personnel should a seizure be observed during or after AED withdrawal. We have observed that marked improvements in the cognitive status of patients frequently coincide with termination of AED prophylaxis.

If a possible late post-traumatic seizure is observed, either during the patient's hospitalization or after discharge, a search for an identifiable seizure precipitant takes place, and includes a neuroimaging study of the brain. If no obvious correctable seizure precipitant is identified, establishment of a diagnosis of seizure disorder ideally precedes initiation of AED therapy. Clinical description of the episode alone, provided by a family member or other witnesses, may be sufficiently convincing to initiate AED therapy. The patient and family are given instructions for keeping a "seizure logbook," and more frequent follow-up visits are often warranted. If a late PTS has been documented, we will typically proceed with selecting an AED for symptomatic seizure management. Most commonly, we choose between a CBZ-extended release formulation, VPA, or LTG. AED selection is influenced by the: 1) patient's cognitive and behavioral status; 2) type/manifestation of the seizure, (e.g., GTC status epilepticus versus SPS lip twitching); 3) perceived need for rapid achievement of a therapeutic dose, and 4) whether or not the patient has already been started on PHT or another AED in the emergency department. If the patient is receiving PHT and seizures are well-controlled, an alternative AED such as LTG is usually substituted at the earliest suitable point to minimize adverse side effects, particularly cognitive impairment.

For most physicians caring for patients with TBI in the rehabilitation setting, the issue of whether to institute prophylaxis of EPTS is usually moot. Nevertheless, postinjury prophylaxis of EPTS with PHT or FPT may be justified in patients with severe TBI belonging to high-risk groups. The patient is at their highest risk for seizure development, at a time when they can least afford to endure complications from a seizure. Prophylaxis may

be continued for approximately 1 week if seizures are not observed, and then tapered gradually. Again, this should take place in a setting in which close observation can be provided. The risks incurred with such a short duration of treatment currently appear minimal, and acceptable.

Insufficient data exist to definitively guide AED therapy among patients whose only manifestation of a seizure disorder are EPTS. Most published reports exclude these patients from further study, thereby losing valuable information regarding the influence of continued AED therapy on LPTS recurrence risk. Issues to consider include onset (day 1 versus day 7 or later), severity (particularly status epilepticus), recurrence frequency, and clinical risk factors for recurrence. Factors favoring continuation of AED therapy would include later time of seizure onset, documented episodes of status epilepticus, persistent epileptiform activity or electrographic seizures on EEG, multiple seizure episodes throughout the first week of injury, and the presence of multiple risk factors suggestive of high risk for LPTS occurrence, such as penetrating TBI. In contrast, it may be reasonable to consider a monitored withdrawal of AED therapy in selected patients with isolated EPTS, particularly those with IPTS. Our experience suggests that most patients with non-penetrating TBI and isolated EPTS will tolerate discontinuation of AED therapy without seizure recurrence (131, 334).

Major themes involving the symptomatic management of patients with PTS have been discussed above, and will not be repeated here. Still, important research questions remain, and involve a broad range of topics pertinent to the diagnosis and treatment of epileptic disorders. Investigation must be directed towards identifying laboratory models that reflect human response to prevention of an initial or recurrent PTS. Further study is needed to clarify the natural history of PTS, the prognostic implications of single or isolated seizures, and the effect of AED therapy upon recurrence risk. Future studies should address the comparative utility and adverse effects of symptomatic seizure treatment, including surgery, *upon adult and pediatric subjects with TBI*, and explore the potential effects of these therapies upon neurologic recovery and functional outcome.

Finally, assessment of each patient's risk and suitability for treatment must be made on an individual basis, guidelines or algorithms notwithstanding. Even with the publication of four guidelines (2, 5, 234, 250) addressing the issue of AED prophylaxis, discussion of issues related to PTS with the patient and family members is useful and important. Moreover, the clinician should be aware of the prevailing regional standards of care regarding symptomatic management. Lastly, in instances where questionable or repeated seizures occur, utilizing the assistance of neurological and neurosurgical consultants with

\*Our exceptions to this general rule include: 1) history of episodes suggestive of EPTS, especially SE; 2) anticipated intracranial surgical procedure within the next 7–14 days; 3) EEG findings consistent with epileptiform activity and/or electrographic seizures; and 4) concurrent serious medical or neurological complications, such as sepsis or hydrocephalus awaiting shunt placement; and 5) patient history of severe alcohol or substance abuse with poor family/caregiver support. (Our experience has found that number of this latter group of patients have probably experienced undiagnosed seizures or epilepsy prior to their most recent TBI.)

specific interest in the unique management issues of this patient population can be invaluable.

## Movement Disorders After TBI

*Joachim K. Krauss*  
*Joseph Jankovic*

**T**rauma to the central and peripheral nervous system is an important etiologic factor in a variety of movement disorders. While it is widely accepted that traumatic brain injury may result in both transient and persistent movement disorders (1, 2), their occurrence after peripheral injury still has not become generally appreciated (3, 4). Kinetic tremors and dystonia are the best investigated posttraumatic movement disorders after severe brain injury (5–7), but many other types of hypokinetic and hyperkinetic movement disorders have been reported as sequelae of injury to the central nervous system. The manifestation of movement disorders after moderate or mild brain injury has been less well documented. The association between brain injury and Parkinson's disease (PD) is the subject of ongoing research (8, 9). Trauma as a cause for the development of movement disorders has multifaceted implications regarding medical and psychological, but also legal aspects (10–12). In some cases of posttraumatic movement disorders a definite cause-and-effect relationship is difficult to establish. This is partly due to associated circumstances, including medicolegal factors, but also because the appearance of movement disorders may be delayed and cause-and-effect relationships may not be recognized.

Posttraumatic movement disorders can lead to marked disability in the affected individual. Reviews on this subject have concentrated more on phenomenological

aspects and medical treatment options (1, 2, 13), and less on neurorehabilitation and neurosurgical options (14). Contemporary functional stereotactic surgery may provide long-term symptomatic and functional benefits in many patients with movement disorders who do not benefit sufficiently from medical treatment (15). Radiofrequency lesioning of the thalamus and pallidum was the method of choice for years for patients with disabling tremor or parkinsonism and levodopa-induced dyskinesias, but in patients with diffuse axonal injury (DAI) ablative procedures, particularly when performed bilaterally, have been frequently associated with complications such as increased dysarthria or gait disturbance. Deep brain stimulation (DBS) is used increasingly as an option in such patients. In this chapter, we review the current understanding of the role of central trauma in the development of movement disorders, their diagnosis and treatment including neurosurgical options.

### MOVEMENT DISORDERS AND BRAIN INJURY

#### Phenomenologic Classification of Movement Disorders

*Movement disorders* in the following context are understood as phenomenological entities manifested either by slowness and poverty of movement, that is hypokinesia,

by excessive, abnormal involuntary movements, that is hyperkinesia, or by other signs and symptoms that can not easily be grouped under these two categories. Note, that the term *movement disorder* is not synonymous with *motor disorder* covering also paresis, spasticity and ataxia which will not be discussed in this chapter. Also, the hypertonic postures seen in comatose patients with decorticate and decerebrate rigidity after severe head injury will not be the subject of this review. Most frequently, movement disorders are associated with dysfunction of the thalamus or the basal ganglia and their circuitry. Therefore, such disorders have also been summarized as *extrapyramidal disorders*, previously. This term, however, is not considered useful anymore, since the arbitrary concept of a pyramidal versus an extrapyramidal motor system does not adequately reflect the complexity of the organization of the motor system. In the past few years, much progress has been made in the understanding of the functional neuroanatomy, the neurochemistry, and the neurophysiology of the basal ganglia and their circuitry. These advances have had an extraordinary impact on new pharmacological treatments and the reevaluation of surgical approaches.

Many different classifications of movement disorders exist. The International Classification of Diseases Tenth Revision: Neurological Adaptation, a result of collaboration between the World Health Organization and the Movement Disorder Society has provided a classification which can be periodically revised and up-dated, and which can serve as a basis for international communication, research, and education (16). *Tremor* has been defined as a rhythmic, oscillatory movement, and it can be further divided according to the position, posture, or motor activity necessary to make it manifest (17). *Rest tremor* is seen when the body part is in complete repose. Maintenance of a posture such as holding the arms outstretched reveals *postural tremor*, whereas moving the body part from one position to another (e.g. the finger-to-nose maneuver) brings on *kinetic tremor* (termed *intention tremor* when tremor occurs only shortly before the goal of the movement is reached). *Dystonia* is characterized by involuntary, sustained, patterned muscle contractions of opposing muscles resulting in repetitive twisting movements or abnormal postures (18). Dystonic movement disorders often are misdiagnosed or they are not even recognized because the full spectrum of phenomenology has not been appreciated. Dystonia may be accompanied by tremor or rapid jerking movements. It may be present at rest, but it is usually exacerbated or elicited by voluntary activity (action dystonia). According to its distribution dystonia can be classified as focal, segmental, generalized or as hemidystonia. The term *athetosis* is used when phasic writhing dystonic movements of the extremities prevail in patients with secondary generalized dystonia. In *chorea*, rapid unpredictable movements spreading

from one muscle group to the other prevail, predominantly affecting the distal limbs. *Ballism* has been defined as continuous, non patterned, purposeless movements involving chiefly proximal portions of limbs (19). It usually presents as hemiballism and is related most frequently to lesions of the contralateral subthalamic nucleus. Experimental data suggest that chorea and ballism are parts of a continuum of movement disorders (20). Ballism, thus, can be considered a form of forceful, flinging, high-amplitude, coarse chorea. *Tics* are usually rapid jerklike movements or involuntarily produced sounds and words occurring out of a background of normal activity. Both motor and vocal tics may be categorized as simple or complex. Tics are differentiated from other movement disorders also with regard to their particular features such as the presence of premonitory feelings or sensations, variability, temporary suppressibility, and distractibility. *Myoclonus* is defined as a sudden, brief, shocklike involuntary movement that may be caused by both active muscle contraction (positive myoclonus) and inhibition of ongoing muscle activity (negative myoclonus). *Hyperreflexia* is characterized by exaggerated startle responses to sudden unexpected stimuli. *Stereotypy* is an involuntary, patterned, repetitive, continuous, coordinated, purposeless or ritualistic movement, posture, or utterance which may either be simple or complex, such as self-caressing. *Akathisia* refers to a sense of restlessness and the feeling of a need to move. *Paroxysmal dyskinesias* occur intermittently with bouts of sudden-onset, short-lived involuntary movements which may be dystonic or choreic. *Parkinsonism* is characterized by a combination of bradykinesia, rigidity, rest tremor, and postural instability. *Bradykinesia*, slowness of movement, is the clinical hallmark of hypokinetic movement disorders.

### Epidemiology of Movement Disorders Related to Brain Injury

Most posttraumatic movement disorders are due to severe brain injury. There are only few epidemiologic studies that have investigated the relative incidence of posttraumatic movement disorders. These studies yielded a wide variability ranging from 13% to 66% of patients who suffered severe brain injury (21–25). In a study on severe pediatric brain injury in Poland “extrapyramidal syndromes” were described in 18 out of 100 (18%) children (25). In another study, from Japan, 33 of 57 (58%) patients who were in a persistent vegetative state secondary to severe brain injury in motor vehicle accidents had “involuntary movements” (23). In this group palatal myoclonus and dystonia were observed most frequently. In another study of severe pediatric closed head injury, 4 out of 31 children were described to develop a “basal ganglia syndrome” (21). Exceedingly high rates of post-traumatic tremors were found in a questionnaire-based

survey, screening severely head-injured children for the presence of “significant tremor” (22). Tremors were reported in 66% of the responders to the survey (131 of 199 children). Taking into account that tremors might not have been present in cases that did not return the questionnaires the frequency of tremor in this pediatric population still was as high as at least 45%. We have analyzed the frequency of posttraumatic movement disorders in survivors of severe head injury who were admitted to a multidisciplinary trauma unit over a period of 5 years (24). This study included 398 consecutively admitted patients with a Glasgow Coma Score (GCS) of 8 or less. Follow-up was available on 221 of the 264 survivors. Overall, posttraumatic movement disorders were found in 22.6% (50 of 221 patients); they were only transient in 10.4% (23 of 50 patients), but were still present at the time of the investigation at a mean follow-up of 3.9 years in 12.2% (27 of 50 patients) (Table 27-1). Tremors were the most frequent movement disorders. Only in 5.4% of all patients, however, were the movement disorders considered disabling. The presence of generalized edema on the CT scan at admission was significantly associated with the occurrence of movement disorders. Similar

associations were detected for focal cerebral lesions, but not for subdural or epidural hematomas.

The absolute number of severe head injuries has decreased in most industrialized countries during the last two decades. Also, the management of head injury has improved considerably. It is still unclear whether these factors will translate into a lower frequency and a difference in the severity of movement disorders secondary to craniocerebral injury in the future. Different movement disorders may co-occur in a patient subsequent to severe head injury. In the study on the frequency of posttraumatic movement disorders in survivors of severe head injury mentioned above, 50 patients had a total of 59 phenomenologically distinct movement disorders (24). Treating one component with medication or surgery will not necessarily have an impact on the other. Furthermore, the co-existence of spastic hemiparesis or quadriplegia is observed frequently. In the individual patient, it may be difficult to distinguish dystonia from accompanying spasticity. It is pivotal to appreciate co-existing neurologic deficits in these patients in order to determine whether or not surgical treatment directed specifically to the movement disorder will make an impact in the patient’s overall functional disability.

Systematic study of the frequency of posttraumatic movement disorders after moderate or mild brain injury is sparse. Such associations have been documented, however, by numerous anecdotal case reports or case series. In a survey of 519 patients who suffered head injury with a GCS between 9 and 15 upon admission to the hospital, 158 patients were available for a detailed follow-up study (26). In 16 of these 158 patients (10.1%) we diagnosed a posttraumatic movement disorder. Overall, movement disorders were transient in 7.6% (12 patients) and persisted only in a minority of 2.6% (4 patients). With regard to possible bias by selection of the sample group, the frequency of posttraumatic movement disorders could be even lower. Movement disorders which occurred in this series are listed in Table 27-2. Postural/ intention tremor phenomenologically similar to enhanced physiological or essential tremor was the most frequent finding. Movement disorders were not disabling and did not require medical therapy in any instance in this series. Patients suffering from “minor” brain injury, that is those with a GCS of 15, developed movement disorders less frequently than those with GCS scores ranging from 9 to 14, the difference being statistically significant.

### General Pathomechanisms in Movement Disorders After Brain Injury

Movement disorders after trauma often have a delayed onset, sometimes up to months or years post-injury. In exceptional cases a delay of more than 20 years has been reported (27). In most patients with movement disorders

**TABLE 27-1**  
*Frequency of Movement Disorders Secondary to Severe Brain Injury*

	TRANSIENT	PERSISTENT
Low frequency intention tremor (2.5 – 4 Hz)	1.4 %	0.9 %
Postural/ kinetic tremor (2.5 – 4 Hz)	–	3.2 %
Postural/ intention tremor (>4 Hz)	4.1 %	3.6 %
Unclassified tremor	4.5 %	1.4 %
Focal dystonia	0.5 %	1.8 %
Hemidystonia	–	0.9 %
Hemidystonia + contralateral focal dystonia	–	0.9 %
Hemidystonia + cervical dystonia	–	0.5 %
Stereotypies	–	0.9 %
Myoclonus	–	0.5 %
Parkinsonism	–	0.9 %
Paroxysmal hypnogenic dyskinesias	–	0.5 %
Hyperekplexia (exaggerated startle)	–	0.5 %

The percentages refer to a cohort of 221 patients (Glasgow Coma Scores between 3 and 8 at the time of trauma) with long-term follow-up at a mean of 3.9 years. Several patients had more than one movement disorder. (from (24) with permission).

**TABLE 27-2**  
**Frequency of Movement Disorders Secondary to Moderate or Mild Brain Injury**

	TRANSIENT	PERSISTENT
Postural/ intention tremor (>4 Hz)	8.2 %	1.3 %
Hyperekplexia (exaggerated startle)	–	0.6 %
Cervical myoclonic twitches	–	0.6 %

The percentages refer to a cohort of 158 patients (Glasgow Coma Scores between 9 and 15 at the time of trauma) with long-term follow-up at a mean of 5.2 years. One patient had both a transient and a persistent movement disorder (from (26) with permission).

secondary to brain injury structural lesions will be seen with modern imaging techniques. The pathomechanisms resulting in a posttraumatic movement disorder are only partially understood. It is likely that both primary and secondary lesions are responsible for their development. Primary damage involves focal contusions particularly to the basal ganglia and their pathways, DAI with preferential lesions of the superior cerebellar peduncles, and ischemia or hemorrhage due to injury of penetrating arteries associated with rotational forces of the trauma (28, 29). Secondary damage caused by hypoxia, hypotension and increased intracranial pressure may also contribute to the extent of the lesion and the subsequent development of movement disorders. Sequential imaging analyses of the lesions that result in

posttraumatic movement disorders have only rarely been performed (30). Figure 27-1 shows serial CT scans and the development of a thalamic lesion causing focal dystonia. Other factors that might be involved in the pathophysiology of posttraumatic movement disorders include the release of toxic cytokines, other neurotoxins, oxidative stress associated with the deposition of hemosiderin and iron facilitating the production of free radicals and other metabolic effects (31–34). The sequelae of mechanical injury have been studied also at cellular and molecular levels (35, 36). Genetic factors may influence the rate and extent of recovery after severe brain injury (37, 38). The balance between neurodegeneration and restorative neuroplasticity may determine whether a lesion results in permanent damage or in subsequent recovery (39, 40). Restorative processes themselves, however, could also contribute to the development of a posttraumatic movement disorder. Neuroplastic phenomena including aberrant sprouting, ephaptic transmission and alterations of neurotransmitter sensitivity could be responsible for the delay of onset of movement disorders (41).

## DIAGNOSIS OF POSTTRAUMATIC MOVEMENT DISORDERS

### Tremor

The most common posttraumatic movement disorder is tremor. High-amplitude postural and kinetic tremors which may interfere with any motor function are the most disabling tremors (42, 43). Often, the tremor is present

**FIGURE 27-1**

Serial CT scans of a patient who sustained severe head injury at age 23 and suffered from posttraumatic dystonia of his right hand showing the development of a left thalamic lesion thought to be responsible for his focal dystonia. The scan obtained immediately after head injury shows a left frontal subdural hematoma and generalized brain edema (**left**); there is less midline shift 10 days after trauma, but a hypodense lesion in the left thalamus is now visible (**middle**); five weeks later the thalamic lesion is clearly demarcated (**right**). (from (30) with permission)

during the whole range of a movement and increases in amplitude towards reaching the goal. The frequency of these coarse tremors, in general, ranges between 2.5 and 4 Hz and the amplitudes can be larger than 10 cm. The rhythmic oscillatory movements may be interrupted by irregular jerking movements leading to a “myoclonic” appearance (44) and may even resemble “hemiballistic” movements (45). Tremor may be present also at rest. Such slow posttraumatic tremors have been categorized as “mid-brain”, “rubral” or “Holmes” tremors or “myorhythmias” (17, 42, 46, 47). In a series of 35 patients with severe posttraumatic tremor the kinetic component of the tremor was the most prominent feature (48). Bilateral tremor was evident in 10 patients. Commonly, posttraumatic tremor affects predominantly or exclusively the upper extremity. Persistent posttraumatic kinetic tremors are usually secondary to severe closed head injury (48, 49). The most frequent cause is automobile accident with a history of deceleration trauma of the car driver. Kinetic tremors have also been described to occur in pedestrians who were struck by cars and suffered closed head injury. The mean age at trauma was 11 years with a range from 3 to 29 years in one series (48). Most patients are comatose for weeks and often exhibit transient apallic syndromes or akinetic mutism during recovery. The delay between the trauma and the manifestation of the tremor is variable, ranging between 4 weeks up to a year. Commonly, the tremors are associated with ataxia of the affected limb. Tremor almost never is an isolated symptom. Psychological/cognitive alterations were found in 91% of patients, dysarthria in 86%, oculomotor nerve deficits in 69%, truncal ataxia in 91%, and residual hemiparesis or tetraparesis in 91% at a mean of 7 years after brain injury (48).

The history of deceleration trauma and the associated clinical findings indicate that the majority of patients with posttraumatic tremor suffer DAI. This is also supported by neuroradiological findings. In a series of 19 patients with posttraumatic kinetic tremor there was evidence of DAI in 18 patients according to late-phase MR studies revealing corpus callosal atrophy, ventriculomegaly, subcortical lesions and brainstem lesions (50). Lesions of the dentatothalamic pathways were found in 22 out of 25 instances (50). Lesions affecting the predecussational course of the dentatothalamic pathway will result in ipsilateral tremor (Fig. 27-2), while postdecussational lesions are responsible for contralateral tremor (Fig. 27-3). Two of three patients with an accompanying parkinsonian-like rest tremor had lesions involving the substantia nigra (Fig. 27-4). Tremor at rest may be present in patients with lesions of the dentatothalamic pathways without any evidence of contralateral nigrostriatal lesions. Traumatic lesions of the red nucleus and adjacent 3<sup>rd</sup> nerve nucleus may cause ipsilateral ptosis and limitation of ocular adduction and contralateral postural and

FIGURE 27-2

Axial magnetic resonance imaging studies at 2.0 T in a 27-year-old man with right-sided postural and kinetic tremor 22 years after a traffic accident. T1-weighted images (**upper**) show a small **ipsilateral** hypointense signal alteration of the right brachium conjunctivum adjacent to the fourth ventricle, that is predecussational. Heavily T2-weighted RARE images demonstrate a corresponding apparently larger hypointense lesion (**middle and lower**). (from (50) with permission)

rest tremor (Benedikt’s or Claude’s syndrome) (51). Isolated cases of thalamic lesions have been reported to cause tremor. In both, cerebellar and thalamic tremors the crescendo appearance with goal-directed movements may be the result of amplification of the tremor in reverberating circuits secondary to impaired thalamic relay. The pathophysiologic mechanisms how lesions of the dentatothalamic pathways result in the delayed appearance of tremor have not been fully elucidated (52). It is well known that such lesions trigger both orthograde and retrograde fiber degeneration. Magnetic resonance spectroscopic techniques suggest transsynaptic changes in the development of posttraumatic tremor (53). Transsynaptic

FIGURE 27-3

Magnetic resonance imaging studies at 1.0 T in a 30-year-old woman with right-sided postural and kinetic tremor 12 years after having sustained severe head injury. **The axial scans reveal a small *contralateral* postdecussational lesion not extending to the substantia nigra.** (from (50) with permission)

FIGURE 27-4

Magnetic resonance imaging studies at 2.0 T in a 37-year-old man with right-sided parkinsonian tremor at rest, postural and kinetic tremor 33 years after severe head injury. **The axial (left) and coronal (middle and right) scans show a *contralateral* postdecussational lesion extending into the substantia nigra.** (from (50) with permission)

neuronal degeneration could also involve the inferior olives, although palatal myoclonus, a well known symptom in olivary degeneration, is not commonly observed in posttraumatic tremor. Finally, the disinhibition of thalamic

rhythmic network oscillations and modifications of long-loop reflexes could be relevant. Marked decrease in  $^{18}\text{F}$ -dopa uptake in the contralateral striatum without significant changes in the D2-specific binding was found

in patients with posttraumatic ‘midbrain’ tremor who improved with levodopa therapy (54). In another patient with posttraumatic tremor who had a complete contralateral loss of the nigrostriatal pathway after midbrain injury as shown by missing [123]FP-CIT uptake in the contralateral striatum, it was thought that concurrent lesioning of the subthalamic nucleus had prevented the occurrence of parkinsonism (55).

### Dystonia

Hemidystonia is the most typical presentation of post-traumatic dystonia (6, 7, 56–58) (Fig. 27-5). In patient series with symptomatic hemidystonia from different etiologies head injury accounted for 7% to 9% of the cases (59, 60). Rare manifestations of craniocerebral trauma include cervical dystonia, segmental axial dystonia and spasmodic dysphonia (6, 61, 62). The presence of the DYT1 mutation does not seem to increase the risk of secondary dystonia, and the latter is not associated with the DYT1

mutation (63). The DYT1 mutation is found more frequently among dystonic patients with Ashkenazi Jewish origin, and it is characterized by a 3 base-pair deletion in a gene coding for an ATP-binding protein, termed torsinA.

Several patients with posttraumatic hemidystonia were described over the decades since the first report by Austregesilio in 1928 (64). Nevertheless, posttraumatic dystonia is probably underreported. There is a predominance of men which, however, most likely reflects the male preponderance among patients suffering craniocerebral trauma. Age at the time of trauma varies, but almost all patients with only few exceptions were in their infancy or adolescence. It is possible that the delay of onset of dystonia after static brain lesions is associated with the age at trauma. Patients with hemidystonia secondary to brain damage before the age of 7 years had a longer latency between the lesion and the manifestation of dystonia than adults who suffered structural cerebral damage (41). Most patients suffer severe brain injury, but occasional cases of hemidystonia and cervical dystonia were reported after moderate or mild head injury (65). Posttraumatic hemidystonia frequently is preceded by or associated with ipsilateral hemiparesis. The delay between trauma and appearance of hemidystonia is variable and may be as short as one day but may take as long as 6 years (41, 60, 66). In a series of patients with posttraumatic hemidystonia the mean latency between injury and the onset of dystonia was 20 months (6). The natural history of hemidystonia seems to be initial progression with spread over months to years, followed by eventual stabilisation (67).

Posttraumatic dystonia is associated most frequently with basal ganglia or thalamic lesions. Pathoanatomical correlations are similar to those reported for other causes of secondary dystonia (59, 60, 67). Figure 27-6 illustrates typical early magnetic resonance imaging findings in a 19-year-old patient who later developed right hemidystonia. In one series, 7 of 8 patients with posttraumatic hemidystonia had lesions involving the contralateral caudate or putamen (6) (Fig. 27-7). Cases of pallidal lesions resulting in dystonia are rare (68, 69) (Fig. 27-8). Occasionally, hemidystonia or focal dystonia, in particular, hand dystonia, is associated with thalamic lesions (30). A contralateral mesencephalic lesion was found in a patient with hemidystonia plus torticollis (6) (Fig. 27-9). Patients with posttraumatic kinetic tremor due to mesencephalic lesions or to lesions of the superior cerebellar peduncles may also have mild dystonic postures (48).

Primary as well as secondary factors are likely to contribute to the basal ganglia lesions in posttraumatic dystonia. Some of the caudatoputamenal lesions in posttraumatic hemidystonia correspond to vascular territories, in particular to the anterior (and more rarely posterior) group of the lateral lenticulostriate branches of the middle cerebral artery. Stretch of these vessels by rotating forces may either result in hemorrhage or in ischemia secondary to lesions of

FIGURE 27-5

Clinical presentation of patients with posttraumatic dystonia. **A:** patient with right-sided hemidystonia and cervical dystonia, before thalamotomy. **B:** same patient at long-term follow-up after left-sided thalamotomy. **C:** dystonic posture of right hand. **D:** left-sided dystonia with superimposed athetotic movements. **E:** right-sided hemidystonia. **F:** typical increase of dystonia upon intended movement. (from (6) with permission)

FIGURE 27-6

Magnetic resonance imaging studies of a 19-year-old man two months after suffering severe closed head injury with an initial Glasgow Coma Score of 4. Later on, right hemidystonia and cervical dystonia developed. **Upper row:** Axial Turbospin-Echo 3000/85 scans show poorly defined lesions of the left putamen. **Lower row:** Axial T2 FLASH 674/26 sequences which are more susceptible to hemosiderin better demonstrate the extent of the hypointense lesions in the putamen and reveal other small lesions in addition. (from (14) with permission)

the intima (70). This mechanism is probably also responsible for the fact that in patients with dystonia due to brain injury as compared to patients with other secondary dystonia, caudotoputaminal lesions are much more frequent than thalamic lesions (59). In general, the prognosis of traumatic basal ganglia hematoma is poor. In a recent series, only 6 of 34 patients (16%) made a favorable recovery (28). Rarely, blunt or penetrating carotid artery injuries have been described to result in ischemic cerebral lesions with subsequent development of dystonia (71, 72). Secondary damage to the basal ganglia is also possible. Many patients with posttraumatic dystonia were reported to have hematoma contralateral to the hemidystonia as well. Hypoxia is known to result in damage following “topistic” patterns, i.e. damage of specific nuclei or to neuronal subpopulations such as selective striatal vulnerability, for example (73).

Deranged function of both the direct and the indirect striatopallidal pathways is thought to underly the

development of dystonia. Regional cerebral blood flow studies in acquired hemidystonia secondary to basal ganglia or thalamic lesions have shown frontal overactivity on movement indicating that dystonia ultimately is due to thalamofrontal disinhibition secondary to disruption of the normal inhibitory control by the basal ganglia (74). It is puzzling that isolated lesions of the globus pallidus internus in healthy people can result in dystonia, but lesioning or stimulation of the same structure in dystonic people can alleviate dystonia. This observation, nevertheless, emphasizes that disturbed pallidal discharge and subsequent deranged pallidothalamic output is responsible for secondary dystonia (75).

### Ballism and Chorea

Overall, ballism is a rare movement disorder. There have been occasional descriptions of hemiballism and hemichorea

FIGURE 27-7

CT scans of a 21-year old man who sustained a severe closed head injury at age 7 and subsequently developed *bilateral* hemidystonia. On the left side there is a lesion of the caudate, anterior internal capsule and putamen corresponding to supply of lateral lenticulostriate branches of middle cerebral artery and small lesions of the ventrolateral thalamus; on the right side there is a lesion of anterior putamen (**upper**). CT scans showing a caudatoputaminical lesion in a 50-year old woman who sustained a moderate brain injury at age 9 and who developed contralateral hemidystonia 4 years thereafter (**lower**). (from (6) with permission)

secondary to craniocerebral trauma (19, 68, 76, 77). While some reports appear to describe true hemiballism, the categorization of the movement disorder remains somewhat unclear in other instances (45, 78). Often, the term “violent” movement disorder has been wrongly used to assign the diagnosis of hemiballism in patients with large amplitude hyperkinesia including tremors with superimposed irregular myoclonic jerks. Posttraumatic hemiballism is associated with severe closed head injury. It may occur with a delay of weeks or months when patients recover from coma. Histopathological examination revealed subthalamic nucleus atrophy in a patient with a traumatic pallidal lesion who developed hemiballism at 2 years postinjury (68). In another patient with posttraumatic hemiballism, no structural abnormalities were found with conventional imaging studies but single photon emission computed tomography (SPECT) revealed a subthalamic lesion (79).

Choreatic movement disorders may be caused by epidural or subdural hematomas in the rare case (80). Chronic subdural hematomas may present with contralateral, ipsilateral or bilateral choreatic movements (81, 82).

### Paroxysmal Dyskinesias

The pathophysiology of paroxysmal dyskinesias remains unclear. It has been assumed that they present a certain type of subcortical epilepsy or reflex epilepsy. They are also thought to be associated with dysfunction of sensory processing at the level of the basal ganglia or the thalamus. There have been several reports on paroxysmal dyskinesias secondary to brain injury (83–90). Imaging findings have been inconclusive. In single cases putaminal lesions were found (83). Positron emission tomographic scan studies showed abnormal metabolism in the

FIGURE 27-8

Magnetic resonance imaging studies in a 32-year-old man with posttraumatic hemidystonia after severe head injury at age 7. The axial scan through the lower part of basal ganglia (**upper**) shows the posttraumatic pallidal lesion extending to posterior putamen and a small lesion in the subthalamic region after stereotactic surgery which provided partial relief of the hemidystonia for more than 16 years. The coronal scans (**middle and lower**) more clearly show the additional lesion to the putamen. (from (6) with permission)

contralateral basal ganglia during an attack of paroxysmal posttraumatic hemidystonia (87).

### Tics and Tourettism

Adult-onset disorders with both motor tics and vocalizations secondary to a known cause have been referred to as “tourettism” to contrast it with the more common idiopathic Tourette’s syndrome (91). Posttraumatic tics and tourettism following head trauma have been described in few patients (92–96). Since tics are relatively common, the coincidental occurrence of tics after head trauma must

FIGURE 27-9

Magnetic resonance scans of a 28-year-old man with right-sided hemidystonia and cervical dystonia. The coronal images show a longish pontomesencephalic tegmental lesion on the left side (**upper row**). The axial scans demonstrate more clearly the lesion also affecting the dentatothalamic pathway thought to be responsible for the additional tremor in this case (**lower row**). (from (6) with permission)

always deserve special consideration. A causative role of trauma is favored in patients with evidence of other posttraumatic sequelae, and a negative history of motor tics prior to head injury. A history of well documented trauma to the head is mandatory. The older age at onset of patients with posttraumatic tourettism is notable, in contrast to Tourette’s syndrome. We studied the characteristics in 6 patients with tics secondary to craniocerebral trauma (93). All patients were male and the mean age at the time of the trauma was 28 years. Craniocerebral injury was moderate or mild in 5 patients, and neuroimaging studies did not reveal basal ganglia lesions. In another patient who had tics and marked obsessive-compulsive behavior secondary to severe brain injury, extensive periventricular and subcortical leukoencephalopathy was detected by magnetic resonance imaging studies (93) (Fig. 27-10). Preexisting tics may exacerbate after head injury (13). Secondary, including posttraumatic tic disorders were recently reviewed (97).

### Other Posttraumatic Hyperkinesias

Various other hyperkinetic movement disorders, often in the frame of case reports, were reported after craniocerebral trauma including instances of myoclonus, opsoclonus, palatal myoclonus, stereotypies, akathisia, and galloping tongue (98–105).

### Posttraumatic Parkinsonism and Parkinson’s Disease

*Parkinsonism after Single Head Injury* Although the concept of posttraumatic parkinsonism was well accepted in

FIGURE 27-10

Magnetic resonance imaging studies of a 33-year-old man with posttraumatic tics and obsessive-compulsive behavior 12 years after he sustained a series of two severe head injuries. There is panventricular dilatation, cortical atrophy, and extensive periventricular and subcortical leukoencephalopathy, particularly of the frontal and the right temporoparietal white matter. There are no focal basal ganglia lesions. (from (91) with permission)

the first part of the 20th century, review of cases in the literature raises doubts that most are truly examples of parkinsonism resulting from trauma (106, 107). The causal relationship in most cases has been largely speculative and the interpretation complicated by medicolegal issues. In some cases, the initial injury actually seemed to have resulted from, rather than caused, motor impairment. Posttraumatic parkinsonism, in general, is secondary to severe closed head injury (108, 109). Occasionally, parkinsonism has been described to be associated with lesions of the substantia nigra (110, 111). Direct lesions to the substantia nigra have been reported secondary to injuries by knives, screwdrivers, shell splinters or gunshots, and usually present with hemiparkinsonism (112–114). The parkinsonian syndrome is dominated by akinetic-rigid symptoms. Other movement disorders and pyramidal dysfunction may be present. We have recently studied a young man who suffered acute flexion-extension injury playing American football, followed by 3-week coma attributed to bilateral hemisphere hemorrhage, who is left with residual, levodopa-responsive parkinsonism, without any evidence of damage to the substantia nigra on imaging studies.

There have been several reports of parkinsonism secondary to chronic subdural hematoma (115). Parkinsonian symptoms become evident within weeks after trivial head injury. The clinical picture is dominated by hypomimia, bradykinesia and tremor. Other neurological signs and symptoms are usually present, although some instances of pure parkinsonism have been described (115, 116). Diagnostic evaluations appear to be delayed and initial misinterpretations are common. Favorable outcome is achieved in most instances after drainage of

the hematoma with complete or almost complete remission of parkinsonism. Chronic subdural hematomas may also cause deterioration of preexisting parkinsonian syndromes (115). Also, acute subdural hematomas when associated with brainstem compression and reduced fluorodopa uptake in the contralateral putamen can induce a hemiparkinsonian syndrome (117).

*Parkinsonism after Repeated Head Injury* Boxing is the most frequent cause for parkinsonism associated with repeated head trauma (118–122). Obvious tremors, bradykinesia and hypophonia in Muhammed Ali has helped to draw the public attention to this problem. Although cumulative brain injury occurs also in other professional sports (123), only exceptional instances of parkinsonism have been reported (122). “Pugilistic” parkinsonism (PP) or “punch-drunk” syndrome is a chronic encephalopathy which results from the cumulative effects of subclinical concussions secondary to rotational acceleration traumas by direct blows to the head. Usually, PP appears with a delay of several years after ending an active boxing career (124). The frequency of PP has been estimated to range between 20% to 50% of professional boxers. The severity of PP correlates with the length of the boxing career and the number of bouts (125). Clinically, a variable spectrum of signs and symptoms can be present including behavioral changes, dementia, and corticospinal and cerebellar symptoms. Another frequent finding is marked dysarthria or hypophonia. In contrast to posttraumatic parkinsonism secondary to a single severe head injury, tremor at rest is a relatively frequent feature of PP. In addition to extensive nigral damage, dysfunction of striatal dopaminergic terminals

has been suggested. Proton magnetic resonance spectroscopy studies have demonstrated a significant reduction in the concentration of N-acetylaspartate in the lenticular nuclei of PP patients as compared to controls and PD patients (126). PET studies showed uniform nigrostriatal involvement but relative sparing of caudate function in PP (122). Neuropathological studies have revealed depigmentation of the substantia nigra but an absence of Lewy bodies, the histological hallmark for PD. While the number of fatalities has decreased steadily over the years due to preventive measures in the ring it remains to be seen whether this will result also in a decrease of PP among boxers (127). There has been controversy as to the development of chronic encephalopathy in amateur boxing. Most studies do not show clinical evidence of chronic encephalopathy (128). In one study finger-tapping performance was worse in some amateur boxers as compared to other athletes (129). It has been shown recently that high-exposure professional boxers with an apolipoprotein epsilon4 allele have significantly greater scores on a scale measuring chronic encephalopathy than those without the allele (130). Thus, genetic susceptibility to the effects of repeated head trauma is likely.

*Parkinson's Disease and Head Trauma* In his original *Essay on the Shaking Palsy* James Parkinson suggested that the disease that now bears his name might result from trauma to the medulla. Head trauma as a possible risk factor for PD has been the subject of controversy for years (8, 9, 131–134). It has been shown that head trauma sustained in motor vehicle accidents can exacerbate parkinsonism transiently in patients with PD, however, without resulting in increased persistent disability or acceleration of the clinical course of the disease (135). Several studies have found a higher frequency of head injury in patients with PD (136, 137). Usually, the history of head trauma dates back to 20 or 30 years prior to onset of PD and, therefore, any cause-and-effect relationship is difficult to establish. With regard to head injury and other possible environmental factors it has been suggested that PD might be the consequence of clinically silent exposure in early or middle life with symptoms becoming manifest only later when there is a further decline of dopaminergic neurons with advancing age. Some studies suggested that susceptibility to trauma is more important than the severity of trauma itself. Several studies which have shown a positive association between head injury and trauma suffer from methodological flaws. The major problem with retrospective case control studies is recall bias. Unfortunately, there is a paucity of cohort studies which might be better suited to answer the inherent questions. One cohort study did not detect a significant increase in standardized morbidity ratios for PD in adults with head injury (138).

However, this study had a 30% probability of not detecting a hypothetical twofold relative risk. In a recent case-control study, subjects who experienced a mild head trauma with only amnesia had no increased risk for PD; however, subjects who had a mild head trauma with loss of consciousness or a more severe trauma had a much higher odds ratio (9). Since head trauma, overall, was considered rather a relatively rare event, the population attributable risk was estimated to be at 5%.

## TREATMENT OF POSTTRAUMATIC MOVEMENT DISORDERS

Rehabilitation of patients with posttraumatic movement disorders must consider both associated neurological and psychosocial dysfunction resulting from brain injury and the specific movement disorders. The physical disability of patients with severe kinetic tremors can be extreme because they are neither able to reach or to manage an object when the syndrome is fully expressed. Their disabilities should be treated according to the standard principles of rehabilitation care. It is important to anticipate and prevent potential obstacles for reintegration, to identify and offer strategies to manage present disabilities, and to develop adaptive and coping skills to achieve more independence. Physical therapy is helpful to prevent contractures in the most severely affected cases with dystonia.

### Tremor after Severe Brain Injury

*Medical Treatment* It is difficult to predict the prognosis of posttraumatic tremor in the initial period after its manifestation. It may lessen or resolve spontaneously within 1 year after its onset. The majority of patients, however, have persistent violent shaking movements. Posttraumatic tremor, then, is notoriously difficult to treat. Only few patients have been reported to respond favorably to medical treatment. Drugs reported to improve posttraumatic tremor include glutethimide, isoniazid, L-tryptophan, propranolol, benzodiazepines, carbamazepine, levodopa/carbidopa and anticholinergics (53, 139–141). Botulinum toxin injections may be helpful to relief the tremor temporarily but the high dosages administered to both proximal and distal arm muscles limit the usefulness of this treatment (142).

*Surgical Treatment* The largest surgical experience for posttraumatic tremor comes from ablative functional stereotactic surgery with radiofrequency lesioning in the ventrolateral thalamus and the subthalamic region, which can effectively abate posttraumatic tremor (45, 48, 143–160) (Fig. 27-11). The data of a total of 128 patients who underwent ablative stereotactic surgery as documented in

FIGURE 27-11

Magnetic resonance imaging studies obtained 3 years after combined ablative stereotactic surgery in the ventrolateral thalamus and zona incerta for treatment of posttraumatic tremor of the right arm. The coronal scans demonstrate the location of the small left stereotactic lesion and its topography in relation to adjacent nuclei. (from (48) with permission)

the literature are shown in Table 27-3. Persistent improvement on long-term follow-up has been observed in 88% of patients with the tremor being absent or markedly reduced in 65% in one study (48). Tremor at rest usually is completely abolished but the most striking improvement is the reduction of postural and kinetic tremor. Also, valuable gain in functional disability has been achieved. Functional improvement was more striking in patients who had severe incapacitating tremor but comparatively less other neurological or mental deficits. There is a marked risk for adverse effects, however, in this vulnerable group of patients. Immediate postoperative side effects have been reported to occur in 50% to 90% of patients and persistent side effects are being observed in up to 63%. Most frequently, such side effects consist chiefly of aggravation of preoperative symptoms such as dysarthria or gait disturbance. There is a trend for patients with left-sided surgery to present more frequently with increased dysarthria than patients who have right-sided procedures. Surprisingly, single patients may benefit from marked amelioration of their dysarthria after radiofrequency lesioning (48). On long-term follow-up, it has been observed that there may be an increase in dystonic postures despite improvement of tremor, or new dystonic symptoms may become manifest. It is unclear whether this is related to the surgical procedure or whether this may present delayed-onset dystonia (41). The high frequency of side effects is remarkably different from that observed after thalamotomy for other types of tremor, for example, essential tremor. The size of the lesions necessary to control severe kinetic tremors has been debated. It has been stated that larger lesions should be made in such cases to achieve long-term relief (154). On the other hand, with regard to the propensity of these patients for postoperative

morbidity, small lesions in the basal ventrolateral thalamus and the subthalamic region involving the zona incerta might be more advantageous. Gamma knife Vim thalamotomy has been reported also to result in modest improvement in posttraumatic tremor (161), but delayed effects of radiation may limit this procedure.

There is relatively little experience with thalamic deep brain stimulation (DBS) for treatment of posttraumatic tremor (162–167). Similar to other kinetic tremors due to stroke or multiple sclerosis (168), DBS has been found to be less effective than in parkinsonian tremor or essential tremor (Table 27-4). Occasionally, thalamic DBS was described as completely ineffective (166). In other instances, however, patients achieved variable symptomatic and functional benefit. It appears that DBS may be less effective in control of tremor but is associated with less side effects than radiofrequency lesioning in this special group of patients. Long-term follow-up data is very limited. There have been divergent opinions what should be considered the ideal thalamic target for DBS to treat proximal kinetic tremors. Nguyen et al. suggested that proximal contacts in the Vim would be most beneficial (165), whereas others think that stimulation of a target located more anteriorly is important (167). Kitagawa et al. recently demonstrated that stimulation of the subthalamic area can be effective in patients with proximal tremors (169). Electrodes placed in the zona incerta were most effective to control contralateral tremor. We recommend to wait at least one year after onset of posttraumatic tremor before surgery is considered. Further studies are clearly necessary to establish the role of DBS in posttraumatic tremor. We prefer DBS over thalamotomy in these patients regarding the high occurrence of side effects, presently.

### Tremor After Moderate and Mild Brain Injury

The postural and intention tremors that may occur after mild and moderate head injury usually do not require therapy and subside spontaneously (26). In some patients tremor persists and head tremor can also develop. In those cases medical therapy with clonazepam, propranolol or primidone, or botulinum toxin injections may provide relief (170, 171).

### Dystonia

*Medical Treatment* In patients with posttraumatic dystonia, spontaneous remission is unusual, although some improvement can be seen particularly in patients with thalamic lesions. Medical treatment is usually ineffective. Occasionally, there is a mild response to anticholinergic drugs. Botulinum toxin injections are the treatment of first choice in patients with posttraumatic torticollis and other focal dystonias (18, 142).

*Surgical Treatment* The prognosis is favorable in the rare cases of dystonia related to subdural hematoma after drainage of the hematoma (172–174). Functional stereotactic surgery is a treatment option in patients with disabling hemidystonia or segmental dystonia (6, 175). Targets include ventrolateral thalamus, the subthalamic region, the pulvinar and the globus pallidus internus. Improvement of dystonia in the early postoperative period has been described in most instances. Experience with long-term follow-up, however, is limited (Fig. 27-9). At a mean follow-up of 18 years after thalamic radiofrequency lesioning, 3 of 6 patients with posttraumatic hemidystonia still benefited from some improvement of their hemidystonia (6). Recently, pallidal surgery has been reintroduced for treatment of dystonia (176). In contrast to thalamotomy, the improvement after pallidotomy may be delayed by several weeks or months. It is unclear at this time whether thalamic or pallidal targets should be preferred in patients with secondary dystonia (177). In a series of patients with various forms of dystonia, the response to pallidal surgery for dystonia was dependent on etiology (178). Patients with secondary dystonia who had extensive structural cerebral lesions had no improvement after pallidal surgery, whereas patients with primary dystonia, particularly those with DYT1 dystonia, had striking benefit and patients with secondary dystonia without structural lesions had mild benefit. Villemure and colleagues reported on two dystonia patients with secondary dystonia who did not improve with pallidal surgery but benefited with thalamic targets (179). In a recent study, on the other hand, no difference in outcome between pallidal or thalamic targets was seen in patients with secondary dystonia (180). Overall, patients with secondary dystonia experienced more modest improvement

as compared to patients with primary dystonia regardless of the target used. The response of posttraumatic dystonia to pallidotomy appears to be difficult to predict. We did not observe improvement of posttraumatic hemidystonia after pallidotomy in a young patient despite his imaging studies did not show structural brain lesions. In contrast, bilateral pallidotomy was reported to result in marked improvement in a patient with generalized posttraumatic dystonia (181).

DBS has been used in only few patients with hemidystonia secondary to craniocerebral trauma. Marked improvement of dystonic movements and postures has been described in a 16-year-old boy with a thalamic lesion who underwent stimulation of the ventroposterolateral thalamus over 8 months (182). We have followed a patient for 6 years who continues to show consistent improvement of posttraumatic dystonia of the left arm with stimulation of the contralateral globus pallidus internus (183) (Fig. 27-12). Chronic intrathecal baclofen administered via implanted pumps may provide useful improvement in patients with more generalized dystonia or accompanying spasticity (184–186).

### Ballism and Chorea

In contrast to vascular hemiballism, posttraumatic hemiballism seems to be more persistent with less tendency for spontaneous improvement. Patients who do not respond adequately to conservative treatment, such as tetrabenazine, a monoamine depleting drug, can benefit from functional stereotactic surgery (187). Due to the rarity of posttraumatic hemiballism, however, experience is very limited. Targets in the contralateral pallidum or thalamus are useful.

In chorea associated with chronic subdural hematoma, the prognosis usually is favorable after drainage of the hematoma.

### Paroxysmal Dyskinesias

Posttraumatic paroxysmal dyskinesias often respond favorably to anticonvulsive medication, in particular kinesigenic dyskinesias (90). Thalamic stimulation has been shown to be beneficial in a patient with paroxysmal non-kinesigenic dyskinesia (188).

### Posttraumatic Parkinsonism

Patients with substantia nigra lesions may benefit from levodopa therapy (111). Medical treatment of posttraumatic parkinsonism, in general, is similar to that for idiopathic PD (189). There are no data available for the specific outcome of functional stereotactic surgery in patients with parkinsonism secondary to brain injury.

FIGURE 27-12

**A:** Stereotactic T2-weighted axial magnetic resonance scan of a 24-year-old man who sustained severe closed head injury at age 15 and who subsequently developed left-sided low-frequency tremor and hemidystonia. The tremor was successfully relieved by a right-sided thalamotomy; hemidystonia, however, increased over the years. This MR image was used for target calculation to implant an electrode in the posteroventral lateral globus pallidus internus (sides are reversed). **B:** Axial CT scan 4 years later demonstrating the position of the electrode in the pallidal target providing relief of dystonic posture and phasic movements and dystonia-associated pain. (from (180) with permission)

## CONCLUSIONS

Traumatic brain injury can result in a variety of movement disorders. The mediation of the effects of trauma and the pathophysiology of the development of post-traumatic movement disorders require further study.

Proper identification of such movement disorders is pivotal for rehabilitation. Functional stereotactic neurosurgery should be considered in patients with disabling movement disorders refractory to medical treatment.

## Balance and Dizziness

***Neil T. Shepard***  
***Richard A. Clendaniel***  
***Michael Ruckenstein***

### INTRODUCTION AND OVERVIEW

While a large number of different etiologies can be the cause for complaints of dizziness (representing a wide variety of specific symptoms) and imbalance, traumatic brain injury (TBI) ranks among those of significant complexity and difficult to rehabilitate. Patients diagnosed with TBI often present with dizziness complaints in the midst of a wide variety of other symptoms, as is evidenced by the diversity of discussion in this text. Experience in treating this group of patients for imbalance and other dizziness complaints shows that the time course of recovery is significantly longer than patients with similar damage to the peripheral or central balance system, yet for reasons other than TBI. To date, as a group those with TBI diagnoses do poorer overall in treatment formats of Vestibular and Balance rehabilitation therapy than other groups with peripheral vestibular injuries, not of a head injury origin. The assumption used to explain these differences in time and level of recovery during group comparisons, is that there are co-morbidities of a central nervous system origin, not distinguished by traditional diagnostics that cause the interference with recovery. Additionally, there are known disorders that can develop secondary to a TBI that are known to limit and slow down recovery of balance and dizziness complaints such as post-traumatic stress syndrome and other psychiatric conditions, or development

of post-traumatic migraine or seizure disorders, all discussed elsewhere in this text.

The purpose of this chapter is to provide an introductory review of the potential sources of complaints of vertigo, lightheadedness and imbalance that can result from a traumatic brain injury. Additionally, the chapter will review the various direct treatment options for these resulting conditions, the principle one being that of Vestibular and Balance Rehabilitation Therapy (VBRT).

For reference it will be useful to start with a brief overview of the elements of the balance system and its normal functioning.

No single structure subserves balance function. Rather, the system consists of multiple sensory inputs from the vestibular end organs, the visual system, and the somatosensory/proprioceptive systems. The input information is then integrated at the level of the brain stem and cerebellum with significant influence from the cerebral cortex, including the frontal, parietal, and occipital lobes. The integrated input information results in various stereotypic responses for eye movement, postural control, and perception of movement and orientation in space. Only a brief overview of the major elements of the input and output structures and their basic physiological functioning will be provided here, other literature providing detailed descriptions is available (1–5).

When considering the function of the balance system, it is helpful to view it in light of the major functional

purposes that the system attempts to accomplish. One can view these purposes as three distinct areas:

- Perceptions of orientation relative to gravity, the direction and speed of movement and when a change in the attitude of movement occurs.
- Maintenance of clear visual imaging of the seen world with the head in motion, target in motion or both in relative motion.
- Ability to maintain static and dynamic upright stance, and to perform volitional movements ranging from routine ambulation to complicated sequences involved in sports, dance etc. There are two areas that sub serve this last purpose (6):
  - Balance-correction responses allowing for automatic responses to unexpected perturbations of the body's center of gravity.
  - Balance-stabilizing responses allow for the volitional control of the movement of the center of gravity of the body.

### Ocular Motor Control and Perceptions of Motion

The membranous labyrinth is housed within the bony labyrinth in the petrous portion of the temporal bone, where it is secured by connective tissue and is bathed in perilymph. Endolymph is contained within the membranous structure, where the specialized sensory neuroepithelium is located. The vestibular apparatus consists of two groups of specialized sensory receptors: (a) the three semicircular canals—lateral (or horizontal), posterior, and superior, and (b) the two otolithic organs—the utricular macula and the saccular macula, both located in the vestibule. The canals and otolith organs are organized into functional pairs. The two members of each pair are in parallel planes of orientation and function in a 'push / pull' manner. Therefore, if one member of the pair is stimulated by a head movement, the other member is inhibited in its neural activity. The function of the semi-circular canals is to be responsive to angular acceleration and deceleration of the head. The otolith organs are responsive to linear acceleration and deceleration, which includes the force of gravity.

Contiguous with the vestibular portion of the membranous labyrinth is that of the auditory structure, the cochlea. Also housed within the petrous portion of the temporal bone the cochlea shares the same perilymph and endolymph fluids with the vestibular end-organ. It is these structures, the vestibular and auditory portions of the labyrinth, their innervating neural elements (VIIIth cranial nerve, auditory and vestibular divisions) and the motor and sensory nerves for facial expression and taste (VIIth cranial nerve that traverses through this portion of the temporal bone) which are in harms way from temporal bone fractures following head injuries.

Acceleration or deceleration movement of the head, producing stimulation of one or more of the receptors on one side with corresponding reduction of neural stimulation (inhibition) on the other side, results in asymmetrical neural input from the vestibular nerves. This asymmetrical input is interpreted by the central nervous system as either angular or linear movement. In addition, the asymmetry resulting from action of the semicircular canals causes a compensatory reflexive eye movement in the plane of the canals being stimulated. This compensatory reflex movement of the eye is called the vestibulo-ocular reflex (VOR), and is opposite to the direction of acceleration. It is the VOR from the semi-circular canals or the otolith organs that is the basis for the primary function of the vestibular end-organ, stabilization of the visual scene while the head is in motion (1, 2, 5). While there is top down control of the peripheral vestibular and auditory systems, this is especially true for the vestibular mechanism. This control is dominated in the brain stem and cerebellum, but cerebral influence can be easily demonstrated (1, 2).

### Postural and Motor System Control

The cerebral cortex influences lower motor centers via projections through two pathways. The first are long fibers of the corticospinal tract (the pyramidal system), which plays a major role in the control of fine, isolated, versatile movements that set the basis for skill acquisition. The second pathway for cerebral cortex projections is the extra-pyramidal system. These extra-pyramidal pathways provide the mechanisms for large gross movement patterns that are primarily reflexive and constitute major postural adjustments. The pyramidal and extra-pyramidal systems are not independent but must function in a coordinated fashion. The skilled movements of the pyramidal system that are non-postural in nature typically require that a coordinated postural adjustment accompany the smooth skilled movement such as picking up an object from directly in front of the subject while standing. This requires a shift in the overall position of the center of gravity just prior to the arm reach and the grasping of the object by the hand.

Three tracts originate from, or are heavily contributed to via, the vestibular nuclei: the medial and lateral vestibulospinal tracts, and the reticulospinal tract. Given the projections from the medial vestibular nucleus to both the ascending and descending portions of the medial longitudinal fasciculus (MLF) in the medial vestibulospinal tract, this tract may play a major role in the cervical-vestibulo-ocular reflexes, coordinating eye-head movements. Similarly, by examining the inputs to the various areas in the vestibular nucleus and the pathways from those areas to the lateral vestibulospinal and reticulospinal tracts, it is suggested that these have greater

influence on the coordination of head and upper body movement with the lower limbs. It is clear that both the central and peripheral structures participate in the tasks of postural control and ambulation. The organization of this cooperative effort, and its normal functioning during routine daily activities is beyond the scope of this chapter, but available from other sources (7–9).

### Central Vestibular Compensation Process

The vestibular system is the only special sensory system in which unilateral loss of function can seriously threaten the long-term survival or well-being of an organism. In humans, injury to the central or peripheral system may result in considerable disability. Fortunately, most disease processes involving the vestibular labyrinth are self-limited, and spontaneous functional recovery can be expected. This is due to the remarkable ability of the central nervous system to recover after a labyrinthine injury, a process known as vestibular compensation. Failure to recover from a peripheral labyrinthine insult may be due to ongoing fluctuating condition in the vestibular end-organ itself or to failure of central vestibular compensation. Being alert to this critical distinction and its clinical implications is crucial for successful management of the dizzy patient (10, 11). The underlying foundations for this process will be discussed in detail in the second half of the chapter.

## SOURCES OF BALANCE AND DIZZINESS COMPLAINTS AFTER A TBI EVENT

Combinations of specific disorders resulting from a head injury can occur, but for the purposes of this discussion the most common entities will be considered individually. For all of the disorders of the peripheral or central systems, the temporal course of the symptoms (length of spells or events if symptoms are not continuous), and the nature of the symptom onset being spontaneous or provoked by head or visual motion and whether hearing loss is involved with the symptoms are the key features of the history. The history, as with other patients complaining of dizziness or imbalance, is the single most important evaluation tool for the investigation of the cause of the complaints. For each of the encapsulated description disorders below these features will be reported.

### Disorders of Peripheral Vestibular Origin

Post-traumatic injury to the peripheral vestibular system can occur in isolation or in association with a hearing loss. In cases where clear indications for peripheral vestibular involvement is lacking, but suspected, the presence of a documented post injury hearing loss adds significantly to the argument for peripheral dysfunction.

*Benign Paroxysmal Positional Vertigo* This is considered one of the most common causes for complaints of dizziness (vertigo) and imbalance, and the most common source for dizziness post head trauma. It is characterized by brief spells (typically <1 minute) of vertigo, falling or lightheadedness provoked by a movement of the head. In the most common form of this disorder, the provocative movements are in the saggital plane. The provoked symptoms are very frequently accompanied by complaints of general imbalance during daily routines. The character of the disorder is to have it resolve spontaneously and then recur. The length of time for symptoms can vary from as short as a single day to greater than 1 year. Resolution length has equally as large a variance. This is a disorder of the inner ear where the semi-circular canals, which are not sensitive to the pull of gravity, have an altered mechanics that make them sensitive to gravity. This occurs secondary to suspected displacement of crystal structures from the otoliths into the semi-circular canal system. Hearing loss is not a typical feature associated with this disorder, but certainly could occur given head trauma as the precipitating source. Treatments are highly successful and typically consist of head maneuvers referred to as ‘canalith repositioning procedures’ during which the crystal structures are repositioned out of the involved canal (see below) (12–17).

*Labyrinthine Concussion* This disorder is characterized by hearing loss and vertigo both of sudden onset following a head trauma. The symptoms typically improve over days and in many cases some recovery of hearing may occur. Usually the symptoms of continuous vertigo resolve into being present only when provoked by head movements in any direction. It is thought that the violent movement of the fluids and tissues within the inner ear can cause tearing of tissues and / or set up a series of events where metabolically the cells undergo deterioration and death. This condition occurs in the absence of a documented fracture of the temporal bone (18). Secondary to the typical long-term symptoms of head movement provoked brief spells (seconds to minutes <5) these patients are good candidates for management with vestibular and balance rehabilitation therapy. Suppressive medication is many times needed at the initiation of this condition to control the sudden onset of vertigo and associated neurovegetative symptoms (19, 20).

A long term consequence of damage to the vestibular labyrinth, independent of the etiology, is the development of spontaneous spells of vertigo lasting minutes to hours. In some cases these can be associated with fluctuant or progressive hearing loss in a format classic for Meniere’s disease. However, this is considered a secondary Meniere’s resulting from the previous trauma. When it takes the form of only the spells of vertigo without associated auditory symptoms the older term is that

of post-traumatic endolymphatic hydrops. If the symptoms involve only the spontaneous events, vestibular and balance rehabilitation therapy is typically not applicable and the treatment options are the same as those used in cases of Meniere's of idiopathic origin (21).

**Temporal Bone Fractures** Both blunt and penetrating trauma to the temporal bone can lead to damage to the ear or VIIIth nerve complex. These injuries may result in a conductive hearing loss secondary to trauma to the external and/or middle ears, or a sensorineural hearing loss secondary to labyrinthine or VIIIth nerve trauma. Vertigo and subsequent imbalance may occur as an isolated symptom, or may be associated with a sensorineural hearing loss.

Approximately 75% of head injuries occur in motor vehicle accidents, with approximately 20% of these patients displaying some symptoms related to temporal bone trauma (22, 23). Thus, motor vehicle accidents are the most common cause of blunt trauma to the temporal bone (45%) with falls (20%), altercations (10%), and athletic injuries (10%) accounting for the majority of the remaining injuries.

Penetrating trauma is a less common cause of temporal bone injury, with etiologic agents for this form of injury ranging from bullets and knives to pencils and cotton swabs.

Temporal bone fractures elicited by blunt trauma have classically been defined by the relationship of the axis of the fracture line to the long axis of the temporal bone. Thus, longitudinal fractures, course along the external auditory canal, through the tegmen of the middle ear, and then pass anterior to the labyrinth to terminate in one of the foramina (lacerum or spinosum).

Transverse fractures run perpendicular to the long axis of the temporal bone, traversing the petrous bone between the foramen magnum and the foramen spinosum or lacerum, typically disrupting either the bony labyrinth or internal auditory canal. More recent data indicate that most temporal bone fractures possess properties of both longitudinal and transverse fractures, and are thus classified as mixed or oblique fractures. Projectiles may involve any or all components of the temporal bone, depending on their trajectory. More benign penetrating objects (e.g. pencils, cotton swabs), may elicit neurovestibular symptoms by disrupting the interface between the stapes and the labyrinth, creating a perilymph fistula (see below).

Trauma to the external canal manifests with bloody otorrhea and severe pain. A traumatic tympanic membrane perforation will have a similar presentation, with hearing loss always being present. Disruption of the ossicular chain most commonly involves the incus and results in a persistent conductive hearing loss. Disruption of the stapes may result in a conductive, mixed, or profound hearing loss (see perilymphatic fistula below).

The hallmark of a labyrinthine injury secondary to blunt or penetrating trauma is the presence of vertigo and hearing loss. In cases of severe head injury, in which the patient has been comatose for a period of time, the symptom of vertigo may be supplanted by the complaint of imbalance. Fractures that approximate a longitudinal course do not cause a direct disruption of the inner ear or VIIIth nerve. However, patients may suffer both sensorineural hearing loss and vertigo secondary to what has been referred to as a *labyrinthine concussion* (see above). In this situation, the vertigo is typically acute and self-limited, and the hearing loss is, at least partially, reversible. In contrast, fractures that traverse the otic capsule or internal auditory canal will cause profound hearing loss and vertigo.

Signs on physical examination indicative of inner ear trauma include tuning fork tests that lateralize to the unaffected ear and spontaneous nystagmus consistent with either an irritative (toward the affected ear) or parietic (away from the affected ear) lesion.

Audiometric assessment will define the nature of the hearing loss (conductive, sensorineural, mixed) and vestibular testing will document a vestibular injury. High resolution CT scan of the temporal bone is indicated to define the nature of the fracture and the structures involved.

External canal trauma should not be manipulated at initial presentation, as a traumatic dural or brain exposure may be present. Once CT scan has ruled-out these complications, the ear should be gently microdebrided and attempt made to reposition any avulsed pieces of skin. A post-traumatic ear canal stenosis may occur which will require surgical repair, both to improve hearing and prevent cholesteatoma formation secondary to the presence of squamous epithelium trapped medial to the stenosis. Tympanic membrane perforations should be managed conservatively as the rate of spontaneous healing is close to 100%. Disruption of the incus will require an ossiculoplasty once the primary healing process is completed (6 weeks to 3 months).

Other than for a perilymph fistula (see below), no specific treatment exists for blunt or penetrating inner ear trauma. Vestibular suppressants can be used for acute vertigo control, if not otherwise contraindicated by the patient's overall medical status. Hearing aid amplification may be useful in patients with partial sensorineural hearing loss, and vestibular rehabilitation therapy is indicated in those patients with a slow recovery from their vestibular loss.

The majority of patients sustaining temporal bone injuries develop little or no inner ear dysfunction. Patients who do sustain a noncompensated vestibular loss generally respond well to vestibular rehabilitation therapy. Benign paroxysmal positional vertigo (BPPV) is a common sequela of head injury and is in fact, the most common form of post-traumatic vertigo. Any patient complaining of

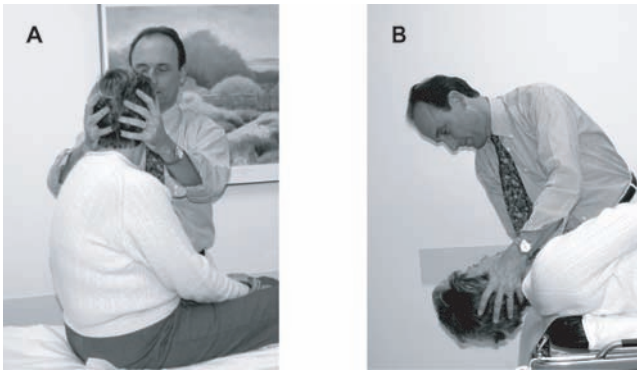

FIGURE 28-1

The left Dix-Hallpike Test. (A) The patient sits with legs extended on the table and cervical spine rotated 45 degrees to the left. The examiner places his hands on either side of the patient's head, with his right fore-arm behind the patient's left shoulder. (B) The patient is quickly brought into supine and the cervical spine extended approximately 10 degrees. The examiner observes the patient for nystagmus and symptoms

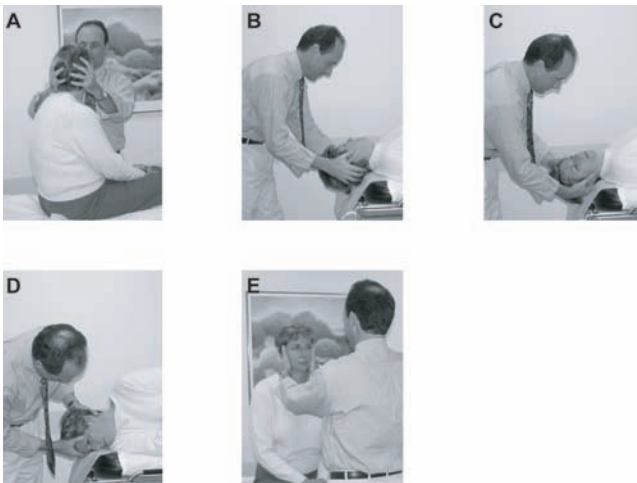

FIGURE 28-2

The Canalith Repositioning Maneuver for left-sided BPPV. (A) The starting position is identical to the initial position in the Dix-Hallpike test, with the cervical spine rotated 45 degrees to the left. (B) The patient is brought into supine and the cervical spine is extended approximately 10 degrees (45 degrees of left cervical rotation is maintained). (C) The cervical spine is rotated 90 degrees to the right to end up in 45 degrees rotation to the right. (D) The patient is rotated onto their right side, maintaining the cervical rotation to the right. The cervical spine is brought out of extension, and is laterally flexed to the right. (E) The patient is brought into sitting. As the patients rises from right side lying to sitting, the cervical rotation to the right is maintained

vertigo after a head trauma should have a Dix–Hallpike maneuver performed in the office (see Figure 28-1). If the diagnosis of BPPV is confirmed, then an canalith repositioning maneuver (see Figure 28-2) should be performed.

This therapeutic maneuver is highly efficacious and greatly appreciated by the patient.

**Perilymphatic Fistula** A Perilymph Fistula (PLF) occurs when the boundary between the middle and inner ear has been violated, allowing egress of perilymph and inner ear dysfunction. The topic of PLF remains controversial, particularly with respect to the spontaneous variety.

Perilymph fistulae are proposed to occur via three possible mechanisms. Congenital inner ear anomalies involving the otic capsule may result in dehiscences in the labyrinth that allow communication between the middle ear and the labyrinthine fluids. These are typically children who present with severe to profound hearing loss and recurrent meningitis or CSF leak (24).

More relevant to this discussion is the development of a PLF due to disruption of the oval (or less commonly, round) window secondary to external trauma. This trauma may be iatrogenic (e.g. post-stapes surgery) or secondary to blunt or penetrating trauma. Barotrauma and acoustic trauma have been proposed to create fistula via the transmission of rapid pressure changes to the round and oval windows (so called “implosive trauma”) (25). However, as indicated above, these forms of trauma rarely result in a frank PLF.

Most of the controversy pertaining to PLF surrounds the spontaneous variety. This is proposed to occur through leaks through congenital dehiscences in the otic capsule, typically occurring in the regions of the oval and/or round windows. The leak through these dehiscences was thought to be precipitated by an increase in intracranial pressure being transmitted to the inner ear (“explosive trauma”) (25). The validity of the concept of a spontaneous perilymph fistula has been critically scrutinized by otologists over the past two decades with a consensus emerging amongst most authorities that spontaneous fistulae rarely, if ever, occur (26–28).

A wide gamut of symptomatology has been ascribed to the PLF. Currently, most otologists would consider the diagnosis of a fistula when a patient presents with a sudden sensorineural hearing loss associated with tinnitus and vertigo, occurring immediately subsequent to a traumatic insult. Fluctuations in hearing may support the diagnosis if they appear provoked by pressure fluctuations or straining.

Despite intense effort no valid and accurate diagnostic test for PLF exists. A fistula test, in which a pressure change is applied to the inner ear via a pneumatic otoscope or tympanometer, may be considered positive if it evokes symptoms and nystagmus. However, this test is nonspecific and may also be positive in Meniere’s disease and otosyphilis. Audiovestibular testing, including electrocochleography, do not reveal any pathognomonic findings. Detection of fluorescein in the middle ear subsequent to intravenous or intrathecal injection has not

proven to be clinically useful. Similarly, the detection of beta2 transferrin in the middle ear has not proven to be an accurate method of identifying a PLF (29).

Most authorities agree that the only manner in which the presence of a PLF can be confirmed is by direct observation of the leakage (30). Based on recent results, it would appear that the most accurate way of performing this exploration is by using endoscopes passed through a myringotomy incision (31, 32). This technique appears to avoid false positive results that occur secondary to pooling of fluid, such as anesthetic injection, during the raising of tympanomeatal flap.

Bed rest, head elevation, and avoidance of straining are the initial treatments employed when a PLF is suspected. If symptoms of fluctuations of hearing and/or vertigo persist for 2–3 days while on this treatment regimen, a middle ear exploration and patching of the fistula site (oval and/or round window) should be considered.

In one study, 68% of patients with identifiable fistulae at the time of exploration improved after patching of the fistula (30). The majority of these patients had undergone previous stapes surgery. In patients who sustain a frank stapes subluxation subsequent to an external trauma, the prognosis is more guarded for recovery of auditory function.

### **Central Nervous System Causes for Balance and Dizziness**

There are multiple sources of injury and secondary disorders to head trauma that can originate in the central nervous system and manifest in symptoms of balance and dizziness. Both post-traumatic seizures and post-traumatic stress syndrome / anxiety disorders can be direct causes for complaints of symptoms ranging from vertigo to vague lightheadedness and imbalance. Mechanisms, investigation and treatment for these entities are considered elsewhere in this text and will not be repeated herein. It is important to realize that there can be dramatic effects of psychological disorders that develop with long term disorders and are expressed in the complaints of dizziness (33–35).

Direct trauma to the brain stem and / or cerebellum will result in complaints of imbalance with standing and walking and occasional complaints of true vertigo. The pathophysiology of injuries of this nature is addressed in another chapter in this text. The nature of the signs and symptoms will vary depending on the location of the lesion within the central nervous system (36). Lesions within the brain stem and cerebellum have typical ocular motor abnormalities that can be recognized during the office or laboratory examinations of these patients (see discussion below). Given that these are typically stationary lesions vestibular and balance rehabilitation therapy will comprise a major portion of the treatment plan.

These are usually not spontaneous events of symptoms but are more likely to be continuous sensations of disorientation, and imbalance with gait (37).

Post-traumatic migraine headaches, as with non-traumatic migraines, can have dizziness as an aura for the migraine event. This can occur with or without the pain phase of the migraine event. When the events of dizziness are not temporally related to actual headaches this entity can be quite difficult to diagnosis as it has to be a diagnosis of exclusion. Symptoms from migraine associated dizziness can be spontaneous spells of true vertigo to vague complaints of increased sensitivity to motion sickness and anything in between. Recognition of this is typically accomplished by having a history that the headaches being experienced meet the criteria for migraine, or pre-trauma the patient had a migraine history. Once diagnosed these are treated by direct treatment of the headaches (38, 39). In some cases the patient can be assisted with the use of vestibular and balance therapy as long as there is simultaneous focused treatment on the underlying migraine disorder.

In addition to the above descriptions of the direct effects of the central nervous system lesions producing symptoms of dizziness and imbalance, all of the above can have an indirect effect as well. In patients with combined peripheral and central lesions, the presence of the central lesion in the brain stem and / or cerebellum may not be causing direct symptoms of dizziness or imbalance but could cause disruptions in the natural central system compensation process. This would have the effect of slowing or preventing the compensation process from reducing the symptoms from the peripheral vestibular insult. This disruption in the compensation process can also occur from psychological difficulties, migraines or seizure disorders. In these instances direct treatment for the other disorders would be necessary in order to allow for as full a compensation process as possible.

### **OVERVIEW OF ASSESSMENT TOOLS AND THEIR USE IN DIAGNOSIS AND TREATMENT**

Even though a head injury with TBI may be the precipitating event that results in complaints of imbalance and dizziness, one must proceed in the evaluation of those complaints in a systematic manner to uncover the source of the symptoms. Therefore, the evaluation is not different from what would be performed for a patient presenting without a known antecedent event. In considering the evaluation of the patient with complaints of vertigo, lightheadedness, imbalance or combinations of these descriptors, one must look beyond just the peripheral and central vestibular system with its ocular motor connections. The various pathways involved in postural control, only part of which have direct or indirect vestibular input should be

kept in mind during an evaluation. The event that produced the head injury could easily have caused injury to any of these postural control pathways independent of the resultant TBI. Additionally, significant variations in symptoms and test findings can be generated by migraine disorders (37, 38) and / or anxiety disorders (33–35), yet these are diagnosed primarily by history requiring a specific line of questioning.

The evaluation of the dizzy patient should proceed being guided by what information is needed to make initial and subsequent management decisions. When various tests are reviewed, and correlated with high level activities of daily living, virtually no significant relationships exist for the chronic dizzy patient. Tests considered extent and site-of-lesion studies, Electronystagmography (ENG), Rotational chair and specific protocols in postural control assessment (5, 40), give results that are unable to be used to predict symptom type, magnitude or the level of disability of an individual patient. Conversely, patient complaints can not be used to predict the outcomes of these tests (41–44). In a limited manner more functionally oriented evaluation tools, computerized dynamic posturography (CDP), dynamic visual acuity testing (45) provide for some correlation between results, patient symptoms and functional limitations. Add to the testing specific or general health inventories like the Dizziness Handicap Inventory (41) and predictive assessment of disability is improved but remains significantly limited. It is hypothesized that the reason for this dichotomy in test results versus functional disability and symptom complaints is the inability of the tests to adequately characterize the status of the central vestibular compensation process (5, 46). It is the exception, not the rule that vestibular and balance laboratory tests return results that would drive management of the dizzy patient. It would be extremely rare that these studies return a diagnosis. Therefore, the routine use of these tools to determine how to proceed with the management of a dizzy patient is a false line of reasoning and not productive in the majority of the patients. In general the laboratory studies are productive in determination of extent and site-of-lesion within the peripheral and central vestibular system and the functional limitations in static and dynamic postural control (44). The use of this information is in the confirmation of the suspected site-of-lesion and diagnosis derived from patient history and direct physical office vestibular evaluation.

To summarize the above discussion, the following are required elements to management decisions for the chronic dizzy patient; detailed neurotologic history, office vestibular and physical examination, and formal audiometric testing given the inescapable anatomical relationship between the auditory and vestibular peripheral systems. The following are considered important, however less likely to directly drive the management in the typical

case; laboratory vestibular and balance-function studies, neuroradiographic evaluations and serological tests. It is important to realize that there will be patients for whom unexpected findings on any one of these latter studies will either alter the complete course of the management or add dimensions to the management not originally considered. But for the majority of patients the vestibular and balance tests will be confirmatory in nature.

The following discussion will be a very brief overview of the major elements available for assessment. A recent comprehensive summary of the evaluation of the dizzy patient and detailed descriptions are found elsewhere for the interested reader (5, 9, 40, 44, 47).

### Neurotologic History

Given the various tools for assessment, the history is the single most important factor in determining the course of management, and therefore requires discussion. The differentiation between the various peripheral vestibular disorders, that can result from a head injury, is particularly dependent upon historical information and the conclusions that the physician draws from the interview. Most vestibular disorders cannot be distinguished from one another simply by vestibular testing or other diagnostic interventions. Failure to properly discriminate these disorders on historical grounds may lead to improper management by the physician. In addition, balance function study results are best interpreted in light of a proper clinical history.

It is very important to question the patient regarding the association of a hearing loss or other auditory symptoms with the onset of vertigo. A complete audiometric assessment should be performed early in the evaluation. The presence of an associated sensorineural hearing loss, whether stable, progressive, or fluctuating, is the single strongest incriminating factor in identifying a pathologic labyrinth. The presence of other otologic symptoms such as aural fullness and tinnitus may also be helpful in lateralization. The features in the history will be the primary determiners of the initial choice for treatment (see Management Options sections below).

### Office Examination

A variety of test procedures may be used in the office setting to assess the balance-disorder patient. These, like the laboratory studies, assist in the identification of the extent and site of the lesion. These straight-forward clinical tests are essentially variations of the related laboratory studies, but have less ability to quantify the outcomes. The theoretical basis behind many of these tests is well founded in the physiological considerations discussed above and in the references provided. Due to the subjective nature of these tools, the validity and reliability of these tests are reduced compared to the formal laboratory studies.

It is important that the person evaluating the dizzy patient be aware that simple tools do exist which provide for an effective evaluation. In the majority of patients this evaluation produces the same impressions as the extensive laboratory studies discussed below. These tools are, however, not as sensitive to mild anomalies as the laboratory studies. A recent summary of these techniques is available in the literature (9).

### Laboratory Studies

*Electronystamography (ENG)* Traditional ENG, using electrodes placed around the eyes or infrared video techniques for eye movement recordings, is a process that estimates the position of the eye as a function of time. Since the primary purpose of the vestibular apparatus is to control eye movements, the movements of the eyes may be used to examine the activity of the peripheral vestibular end organs and their central vestibulo-ocular pathways. The ENG evaluation is a series of sub-tests performed to assess portions of the peripheral and central vestibular systems. It is important to understand that peripheral vestibular system assessment with ENG is significantly limited, typically reflecting function of the horizontal semicircular canal with restricted information from vertical canals and otolith organs. With the use of computerized ENG systems, which afford significant visual stimulus control and quantitative analysis, evaluation of the central vestibulo-ocular pathways can be quite thorough.

*Rotary Chair* Rotary chair testing has been used to expand the evaluation of the peripheral vestibular system. As with the ENG findings, the rotational chair evaluation can assist in site-of-lesion determination, counseling the patient and confirmation of clinical suspicion of diagnosis and lesion site, but is not likely to significantly alter or impact on the course of patient management, excepting the bilateral peripheral weakness patient.

As with the ENG, electrode or video techniques are used to monitor and record the outcome measure of interest, jerk nystagmus, that is generated in response to the angular acceleration stimulus produced by the circular movements of the chair.

*Postural Control Assessment* Just as all patients that are being evaluated in the laboratory need tests for peripheral and central vestibulo-ocular pathway involvement, they also require some assessment of postural control ability. There are several different general approaches to formal postural control testing, each with specific technical equipment requirements and goals for the testing (5, 48). Briefly, the most common equipment detects vertical and horizontal forces from the feet by two independent force plates upon which the subject stands. Three principle testing

protocols are used in patient evaluation, the Sensory Organization Test (SOT), the Motor Control Test (MCT) and Postural Evoked Responses (PER). These allow for assessment ranging from strictly functional (not site-of-lesion) with the SOT to site and limited pathology specific results with PER. Because of the functional assessment using SOT, postural control assessment is useful in the development and monitoring of vestibular and balance rehabilitation management option discussed below.

### OVERVIEW OF TREATMENT OPTIONS

The options for management of the dizzy and balance-disordered patient fall into the major categories of medication, surgery, dietary changes and vestibular and balance rehabilitation therapy (VBRT), or combinations of these techniques (5). In general it will be the rare patient with dizziness secondary to head injury that is going to be managed with medication alone. The most common use of medications in this arena would be short term or 'as needed' use of vestibular suppressant medications for acute symptom control at the onset or with recurrent spontaneous events of vertigo lasting hours. Other than migraine and psychological disorders there is little call for use of chronic medication. Of the medications most commonly used for vestibular suppression the primary classes are those of antihistamines (Meclizine & Promethazine), anticholinergics (Scopolamine), phenothiazine (Prochlorperazine) and benzodiazepines (Diazepam, Lorazepam & Clonazepam). There are other classes and other specific medications within these listed drug classes that have been used for the control of acute vertigo and the vegetative symptoms that accompany the sensation of vertigo. It is important to remember that use of these medications should be on a short term basis and only 'as needed' when possible. These classes of medications have an effect that can significantly slow the natural compensation process and the effectiveness of VBRT (17).

Surgical intervention for this group of patients is used even less frequent than medication. The patients for whom surgery may be considered are those discussed above associated with temporal-bone injuries and perilymphatic fistulas. The treatment option that would be the most common is VBRT. This option will be discussed in detail below.

The major feature that drives an initial decision as to the use of medication / surgery versus VBRT is the evidence that the peripheral or central vestibular lesion is unstable (varying over time), as opposed to an uncompensated stable lesion. This distinction comes dominantly from the patient's presenting symptoms. Therefore, the patient should be asked to describe the progression of symptoms over time, along with the nature and duration of typical spells. Specifically, one wishes to know if the

symptoms are continuous or occur in discrete episodes. If the symptoms are episodic, it is extremely important to distinguish whether they are spontaneous or motion-provoked. If the symptoms are brief and predictably produced by head movements or body position changes, the patient most likely has a stable lesion, but has not yet completed central nervous system compensation. Those who describe these symptoms sometimes also note a chronic underlying sense of disequilibrium or lightheadedness. The chronic symptoms may be quite troublesome, but any intense vertigo should be primarily motion-provoked. These patients are suitable candidates for vestibular rehabilitation. It is important to point out that historical information is essential in deciding who might benefit from rehabilitation therapy.

If the episodic spells described by the patient are longer periods of intense vertigo that occur spontaneously and without warning, this is probably a progressive or unstable peripheral dysfunction. One must also suspect a progressive lesion if the vertigo is accompanied by fluctuating or progressive sensorineural hearing loss. Such patients are managed with medical therapy, and if this fails, they constitute the best candidates for surgical intervention. Such patients are not candidates for vestibular rehabilitation, except as an adjunctive modality. For the chronic patient, including those with known head trauma event, the primary effort is to determine why they have not had the natural central compensation process run to completion.

When dealing with the TBI patient group, VBRT is many times used as one component of a comprehensive traumatic brain injury rehabilitation program involving physical, occupational, speech and cognitive therapy aspects.

### **VESTIBULAR AND BALANCE REHABILITATION THERAPY PROGRAMS**

As indicated above, VBRT is the most frequently used management option for patients with balance and dizziness complaints from head injury, or other causes. Therefore, the remainder of this chapter will be a detailed discussion of this technique.

Since traumatic brain injury can lead to damage of the vestibular system from peripheral to central structures, as well as cause other CNS damage, the types of exercises used to treat the dizziness and imbalance can be quite comprehensive. The aims of the following sections of this chapter are to 1) review the rationale behind vestibular and balance rehabilitation therapy (VBRT), 2) identify the types of problems that can be treated with VBRT, 3) describe the various types of exercises used in VBRT, 4) discuss modifications of treatment programs for individuals with traumatic brain injury, and 5) describe the outcomes to date.

The use of exercise for the treatment of individuals with vestibular dysfunction is not new. In the 1940's Sir Terrence Cawthorne, an otolaryngologist, and F. S. Cooksey, a physiotherapist, devised a series of exercises for the treatment of individuals with unilateral vestibular paresis and post-concussion syndrome (49–51). Cawthorne and Cooksey realized that head movements often provoked an individual's symptoms of dizziness. They also observed that patients who were active recovered faster and hypothesized that head movements must be important in the recovery of function. Their initial exercise program consisted of a variety of eye, head, and body movements to habituate the dizziness. Since the development of those exercises, several other approaches to the treatment of patients with complaints of vertigo and dysequilibrium have been described. These exercises generally fall under four different categories, exercises to promote habituation, exercises to promote adaptation, exercises to promote substitution, and exercises designed to treat benign paroxysmal positioning vertigo. Any of these exercise approaches may be indicated in an individual with dizziness secondary to traumatic brain injury. The challenge to those treating these individuals is to identify the nature of the cause of the dizziness and to design the appropriate treatment programs.

Habituation exercises, like those described initially by Cawthorne and Cooksey, are based on the principle that repeated exposure to a noxious, or provocative, stimulus (in this case movements) will lead to a reduction in the body's response to that stimulus.

The exercises to induce adaptation of the vestibular system, while similar to the approaches mentioned above, reflect our increased knowledge of the function and adaptation of the vestibular system. Adaptation exercises are designed to promote long term (plastic) changes in the neuronal response of the vestibular system to a given head movement, with the goals of decreasing retinal slip, improving postural stability, and decreasing symptoms. These exercises are typically used in individuals with an uncompensated unilateral vestibular loss. The treatment approach for individuals with unilateral vestibular hypofunction differs in both theory and practice from the approach for individuals with bilateral vestibular loss. For individuals with bilateral vestibular loss, exercises to promote the substitution of alternative strategies for gaze stability and postural control are appropriate.

Finally, the exercises to treat BPPV are based upon the hypothesis that there are crystalline structures, which are consistent with degenerating otoconia from the otolithic membrane (52). These crystals cause an abnormal mechanical stimulation of the vestibular system with changes in head position relative to gravity. These exercises, while simplistic in the current arena of high tech medicine, are very effective in alleviating the signs and symptoms of BPPV. Benign Paroxysmal Positioning

Vertigo can occur in conjunction unilateral vestibular loss, central vestibular disorders, and in some cases with bilateral vestibular loss. Consequently, the treatment of BPPV is often combined with other exercise approaches to treat the identified problems. Determination of the appropriate exercise program rests on the findings of the clinical examination and available vestibular function tests.

### **Who Is an Appropriate Candidate for Vestibular Rehabilitation?**

Generally, individuals with stable vestibular function and symptoms provoked by head motion (either self-motion or motion in the environment) or environmental situations (e.g. absence of visual cues, altered somatosensory cues) will benefit from vestibular rehabilitation. Individuals with vestibular function that fluctuates, as in Meniere's disease, or those who have true spontaneous episodic bouts of dizziness, typically will not benefit from vestibular rehabilitation.

### **Treatment of Individuals with Benign Paroxysmal Positioning Vertigo**

Benign Paroxysmal Positioning Vertigo (BPPV) can affect any of the three semicircular canals, although the most commonly encountered presentation is that of posterior canal BPPV (53). In addition, the BPPV is thought to be caused by one of two mechanisms, cupulolithiasis (54) or canalithiasis (55, 56). In canalithiasis, the otoconia are mobile in the long arm of the semicircular canal; in cupulolithiasis, the otoconia are adherent to the cupula. The effect, in both cases, is to make the involved canal sensitive to the pull of gravity. The presentation of the two types of BPPV differs, as do the treatments for each condition. The methods used to determine the involved canal and the nature of the BPPV as well as a comprehensive review of the various treatment techniques are beyond the scope of this chapter. The interested reader is referred to the following articles for review (57, 58). Identification and treatment of posterior canal canalithiasis, the most common form of BPPV encountered in the clinic, will be reviewed here. The test for BPPV is the Dix-Hallpike maneuver (59). To perform this test, the patient sits with their legs extended on the examination table, their cervical spine is rotated approximately 45° to one side, their head is supported in the examiner's hands, and they are quickly brought into supine, with the cervical spine extended 10° to 20° and the head hanging off the table (see Figure 28-1). The patient is held in this position for up to 60 seconds, and the eye movements and the patient's symptoms are monitored. In a patient without BPPV, this test will produce no vertigo and no nystagmus. In a patient with BPPV, the Dix-Hallpike test will provoke both vertigo and a mixed vertical-torsional nystagmus.

The fast phase (beat) of the vertical component of the nystagmus will be upwards (relative to the patient). Torsional eye movements are rotations of the eye around the line of sight axis, and the direction of the nystagmus is named for the movement of the superior pole of the eye (again relative to the patient) during the fast phase of the nystagmus. The torsional component of the nystagmus will beat towards the involved ear, which is generally the dependent ear in the Dix-Hallpike maneuver. The nystagmus and vertigo will be present less than 2 minutes, and will generally persist for 30 seconds or less. The observed nystagmus and vertigo are due to an abnormal stimulation of the posterior semicircular canal, presumably due to movement of the otoconia away from the cupula. On arising to sitting, there is often a recurrence of the vertigo and a reversal of the nystagmus. This reversal of the nystagmus is due to the otoconia now moving back towards the cupula of the semicircular canal.

Treatment of this form of BPPV is straightforward. John Epley (60) first described a series of positioning maneuvers designed to move the offending otoconia out of the involved canal. Others have modified his procedure by altering some of the movements, changing the time in each position, and not using a mastoid vibrator during the treatment. This modified procedure is typically referred to as the canalith repositioning maneuver (CRM) or canalith repositioning procedure (CRP) (57, 61, 62). For the following description of the maneuver, we will assume that the patient has left-sided, posterior canal canalithiasis. If the patient had right-sided, posterior canal canalithiasis, the direction of the rotations would be reversed. To begin the CRM, the patient is long sitting on a treatment table, with the cervical spine rotated 45° to the affected side (Fig. 28-2A). The patient, whose head is supported by the examiner, is then brought into supine, and the cervical spine is extended 10° or 20° (Fig. 28-2B), and this position is maintained for 30 seconds to 2 minutes. The patient's neck is then extended further (if possible) and then rotated 90°, so that the final position is 45° rotation to the right (Fig. 28-2C). This position is maintained for 30 seconds to 2 minutes. The patient then rolls onto the right side, maintaining the same degree of cervical rotation. During this rotation of the body, the cervical spine is brought into neutral with respect to flexion and extension and laterally flexed to the right, to bring the head down toward the treatment table (Fig. 28-2D). This position is maintained for 30 seconds to 2 minutes. The patient is finally brought to into sitting from the side lying position, maintaining the cervical rotation until the patient is upright (Fig. 28-2E). The time spent in each position varies among practitioners. Epley (60, 63) suggested that each position be held for 1.5 times the duration of the nystagmus observed in the Dix-Hallpike test. Post-treatment instructions to the patient also vary among practitioners. Some suggest that the patient remain

upright for 24 hours post-treatment; while others will retest the patient to determine the efficacy of the treatment. If one elects to re-assess the patient after the initial treatment, then one should repeat the treatment even if the post-test is negative. The treatment is repeated to avoid the possibility of having the otoconia move back into the affected semicircular canal during the re-assessment. Following successful treatment, patients are generally instructed to perform the CRM or Brandt-Daroff exercises at home in an attempt to prevent a recurrence of the BPPV.

### Treatment of Gaze Instability

One of the primary functions of the vestibular system is to generate compensatory eye movements to a given head movement, the vestibulo-ocular reflex (VOR). The VOR, when functioning appropriately, allows the individual to maintain the object of interest on the fovea, thereby preserving visual clarity. If the vestibular system is not functioning appropriately, the eye movements generated in response to head movement will not be sufficient to keep the object of interest on the fovea. The resulting movement of the image on the retina, retinal slip, will lead to a degradation of visual acuity. In individuals with remaining vestibular function (for example those with a unilateral vestibular deficit), the exercises are designed to foster adaptation of the remaining vestibular signals to generate the appropriate eye movement responses. For those individuals without vestibular function (for example those with bilateral vestibular loss) there is no remaining vestibular signal to adapt. Consequently, the exercises for these individuals are designed to promote the use of alternative strategies to promote gaze stability during head movements. The two general exercise approaches and the rationale behind the exercises will be explained separately.

*Exercises to Enhance Vestibular Adaptation* The rehabilitation of individuals with unilateral peripheral vestibular hypofunction or loss (UVH) is based upon the plasticity inherent within the vestibular system. The ability of the vestibular system to modify its behavior during development, as well as in disease states, has been well documented (for a review see review by du Lac and colleagues (64)). In the case of an insufficient VOR, due to vestibular hypofunction, the vestibular system will not generate sufficient eye movements in response to head movements. This will cause the visual image to move across the retina. This retinal slip in the presence of head movements appears to be an effective stimulus for inducing adaptation of the VOR (65). For patients with remaining vestibular function, the exercises used in the treatment of gaze stability deficits are designed to generate these error signals and thereby foster adaptation of the vestibular system (66). The goals of this aspect of the rehabilitation program are to 1) improve

visual acuity during head movements, 2) improve visual-vestibular interactions during head movements, and 3) decrease the individual's sensitivity to head movements.

As a consequence of the error signal produced by the exercises, performance of the exercise is frequently associated with symptoms of dizziness or nausea. The patient must be aware that provocation of their symptoms is a necessary part of the rehabilitation process. If there is no symptom provocation with the exercises, then the patient is not challenging the vestibular system and adaptation will not occur. The first exercise to address the gaze instability issue is often called x1 (times one) viewing, since the eye velocity must equal the inverse of the head velocity to maintain visual fixation (Fig. 28-3A). To perform the exercise, the patient fixates on a visual target (a small letter or number) located on a plain visual background, approximately 3 feet away. The patient then rotates his/her head, maintaining fixation on the visual target throughout the head rotation. The image should remain in focus and stable in space. The amount of head rotation should be approximately 30°–45° to either side of midline. The patient should avoid maximum deviation of the eyes as visual acuity decreases in these positions and end gaze nystagmus should be avoided. Cervical range of motion limitations and glasses, especially bifocals, may limit the degree of head rotation. Head rotation, both horizontal and vertical, should be performed as rapidly as the individual can tolerate, with the restriction that the visual target must remain in focus and stationary. Oscillopsia will develop if the velocity of the head rotation exceeds the capacity of the VOR. The exercise should be performed continuously for 1 (initially) to 2 minutes. The duration should be progressed gradually to avoid severe exacerbation of the symptoms or provocation of cervical pain. As the individual improves, the velocity of head rotation can be increased. Altering the postural demands or the visual conditions will vary the stimulus context. If the patient has difficulty with independent stance, then the exercise can be performed initially while sitting. Having the patient stand with a wide base of support on a firm surface increases the postural demand. This condition forces the CNS to utilize somatosensory and visual cues to maintain balance in the presence of fluctuating vestibular signals. As the patient improves, they begin to perform the exercise with a narrower base of support, which is a more challenging position. This gradual reduction in the base of support is continued until the patient can perform the exercise in tandem stance. The exercise can also be performed on a foam cushion to perturb the somatosensory signals. This progression in postural demands occurs over the course of several weeks. On any given day the patient will perform the x1 viewing exercise under only one postural condition.

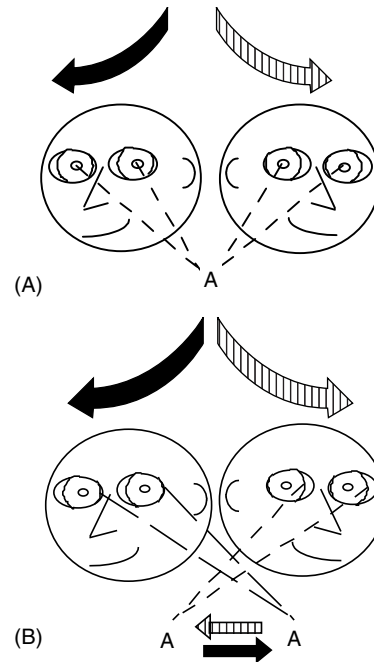

Since adaptation of the vestibular system is context specific, (67) the context of the visual stimulus should vary to reflect the different visual conditions that an individual

normally encounters. The influence of the optokinetic system (parafoveal visual stimuli) on gaze stability can be incorporated into the exercise program by placing the visual target within a “full-field” visual stimulus such as a checkerboard. When the visual target is at the same depth as the full-field visual stimulus, then the optokinetic system will assist the VOR in generating the appropriate compensatory eye movements. If the visual target is in front of the full-field visual stimulus, then the optokinetic system will actually generate anti-compensatory eye movements, since the visual world behind the object of interest appears to move in the same direction as the head movement. Since both of these stimulus conditions are encountered in normal activities, both conditions are incorporated into the rehabilitation program.

When the object of interest is near, the translation of the eyes relative to the visual target is greater than when the target is at a distance. The neural circuitry controlling the VOR normally takes target distance into account when generating the compensatory eye movements. Therefore the x1 viewing exercises are also performed with larger visual targets at a distance (8–15 feet). Again these exercises are performed in standing, with the feet positioned to challenge postural stability. The head is rotated as quickly as possible for 2 minutes, with the restriction that the visual target must remain in focus and stationary.

Gaze stability during head movements requires not only normal functioning of the VOR, but also interaction with other visual systems, such as the smooth pursuit system. To encourage this interaction, the x1 viewing exercise is modified. The individual is again challenged to maintain clear and stable vision during head movements; however, rather than use a stationary target, the individual holds the target and moves it in the direction opposite to the head movement (Fig. 28-3B). If the target moves at the same speed as the head but in the opposite direction, then the eyes have to move at twice the head velocity to maintain clear vision. Consequently this exercise is often referred to as times two (x2) viewing. This exercise can be performed in sitting, if necessary, and progressed to standing with a progressively decreasing base of support. The exercise can be performed with both a simple visual target as well as a target located in a complex visual background.

*Exercises to Foster the Substitution of Alternative Strategies for Gaze Stability* Bilateral vestibular hypofunction (BVH) may result in major or complete loss of bilateral vestibular function. Therefore, the exercises are designed to enhance the remaining function of the vestibular system and to foster substitution for the loss of vestibular function with alternative strategies to maintain gaze stability (66). In the absence of vestibular signals, these individuals must use cervical inputs and knowledge of upcoming head movements (pre-planning) to generate the compensatory eye movements (see Table 28-1).

**FIGURE 28-3**

Exercises to induce adaptation of the vestibulo-ocular reflex. (A) x1 viewing exercise. The patient views a stationary target, which should be a letter, number or word (in this case the letter A), while he turns his head back and forth. The speed of the rotation is increased to the point where faster movements would induce oscillopsia. Both horizontal and vertical rotations are performed. (B) x2 viewing exercise. The patient views a target that moves in the opposite direction of the head movement, while he turns his head back and forth. As with the x1 viewing exercise, the target should be a letter, number or word (in this case the letter A). The speed of the rotation is increased to the point where faster movements would induce oscillopsia. Both horizontal and vertical head rotations and target movements are performed

The cervical-ocular reflex (COR) normally contributes less than 15% to the generation of compensatory eye movements for low frequency head rotations (66). Following bilateral vestibular loss, the COR can account for up to 25% of the compensatory eye movements for both low and high frequency head rotations (68). The x1 viewing exercise described in the previous section can be used to increase the gain of the COR and to enhance the remaining function of the VOR. Generally, these exercises will be conducted at lower velocities than in individuals with unilateral vestibular hypofunction. When these exercises are performed actively, the CNS can also use foreknowledge of the upcoming movement to generate a compensatory eye movement. If performed passively, then the preplanning information is lost and the eye movements must be generated by the COR.

Another exercise which may improve the response of the COR, but also uses the central nervous system's

**TABLE 28-1**  
*Exercises to Promote Alternative Strategies for Gaze Stability*

1. X1 viewing exercises
2. Active eye-head movements between two targets:
 

Horizontal targets: Look directly at one target being sure that your head is also lined up with the target. Look at the other target with your eyes and then turn your head to the target. Be sure to keep the target in focus during the head movement. Repeat in the opposite direction.

Vary the speed of the head movement, but always keep the targets in focus.

*Note:* Place the two targets close enough together that when you are looking directly at one, you can see the other with your peripheral vision. Practice for 2–5 minutes, resting if necessary. This exercise can also be performed with two vertically placed targets.
3. Visualization of imaginary targets:
 

Look at a target directly in front of you. Close your eyes and turn your head slightly, imagining that you are still looking directly at the target. Open your eyes and check to see if you have been able to keep your eyes on the target. Repeat in the opposite direction. Be as accurate as possible.

Vary the speed and the amount (stopping point) of head rotation.

Practice for 2–5 minutes, resting if necessary.

*Note:* This exercise can be performed actively or passively while looking at a near target (within 2 feet) or at a distant target (across the room); it can also be performed vertically.

knowledge of upcoming movements, is the visualization of a remembered target location during head rotation. In this exercise the patient fixates a visual target, closes his eyes, and rotates his head in one direction. While turning his head, the patient attempts to keep his eyes on the target location. When the patient stops the head rotation, he opens his eyes and looks at the visual target. If his gaze is accurate, he will be looking directly at the target. If his compensatory eye movements are insufficient, his eyes will have moved with his head and he will have to make a corrective saccade to view the target. This exercise should be performed with both horizontal and vertical head movements. The visual target should be placed at different eccentric positions and different distances relative to the patient. The degree and speed of the rotation should be varied to force the patient to attend to all sensory cues.

Difficult tasks for individuals with BVH are gaze shifts that require both eye and head movements. Normally this task is accomplished by a patterned response. Initially, there is a saccade that is directed toward the object of interest. A head movement towards the target begins shortly after the saccade. While both the eye and head are moving towards the target, the VOR must be suppressed. When the eye reaches the desired location, the head is typically still turning. At this point the VOR must be used to keep the eyes on target during the remaining head movement. For patients with BVH, this head movement would cause the eyes to move beyond the intended object of interest and visual acuity would diminish. Individuals with BVH typically adopt one of two strategies to minimize this visual disturbance (68). One

strategy is to make a hypometric saccade and allow the head movement to carry the eyes onto the object of interest. A second approach is to make an accurate initial saccade, followed by a corrective backward saccade that is triggered by the head movement. Both of these strategies will minimize the amount of time that the visual image is not on the fovea. We do not attempt to teach one strategy or the other. We simply have the patient perform an activity that will encourage adoption of one of these strategies. For instance, two targets are placed at eye level, arm's length away, and slightly greater than shoulder width apart. The patient starts with her head rotated to the right, directly facing the target. The patient then shifts her gaze to the target on the left. The patient is told to move both her head and her eyes so that she is looking directly at the target. She is instructed to perform this as quickly as possible, but to keep the target in focus. The movement is then repeated in the opposite direction.

### **Treatment of Motion Sensitivity**

Symptom provocation due to either head movements or visual motion is a common finding in individuals with vestibular dysfunction, and these findings are very common in individuals with dizziness secondary to TBI. Patients with sensitivity to head movements will describe increased symptoms associated with either head movements in general or rather specific movements. Patients with visual motion sensitivity will note increased symptoms when they are in busy visual environments such as crowds, department / grocery stores, or in traffic. The determination of head motion or visual motion sensitivity can often be made through the

patient interview. One method of determining head motion sensitivity is through a series of rapid positioning maneuvers designed to elicit symptoms (69). These movements incorporate horizontal, vertical, and diagonal head movements with the head in different orientations relative to gravity. The symptom severity and duration in each of these movements is noted and used to determine a “Motion Sensitivity Quotient”. The results of this test can be used to identify patterns of motion that provoke symptoms and to track changes in the patient’s motion sensitivity. The general approach to the treatment of motion sensitivity is that of habituation, defined here as the long-term reduction of the response to a noxious stimulus (specific movement), brought about by repeated exposure to the provocative stimulus. The motion-provoked symptoms in patients with vestibular dysfunction is thought to be due to the sensory mismatch among the vestibular, visual, and somatosensory systems, which is brought about by movement. Repeated exposure to these movements is thought to lead to central adaptation and reorganization of the inputs to decrease the sensory mismatch and decrease the symptoms (70).

*Exercises to Decrease Head Motion Sensitivity* The x1 viewing exercises, since they involve head movements can be used as a habituation exercise. So in some individuals with head motion sensitivity, who have normal visual acuity during head movements, performance of the x1 viewing exercise can lead to a reduction in their symptoms. For other individuals, however, performing the x1 viewing exercise may be too symptom provoking, or may not reduce all of their symptoms. In these cases habituation exercises may be used to reduce the motion sensitivity. These exercises are generally of greater amplitude and velocity than the x1 viewing exercises. However, the amplitude and velocity of the head movement is adjusted

to the patient’s condition. The exercises are designed to provoke symptoms, but following completion of the each exercise session, the symptoms should return to baseline levels within 15 to 30 minutes. The selection of the exercises and movement patterns may be based on either the patient’s description of provocative movements or on the results of the motion sensitivity examination. Examples of these exercises are presented in Table 28-2. Typically up to 4 specific movements are selected for each exercise session. Generally, one pattern of movement (horizontal, vertical, or diagonal) is chosen for the exercise program and then the program progressed over time. Caution should be taken with the exercises that have patients move from a “heart low” to “heart high” position if there are concerns about orthostatic hypotension.

*Exercises to Decrease Visual Motion Sensitivity* A number of the previously described exercises can be used to try and decrease visual motion sensitivity. Performance of the x1 viewing exercise with the visual target located in front of a complex visual background can be used as an effective exercise to decrease visual motion sensitivity. As noted above, this exercise will induce movement of the visual background in an anti-compensatory fashion relative to the head movement. The habituation exercises described above (particularly the horizontal and vertical head movement exercises), if performed with eyes open, facing a visual scene with lots of color and contrast, can also be used as an exercise to decrease the visual motion sensitivity. If the combination of visual motion and head motion is too symptom provoking, then another exercise, which does not involve head movement, may be used. In this case, the patient performs a visual following task, with the object of interest located in front of a busy visual background. The exercise is similar to the x1 viewing

**TABLE 28-2**  
*Exercises to Decrease Motion Sensitivity*

1. While sitting, turn your head quickly from right to left 5 times. Look in the direction you are turning. Wait for your symptoms to subside. Repeat 3 times.
2. While sitting, alternate looking up at the ceiling and down at the floor quickly 5 times. Look in the direction you are moving your head. Wait for your symptoms to subside. Repeat 3 times.
3. Sit on the edge of your bed. Turn your head about 45 degrees to the left. Now quickly lie on your right side. Wait for any symptoms to pass. Keeping your head turned, quickly sit up. Again, wait for the symptoms to pass. Now turn your head approx. 45 degrees to the right. Quickly lie on your left side. Wait for the symptoms to pass. Quickly sit upright. Wait for the symptoms to pass. Repeat 5 times.
4. Lie on your back. Quickly roll to the right side. Wait for symptoms to pass. Return to your back. Quickly roll to the left side. Wait for symptoms to pass. Return to your back. Repeat 5 times.
5. While sitting in a chair, bend your head forward about halfway toward your knees. Now quickly sit upright. Wait for the symptoms to pass. Repeat 5 times. (*Note:* this can be done tipping the head to right or left knee instead of straight down if that movement is more provocative)
6. Stand in a corner with your back to the wall. Now make a quick turn so that you are facing the wall. Stop and wait for symptoms to pass. Now make a turn in the opposite direction so that your back is again facing the wall. Repeat 5 times.

exercise; however, the patient keeps their head still and moves the visual target from side to side (or up and down). Since the smooth pursuit system is limited in frequency and velocity, the movement of the target will be relatively slow. Again, the patient's task is to keep the visual target in focus during the movement. Like the x1 viewing exercise, this exercise is performed for 2 minutes at a time.

Another approach to this problem is to immerse patients in the environments that provoke their symptoms. Patients are encouraged to walk through grocery stores, department stores, shopping malls, or crowds (provided these environments provoke symptoms). They can grade the intensity of the exercise in several ways. One, they can control their exposure by limiting the time they are in the particular environment. They can often adjust the intensity of the visual motion by selecting different times of the day to perform this exercise. Early in the morning there are generally fewer people in the stores than later in the day or evening. As their symptoms decrease, they are encouraged to walk for longer periods of time and at times when the stores are more crowded.

### **Treatment of Postural Instability**

Another function of the vestibular system is to help maintain postural stability, or postural control. Postural control is defined as the ability to maintain the center of gravity over the base of support within a given sensory environment. Postural control requires the ability to perceive sensory information (somatosensory, visual, and vestibular), to centrally weight and select the appropriate sensory information, and to generate a suitable motor response to maintain stability. The selection of the appropriate motor response is based upon the available sensory information, biomechanical constraints, environmental contexts, and prior experience. Vestibular, visual, and somatosensory cues are all used to detect movement of the body and to trigger appropriate postural responses. If the vestibular system is not functioning appropriately, then the individual will have difficulty maintaining their balance when visual or somatosensory cues are altered or absent (e.g. at night, walking on uneven or compliant surfaces). In individuals with remaining vestibular function (for example those with a unilateral vestibular deficit), the exercises are designed to foster adaptation of the remaining vestibular signals to generate the appropriate postural responses. Unlike the VOR, the signal utilized for modification of the vestibulo-spinal reflexes (VSR) is not known. Presumably a similar visual-somatosensory-vestibular error signal is needed (71). Exercises used in the treatment of UVH are designed to generate these error signals and thereby foster adaptation of the vestibular system (66). For those individuals without vestibular function (for example those with bilateral vestibular loss) there is no remaining

vestibular signal to adapt. Consequently, the exercises for these individuals are designed to promote the use of alternative strategies to promote postural stability. The two general exercise approaches and the rationale behind the exercises will be explained separately.

*Exercises to Improve Static and Dynamic Postural Stability in Patients with Remaining Vestibular Function* Exercises to promote static and dynamic postural stability in various sensory environments involve the manipulation of visual, vestibular and somatosensory cues to force the individual to utilize vestibular cues for postural stability (see Table 28-3). Single, progressing to multiple, sensory modalities are manipulated to increase the difficulty of the postural control task. Varied sensory conditions may include: 1) somatosensory changes (firm, conforming, level, uneven, and moving surfaces), 2) visual changes (eyes open with foveal, full field, or moving visual stimuli, or eyes closed), and 3) vestibular changes (different head orientations and head rotation). The exercises are also progressed from static to dynamic activities.

The initial exercise to improve standing balance progresses from standing with minimal external support to standing without assistance. Once the individual can stand independently (usually within 2 to 3 days from the onset of the UVH), they perform the exercise with a decreasing base of support to increase the task difficulty. This exercise sequence may be performed with the arms outstretched to facilitate stability. As the individual's balance improves, the exercise is performed with the arms at the side or folded across the chest to increase the difficulty of the task. Sensory cues can be modified to increase the difficulty of the task. Visual cues for postural stability can be removed by having the individual perform the exercise with their eyes closed. Having the individual stand on 4-inch thick, medium density foam, or pillows while assuming the various stance positions can alter somatosensory cues. Obviously, visual and somatosensory can be altered simultaneously by having the individual perform the exercise with eyes closed while standing on the compliant surface. This sequence of standing balance exercises can be repeated while standing on inclines. The exercises can also be repeated with the head tilted in various directions to alter the otolith inputs.

Exercises for improving dynamic postural stability involve progressively more difficult head and trunk movements while moving through space. Initially, the individual works on simple weight shifting activities, holding the end range position for three to five seconds, and independent ambulation. The progression from assisted to independent ambulation is usually very rapid. Providing there are no underlying orthopedic or other neurological problems, the patients are generally able to walk independently within several days of the initiation of ambulation. Typically these individuals avoid head rotation

**TABLE 28-3**  
***Exercises to Improve Static and Dynamic Postural Stability***

The purpose of these exercises is to develop strategies for performing daily activities even when deprived of visual, somatosensory, or normal vestibular inputs. The activities are designed to help you develop confidence and establish functional limits. On all of these exercises, precautions should be taken to prevent *falls*.

1. Stand with your feet shoulder width apart with both hands helping you keep your balance by touching a wall (or countertop). Take your hands off the wall for longer & longer periods of time while keeping your balance. Try moving your feet closer together. Practice for 5 minutes.
2. Stand with your feet shoulder-width apart, eyes open, looking straight ahead at a target on the wall. Progressively narrow your base of support (move your feet one inch at a time) from feet apart, to feet together, to a semi-heel-to-toe position, to heel-to-toe (one foot in front of the other), to heel-to-toe onto to on "tip-toes."  
Do the exercises first with arms outstretched, then with arms close to your body, and then with arms folded across your chest.  
Hold each position for 15 seconds, and then move to the next most difficult position.
3. Repeat exercise #2 with head bent forward 30 degrees and then bent back 30 degrees.
4. Repeat exercise #2 with eyes closed, at first intermittently and then continuously, while making an effort to mentally visualize your surroundings.
5. Repeat exercise #2 and/or #4 while standing on a foam pillow.
6. Stand with your feet a comfortable distance apart and eyes open. Now sway forward and back so that weight shifts from your toes to your heels. Make sure there is no jack-knifing at the hips. Practice this for a minute or so. Now stop and close your eyes and stand as still and steady as possible. To progress this activity: Practice the swaying activity with eyes closed, practice with narrow base of support, and practice on compliant surfaces.
7. Walk close to a wall with your hand available for balancing. Walk with a narrower base of support. Finally, walk heel-to-toe. Do this with eyes open / closed. Practice for 2 minutes.
8. Walk close to a wall and turn your head to the right and left as you walk. Try to focus on different objects as you walk. Gradually turn your head further & faster. Practice for 2 minutes.
9. Practice turning around while you walk. At first, turn in a large circle but gradually make smaller and smaller turns. Be sure to turn in both directions.
10. Take 5 steps and turn around to the right (180°) and keep walking. Take 5 more steps, turn left (180°) and keep walking. Repeat 5 times, rest, and repeat the entire sequence.
11. Walk outside on an uneven surface or walk inside on a compliant surface.
12. Climb up your stairs without using your arms. Practice for 2 minutes.
13. Practice walking in a grocery store. To make it more difficult:
  - try to walk without a grocery cart,
  - go when there are few people there, then when it is crowded,
  - increase the number of aisles you walk through.
14. Practice walking in a shopping mall:
  - first when it is not crowded, then
  - when it is crowded, but walk with the flow of the crowd, then when it is
  - crowded, but walk against the flow of the crowd.
15. Participate in golf, tennis, dance, racquetball, etc.

*The following balance exercises are performed at home with a partner:*

While standing, kick a ball between you.

Practice batting a nerf ball.

Play a game of catch. Progress in the following manner:

Start with just an easy game keeping the ball in the midline.

Then throw to either side.

Take a step to the side to catch the ball. Your partner should let you know to which side he will be throwing the ball.

To further progress throw randomly from one side to another.

Catch the ball without taking a step as the ball is thrown to either side.

---

*All of the activities listed above can be performed on a compliant surface.*

during ambulation and assume a wide base of support while walking. Once they are able to walk independently, low frequency, small amplitude head rotations with concurrent gaze shifts are incorporated into the exercise program. To avoid excessive symptom provocation and marked gait ataxia, the individual performs the head rotation – gaze shift every 5th step. This may be performed with both horizontal and vertical head movements. This exercise forces the individual to adapt to the head rotations and prevents them from using visual fixation for postural stability. As recovery proceeds, the amplitude and peak velocity of the head rotation can be increased. To decrease the base of support, the patients walk with a progressively narrower base of support, ultimately walking heel to toe (tandem gait). Patients can also walk with the head tilted in either the frontal or sagittal planes to alter the otolith inputs. Patients are also encouraged to walk outdoors, which poses two distinct sensorimotor challenges. One, the support surface will change, which necessitates rapid postural adjustments. Two, visual cues for postural stability are at a greater distance than those indoors. This change in visual cues often causes increased dysequilibrium because the normal degree of postural sway results in smaller movements of visual images across the retina. This is an analogous situation to the normal experience of height vertigo.

The exercises described above challenge an individual's ability to move linearly. Another set of exercises is designed to rehabilitate the ability to rotate. This exercise involves walking approximately ten feet and turning around 180°. This is then repeated with rotation in the opposite direction. As the individual's balance improves, the radius of the turn is gradually decreased. This exercise can ultimately be performed with an abrupt rotation, or standing pivot. This exercise can also be performed with the eyes closed. A further extension of the exercise for the advanced stages of the rehabilitation process is rapid rotation combined with higher velocity linear movements. Examples include dance steps or shifting from a forehand to backhand in any of the racquet sports.

A more rigorous exercise to improve dynamic postural stability is hopping on one foot. Caution must be used with this exercise, or any exercise, which involves jarring movements to the head, post-surgery. There must be adequate time to allow for healing of the involved tissues before these strenuous exercises can be attempted. The difficulty of this exercise can be increased by eye closure. One of the final exercises used in the rehabilitation of dynamic postural stability is an obstacle course, where the individual walks over various surfaces, rotates, side-steps, and goes through a series of position changes (sit to stand, bending over, reaching, etc.). Lastly individuals are encouraged to resume their normal activities, especially those activities that involve postural changes and head movements, such as dancing, racquet sports, and golf.

*Exercises to Improve Static and Dynamic Postural Stability in Patients without Vestibular Function* The exercises to improve static and dynamic postural stability are similar to the exercises described for patients with remaining vestibular function (Table 28-2). Unlike the individuals with compensated unilateral vestibular lesions, those with bilateral vestibular hypofunction will have varying degrees of difficulty maintaining their balance when both visual and somatosensory cues are perturbed. Consequently, the exercises may need to be modified to allow the utilization of one sensory cue or to decrease the task complexity by widening the base of support.

The initial postural stability exercises for patients with BVH are simple standing balance exercises, with the goal of developing independent stance. As the patient is able to stand without assistance, the exercise is made more challenging by progressively decreasing the base of support, until balance cannot be maintained. As with the static postural stability exercises for individuals with UVH, these exercises can be performed initially with the arms outstretched, then at the side, and finally folded across the chest. In these exercises both visual and somatosensory cues are available to the patient.

Individuals with BVH tend to initially rely solely on visual cues but gradually utilize somatosensory cues for postural stability (72). If the examination of the patient reveals that they are not using somatosensory cues for postural stability, then the standing balance exercises can be performed with the eyes closed. Eye closure may need to be intermittent at first but is progressed until the patient can perform the exercise for 30 seconds. It is often helpful in the beginning stages of this exercise to have the individuals visualize their surroundings when their eyes are closed. In addition, active weight shifting with eyes closed increases somatosensory awareness and awareness of the supporting surface. Should the unlikely situation arise where an individual is attending to somatosensory and not visual cues, the postural stability exercises can be performed with eyes open while standing on a compliant surface, such as a foam pad, to perturb the somatosensory inputs. Altering visual and somatosensory input to optimally challenge the individual should only be performed with the necessary safety measures to prevent falls.

The role of cervical input in the maintenance of postural stability is questionable. Bles et al (73). reported that static cervical positions did not contribute to postural stability in BVH. In light of these findings, the static postural exercises performed with head tilts may challenge the balance system by changing the visual frame of reference. The role of dynamic cervical input is not known at this time. Individuals with BVH have difficulty maintaining balance with head rotation during ambulation. This degradation of balance may be due to the loss of a stable visual frame of reference. However, their ability to walk and turn their head does improve with practice.

Patients with BVH also tend to walk with a wide base of support. Having these patients walk with a decreased step width, ultimately ambulating heel to toe, can challenge their dynamic postural stability. Changes in direction, as described for the patients with UVH, are also a challenge for the individual with BVH. An obstacle course or functional tasks that require positional changes, movement, and changing visual or somatosensory cues are also beneficial by forcing the patient to adapt to changing environmental conditions and to shift between the available sensory cues.

Patients should be instructed in behavioral and environmental modifications to optimize function and reduce the risk of falling. Environmental modifications may include: adequate lighting (including emergency lighting in case of a power failure), removal of thick carpeting and area (or throw) rugs, non-skid floors, pathways clear of obstructions, stable tables and chairs, reorganization of cabinets and shelves to minimize bending and reaching, and stairs with railings. Behavioral modifications may include: learning to plan movements, avoiding hurried movements, sitting to work, visual fixation on distant objects for stability, light touch on objects for balance, restricting rapid head movements and walking in crowds. Frequently, individuals with BVH are unable to drive due to oscillopsia. For those that have adequate visual acuity during head movements, many are unable to drive at night due to reduced visual cues. While assistive devices may not be needed around the home or during the day, the devices may be needed for safety concerns at night, in unfamiliar environments, and on uneven surfaces. For some individuals, an assistive device is necessary as an outward sign that there is a physical problem. Since there are no outward signs of a vestibular deficit, the individual is concerned that their staggering may be perceived as inebriation.

### **Exercise Guidelines for Individuals with TBI**

Confounding orthopaedic and neurological factors often complicates treatment of vestibular deficits in patients with traumatic brain injury. First, the exercise programs described above will provoke the patient's symptoms. The exercises, if conducted appropriately, will generate an error signal in the CNS, which is thought to provoke symptoms of vertigo, dizziness or dysequilibrium. Depending upon the individual's symptoms, cognitive level, and degree of agitation, the symptom provocation may not be tolerated well. In those individuals with marked dizziness, motion sensitivity and agitation, the x1 viewing exercises may simply provoke too many symptoms. In these cases, it is recommended that the initial course of vestibular rehabilitation be simple habituation exercises, performed to tolerance. Once the habituation exercises have decreased the motion sensitivity, then x1 viewing exercises, if needed, may be initiated.

As the patient's status improves and their agitation decreases, the intensity of the exercises (either habituation or adaptation exercises) can be increased. With this increase, patients are told to expect greater symptom provocation and that provocation of their symptoms is actually beneficial to their recovery. A general guideline is that symptoms may be provoked for 15 to 30 minutes following the exercises. If the increased symptoms persist longer, the speed, duration, or context of the stimulus should be reduced. If the exercises are performed in a manner that does not challenge the system or provoke the symptoms, then the error signal will not be generated. Consequently, there will be no stimulus for adaptation. Similarly, the use of CNS depressants (such as meclizine or benzodiazepines) to treat the symptoms of vertigo and dysequilibrium are thought to retard the adaptation process.

The exercises may need to be modified due to other aspects of their injury. If for example, the patient suffers diplopia on lateral gaze to one side due to lateral rectus muscle palsy from the injury, then the x1 viewing exercise is modified to avoid lateral gaze to the affected side. Similarly, static and dynamic postural stability exercises may need to be modified due to muscle weakness, spasticity, or lower extremity fractures. Clinical judgment is required to adapt the basic exercise programs described above to meet the needs of the individual patient.

### **Vestibular and Balance Rehabilitation Therapy Outcomes**

At this point, there have been no comprehensive studies examining vestibular and balance rehabilitation therapy outcomes inpatients with TBI. There are, however, numerous studies that have demonstrated the efficacy of VBRT programs in different populations of patients with vestibular disorders (54, 74, 75–77). Herdman and colleagues (74) demonstrated that, following acoustic neuroma resection, patients that underwent vestibular adaptation exercises demonstrated improvements in dysequilibrium, ataxia, and static postural stability as compared to individuals that had undergone a sham exercise program. Horak and colleagues (54) reported that individuals with chronic vestibular dysfunction treated with vestibular rehabilitation exercises developed improved motion sensitivity measures and static postural stability measures when compared to similar individuals treated with either condition exercises or vestibular suppressant medication. Similar results have been shown in patients with bilateral vestibular loss (76). Shepard and colleagues (75) reported that patients that underwent a customized VBRT program had greater improvements than those that received a generic VBRT program. Are the exercises always effective? No, but reports suggest that the exercise approach is successful in reducing symptoms and improving function up to 85% of the time (75, 78).

### INTRODUCTION

Complaints concerning vision are common following a traumatic brain injury (1). A traumatic brain injury can cause a wide variety of symptoms related to vision such as headaches, diplopia, vertigo, asthenopia, inability to focus, movement of print when reading, difficulty with tracking and fixations, and photophobia. Persons experiencing these types of visual problems frequently will have other medical sequela related to the TBI.

Epidemiological studies of vision problems relating to traumatic brain injury have been sparse in both literature and research. However, a limited number of studies demonstrate that vision dysfunction is common following a TBI and can affect any part of the visual process (2).

In one study, the most common complaint was blurred vision (46%) followed by diplopia (30%) and headaches (13%). Thirty-five percent of the subjects displayed a visual field defect of which the most common was a compression of peripheral fields followed by

homonymous hemianopsia. Thirty-three percent of the subjects experienced cranial nerve palsies of which third nerve palsy (exotropia) was the most common. Ninety-five percent of these subjects had normal funduscopic findings while of those with abnormal funduscopic evaluations, twenty-six percent demonstrated optic nerve abnormality.

Binocular dysfunction is highly prevalent (3) following a TBI and relate to many of the symptoms regarding vision that a person may experience (4). Often, exotropia (an eye deviated outward) or exophoria (tendency for the eyes to deviate) occur following a TBI either through direct cranial trauma or whiplash (5, 6).

Following a TBI, visual sensory deficits can be caused by areas other than the stria of the occipital lobe which is often noted as the primary visual cortex (7). The extent and impact of a TBI on overall sensory function can be quite profound but due to the true nature and primary influence of visual processing, no interference can be as significant as that of the visual system following a

TBI. Mechanisms for sensory deficits require awareness and recognition of the problem by the affected person without which, there is a significant potential for interference in the overall rehabilitation process (8).

The use of vision to lead and guide motor function is often compromised following a brain injury (9) affecting visual perception and visual motor dysfunctions. New evidence has emerged demonstrating that neuro-motor function also contributes to spatial awareness and affects egocentric concepts of visual midline (10) beyond the role of acuity. Visual midline is the perceived lateral and anterior-posterior visual concept of egocentric position relative to sensory-motor concepts. The influence of homonymous hemianopsia will also directly affect the perception of visual midline, posture, and balance.

Use of visual evoked potentials (VEPs) have disclosed that dysfunction in visual processing may be a cause of many of the conditions of strabismus following TBI (11). Researchers have also documented through VEP patterns that there are many visual abnormalities significantly related to the clinical disability of persons with TBI (12). The result of such research are leading many to begin questioning the traditional examination methods of examining persons with a TBI relative to diagnosing binocular dysfunction or to assess visual processing of the bimodal system of vision.

Recent studies (11, 13) involving visual evoked potentials (VEPs) have directed consideration that binocular dysfunction and visual midline shift are due to dysfunction of visual processing and not necessarily due to muscle or cranial nerve palsy following TBI. Until recently, research involving the bimodal process of vision had not been considered clinically relevant at the same level as binocular function. In particular, dysfunction of binocularity had been looked at primarily as the cause related to the symptoms. Understanding the true nature of the bimodal visual process may now give the documentation necessary to understand the nature of binocular function in relationship to cortical and subcortical mechanisms that organize vision and sensory motor information. In turn, the visual evoked potential may now give the researcher as well as the clinician the means to join in the study of process related to clinical function. In addition, it may also provide new means of understanding the significant interferences caused by TBI related to a wide variety of visual symptoms following a TBI.

It is common for persons to experience vertigo, dizziness, and other balance disorders following a TBI (14). While studies have emphasized the vestibular system as the primary mechanism for maintaining stability of the visual field, new information regarding the role of the pretectum and superior colliculus offers insight into vision stabilizing the retinal image and establishing peripheral fusion. In addition, the superior colliculus also mediates visual processing affecting posture, movement, and

orientation to positional space (15). A new model of processing related to the sensorimotor feedback loop providing a feedforward system to other higher areas of cortical function has been proposed and gives real insight into the role of the motor system affecting sensory perception and stability (16).

### VISION: A BIMODAL PROCESS

Seventy percent of all sensory processing in the entire body is directly affected by information coming from the two eyes (17). These visual influences are directed to the midbrain and the majority extend themselves to the occipital cortex for purposes of seeing (15). As a dominant system in the sighted person, vision is often taken for granted. Fortunately, we do not have to think about the process of using vision as we automatically employ vision in our daily activities. The important dynamics of visual processing are masked behind our intense attention and concentration to the accomplishment of the task at hand. For example, the task of writing involves vision but we do not think about where we are looking when we move the pen on the page. Nor do we think of how we see print as we read. Do we see each individual letter on the page or do we see more globally and embrace whole words and phrases?

Trevarthen (18) and Liebowitz and Post (19) have disclosed that there are two modes of visual processing; the focal process and the ambient process. The focal process delivers information for the purpose of attention, concentration, and higher cognitive processing. Information is sent primarily to the occipital cortex for the purpose of seeing detail. This is the portion of the system which enables us to attend to a task or concentrate. If we had only the focal process, the world we see would break apart into a mosaic of fragments. We would see only the lines, shadows, and shapes on a person's face and although we would see clearly, we would not be able to recognize the inter-relationship of all of these details. We would not be able to recognize the person's face as a familiar gestalt.

Approximately twenty percent of fibers from the peripheral retinas of both eyes are delivered to the midbrain (20). Here, the visual process matches information gathered from the kinesthetic, proprioceptive, tactile, and vestibular systems. This function has been labeled the sensory-motor feedback loop (21). It serves to organize spatial information about balance, movement, and orientation in space. The visual process is very much involved in movement and postural control. The superior colliculus, a critical area in the midbrain system, receives fibers from the optic tract via the superior brachium, occipital cortex via the optic radiations through the lateral geniculate, and from the spinotectal tract connecting it with

sensory motor information from the spinal cord and medulla. It is in the midbrain that sensorimotor matching concepts of midline, body awareness, posture, and orientation are established. Once this is accomplished, a feedforward phenomenon occurs. Information is relayed from the midbrain to the occipital cortex where it is used to preprogram the higher seeing area as to how to organize or look at incoming visual information. This is first done spatially and has been termed the ambient visual process. Following this, focalization on detail will occur. In this manner, the occipital cortex will organize information spatially before it looks at the detail. In other words, it is as if we know where to look before we completely identify the target. Spatial information from this midbrain ambient visual system is also used in other processing levels at the occipital cortex for purposes of bringing together detail information relative to spatial boundaries. In particular, the binocular coordination cells that receive information imaging from both the right and left eye have the primary purpose of beginning to integrate or fuse the two separate images together as one. It is the spatial information from the ambient visual process delivered by the superior colliculus that becomes the binding format of the fusion process (22).

In fetal development, the eye is created from endoderm, mesoderm, and neuroectoderm. Of importance is the fact that neuroectoderm also develops the cortex which allows for recognition that the eyeball is neurologically an end result in part of developing brain tissue. The eyeball is richly endowed with nerve fibers that feed all aspects of the cortex as well as relaying information to midbrain structures. Nerve fibers emanating from the macula or central portion of the eye will align centrally in the optic nerve and optic tract directing themselves to localize in central areas of the visual occipital cortex. Peripheral retinal nerve fibers orient themselves in the optic nerve and optic tract around the central fibers and align themselves in peripheral areas of the occipital cortex.

While the central image from the macula occupies the major portion of our cortical attention and concentration for perception and cognitive processing, how we organize and process visual information is not a simple phenomenon. The dorsal ganglion of the lateral geniculate body seems to function as an integrating center in addition to its role as a relay and distribution center. Therefore the lateral geniculate is important to the relay of visual information to portions of the brain other than the occipital cortex.

It has also been demonstrated that 20% of the peripheral retinal nerve fibers relay information through axons to the thalamus or midbrain for spatial match with kinesthetic, proprioceptive, and vestibular information being received from other sensory-motor systems. The developmental purpose is to organize spatial information to orient higher sensorimotor experiences affecting

posture, movement, and balance. Once this has been established, information from the thalamus is sent to higher cortical functions (16). The occipital cortex is not an exception to this process. It receives spatial information in order to organize the detail information processed.

Ganglion cells from the retina emanate through the optic chiasm to the optic tract where they reach three major destinations: 1) the lateral geniculate body for relay to the visual cortex, 2) the pretectal nucleus (pupillary constriction), and 3) the superior colliculus which becomes related to posture, movement, and orientation to positional space (15).

In order to shift the position of the eyes from one point to another, we must spatially orient to the next destination before shifting the eyes (aiming the fovea) to look at detail (23). The ambient process is critical for anticipating change. Without this process, visual information becomes isolated details and there is difficulty shifting visual regard and attention. Also, there is a lack of awareness of body position in a spatial context caused by a shift in visual midline. Due to a mismatch between the ambient visual process, the kinesthetic, proprioceptive, the vestibular input system and the ambient visual process, the concept of visual midline will shift. As will be discussed later in this chapter, if the visual midline shifts, it will reinforce and/or cause postural imbalances.

The ambient process is not a conscious process as is the focal system. We orient this portion of the visual system to monitor and manipulate the spatial environment. The ambient visual process works to integrate sensory-motor information. Without the ambient visual process, an individual would experience fragmented vision as well as difficulty with organizing posture and movement. The bimodal process, however, in many ways has been ignored and/or misunderstood clinically (24).

Ganglion cells traveling from the retinas can be categorized based both on physiology and function into three types; P-cells (parvocellular), M-cells (magnocellular), and K-cells (koniocellular). These cells provide information similar to that which was discussed previously regarding the focal and ambient process. The M-cells and P-cells provide a physiological substrate for the ambient and focal processes. M-cells transmit visual information about shape and movement rapidly, but without detail. P-cells transmit the detail information contained in shapes and are much slower. These cells emanate from the retina through two major brain pathways; the retino-geniculo-cortical pathway and the retino-tectal pathway. The retino-geniculo-cortical pathway contains both P-cells and M-cells and is the most recent in evolution providing a mechanism for focal processing in the cortex. The retino-tectal pathway is mainly derived from M-cells and is more primitive and provides a basis for spatial information particularly related to spatial orientation prior to focalization. For example, a saccadic eye movement (via the

ambient pathway) first requires spatial orientation to establish the direction and trajectory of the eye movement prior to the focalization response. The retino-tectal pathway is most critical in early development of the child and some functions are taken over later in development by the retino-geniculo-cortical pathway (25). However, the midbrain ambient system remains important for spatial orientation and balance. It can be demonstrated clinically that children and adults with oculomotor dysfunction and aspects of dyslexia affecting reading ability demonstrate improvement with pursuit tracking and saccadic fixations as well as with the ability to track a line of print with sensory motor support such as by physically pointing at words.

The P-cell subsystem has been related to the focal visual process whereas the retino-tectal projection of the M-cell subsystem is a substrate for the ambient visual process. Neurons in the retino-tectal pathway are almost completely myelinated at birth whereas those of the retino-geniculo-cortical pathway are not. It is also of interest to know that the superior colliculus has essentially a normal adult organization and neuronal activity at birth whereas the occipital cortex does not (26). These authors have emphasized that while cerebral cortical processes have taken over much of the visual motor functioning, massive innervations still remain between cortical and midbrain structures.

Through development, experience is established to couple and bring balance between the ambient and focal visual process as well as the M-cell and P-cell subsystems. While balance between the spatial (ambient) and detail (focal) visual processing systems provide a means by which organization of time and space become a normal process for humans, injury as a result of a TBI can affect the balance between the systems. A decoupling of the focal and ambient visual process including the magnoparvo cellular systems is suggested as a basis for interference with function and performance. M-cells have larger diameter axons and have demonstrated to be more susceptible to damage in conditions such as ischemia and glaucoma.

More specifically, the decoupling of cerebral blood flow (CBF) and cerebral glucose metabolism (CMGL) has been described. This decoupling is described in terms of ischemia-hyperemia resulting in metabolic imbalances which derange neuronal energy production and cell membrane permeability ultimately causing potential cytotoxicity (27) even in a minor whiplash accident. This can be the basis of visual problems following TBI.

A patient with mild TBI is most frequently underdiagnosed or misdiagnosed relative to visual impairments (28, 29). The walking wounded with a negative CT scan or MRI is a potentially classic case of an injured person whose symptoms are frequently dismissed as exaggerated and/or psychosomatic in origin. The many individuals

who suffer significant visual symptoms following a brain injury potentially suffer equally from discrimination without identification of the causative factors (29).

The basis of the dysfunction of the visual process is related to the traumatic force imposed upon the central nervous system whether through blunt trauma or inertial acceleration or angular acceleration trauma of whiplash (hyperextension/hyperflexion). This can affect potassium adflux and secondary calcium influx. It is the influx of calcium ions that activate cellular protease enzymes triggering cytoskeletal disruption and simultaneous neurotransmitter hypercholinergic activity.

It is hypothesized to be the cytotoxic response that initiates cytoskeletal collapse and ultimately deafferentation that is etiologic to the symptoms of post-trauma vision syndrome. In turn, the lifelong established engrams that provided the automaticity of controls affecting the very complex sensory motor components that subserve the visual process become eroded resulting in degradation of our dominant sensory perception, our dominant guidance system: visual information processing (30).

### POST-TRAUMA VISION SYNDROME (PTVS)

Following a TBI, visual symptoms may occur (31) such as diplopia, seeing words and print appearing to move, difficulty shifting gaze, difficulty adapting to environments where there is movement in the periphery (such as in a store), and photophobia (Table 29-1). Characteristically, an examination of the visual system may demonstrate binocular dysfunction such as strabismus, convergence insufficiency, divergence excess, oculomotor dysfunction, and accommodative insufficiency. Some researchers have reported that diplopia, reduced acuities, and poor accommodation are prevalent among those with traumatic brain injuries (28). Others have reported intermittent diplopia present in certain positions of gaze (31). Soden and Cohen (32) as well as Nelson and Benabib (21) have correlated postural adaptation of the body with compensation for vision dysfunction and diplopia produced in certain positions of gaze. In addition, these researchers have found secondary contracture and/or muscle spasms due to poor body posture. A high prevalence of exotropia and exophoria have been reported for persons who have suffered even a mild traumatic brain injury (4, 5, 33).

Studies of binocularity have recognized dysfunction of oculomotor, convergence, and accommodations. A high prevalence of exotropia (5, 6, 34) is evidenced in the literature. While symptoms and characteristics are logically related to the visual dysfunction attributed to nerve palsy (35), the mechanism for the cause of the binocular dysfunctions appear to be more complexly related to the affect of the trauma on the bimodal visual processing systems as related by more recent studies

**TABLE 29-1**  
**Post-Trauma Vision Syndrome**

Common characteristics and symptoms associated with post-trauma vision syndrome characteristics:

- Exotropia or high exotropia
- Accommodative dysfunction
- Convergence insufficiency
- Low blink rate
- Spatial disorientation
- Poor fixations and pursuits
- Unstable ambient vision

Symptoms:

- Possible diplopia
- Objects appear to move
- Poor concentration and attention
- Staring behavior
- Poor visual memory
- Photophobia (glare sensitivity)
- Asthenopic symptoms
- Associated neuro-motor difficulties
  - Balance and coordination
  - Posture

on visual evoked potentials (11, 13). In this study, the researchers demonstrated that changes in amplitude under binocular testing were found to correlate statistically with an experimental population (persons with TBI) compared to a control group of which the experimental group of subjects also experienced symptoms and demonstrated characteristics as discussed in the previous paragraph. An increase in amplitudes was produced following treatment with base-in prism and binasal occlusion for the experimental group of subjects. A decrease in amplitudes was found for those in the control group. Changes were also reported in amplitudes and latencies following a TBI.

The researchers have explained that following a TBI, there appears to be interference in the ambient (spatial) organization of the visual field which as a result, affects the focalization process (36). As mentioned previously in this chapter, the spatial match of information between the ambient and sensory motor process can provide a feedforward (37) to the higher cortical processes including the occipital cortex of which the binocular integration cells require the spatial information to bind and establish peripheral vision fusion. A decrease in amplitude of the binocular visual evoked potential as demonstrated by the study emphasizes the role of the ambient visual process in providing this spatial binding for the fusion process. In turn, the decrease in the amplitude provides evidence of the lack of ambient vision feedforward support for higher binocular fusion prior to the focal visual process establishing awareness of detail.

The result of the dysfunction of ambient visual processing becomes characteristic of the binocular dysfunctions such as convergence insufficiency, accommodative insufficiency, exophoria, and may even be the basis for post-traumatic exotropia (38).

The characteristics of dysfunction of the binocular vision process as well as commonly measured comitant and noncomitant strabismus may be more a function of disruption related to ambient and focal visual processing than of specific neuronal interferences. Other studies have demonstrated that lesions in the superior colliculus can produce disturbances of convergence ability (39).

The dysfunction and lack of support through ambient visual processing leaves the person compromised in the attempt to use the focal visual process which isolates detail and does not serve the need for anticipation of change (23). For example, following a TBI, persons will often have to work harder at near vision tasks. The research provides evidence that the ambient process being compromised also interferes with the anticipatory spatial role to provide for release of fixation and detail as well as for change. In turn, the visual process becomes focally bound, isolating to detail rather than utilizing the ambient visual process for release from detail and the anticipation of spatial organization that affects continuity and sequence of visual performance.

This research also demonstrates that the structure of binasal occluders (vertical boundaries in the nasal portion of the visual field) in addition to base-in prism (prism affecting spatial organization), rebalances the ambient visual process. In turn, a reduction in symptoms was noted in these subjects corresponding to implementation of this mode of treatment. Specifically, subjects reported a significant reduction in symptoms (11) as previously mentioned.

The effects of dysfunction between ambient and focal processing as related to common characteristics of binocular dysfunction as frequently seen following a TBI are more common than previously recognized. Binocular dysfunction such as convergence insufficiency is a frequently misdiagnosed condition following a traumatic brain injury. Convergence insufficiency should always be considered in the diagnosis of patients with head trauma.

The dysfunction relative to focal and ambient visual processing has been termed post-trauma vision syndrome (PTVS). Persons who suffer from post-trauma vision syndrome will often have clear sight and their eyes will be healthy. Upon being referred for a routine eye examination, if the examiner is not familiar with PTVS, the examiner will often report that there is nothing wrong with the person's eyes and the symptoms appear to be more psychological in nature. Many persons will spend years suffering from this condition unless it is diagnosed and treated appropriately. Needless to say, this can be the cause of additional inappropriate referral and treatment

at a high cost to families and third party reimbursement systems. Appropriate treatment will not only reduce symptoms, but directly affect attention, concentration, and cognitive processing while preventing secondary emotional complications. The methods of evaluation and treatment through neuro-optometric rehabilitation and neuro-ophthalmological evaluation will be discussed later in this chapter.

### **VISUAL MIDLINE SHIFT SYNDROME (VMSS)**

Postural orientation is vital for daily function for both adults and children. Postural adaptation that begins in the early stages of development provides a means for the infant to organize space for balance, spatial orientation, and ambulation. For functioning adults and children, anti-gravity alignments are initiated with limbs and/or with head movements. The vestibular system contributes a balance response necessary when the center of gravity has shifted while the cerebellar and midbrain structures through ambient/sensory motor support contribute to the desired qualities of smoothness and coordination for motor planning.

The ambient visual process is primary in the establishment of postural orientation related to boundaries by orienting boundaries in the vertical and horizontal planes with spatial information from sensory motor systems. Early in development, this establishes concepts of visual midline that provide experience for postural orientation (20). Established in relationship with multi-sensory motor cooperation, the ambient visual process together with sensory motor match, feedforwards information to diverse areas of the cerebral cortex including the occipital cortex. This vital component enables anticipation for postural adaptation and movement (37).

Following a TBI, a person may be left with hemiplegia or hemiparesis. The loss of neurological and motor function has traditionally been thought to be the sole cause for the inability to weight-bear on the affected side. Also, in cases of visual field loss such as with homonymous hemianopsia, it has been observed that individuals will begin to lean away from the side of visual field loss even if they do not have a hemiparesis.

Prior to the consideration of vision as a bimodal process, discussion has been centered on a lack of visual cognition and attention leading to neglect (40, 41). These authors have identified the phenomenon where people have limited or no attention to a specific side of their body as well as correlating field of vision. Right hemisphere damage often produces the characteristic left field neglect (42, 43). The spatial component of vision has been primarily considered related to the relationship of magnocellular function with right hemisphere involvement. The complete concept of the ambient process related to

midbrain and sensory-motor interaction should also be considered.

Relative to the concept of the bimodal process of vision, inattention is a focal processing phenomenon. The authors of this chapter offer the possibility that the focal visual processing dysfunction of inattention is secondary to the spatial ambient visual processing disorder that is more directly associated with the affect on sensory-motor processing from the TBI.

Studies (10) have demonstrated that the visual midline will shift relative to a hemiparesis and/or homonymous hemianopsia. This may be observed by passing an object in front of a person's face and asking them to report when the object appears to be directly in front of their nose. In the case of a visual field loss such as a homonymous hemianopsia, the person will often report the target in front of their nose when it is directed to the side away from the visual field loss. An interesting observation occurs when working with patients with hemiparesis or hemiplegia. The person will also project the concept of midline in the majority of cases by leaning away from the neurologically affected side. The shift affects weight-bearing on the affected side in most cases and in turn, interferes with aspects of physical rehabilitation. The shifting of perceived visual midline away from the affected side is a compensatory mechanism and essentially reinforces the neglect of visual space caused by the hemiparesis and/or hemianopsia.

The shifting of the visual midline is caused by a distortion (compression and expansion) of the ambient visual process. The midline can shift laterally and/or in the anterior/posterior axis. The perceived visual midline will usually shift away from the affected side. This has been termed visual midline shift syndrome.

### **NEURO-OPHTHALMOLOGY**

Progress and overall rehabilitation for a person who has suffered a TBI are often interfered with due to visual problems that are sometimes ignored or misdiagnosed (2).

The provision of skilled neuro-ophthalmological services can positively affect the rehabilitation outcome. Referrals for neuro-ophthalmological evaluations are often initiated by physicians or rehabilitation professionals and optometrists practicing neuro-optometric rehabilitation who recognize visual interference with daily living skills and/or perceptual motor function.

The literature lacks good demographic studies on the prevalence of neuro-ophthalmological problems in TBI. Sabates reports that of 181 consecutive patients referred with visual complaints following head trauma, the most common etiology was motor vehicle accident in 57% of the cases. For direct trauma to the head, 15% were represented and 13% were related to injuries

sustained from a fall. He also reports that in over 88% of the eyes tested, acuity of 20/20 was reported. Of this population, 33% suffered cranial nerve palsy.

## NEURO-OPTOMETRIC REHABILITATION

Neuro-optometric rehabilitation represents a new and evolving specialty within the profession of optometry devoted to clinical assessment and rehabilitative treatment of visual binocular/processing disorders following a traumatic brain injury. While there is overlap in the assessment between ophthalmological/neuro-ophthalmological and neuro-optometric rehabilitation, the latter emphasizes rehabilitation of visual processing disorders. The fields of ophthalmology and optometry work in conjunction with individuals who have suffered visual and ocular-visual problems following a TBI.

Neuro-optometric rehabilitation is defined as:

Neuro-optometric rehabilitation is an individualized treatment regimen for patients with visual deficits as a direct result of physical disabilities, traumatic and/or acquired brain injuries. Neuro-optometric therapy is a process for the rehabilitation of visual/perceptual/motor disorders. It includes but is not limited to acquired strabismus, diplopia, binocular dysfunction, convergence, and/or accommodation, paresis/paralysis, oculomotor dysfunction, visual spatial dysfunction, visual perceptual and cognitive deficits, and traumatic visual acuity loss.

Patients of all ages who experience neurological insults can benefit from neuro-optometric rehabilitation. Visual problems caused by traumatic brain injury, cerebrovascular accident, cerebral palsy, multiple sclerosis, etc. may interfere with performance causing the person to be identified as learning disabled or as having attention deficit disorder.

The visual dysfunctions can manifest themselves as psychological sequela such as anxiety and panic disorders as well as spatial dysfunctions affecting balance and posture. A neuro-optometric treatment plan improves specific acquired vision dysfunction determined by standard diagnostic criteria. Treatment regimens encompass medially necessary noncompensatory lenses and prisms with and without occlusion and other appropriate rehabilitation strategies (23).

The role of the ophthalmologist is to provide excellence of care relative to treatment of disease and trauma affecting the eye orbit and neurology affecting visual function. The ophthalmologist can and should be involved in treatment for acute care as well as long term ophthalmological needs for the person who has suffered a TBI.

The optometrist practicing neuro-optometric rehabilitation can affect visual processing disorders such as PTVS, VMSS, and other binocular spatial disorders

causing diplopia, vertigo, etc. as rehabilitation is established. The neuro-optometric rehabilitation assessment includes a careful review of medical and rehabilitative records as well as establishing a history based on visual and spatial dysfunction.

## Evaluation and History

The neuro-ophthalmological and neuro-optometric rehabilitation assessment requires a complete history and differentiation of symptoms and characteristics from pre-morbid conditions. The symptoms must be assessed relative to the medical history and a complete review of medical records and medications is imperative. It is important to reconstruct the event relative to the history in order to assess injury and lesions relative to inertial force and impact. Understanding the pre-event medical history is necessary relative to determining the nature of injuries.

*Oculomotor and Binocular Function Assessment* An oculomotor evaluation is performed to determine cranial nerve function. One of the most debilitating visual conditions following a TBI is diplopia. Strabismus can often occur following lesions affecting cranial nerve 3 (oculomotor nerve), 4 (trochlear nerve), or 6 (abducens nerve). These lesions can occur from blunt head trauma affecting origin, insertion, and or innervation of the extraocular muscles, trauma to brain stem, midbrain or cortex, vestibular trauma, and/or trauma affecting orbital structure and orbital space occupying lesions (21, 39). Often, as is the case, CT scans and MRI are unable to detect lesions related to these specific oculomotor neurons. The authors have previously suggested a dysfunction of the ambient visual process and the lack of feedforward support for peripheral fusion lock.

The inability to provide spatial information will cause a highly focalized nature of vision. In turn, the visual world becomes fragmented. This causes increased concentration on detail and yields increased fragmentation of the visual world. The result can be diplopia that will be characterized and measured by strabismus (exotropia, esotropia, hypertropia, hypotropia). When an individual has diplopia, the spatial reference by which to use vision to lead posture, balance, and motor function is compromised. In turn, it can affect cognitive-perceptual processing due to the distracting influence of physiological stress. In one study (2), the second most common symptom was that 30% of the subjects experienced diplopia following a TBI.

The most common result of lesions of the cranial nerve following a TBI is third nerve palsy. A third nerve palsy is associated with exotropia as well as ptosis and mydriasis of the pupil on the affected side with complete compromise. In most cases, the affect is incomplete causing

variations from decompensated exophoria to intermittent exotropia. Diplopia depends on visual fatigue and chronic development of suppression. Vertical palsies resulting from the affect of cranial nerve 4 will produce hyperphoria and hypertropia as well as decompensation in specific gaze direction and head tilt. Sixth cranial nerve palsy interferes with abduction of the related eye, causing esotropia.

A variety of cranial nerve and binocular function tests are designed to provoke oculomotor failure causing decompensation of binocularity. These tests are described as follows:

1. **Cover Test:** The examiner will perform this test with the patient first fixating on a distant target (ten feet or beyond) and then at a near target (40 cm). The Alternate Cover Test is done by passing a cover alternately from one eye to the other and observing the movement of the eye emerging from under the cover. A heterophoria can be elicited. If observed, the examiner will perform a Cover Test by covering and uncovering each eye to discern from a tropia.
2. **Krimsky Test:** This is similar to the Cover Test, however, compensating prism is introduced to neutralize the motion of the phoria or tropia to determined the extent of deviation.
3. **Bielchowsky's Head Tilting test:** Cranial nerve and oculomotor function is analyzed by having the patient hold fixation in primary gaze while the examiner rotates the patients head first to the left and then to the right testing 3rd and 6th nerve function. The patient's head is moved in extension and flexion and tilted first to the right shoulder and then to the left shoulder to evaluate 4th nerve palsy affecting over and under-compensating oblique muscles.
4. **Lancaster Red/Green Test:** The patient is given glasses in which the OD has a red lens and the OS has a green lens. The examiner holds a red flashlight and the patient holds a green flashlight. The examiner shines the red flashlight on a screen and moves it into the nine cardinal gazes of fixation while asking the patient to superimpose their projected green light on the red light. Any deviation in a particular gaze direction will be noted and related to an underactive, overactive, or restricted ocular muscle.
5. **Red Lens Test:** The examiner holds a red lens before one of the patient's eyes and the patient is asked to fixate on a penlight. If the patient reports seeing two lights, the test is positive for diplopia at the respective working distance.
6. **Worth Four Dot Test:** The patient is given red/green glasses to wear while looking at the projection of four dots that form a diamond. The top dot is red, the inferior dot is white, and the lateral dots are both green. If the patient is binocular, four dots will be

seen. If binocularity is compromised and the patient reports seeing five dots, diplopia has been elicited. If two or three dots are observed, a corresponding suppression is present.

7. **Maddox Rod Test:** The examiner holds a cylinder before one of the patient's eyes while the patient observes a penlight. The eye behind the cylinder will see a vertical or horizontal line of light depending on how the cylinder is positioned. If the line is reported to either the left or right side of the light, a heterophoria or tropia is present at the respective working distance. If the line appears above or below the light, a vertical deviation has been elicited.

Binocular dysfunctions often present as convergence insufficiency or strabismus of which exotropia is the most common following a TBI. This can cause diplopia. The diplopia can be masked by intermittent suppression or accompanying field loss (i.e. homonymous hemianopsia). Any interference with binocularity will affect stereopsis and depth perception. In addition, oculomotor disturbances will affect pursuit tracking, saccades, and fixations.

For those experiencing blurred vision at near, accommodative insufficiency or accommodative spasms have been found as an interfering mechanism causing the related symptoms. Studies have also related binocularity with the neurological correlates such as cranial nerve palsies (35).

The term divergence paralysis was first described by Parinaud in 1883. Relative to TBI, the literature emphasizes the third nerve palsy as being the cause of the majority of those with exotropia following a TBI (34). Other types of neurological disorders affecting binocularity are sixth nerve palsies causing esotropia and fourth nerve palsies affecting vertical imbalances.

Sensory motor and binocular analysis should be performed to evaluate oculomotor function. Assessment should use quantity of function to analyze any limitations of oculomotor movements as well as quality of function (assessing fixation losses and difficulties encountered with pursuit tracking or saccadic fixations into particular fields). This may relate to oculomotor palsies. The assessment of convergence and accommodation quantitatively as well as qualitatively will enable the clinician to begin to understand levels of visual stress in performing visual skill activity (23).

The refractive sequence will objectively and subjectively analyze refractive error as well as variations in refractions which may relate to an unstable nature of accommodation and/or subluxation of the accommodative lens following trauma to the eye or head. Careful analysis of eye muscle balance through phoria, vergence, and duction testing will provide the clinician with an understanding of states of eye muscle balance and muscle reserves related to dysfunction of ambient and focal

processing. More specifically, a dysfunction of the ambient visual process will cause a lack of spatial support, thus affecting phoria, duction, and/or vergence measurements causing PTVS. In the most severe condition, exotropia can be produced, which is also known as third nerve palsy.

Surgical intervention has been used to affect oculomotor paresis. However, the success from surgery can be compromised if there is interference with the ambient spatial feedforward to binocular cortical cells (23).

The use of botulinum toxin has been found effective in reducing over action and muscle spasticity in affecting general muscle tone in the body as well as in cases of oculomotor spasm (45).

Pupillary assessment can offer an understanding of interruption of afferent and efferent sensory pathways (46). Defects in pupillary function can cause variations in response such as with the Marcus-Gunn pupil (47). Dilation of the consensual response indicates asymmetry in the conduction of afferent sensory fibers anterior to the chiasm and it differentiates a unilateral occurrence.

Wernicke's hemianopic pupil is another method by which to differentiate homonymous hemianopsia of tract lesions from the homonymous hemianopic lesions occurring in optic radiation dysfunction. The pupil sign demonstrates an inappropriate or impaired reaction in both pupils when light is specifically delivered to the amourotic half of either retina (47). Parinaud's syndrome can occur following a TBI and is characterized by displaced pupils, ptosis, nystagmus, oculomotor palsies (limitation of supraduction), papilledema, as well as producing symptoms of vertigo and ataxia (48). Papilledema and optic nerve atrophy are also characteristics that should be carefully evaluated through direct and indirect ophthalmoscopy (48).

## PSYCHOPHYSIOLOGICAL TESTING

Evaluation of visual function is important to identify lesions for the purpose of diagnosis and prognosis of treatment in visual problems following a TBI. Two kinds of examinations, psychophysiological and electrophysiological, allow assessment of the disorders in the entire length of the visual pathway. The following is a description of psychophysiological testing.

### Visual Acuity

Acuties should be functionally based and objectively based. The assessment of visual acuity should be performed both monocularly and binocularly. The standard Snellen Acuity Test can be performed at six meters and forty centimeters. However, other types of tests may be more appropriate if there is vision impairment present.

Tests such as the Feinbloom charts and the Sloan Acuity Charts may offer more precise measurements.

Behavioral assessment and functional variations should be noted such as a monocular acuity that is better than a binocular acuity. Often, interferences with contrast sensitivity following post-trauma vision syndrome will affect acuity in varying environmental conditions (49).

Visual acuity and visual field assessments are routinely psychophysiological tests. However, motion perception is also one of the elementary visual phenomena, especially in the affect from neurological trauma.

*Visual Field* Also important is a careful assessment of the visual field (50, 51). Visual field is an island or hill of vision in a sea of darkness (Figure 29-1). When visual defects occur, the corresponding part of the island is lost. The field of vision at any particular sensitivity level is changed.

Abnormalities of any point along the visual pathway affect the visual field, often in a pattern characteristic of a particular disorder process or location. The visual field defects in the visual pathway correlate with the lesion sites and field defects. Homonymous refers to a defect present in both eyes with the same laterality, while heteronymous refers to visual loss that usually respects the vertical meridian. Congruous fields are symmetric in both eyes. The lesions of upper or lower occipital banks produce quadrantanopia defects, while lesions within the temporal and parietal lobes cause field defects that tend not to respect the horizontal meridian.

More sensitive and precise evaluation of visual field can be obtained by automated and computerized threshold perimeter or kinetic testing of Goldmann perimeter. In many instances, the computerized threshold perimetry is a more reproducible test for patients with defects on optic neuropathies, chiasmal disturbances and so on. Computerized threshold perimeter performs static threshold

FIGURE 29-1

Visual field is an island or hill of vision in a sea of darkness (57)

measurement. New statistical software empowers the user with additional means of refining the assessment and representation of visual field.

The Goldmann perimeter allows interaction with the examiner and may be more appropriate for patients with neurological impairments. It is a substantially more sophisticated method of field assessment. Kinetic perimetry is usually the preferred method. It involves moving the target from a non-seeing area into a seeing area. A contour map of the island of vision can thus be established by using targets of varying size and brightness. Computerized perimetry is currently the more popular test method in visual field testing.

The visual field must be tested for each eye separately. The visual field is a dynamic area that changes according to a large number of variables. It should always keep in mind that all modalities for visual field evaluation are subjective and depend on the patient's level of alertness, cooperation, ability to fixate centrally, and response rapidity.

Visual field assessment should include standard objective instrument measurements of threshold visual fields when possible, but persons with traumatic brain injury may not be able to sustain attention and organization for a purposeful evaluation in automated field tests. Confrontation visual field assessment which will include holding the person's gaze while presenting objects in the peripheral field are effective as well as a saccadic confrontation visual field assessment. The latter can be used effectively for individuals who cannot hold fixation and are peripherally distractible.

The methods for this form of testing are to provide stimuli or targets in various portions of the field. The examiner observes the functional behavior of the patient as they shift their eyes via saccadic movements into the various visual fields. This may be performed monocularly as well as binocularly.

Homonymous deficits often will relate to spatial problems affecting posture and balance. Visual field neglect is a condition in which there is no hemianopsia, but spatial information in the affected field (usually the left visual field) is ignored (24). Dysfunction caused by field loss will be discussed later in this chapter.

*Motion Perception* Motion perception is as elementary a visual perception as form or color senses (52). It includes three-dimension stereo-sense, location, and layer sense. The projected pathway of motion perception is from retinal sensory cells through ganglion cells, lateral geniculate body of thalamus to striate cortex. The abnormalities of motion perception have been seen in optic neuropathy and glaucoma and it was also reported that motion perception decreased or diminished in cerebral traumatic patients with normal visual acuity or color perception.

Three methods for evaluating motion perception are used: 1) using the motion stimuli of the random dots; 2) using the stimuli of sinusoidal grating strips; and 3) using bar target stimuli. The bar targets projected on a monitor can be observed clearly and distinguished easily by subjects. The size and density of bar targets as well as variations in direction of the bars and flickers can be controlled (vertical, horizontal, and oblique).

## ELECTROPHYSIOLOGICAL TESTING

Most electrophysiological tests are evoked responses for which adjusting stimulus conditions and techniques of recording makes possible a representation of the sequence of events along the visual pathway (53–55). Besides international standards of ERG, PERG, EOG, and VEP, it is necessary that each laboratory should have its own normal data to evaluate patient's response recording because the amplitude and implicit time of wave may vary among laboratories.

### Visual Evoked Response (VEP)

Visual evoked response is a measure of the electrical activity through the visual cortex. Certain conditions are required for VEP measurement: visual stimulus, scalp electrodes, amplifier, averaging system, and recording equipment. The electrodes are positioned in the midline at the occipital and posterior frontal region. An electrode placed on the ear provides a ground.

VEP is response to stimulation by flashes or pattern stimuli with alternating checkerboard or stripes on a monitor. The flash VEP is applied in the persons with very poor vision. A full field Ganzfeld stimulator is used for flash stimuli. The pattern stimulus is preferable when the eye is optically correctable, since the occipital cortex is more sensitive to sharp edges and contrast, while it is relatively insensitive to diffuse light.

The VEP is characterized by the waves N, P, N, and P. The amplitude and implicit time of the wave depends on the check size, contrast, and frequencies of the stimulus. The temporal aspect (latency) of the VEP is more reliable with the significance in clinical application of acuity and focalization, however, the amplitude of VEP under binocular assessment has more relevance to ambient spatial relationships.

The VEP traditionally has been used to confirm the diagnosis of neuropathy in the visual system. It assesses disorder of optic nerve fibers, estimates visual acuity in nonverbal and verbal persons, evaluates potentials for reasonable visual acuity in some kinds of patients, and detects and locates visual field. In some cases, the VEP is even more sensitive for detecting compressive lesions than subjective perimetry.

## Multifocal Visual Electrophysiology

### *Multifocal Electroretinogram (mfERG)*

*Multifocal Evoked Response (mfVEP)* In 1992, Sutter and his co-workers reported presenting pseudorandomly multifocal stimulation together with retinal or cortical scaling of the size of the stimulated areas. They were able to stimulate numerous locations of the visual field simultaneously and to extract individual responses from each of them. The electrode permitted the recording of reliable responses from numerous retinal locations such as areas 61, 103, 241 loci of the visual field. This work establishes the multifocal electroretinogram (mfERG) and multifocal visual evoked response (mfVEP) with field topographic mapping of ERG or VEP components.

The mfERG or mfVEP is based on the Wiener kernel expansion and uses deterministic pseudorandom binary m-sequence stimulation. It permits computation of the signal by cross-correlation of the response evoked by m-sequence stimulation with m-sequence itself. Therefore, it is very effective for mapping.

The technique allows computation of the first order or higher order kernel which characterizes the nonlinear interaction between visual events. The amplitude of the averaged quadratic VEPs is in proportion to visual field losses. The mfERG or mfVEP is a powerful method for the investigation of brain activity and mechanisms of human visual perception.

Electrophysiological analysis through use of binocular visual evoked potentials assesses the relationship of support for focal processing by the ambient (spatial) system (10).

The visual evoked potential should be performed with habitual corrective lenses. A P100 cross-pattern reversal analysis is performed. Following the initial response, two diopters of base-in prism in conjunction with binasal occlusion should be introduced before both eyes in addition to the corrective lenses. The amplitude and latency of the P100 should be compared. An amplitude increase following the introduction of base-in prism with binasal occlusion is seen as a test positive for PTVS (11).

*Electro-Oculogram (EOG)* The EOG technique of recording eye movement is widely available and reliable. Since the eye acts as a dipole, the electrical current changes are caused between the cornea and posterior pole of the eyeball when the eye is moving in different directions. The EOG is performed by placing four cutaneous electrodes are placed on the canthal regions of both eyes. An electrode placed on the ear serves as the ground. The potential is recorded when alternate fixations or target movement is performed. Changes in illumination, skin resistance, and speed of the target will affect the results of the EOG. The EOG can yield reasonable recordings of horizontal movements, however,

vertical movements may be affected by eyelid blinks and nonlinearities.

Observation of eye movements by the clinicians provides a simple qualitative assessment and in most cases is able to identify most abnormalities. Therefore, the EOG is used to distinguish the affects of specific ocular modalities and to determine the presence or absence of improved motor function during therapy for visual pathways.

## NEURO-MOTOR ASSESSMENT

The neuro-motor assessment can be performed to evaluate the role of the ambient visual process in establishing concepts of visual midline and how it affects posture, balance, and movement. Concerning posture, dysfunction of the ambient visual process will also affect seating position and posture.

The visual midline test may be performed in those individuals that can respond actively (10). Observation of the patient in a seated position as well as during ambulation should be performed to evaluate the correlation of the visual midline shift test to tendencies to drift to one side and/or lean forward or backward during ambulation. Lateral shift of the visual midline will often cause a lean or drift during ambulation. An anterior shift can cause a lean or flexion forward. In more severe cases of the anterior shift of visual midline, toe-walking will develop in an attempt to compensate for the imbalance. A posterior shift of visual midline will cause an extension posture and tendency to lean backward in retropulsion.

## VISUAL-VESTIBULAR INTEGRATION DYSFUNCTION

There are numerous treatises that discuss the anatomy, physiology, and treatment of the separate visual, vestibular, and sensory motor systems, however, until recently, few were able to discuss the functional integration and relationships that exist between these three systems. Dizziness, vertigo, and imbalance are common symptoms following a TBI and often indicate miscommunication between these systems. Inner-ear disorder of the vestibular system is a common diagnosis, however, the relationship to the visual process is often overlooked or misinterpreted.

Coordinated movement involves a complex interaction between sensory afferents from the visual system, somatosensory system, and the vestibular system. In particular, the semicircular canals and utricle/sacculle respond to rotational and linear/gravitational information and is transmitted via the vestibule-cochlear nerve through the ascending and descending axon branches of the brainstem vestibular nuclei. At times, vision supercedes or enhances vestibular input. The vestibulo-ocular reflex

(which maintains foveal fixation during head movements), the vestibulospinal pathways (which are responsible for postural control under static and dynamic circumstances), and the vestibulocerebellar pathways (allowing for modulation of motor output via the flocculonodular lobe of the cerebellum) are all integrated at this level of the brainstem.

The vestibular nuclei accept information from the visual system relative to the ambient visual process to support movement and visual interaction of the environment. The subset of the ambient process, the magnocellular system, provides information about perception of contrast and movement involving short wavelength and low and middle spatial frequency input. This affects awareness of depth perception, motion detection, and alterations in brightness. The parvocellular system is mostly responsible for detail discrimination, color perception, and identification of patterns or shapes.

An important differential between magnocellular and parvocellular processing is that the former is responsive to the onset and offset of receptive stimuli, whereas the latter is responsive to longer stimulus duration. Parvocellular input projects to the occipital lobes along the retinal-geniculate-cortical pathway and then may send axons to the temporal brain region. It is the ambient process inclusive of the magnocellular system that supports posture, balance, and spatial orientation. Information synapsing in the occipital lobe will proceed to temporal and parietal lobes for higher level processing while the information from the superior colliculus will integrate with head and body postural reflexes flowing through the vestibulospinal and vestibulocerebellar tracts.

The vestibulo-visual relationship supports a stabilization of vision during movement of the head, neck, or body. Diplopia is the most frequently considered symptom of disruption in this interaction in addition to other interferences with binocularity.

The significance of the vestibulo-oculo-cervical triad is the quality and organization of somatosensory input (20) which occurs in the thalamus and is transmitted to the cerebellum and primary somatosensory cortex within the parietal lobe. Multisensory integration and conscious perception occur as this information is projected into the secondary and association cortices of the frontal, temporal, and parietal lobes where the perception of dizziness, vertigo, or imbalance may be the result.

A complete medical history with careful analysis of the visual process and vestibular system is necessary for diagnosis and prognosis. Too often, functional vestibular rehabilitation for vertigo and dizziness is begun before the relationship to visual processing problems is determined. Under the age of fifty, TBI is the most common cause of dizziness and vertigo from a direct head trauma and whiplash.

Differential diagnosis for dizziness without vestibular dysfunction includes PTVS, hyperventilation, dehydration,

orthostatic hypotension, vasovagal syndrome, arteriosclerosis, osteoarthritis, and central nervous system disorders. A Group II Disorder such as aortic, carotid, vertebrobasilar, subclavian, and cerebral artery insufficiency should be ruled out.

Once a Group II disorder has been ruled out, vestibular anomalies such as vestibular neuritis (acute labyrinthitis), benign paroxysmal positional vertigo (BPPV), nucleo-reticular vestibular syndrome, Meniere's Disease, Perilymphatic Hypertension, and Perilymphatic Fistula should be ruled out.

Since destabilization of the ambient process following trauma has been clinically found to cause vertigo and dizziness which are symptoms of PTVS. By treating PTVS, stability is created in ambient visual processing, thereby increasing the efficiency of matching information with vestibular, kinesthetic, and proprioceptive processes. This, in turn, frequently reduces or eliminates symptoms of vertigo and dizziness.

### VISUAL FIELD DYSFUNCTION

A visual field loss is relative to the area of cortical lesion or optic nerve insult. Field defects that occur beyond the optic chiasm will always cause a homonymous hemianopsia not necessarily congruous (56). Depending upon the area of the cortex affected, geniculate lesions are often not suspected and are rarely diagnosed. However, in the case of a homonymous hemianopsia involving primarily the central visual field sparing the peripheral field, the geniculate body should be considered as the source.

Temporal lobe lesions will often produce an incongruous superior quadrantanopsia with a sloping margin. In addition to field loss, parietal lobe lesions cause a lack of awareness of the field loss. It can be differentiated by confrontation visual field assessment when the clinician presents simultaneous targets in opposite fields. The parietal lobe lesion will cause an extinction phenomenon yielding a person to be aware of only one target at a time. If the target is moving in both fields, often the extinction phenomenon will not occur. The target must be stationary in order to demonstrate the possibility of a parietal lobe lesion. The common defect is an inferior homonymous quadrantanopsia.

Occipital lobe lesions are characterized mostly by their congruous nature. These can encompass the entire hemianopic field or portions thereof depending on the specific location of the lesion. Riddoch's phenomenon described in 1917, involves the inability to see stationary objects presented on the affected side but could see objects that were moving. Recent research related to focal and ambient visual processing suggests that the ambient visual process is a survival system that particularly responds to movement in the peripheral vision. Perhaps an additional

interpretation from the original one would be that areas of the lesion are being circumvented when feedforward occurs from the ambient visual process. However, when stationary targets are presented to those with PTVS in conjunction with a field loss, it will cause them to over-focus on the sensory component of the target they are looking at. This over-focalization and lack of an ambient feedforward response can possibly cause a condition related to field neglect and/or extinction phenomenon.

Like visual field loss, visuospatial neglect may manifest as a complete loss of visual perception on the side affected or as a relative loss where less is perceived in the neglected field particularly when there are competing stimuli in the opposite hemifield (57). With appropriate treatment, the functional effect of the hemianopsia and/or neglect can be minimized. Patients with visual field loss who do not receive training, rarely use adaptive search strategies (58). Training the patient to scan into the area of loss, in some cases, creates incomplete recovery of visual field (59–62). Zihl and von Cramon (63) have reported extensive field recovery taking place only during periods of appropriate treatment. Patients with visuospatial neglect require additional training to gain skills for compensation for many activities of daily living.

A homonymous hemianopsia can be functionally very debilitating to the patient in rehabilitation. Not only does it represent a complete loss of visual field, but it also affects concepts of midline. The concept of visual midline shift syndrome is an important one to understand relative to visual motor rehabilitation for any person following a TBI, but particularly for those who have suffered a homonymous hemianopsia. When the visual midline shifts and the individual begins to lean in the direction of the midline, the sensory stimulation from the proprioceptive, kinesthetic, and vestibular system will reinforce the lack of weight bearing on the paretic side. In turn, this also reinforces the development of spatial neglect.

To counter the compressions and expansions that distort spatial perception following TBI, prisms can be effectively used. A prism is a wedge of glass or plastic. Optically when one looks through a prism, the image of what is being looked at appears to be shifted toward the apex or thin edge of the prism and away from the base or thick edge. The shift in image occurs because the prism expands space on one side and compresses space on the other. The prism expands and compresses in a three dimensional manner, but for the purpose of this discussion let us consider it only two dimensionally. The prism can be used to alter the distortion of space caused by a visual midline shift if placed in the appropriate direction before each eye. This is termed a yoked prism system. The amount of prism can be varied depending upon the amount of distortion in the visual process. Yoked prisms are an effective means by which to shift the concept of visual midline, but also should be used in conjunction

with other methods of field enhancement or to increase awareness in the affected homonymous hemianopic field.

An enhanced sector prism system is used to affect homonymous hemianopsia by increasing awareness of peripheral visual fields on a sensory level, whereas the yoked prism is used to affect VMSS sensory motor level. The enhanced sector prism system (mounted binocularly or monocularly) is positioned to the side of the line of sight in a spectacle frame with the base end of the prism positioned temporally in the direction of the hemianopic field. When looking into the prism(s), the image will be shifted toward the apex enabling the individual to see objects to the side they would normally not be able to see unless they took a significant eye and head turn in the direction of the hemianopic field. Many individuals with a homonymous hemianopsia frequently bump their head and body on objects that they did not see. This causes numerous bruises as well as the possibility of more significant injuries.

The experienced clinician will recognize that individuals who have a visual midline shift syndrome as well as a homonymous hemianopsia will often have difficulty adapting to the use and succeeding with an enhanced sector prism system because the midline reinforces the spatial neglect. Therefore, treatment with yoked prisms for VMSS is necessary prior to or in conjunction with an enhanced sector prism system. By addressing the issue of VMSS, the success of rehabilitation with an enhanced sector prism system will be increased. The combination of yoked prism in the carrier lenses as well as the sector field prism positioned appropriately laterally to the line of sight can be an effective combination. Rehabilitation with yoked prisms to treat visual midline shift syndrome will directly affect field neglect as well as VMSS. Training can then be established to utilize the enhanced sector prism systems (49, 64). In other cases of visual loss including trauma with constricted visual fields, single or multiple prisms are used mounted laterally on each lens (65).

Sector prism systems used to increase a patient's peripheral awareness can be made out of Fresnel press-on prisms (66). Peli (67) reported that the press-on sectoral prisms when applied to the upper and lower part of the spectacle lens causes a refractive exotropia and thus improves simultaneous awareness and greater obstacle avoidance. However, due to the poor optical quality of the press-on Fresnel prisms, sometimes patients experience a decrease in acuity, or have problems with reflections or distortions which negatively affect the patient's acceptance and success (66). Gottlieb, et al. (65) found that press-on prisms sometimes even decreased a patient's tendency to scan into their field of neglect due to their dislike of looking through these prisms and hence amplified avoidance of this area.

Complex visual loss is no longer an insurmountable obstacle in the way of effective rehabilitation and recovery

of function. Using technology along with proven rehabilitation strategies can aid in meeting the goals of the patient and rehabilitation team.

Literature reinforces that enhanced sector prism systems yield fewer mishaps of bumping into objects or people and their fear of collisions notably decrease (68, 69). The primary result of this improved function is an increase in safety and secondarily a decreased risk for insult and injury (70). In the long term, a patient may experience some recovery of vision in the hemianopic field (49). In a study by Gottlieb, Freeman, and Williams in 1992, 27 of the 34 patients who had been fitted with enhanced sector prism systems to use them full or part time over the next 2.5 years. The prism used in this study increased the patient's peripheral field awareness an average of 13.25 degrees.

### VISUAL PHENOMENA ASSOCIATED WITH TBI

Visual phenomena following a TBI can be quite diverse. Sometimes these phenomena are bizarre and assumed to be of psychological nature. Some of these symptoms will be visual hallucinations, flashing lights, palinopsia, variations in homonymous field defects, and scintillating scotomas. It has been reported that visual hallucinations can be associated with temporal and parietal lobe lesions. Following a TBI, individuals may report hallucinations that take several forms. Some individuals will experience movement of the visual field. Sometimes, the entire visual field will appear to shift or move as they move their eyes or body. Others will report seeing movement in their peripheral vision but when they turn to look, they find only stationary objects. Another common hallucination is seeing things or persons in the periphery and/or central vision. Some patients report seeing snakes dropping from the ceiling or wriggling across the floor. Others will perceive strange type of creatures appearing to move and shift.

Many of these phenomena are reported by persons who have PTVS. It has been found clinically that treatment for post-trauma vision syndrome will often stop the perceived hallucinations (23). Although it has been noted in literature that parietal and temporal lobe lesions as well as occipital lobe lesions can be the cause of these hallucinations, it has also been suggested that some of the hallucinations may be due to psychiatric disorders. It is not uncommon for persons following a TBI who are experiencing hallucinations to be placed on psychotropic medications. It is the author's experience that many of the hallucinations will persist even though these medications are being used.

One possible explanation for the existence of hallucinations following TBI is that when there is dysfunction to the ambient visual process, the ability to stabilize

the retinal image is compromised. The superior colliculus is responsible to a great extent for providing the spatial matched information for ambient and sensory motor processes to the occipital cortex but more specifically, to provide a stabilization of the peripheral retina. When the ambient visual process is compromised, the visual processing system that remains, the focal process, isolates to detail but does not have a spatial grounding to stabilize the retinal image.

It has been noted clinically that persons experiencing PTVS will perceive words on a page or objects in the field appear to move when they perform movements of their eyes such as saccadic fixations. Saccadic fixations in a field of vertical lines will produce a shimmering movement of the vertical lines. The lines will appear to move in various manners similar to the movement of a snake. It is hypothesized that at least some of the hallucinations experienced following a traumatic brain injury are due to the unstable nature of the ambient visual process in PTVS. The interpretation of 'snakes' and other objects appearing to move are perceived movement of vertical and horizontal lines in their environment due to the unstable nature of the peripheral retina related to the compromise of the ambient visual process. It has been found clinically that by treating individuals for PTVS, the hallucinations will often cease within hours to days.

### BINOCULAR INTERVENTION

Treatment for diplopia varies depending upon the philosophy of the treating doctor as well as the rehabilitation program. Some do not recommend any treatment and choose to wait to determine if time will be the healing factor. Others recommend patching of the deviating eye to eliminate the diplopia, whereas others recommend patching of the fixating eye in order to stimulate fixation in the eye that is deviating. The lack of any treatment approach and often an inappropriate treatment regimen for a person in a state of diplopia can and will interfere with all aspects of rehabilitation.

The visual process is the dominant and primary sensory motor system affecting all aspects of posture, movement, balance, as well as cognitive-perceptual function. Vision works to reinforce all that we do. If vision is dysfunctional, it will interfere with all performance.

Failure to eliminate diplopia can directly affect the outcome of rehabilitation which financially is being undertaken at tremendous costs by insurance programs as well as individual funding from families and relatives. Therefore, in view of the limited amount of time for rehabilitation and the extraordinary amount of money that is often spent to rehabilitate the person, it is logical to attempt to rehabilitate the condition causing diplopia through treatment of PTVS, compensating prism, and/or

vision therapy. It has been suggested that surgical intervention, while possible, is at best a challenge for treating diplopia following a traumatic brain injury (44).

### **Pathophysiology of Injuries Contributing to Diplopia**

Injury to the visual system can be diffuse and/or focal and can localize to any, or a combination of the ocular structures, cortical areas, midbrain, or nerve nuclei. Brain injuries affecting vision typically occur via axonal shearing, hemorrhage, infarct, inflammation, and/or compression. Ophthalmoplegias (cranial nerve palsies) may completely, or partially involve any single or all three of the nerves controlling ocular motility.

The third nerve controls the medial, superior and inferior rectus muscles, inferior oblique, ciliary body, levator, and papillary sphincter muscles. Clinically, a complete acquired CNIII palsy will present with ptosis, hypoexotropia, dilated and fixed pupil, paralysis of accommodation and limitation of gaze on the affected side. Partial involvement can be any combination of, but not all of the above. Spontaneous recovery, if any, is usually within six months.

The sixth nerve controls the lateral rectus muscle. Clinically, the patient will have an esotropia in primary gaze that increases as they attempt to look towards the affected side. There is a limitation of gaze to abduction of the affected eye. Spontaneous recovery, if any, is usually within six months.

The fourth nerve controls the superior oblique muscle. Clinically, the patient will present with their head tilted to the contra-lateral side in an effort to offset cyclical, or torsional movement of their eyes. Spontaneous recovery, if any, usually occurs within six months.

### **Vision Rehabilitation**

*Vision Therapy.* Vision therapy (also referred to as vision training or orthoptics) is a clinical approach to treat a variety of visual disorders including certain strabismic conditions. The practice of vision therapy uses a variety of non-surgical procedures to modify the visual process affecting function. By first evaluating the bimodal processing of vision, the doctor will establish a plan of treatment designed to affect balance between the focal and ambient visual processes as well as the ability to match information with sensory motor systems. The goal is to improve the visual process and affect binocularity, spatial organization, balance, movement, etc.

Vision therapy will typically involve a series of treatments. During treatment sessions, individually planned activities are conducted under optometric supervision. The specific procedures and necessary instrumentation are determined by the individual patient's needs and the

nature and severity of the diagnosed problems. Vision therapy techniques employ the use of lenses, prisms, computers, biofeedback, stereoscopic devices, and a variety of other instruments and techniques designed to affect the visual process.

*Prism Rehabilitation* As mentioned previously regarding VMSS and visual field loss, prisms are ophthalmic tools that refract light while also compressing and expanding it. Prisms are used clinically in a therapeutic manner to reestablish balance of ambient and focal visual relationships causing visual dysfunction or in a compensatory manner to offset the affects of a binocular imbalance.

In binocular and strabismic dysfunctions, use of prism can reduce symptoms, improve function, and hasten recovery. In these situations, prescription of therapeutic prism (an amount, type, and orientation of prism to reduce or neutralize the binocular/vision dysfunction or to stimulate visual function and fusion) can help reduce or eliminate symptoms and aid treatment. To affect spatial imbalance caused by ambient and focal dysfunction (see PTVS and VMSS), yoked prisms are prescribed.

There are times, patients, and situations when remediation of a visual problem is not possible or feasible. In these situations, prescription of compensatory prism (an amount, type, and orientation of prism to reduce or neutralize the binocular strabismic dysfunction) can help reduce or eliminate diplopia.

*Patching.* Patching has frequently been used to eliminate diplopia (21, 71). While effectively eliminating diplopia, patching renders the patient monocular. The chief problems of monocular vision are loss of stereopsis, reduction of peripheral visual field, and VMSS (10, 21, 72).

Monocular vision reduces the field of vision by approximately 25%, decreases stereoscopic vision, decreases visual acuity (due to lack of binocular summation), and impairs spatial orientation. Monocular versus binocular individuals will have a disadvantage in visual motor skills, exteroception of form and color, and appreciation of the dynamic relationship of the body to the environment which facilitates control of manipulation, reaching, and balance (44).

Problems arising from acquired monocular vision will manifest as difficulties in eye hand coordination, clumsiness, bumping into objects and/or people, ascending or descending stairs or curbs, crossing the street, driving, various sports and other activities of daily living which require stereopsis and peripheral vision (72).

In the case of diplopia following TBI, a standard recommendation in acute care facilities and rehabilitation hospitals is to patch one eye. As discussed previously in the section about VMSS, this will cause and/or reinforce a shift in concept of visual midline affecting posture and balance as well as having an adverse affect on physical/occupational therapy.

Patching can be performed but should be done with respect to the ambient visual process. A central occlusion patch can be placed on the deviating eye. For example, if there is a left exotropia, vertical adhesive tape can be placed in front of the deviating eye so that it is built from the nasal portion of the eyeglass frame out to just block the center of the pupil or line of sight. In this way, diplopia will be eliminated when the person looks directly at something, but the peripheral field of the deviating eye is respected by not covering it. In turn, it allows the ambient visual process of both eyes to begin to match information with other sensory motor systems. This will support visual midline concept for posture, balance, and ambulation.

Another method involves use of a partial and selective occlusion. The spot patch is a procedure that eliminates diplopia without compromising peripheral vision (73). It is a small, usually round or oval patch made of adhesive tape, blurring film, or other filters. It is placed on the lens of glasses and directly in the line of sight of one eye. The diameter is generally about one centimeter, but will vary on the individual angular subtense required for the particular strabismus, ophthalmoplegia, or gaze palsy. Final size and placement is determined by evaluating different sizes and shapes to arrive at the smallest one which effectively eliminates the diplopia. If there is a paresis, the spot patch should be placed in front of the affected eye.

By eliminating diplopia through central occlusion, the ambient process becomes more effective and supportive. The spot patch is indicated in cases of intractable diplopia where other methods of treatment are either not viable, have failed, or are contraindicated. Examples of such cases include refractory, third nerve ophthalmoplegia, sixth nerve palsy, and inter-nuclear ophthalmoplegia. Central occlusion is effective if the diplopia is constant and the patient exhibits relief and improved general function as a result of eliminating the diplopia.

Determining size, shape, and placement of a central occlusion patch requires measuring the diplopic field, determining limitation of ocular motility, and measuring the angle of strabismic deviation.

## CONCLUSION

Rehabilitation of a person with a traumatic brain injury requires applying the science of understanding neurological dysfunctions as they pertain to interference with motor, sensory, and cognitive processes. Until recently, if a person suffered visual dysfunction in the way of binocular, spatial perception, and/or perceptual motor dysfunction, rehabilitation treatment was limited to patching of the deviating eye causing diplopia or primarily hospital based occupational and physical therapy.

Recent research has demonstrated that often traumatic brain injury affects visual processing which can cause

or relate to the performance dysfunction as well as binocular problems. Neuro-ophthalmology has provided an important means of intervention for neurological problems affecting the visual system. Diagnostic assessment through use of electro-physiology analysis in addition to the state of the art assessment through MRI and CT scan enables a neuro-ophthalmologist to function as a critical member of a multi-disciplinary team serving the person with a TBI. A careful evaluation of cranial nerve function and abnormalities is essential for establishing the diagnosis as well as determining appropriate neuro-medical recommendations for treatment. A range of options are available such as utilizing medications, botulinus toxin, and surgery.

Experience has shown that skilled optometrists familiar with the practice of neuro-optometric rehabilitation can be an important contributing member to the rehabilitation team. The skills of the optometrist are in applying the new science and understanding of the bimodal process of vision to the art of visual rehabilitation. The neuro-optometric rehabilitation evaluation involves the careful analysis of binocularity and spatial and perceptual motor function related to dysfunction between the ambient and focal visual processes by utilizing a variety of techniques incorporating lenses, prisms, and sectoral occlusion. The optometrist can affect performance and function at the appropriate critical stages of rehabilitation not being provided in rehabilitation hospitals and long-term care programs. This does not exclude individuals who are still suffering from binocular and spatial-motor disorders after being released from such programs. Neuro-optometric rehabilitation has been found effective in improving binocularity as well as visual spatial-motor dysfunctions affecting balance and posture by treating PTVS and VMSS years after the neurological insult has occurred.

The role of the neuro-ophthalmologist as well as the optometrist practicing neuro-optometric rehabilitation are important in advancing overall rehabilitation for a person with a TBI. The neuro-ophthalmologist and optometrist will provide critical insights into neurological dysfunction as well as the means by which to rehabilitate the high incidence and prevalence of visual dysfunction affecting performance following a traumatic brain injury.

## Cranial Nerve Disorders

*Flora M. Hammond*  
*Brent E. Masel*

### INTRODUCTION

Cranial nerves provide motor and sensory innervation to the head and neck, and are termed such owing to the fact that they emerge from the cranium. Injury to the cranial nerves is common with traumatic brain injury (TBI). In this chapter the anatomy, pathway, function, injury incidence, mechanism of injury, examination, treatment, and prognosis will be discussed for each of the cranial nerves. Introductory information about cranial nerves and their injury is briefly reviewed before discussing each nerve individually.

The true incidence of cranial nerve injuries is difficult to estimate. The olfactory nerve (cranial nerve I) is reported to be the most often injured, followed next in frequency by the facial and vestibulocochlear nerves, less commonly the optic and oculomotor nerves, and rarely the trigeminal and lower cranial nerves (1). Cranial nerve palsies may occur with TBI for several reasons, including acceleration-deceleration, shearing forces, skull fracture, intracranial hemorrhage, intracranial mass lesion, uncal herniation, infarct, or vascular occlusion. These circumstances may cause insults to the nerves through such mechanisms as compression, traction, transection, or ischemia. Central injury may occur from brainstem or cerebral damage; peripheral injury results from fracture or local injury. Cranial nerves are particularly at risk for injury as they traverse over bony protuberances and

through bony canals, or by direct injury from basilar skull fracture. The cranial nerves most susceptible to injury due to fracture are: olfactory, optic, oculomotor, trochlear, facial, auditory, and trigeminal (first two branches). The site of cranial fractures should indicate to the clinician the possibility of cranial nerve injury.

Injury to the cranial nerves may result in significant consequences to the individual with TBI, which may be further compounded by the deficits caused by cortical injury. Resulting impairments in sensation (sight, hearing, smell, taste) and motor function (facial expression, mastication, swallowing, speech) may impact such things as appetite, safety, interpersonal communication, and cosmesis.

Cranial nerves pass through the brainstem, and thus, abnormality in these nerves may serve as a reflection of injury severity. For example, pupillary, oculo-vestibular, and oculocaloric reflexes have been shown to be strong prognostic indicators of mortality (2–6) and persistent cognitive disability (7).

Diagnosis is generally based on physical examination. Table 30-1 lists the examination tests and supplies for each cranial nerve. In the presence of altered consciousness examination may be difficult and incomplete. Thus, as one recovers from TBI those aspects of the examination that were previously not possible will need to be performed. A good cranial nerve examination can help identify important problems, and direct treatment. Electromyography and nerve conduction studies may aid the clinician in lesion

**TABLE 30-1**  
*Cranial Nerve Function and Examination*

NERVE	FUNCTION	TEST	SUPPLIES
Olfactory (I)	Smell	Evaluate patency of the nasal passages. Then, determine if the person can detect familiar, non-noxious smells with eyes closed. Giving the person choices may help overcome word finding problems.	Odors or smelling card
Optic (II)	Visual acuity; visual fields	Have patient identify # of fingers held in visual fields and read up close and far away	Snelling visual acuity card
Oculomotor (III)	Pupillary reaction; lid retraction; and eye movement	Shine light in each eye to assess pupil reaction; note lid function; test eye movement for upward, downward, & medial gaze	Penlight
Trochlear (IV)	Intorsion and downward eye movement	Have patient follow finger to move eye downward	
Trigeminal (V)	Facial sensation; corneal sensation; chewing function	Test facial sensation for all three divisions; test corneal reflex; hold mouth open against resistance; clench teeth	
Abducens (VI)	Lateral eye movement	Have patient move eyes from side to side, lateral gaze	
Facial (VII)	Facial motor function; lid closure; taste sensation (anterior)	Smile, wrinkle forehead, wink, puff cheeks, close eye tight, identify tastes with anterior tongue	
Acoustic (VIII)	Hearing; balance	Test hearing; assess for nystagmus; finger to nose & heel to knee; Dix-Hallpike; vestibulo-ocular reflex; Romberg; Sharpened Romberg; Fucada Stepping Test; Caloric Stimulation Test	
Glossopharyngeal (IX)	Swallowing; voice	Say "ah"; swallow; test gag reflex	Tongue depressor
Vagus (X)	Gag reflex	Tested above via gag reflex	Tongue depressor
Spinal (XI)	Neck strength	Resist head rotation, shoulder shrugs	
Hypoglossal (XII)	Tongue movement & strength	Stick out tongue; resist tongue movement with tongue depressor	Tongue depressor

localization and prognostication. A range of treatment approaches exist for cranial nerve deficits. With many of the nerve injuries measures should be instituted to avoid secondary injury.

The cranial nerves carry up to six modalities as defined in Table 30-2: general sensory, visceral sensory, special sensory, somatic motor, branchial motor, and visceral motor. The modalities served by each cranial nerve are indicated by color in Figure 1 and are summarized below:

**Sensory Pathways** Three neurons make up the cranial nerve sensory pathways: primary, secondary, and tertiary. The cell bodies of the primary neuron of cranial nerves are located in ganglia outside of the central nervous system. The secondary neuron cell bodies (sensory nuclei) lie in the brainstem and project to the thalamus. From the thalamus the tertiary neuron projects to the sensory cortex. The sensory loss resulting from a cranial nerve injury depends on the lesion location. Peripheral nerve lesions result in a loss of all sensations supplied by that nerve, whereas central nerve injury to the sensory pathway depends on the part

injured. Damage in the thalamus causes contralateral patchy hemianesthesia and hemianalgesia.

**Somatic and Branchial Motor Pathways** The cranial nerves carrying motor functions are: III, IV, V, VI, VII, IX, X, XI, XII. Two neurons, the upper and lower motor neurons, compose the cranial nerve motor pathways. The upper motor neuron originates in the cerebral cortex and projects to the corticobulbar tract for synapse with the lower motor neuron. Most project bilaterally to contact lower motor neurons on both sides. Lesions to upper motor lesions are evidenced by paresis/paralysis, increased muscle tone, and hyperreflexia. The cell body of lower motor neurons reside in the brainstem and project peripherally. Lower motor neuron lesions cause paresis/paralysis, loss of muscle tone and muscle stretch reflexes, rapid atrophy, and fasciculations.

**Visceral Motor Pathways** The cranial nerves that perform parasympathetic efferent functions include: III, VII, IX, and X. Three neurons compose the visceral motor

**TABLE 30-2**  
*Components of Cranial Nerves*

MODALITY	CRANIAL NERVES	FUNCTION
General sensory	V, VII, IX, X	Touch, pain, temperature, pressure, vibration, proprioception
Visceral sensory	IX, X	Sensory input (except pain) from viscera (carotid body and sinus, pharynx, larynx, thoracic, abdominal viscera)
Special sensory	I, II, VII, VIII, IX	Smell, vision, taste, hearing, balance
Somatic motor	III, IV, VI, XII	Motor function of muscles developed from the somites (extraocular eye muscles and tongue muscles except palatoglossus)
Branchial motor	V, VII, IX, X, XI	Motor function of muscles that develop from the branchial arches (muscles of mastication, tensors tympani, veli palatine, facial expression, stylopharyngeus, pharynx, sternomastoid, and trapezius)
Visceral motor	III, VII, IX, X	Motor function of viscera, including glands and smooth muscle (ciliary and constrictor pupillae muscles; lacrimal, submandibular, and sublingual glands; oral and nasal mucosa; parotid gland; carotid body vasculature; smooth muscles of pharynx, larynx, thoracic and abdominal viscera; cardiac muscle)

pathways to regulate smooth muscle, cardiac muscle, and secretory cells: first-order, second-order, and third-order neurons. The first order neurons originate from the hypothalamus and higher centers and project to parasympathetic nuclei in the brainstem. From the nuclei the second-order neurons project to ganglia that lie out of the central nervous system. The third-order neurons in turn project peripherally to their targets.

### OLFACTORY NERVE (CRANIAL NERVE I)

Cranial nerve I provides the special sensory function of smell. The central axons of the bipolar olfactory neurons pass through the cribriform plate of the ethmoid bone, synapsing in the olfactory bulbs to relay sensations of smell to the brain. From here projections travel to the entorhinal cortex, hypothalamus, and the dorsal medial thalamic nucleus and then to the orbitofrontal cortex.

Cranial nerve I lesions may result in alteration of smell. Olfactory nerve injury may also alter the sense of taste because flavor perception results from a combination of smell, taste, and stored memories. Altered smell and taste may impact safety, appetite/weight control, confusion, behavior, daily activities, avocational and vocational pursuits.

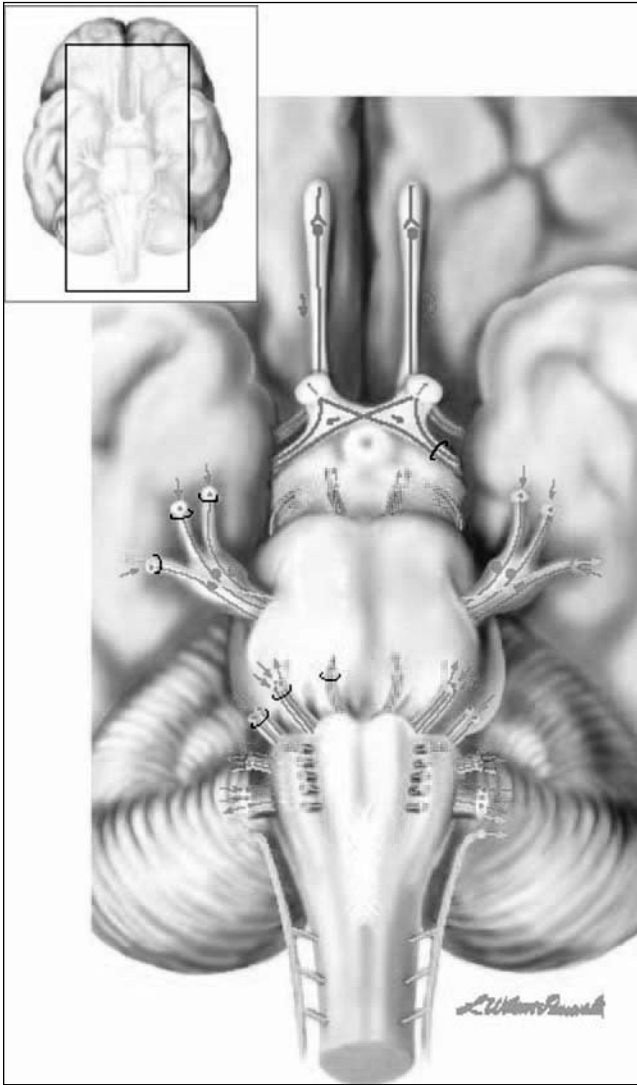

The following are terms used to describe the nature and extent of the altered olfactory sensation:

- Dysnosmia = impaired sense of smell.
- Anosmia = complete loss of smell.
- Hyposmia = partial loss of smell.
- Parosmia = sensation of smell in the absence of stimulus.

- Cacosmia = awareness of a disagreeable or unusually offensive odor that does not exist; may be part of an aura prior to seizure onset.

As many as 2 million people in the United States experience some type of olfactory dysfunction, causes of which include head trauma, upper respiratory infections, tumors of the anterior cranial fossa, and exposure to toxic chemicals or infections. It is difficult to estimate the true incidence of olfactory nerve injury in association with TBI due to the inability to examine cranial nerve I function in the unresponsive patient, and also the inconsistent seeking of medical attention after mild TBI. Olfactory nerve injury is reported to occur in 7% of all patients with TBI (8–11). The incidence is higher following moderate and severe TBI than mild TBI. Costanzo and Becker (12) report 19.4% with moderate TBI and 24.5% with severe. Injury to the olfactory nerve is the only cranial nerve commonly associated with mild TBI. This is because the fine nerve filaments of the olfactory nerve are particularly at risk for injury, even in mild TBI, as the fibers run through the cribriform plate of the ethmoid bone to reach the olfactory bulb. There should be a high index of suspicion for olfactory nerve injury in the following cases: cerebral spinal fluid rhinorrhea, frontal and occipital blows, frontal vault fractures. It is reported that 40% of those with CSF rhinorrhea after TBI experience anosmia.

Cranial nerve I injury may occur from damage to the olfactory nerves in the nasal mucosa, damage to the nerves as they cross the cribriform plate, or intracranial lesions affecting the olfactory bulbs. The olfactory filaments are particularly vulnerable to injury, as they may be sheared during the rotation of the brain or injured by cribriform plate fractures. The olfactory bulbs may be

**FIGURE 30-1**

Basal view cranial nerves exiting the brain and brainstem. The components of the cranial nerves are indicated by color: aqua = general sensory; purple = visceral sensory; green = special sensory; pink = somatic motor; yellow = branchial motor; blue = visceral motor. (see color plate)

compressed by hemorrhage, edema, contusion, or abrasion by the cribriform plate. Olfactory structures also can be injured during craniotomies involving the anterior cranial base or from subarachnoid hemorrhage, which may disrupt the fine fibers of the olfactory nerve. Delayed onset of olfactory nerve dysfunction may be the consequence of scarring or gliosis of the tissues in the cribriform plate. Other causes of olfactory sensory abnormality should also be considered, such as nasal obstruction, injury to the nasal passages, acute viral respiratory infections, rhinitis sicca, allergic sinusitis, chronic polyposis, depression, medications, and seizures. Partial complex

epilepsy with a mesial temporal focus classically includes an aura of foul-smelling odors that occur before seizure onset. Olfactory hallucinations from uncinate fits do not imply actual olfactory nerve involvement. Paranasal sinus endoscopy may lead to violation of the cribriform plate with associated olfactory nerve injury, and also potential infectious complications.

Report of impaired smell may be the first signal of olfactory nerve injury. Because olfactory nerve function is not often evaluated in an emergency situation, the dysfunction may not be detected until weeks after the injury when the patient complains of changes in taste or smell. To examine cranial nerve I function, first evaluate the patency of both nasal passages. Then, determine if the person can detect odor in each nostril by testing with a familiar substance and an empty bottle. Stimulants such as organic solvents, camphor, peppermint, or ammonia should be avoided as they may also stimulate cranial nerve V (13). Next smell discrimination can be tested with the patient choosing between a series of common odors, such as coffee, lemon, and soap. Providing choices is a helpful way of limiting the influence of word finding problems on testing. Several different scratch and sniff cards are available to make testing more convenient. The University of Pennsylvania Smell Identification Test (UPSIT) is one useful tool, consisting of 40 items which evaluate olfactory and trigeminal nerve function in the nasal cavity. Central hyposmia may manifest as abnormalities in odor recognition rather than odor detection.

Olfactory encephalography establishes the presence of alpha rhythm, and its disappearance with odor perception. Ethmoid tomography may be used to determine if a basal skull fracture is present. Positron emission tomography (PET) and functional MRI are promising modalities to assist in making the diagnosis of different types of hyposmia (central vs peripheral), as well as in delineation of the role of limbic structures as sites of odor recognition, memory, and integration of multisensory inputs. Thorough evaluation of patients who have anosmia includes imaging of the anterior cranial structures. Patients experiencing parosmia should be evaluated for seizure activity on electroencephalography.

Unfortunately, there are no established effective treatments for this condition (1), while nontraumatic causes and seizure may be amenable to treatment. Early recovery may occur due to resolution of edema or pressure; while later recovery is contributable to neurofibril regrowth and central adaptation (14). Many regain the sense of smell within 2 years, but for some this remains a permanent problem. Costanzo & Becker (12) observed 33% recovery, 27% worsening, and 40% no change. Although it is a generally annoying development, parosmia may be the first evidence of functional return. When recovery occurs, it is usually noticed within the first 6 months and complete by 12 months post-injury (13).

However, late recoveries, up to 5 years, have been reported (8). For safety purposes, individuals with altered sensation should be aware of potential risks associated with the lack of smell (eg, inability to detect dangers such as smoke, spoiled foods, toxins), reminded to install smoke alarms on all floors of their home.

### OPTIC NERVE (CRANIAL NERVE II)

The optic nerve, a fiber tract of the brain containing one million axons, provides the special sense of sight. This nerve receives its input from the rods and cones (first order neurons) which pass the signal to the ganglion cell layer of the retina (secondary sensory neurons). The long axons of the ganglion cells penetrate the lamina cribrosa as the optic nerve, which passes posteriorly through the optic canal. At the optic chiasm, where fibers from the nasal halves of the retina cross, the optic tract is formed, containing fibers from the ipsilateral halves of the retina. The optic tract continues posteriorly to the lateral geniculate bodies, where a third synaptic relay occurs. At this point, a small number of axons leave the optic tract and project to the pretectal midbrain to form the afferent loop of the Edinger-Westphal nucleus. From the lateral geniculate body, the optic tract continues posteriorly as the optic radiations, which project to the occipital lobe. Throughout their projection to the occipital lobe, the neurons maintain a highly topographic orientation of the retinal image.

Optic nerve injury occurs in up to 5% of patients with TBI (9). Optic nerve palsy may occur with injury to the globe, causing damage to the intraorbital portion of the nerve within the optic canal (15). In the orbit, the nerve is redundant and cushioned by fat. It is, therefore, not liable to indirect injury. However, the nerve is strongly tethered to bone intermittently throughout the canal. It is therefore subject to shearing forces as the brain and orbital contents are free to move, while the nerve is not (16). Injury to the optic nerve occurs most frequently in the intracanalicular portion of the nerve (17). Injury to the intracranial portion is less common.

Injury to the optic nerve typically occurs in one of two ways: 1) primary lesions causing hemorrhages in the nerve, dura and sheath spaces, tears in the nerve or chiasm, and, rarely, contusion necrosis; or, 2) secondary lesions from circulatory events subsequent to the initial injury causing edematous swelling of the nerve, necrosis from circulatory failure or local compression, and infarction related to vascular obstruction. Because the optic nerve is a direct extension of the brain, any injury to the optic nerve axons which do not regenerate is permanent.

Immediate monocular blindness occurs with great frequency in optic nerve injuries, especially in the intracanalicular portion of the nerve. Monocular blindness may be partial, and the extent of partial blindness should

be documented immediately and followed closely for deterioration. The treatment of traumatic optic neuropathy is controversial. Although some studies have shown that steroids and/or optic canal decompression to be of benefit (18–20), other studies have shown that irrespective of timing post injury, neither treatment improved visual outcome (21, 22). Complete monocular blindness with preservation of normal pupillary reflexes is usually a sign of malingering or other types of functional (non-organic) disorders.

Visual field defects are due to injury to the optic nerve or its tracts posterior to the bulbar portion. These defects are quadrantanopsias or hemianopsias of varying degrees. When such defects are due to causes other than direct pressure from a mass lesion, surgical intervention is rarely helpful. Some visual field deficits may be helped by special optics that allow the patient to “see” in the affected field (15, 23). Careful evaluation by a neuro-ophthalmologist or neuro-optometrist is warranted, and training in the use of such lenses is often necessary. Visual training may improve the visual spatial disorders for those with visual neglect (24). It is also important for the clinician to recognize non-physiologic visual field deficits.

Non-nerve-related injury also may affect visual function. Trauma to the cornea may cause visual blurring and scotomata. Visual blurring may be caused by vitreous tears, traumatically induced cataracts, retinal hemorrhage, or retinal detachment. Injury to the cornea or contents of the anterior chamber (including the lens) may cause monocular diplopia (25). If eyeglasses are of no benefit, surgery may be necessary to correct blurring caused by either corneal or lens problems. Visual blurring also may be caused by Torsion's syndrome (intraocular hemorrhage). The hemorrhage may resorb spontaneously over time or may require surgical removal for complete restoration of vision. The potential presence of occipital seizures should also be considered (26).

Examination includes testing visual acuity, visual fields, pupillary reactivity, and direct visualization by ophthalmoscope. These tests are reviewed briefly:

*Pupillary Reactivity to Light* Light is shown into each eye and pupillary constriction (or lack of response) observed. It is also helpful to test for an afferent pupillary defect using the swing eye-to-eye test. If there is an afferent lesion involving the optic nerve, light shone into the affected eye fails to produce a response in either eye (contrast that with an efferent defect as described with cranial nerve III injury in the following section). This test may be difficult to assess due to altered level of consciousness.

*Vision Acuity* This can be performed by testing the ability to read a visual acuity card or newsprint. Unfortunately, this is often unable to be performed in patients who are minimally responsive, confused, or aphasic.

Saccadic responses to optokinetic stimuli may be checked to provide evidence of residual visual acuity function. The presence of an accommodation reflex can also provide evidence of visual fixation. Visual-evoked potentials may also help establish the integrity of the optic nerve and its cortical pathways.

*Visual Fields* This entails asking the person to count fingers or identify a small object along the periphery of the vision. Each eye should be tested separately. Confrontation using a red-colored object is preferred. Evidence of visual inattention may be detected using a test of double, simultaneous extinction by presenting the test stimulus to bilateral visual fields at the same time. Tangent screen testing can provide visual field maps of deficits. Deficits may not be detected if the person is not able to fixate.

*Direct Visualization by Ophthalmoscope* This may be helpful in identifying papilloedema (a hallmark of increased intracranial pressure), anterior chamber hemorrhage, and retinal detachment.

### OCULOMOTOR NERVE (CRANIAL NERVE III)

The oculomotor nerve provides somatic motor and visceral motor functions. The nucleus of the oculomotor nerve arises in the paramedian midbrain ventral to the aqueduct of Sylvius near the superior colliculus. Mainly uncrossed fibers course anteriorly through the red nucleus and inner side of the substantia nigra, emerging on the medial side of the cerebral peduncles near the pontomedullary junction at the midline, penetrating the dura at the cavernous sinus. It travels along the lateral wall of the cavernous sinus, adjacent to the trochlear nerve, and superior to the abducens. Parasympathetic fibers from the Edinger-Westphal nucleus, which lies superior and dorsal to the oculomotor nucleus, course in close proximity to the oculomotor nerve through the cavernous sinus. The oculomotor nerve emerges through the superior orbital fissure to innervate the internal, superior and inferior rectus muscles, the inferior oblique muscle, and levator palpebrae muscle. The parasympathetic nerve fibers that travel with the oculomotor nerve innervate the sphincter muscle of the iris and to the ciliary muscle, which controls the shape of the lens during accommodation.

A palsy of this nerve can be caused by brain disorders (such as a head injury, tumor, or an aneurysm in an artery supplying the brain) or by diabetes. Injury may occur along its course: at the orbit, cavernous sinus, or an intracranial locus. This nerve is often injured at the point it exits through the dura, or from compression caused by uncal herniation due to increased intracranial pressure.

Isolated oculomotor nerve palsies due solely to TBI are not unusual, occurring in 17% of patients in one

study (27). Another study showed that persons with complete oculomotor palsy have a high incidence of traumatic subarachnoid hemorrhage (71%) or skull fractures (57%) (28). An orbital blowout fracture may produce clinical findings suggesting an oculomotor palsy; however, the simultaneous finding of infraorbital numbness argues against the diagnosis of an oculomotor nerve palsy (8).

Oculomotor nerve palsy causes a characteristic clinical picture: Divergent strabismus, since the eye is turned out by the intact lateral rectus muscle and slightly depressed by the intact superior oblique muscle. The eye may only be moved laterally. The affected eye turns outward when the unaffected eye looks straight ahead, producing double vision. The affected eye can move only to the middle when looking inward and cannot look upward and downward. There is ptosis of the eyelid, absent accommodation and in cases of complete palsy, a dilated and fixed ipsilateral pupil.

Examination involves tracking an object in the six cardinal positions, convergence on near targets, pursuit movements, saccades, pupillary reaction, and eyelid elevation. Clinical testing of oculomotor function in the conscious patient is not difficult. The examiner observes difficulty in moving the eye inward, or upward and downward, with preserved outward movement suggesting third nerve dysfunction (often with pupillary dilatation and ptosis).

In the unconscious patient, oculomotor testing is not possible, and thus, information is gathered during the performance of such tests as the doll's eye maneuver and pupillary light testing. Such tests must be performed serially, especially in the acutely injured patient, to ensure that an expanding lesion, uncal herniation, and/or hemorrhage is not overlooked. A blown pupil serves as a warning sign of herniation because of the nerves location medial to the temporal lobe at the edge of the tentorium. Dilation and fixation of both pupils indicates deep coma and possibly brain death.

Each eye is tested separately for pupillary reaction to light. With an efferent defect involving CN III, light shone into either eye fails to produce a response in the affected eye while light shone in the affected eye produces constriction of the opposite pupil. Pupillary dilation on one side is characteristic of cranial nerve III palsy, and is commonly accompanied by ptosis and lateral eye deviation (due to unopposed abducens's function). The swinging flashlight test (moving light rapidly from one eye to the next) may be helpful. The normal response to this test is constriction in the illuminated eye. A Marcus Gunn sign is present when there is dilation of the pupil of the abnormal eye after light is shone briefly into it.

The diagnosis is based on the results of neurologic examination as described above and computed tomography (CT) or magnetic resonance imaging (MRI). A spinal tap (lumbar puncture) is performed only if hemorrhage is

suspected and CT does not detect blood. Cerebral angiography is performed when a hemorrhage due to an aneurysm is suspected or when the pupil is affected but no head injury has occurred.

Return of function may begin within 2–3 months of injury, but generally remains incomplete. The chances for complete recovery are poor (28), with 40% reported to experience complete recovery (25). However, the majority fortunately experience functional recovery, which generally occurs within 6–12 months of injury.

Occlusive therapy (patching) will resolve the diplopia while the patch is on, but produces no long-term effects. Pleoptics (eye exercises) also have not been proven to be very effective (29). Strabismus surgery should not be undertaken until maximum visual acuity has been restored. Surgery should be delayed 6–9 months post injury, as one-third of patients will recover spontaneously (30). The procedure is empirical and consistent results cannot be guaranteed. Nevertheless, one large study showed successful alignment in 81% of adults who underwent strabismus surgery (31). This correction only improves the cosmetic deformity, however, and does nothing to improve the underlying cause.

#### TROCHLEAR NERVE (CRANIAL NERVE IV)

The trochlear nerve is the smallest of all the cranial nerves. It is somatic motor and innervates only one muscle, the superior oblique muscle. The trochlear nucleus is located in the lower midbrain and projects dorsally to cross the midline and eventually emerges from the dorsal aspect of the midbrain immediately caudal to the inferior colliculus. The trochlear nerve then traverses the lateral aspect of the cavernous sinus and enters the orbit through superior orbital fissure to innervate the *contralateral* superior oblique muscle. Injury of the trochlear nerve may result from trauma, ischemia, infarction, hemorrhage, aneurysm, cavernous sinus thrombosis, inflammation, meningitis, or tumor. TBI is the most common cause. The trochlear nerve is particularly liable to traumatic injury in that it has the longest course of any cranial nerve within the skull. Trochlear nerve injury is reported to occur in 0.2–1.4% of individuals with TBI (25).

Usually, the diagnosis is suspected in a person who, after a head injury, complains of vertical diplopia and cannot turn the affected eye inward and downward. The affected eye is typically observed to be rotated outward. The individual may also have a compensatory head tilt away from the affected side. In this position, unaffected muscles are employed and the vertical diplopia can often be eliminated. The double vision is commonly precipitated when walking down stairs.

What causes the vertical diplopia? With the superior oblique muscle paralyzed on one side, the antagonist

inferior oblique extorts and slightly elevates the involved eye. Consequently, the visual fields are projected onto different areas of the right and left retinæ resulting in the perception of two different images.

The superior oblique muscle performs two major functions: intorsion and downward gaze. Intorsion is difficult to detect on examination. Watching for movement of the conjunctival vessel may prove useful in this effort. Downward gaze is easier to detect. Thus, cranial nerve IV is generally tested by having the person adduct the involved eye and attempt to gaze downward. Individuals with trochlear nerve palsy are unable to look downward when the eye is adducted. Adduction of the eye prior to testing downward gaze is important because movement of the superior oblique muscle depends on the starting position of the eye.

Further examination may be pursued with CT scan or MRI imaging. Treatment depends on the cause of the palsy. Eye exercises may help. Sometimes surgery is necessary to eliminate double vision.

#### TRIGEMINAL NERVE (CRANIAL NERVE V)

The trigeminal nerve provides general sensory and branchial motor modalities. The nerve arises from the ventrolateral pons with a large sensory and small motor root. The two roots extend forward to the tip of the petrous bone, where the sensory portion merges with the gasserian (semilunar) ganglion and then forms the three divisions of the trigeminal nerve. The motor portion travels along the inferior aspect of the ganglion and becomes part of the mandibular division.

The motor fibers exit through the foramen ovale to innervate the muscles of mastication: the masseter, temporalis, and medial and lateral pterygoid muscles. The fibers also innervate several smaller muscles: the tensor tympani and tensor veli palatini via the otic ganglion, and the mylohyoid and anterior belly of the digastric via the mylohyoid nerve.

The ophthalmic division (V-1) exits through the cavernous sinus and then the superior orbital fissure to supply sensation from the forehead, conjunctiva and cornea, as well as the mucosa of the nose, frontal, sphenoid and ethmoid sinuses, and the lacrimal duct. The maxillary division (V-2) also travels through the cavernous sinus and exits the foramen rotundum to supply sensation from the skin of the mid-face, the mucosa of the anterior nasopharynx, the upper portion of the hard and soft palate, the gums of the upper jaw and the upper teeth. The sensory portion of the mandibular division (V-3) supplies sensation from the lower face, the mucosa of the lower jaw, floor of the mouth, lower teeth and gum. It supplies general sensation (but not taste) from the anterior two-thirds of the tongue.

The incidence of trigeminal nerve injury from TBI is 1.4–2% (8). The supraorbital nerve, from V-1 and the infraorbital nerve, from V-2 can be injured exiting the skull as the result of direct trauma such as blow out fractures of the orbit. Such injuries tend to occur in motor vehicle accidents, unprotected falls, golfing and baseball injuries. The peripheral branches can also be injured by a superficial blow to the face. Numbness typically follows the distribution of the nerve.

The roots and/or the gasserian ganglion may be damaged in transverse skull fractures (32), but are rare in blunt head trauma (8). Penetrating wounds involving the gasserian ganglion are also rare but may cause severe dysesthesias and trigeminal neuralgia-type pain.

Clinical testing of the trigeminal nerve involves testing of all three divisions for sensation along all of the peripheral pathways. The examiner should look for sensory sparing at the angle of the jaw which is supplied by the upper cervical roots. Testing of corneal sensation involves a crossed reflex, and involves a motor response from the facial nerve. Thus, touching one cornea lightly with a wisp of cotton normally evokes a prompt closure of both eyelids. The masseters are amongst the most powerful muscles in the body, and subtle weakness may be difficult to detect. Pterygoid weakness is easier to detect, and the examiner may note jaw deviation toward the affected muscles on jaw opening.

Decreased corneal sensation may lead to corneal abrasions and drying as indicated by marked scleral injection. Treatment includes frequent eye irrigation and use of a lubricating gel with patching of the affected eye, especially at night. If irritation continues, lateral or complete tarsorrhaphy becomes the treatment of choice to avoid corneal ulceration and the development of corneal opacities.

Although injuries to the gasserian ganglion causing dysesthetic pain are rare, as with any peripheral nerve, stretch injuries tend to damage the nerves at fixed attachments at points of sharp angulation (8). Patients with trigeminal injuries may therefore complain of dysesthesias and symptoms of trigeminal neuralgia. Patients may respond to various anticonvulsants including: carbamazepine, gabapentin, lamotrigine, zonisamide, oxcarbazepine and levetiracetam (33).

### ABDUCENS NERVE (CRANIAL NERVE VI)

The abducens nerve is somatic motor. The nerve originates at the abducens nucleus in the pons; exits the ventral pons near the midline at the pontomedullary junction; pierces the dura lateral to the dorsum sellae of the sphenoid bone; continues forward between the dura and the petrous temporal bone; takes a deep right angle turn; traverses the cavernous sinus and enters the orbit through

superior orbital fissure to innervate the lateral rectus muscle. Within the cavernous sinus the 6th nerve is situated lateral to the internal carotid artery and medial to cranial nerves III, IV, V<sub>1</sub> and V<sub>2</sub>. The cranial nerves III, IV, V<sub>1</sub> and V<sub>2</sub> travel through the dural wall, while the 6th nerve does not travel through the dura but is free within the cavernous sinus. Cranial nerve VI palsies are the most commonly reported ocular motor palsies, owing to its long intracranial course (34). This nerve has the longest intracranial course of all the cranial nerves.

Abducens nerve palsy may result from TBI, tumor, diabetes, hypertension, multiple sclerosis, meningitis, blockage of an artery supplying the nerve, aneurysm, surgery, increased pressure within the skull, orbit fractures, hydrocephalus/shunt malfunction. Injury to the Abducens's nerve in association with TBI is reported to occur in 0.4–4.1% (25).

Cranial nerve VI is often associated with injury to other cranial nerves depending on where along its course the abducens nerve is injured. Injury at the abducens nucleus is invariably associated with ipsilateral fascial nerve palsy as fascicles of fascial nerve loops around the sixth nerve nucleus. Cranial nerves III, IV, V<sub>1</sub> and V<sub>2</sub> may also be damaged when the injury occurs within the cavernous sinus due to their close proximity. When injured as the nerve passes through the superior orbital fissure, cranial nerves III, IV, and V<sub>1</sub> may be affected as they also pass through the fissure.

The lateral rectus muscle serves to move the eye laterally away from the midline (abduction). The affected eye cannot fully turn outward and may be turned inward when the person looks straight ahead. Double vision results when the person looks toward the side of the affected eye. Coordinated movements of the medial and lateral rectus muscles are required for horizontal movements. If both eyes cannot align on the same target the visual fields will be projected to different areas of the right and left retinae, resulting in the perception of two images.

These patients have an esotropia that is worsened by lateral gaze, and will often turn their heads laterally toward the paretic side to compensate. To test the abducens nerve function specifically, the patient is instructed to move the eyes through the full extent of the horizontal plane while the examiner looks for deficiency in lateral gaze.

Usually, doctors can easily identify an abducens nerve palsy, but the cause is less obvious. In the case of TBI, the cause is often apparent, but not necessarily the location. Depending on the history and presentation further work up may be needed. CT scan or MRI may be warranted to exclude tumors. A spinal tap (lumbar puncture) may be useful if meningitis is suspected. Injury to the nucleus of the nerve causes complete lack of ipsilateral gaze; injury to the nerve after it comes off the brainstem results in inability to look to the side.

Treatment depends on the cause of the palsy. When the cause is treated, the palsy usually resolves. Abducens nerve palsy following TBI generally resolves over time.

### FACIAL NERVE (CRANIAL NERVE VII)

Four modalities are carried by the facial nerve: general sensory (tactile sensation to parts of the external ear, auditory canal, and external tympanic membrane), special sensory (taste sensation to anterior two-thirds of the tongue), branchial motor (muscles of facial expression), and visceral motor (lacrimal glands and mucous membranes of mouth and nose; submandibular and sublingual salivary glands). The sensory components originate in the geniculate ganglion, the branchial motor in the main motor nucleus (pons), and the visceral motor in the superior salivatory nucleus (pons). The facial nerve exits the lower pons laterally and passes through the internal auditory meatus into the middle ear (where the chorda tympani branch arises to carry taste fibers); then enters the facial canal and exits the cranium through the stylomastoid foramen. In the parotid gland the facial nerve divides into its terminal branches.

The main function of each of the two seventh cranial nerves is ipsilateral facial movement including forehead wrinkle, eyelid closure, and movement of half of the face. A message is sent from the motor strip of the cerebral cortex crossing over to stimulate the contralateral seventh cranial nerve.

Injury to the facial nerve is the second most common, one-third as common as olfactory nerve palsy (1). Facial nerve injury most commonly occurs within its passage through the temporal bone, though it may occur at any point (13). Facial nerve injury due to TBI is most commonly peripheral, in association with temporal bone fractures. Temporal bone fractures are most commonly longitudinal accounting for 90% of all temporal bone fractures (14). Transverse fractures of the petrous bone result in immediate and complete CN VII paralysis in 30 to 50% of cases due to tearing of the nerve (13, 14). The facial nerve and vestibulocochlear nerve (CN VIII) course through the petrous bone in close proximity, and thus transverse petrous bone fractures may injure one or both of these nerves. Fractures near the internal auditory meatus usually involve both nerves resulting in ipsilateral facial weakness (i.e., the forehead musculature is involved as well as the face), ageusia in the anterior two-thirds of the tongue, and ipsilateral deafness. Temporal bone fractures further along its course may result in ipsilateral facial weakness (1).

Longitudinal fracture may result in a delay of CN VII paralysis from 2 to 3 days and up to 2 weeks. Delayed facial weakness, especially in patients with hemotympanum, is indicative of facial nerve swelling in the facial

canal. In this setting, corticosteroids should be initiated, otolaryngology consulted, and facial nerve decompression considered (1). The nerve is usually intact, and typically recovers within 6–8 weeks (13, 14).

Facial nerve palsy may occur from injury anywhere along its course from the cortex to the innervation site. Forehead wrinkle is the one clinical feature that can differentiate the cause of facial weakness. Owing to the bilateral innervation of the upper face by the two cerebral hemispheres, upper motor neuron lesions (lesions above the level of the motor nucleus of cranial nerve VII) only cause contralateral paralysis of the face below the eyes. This occurs because the part of the nucleus that innervates the frontalis and orbicularis muscles continues to receive input from the ipsilateral hemisphere, allowing these muscles to continue functioning. On the other hand, lower motor neuron VII lesions (damage to the facial nucleus or its axons along its course after leaving the nucleus) cause ipsilateral paralysis of the entire face on one side with flattening of the forehead and inability to close the eye. Pontine lesions involving the facial nucleus cause complete ipsilateral facial paralysis along with contralateral hemiparesis (resulting from damage to the descending corticospinal fibers from the motor cortex before crossing over in the medulla), and are often accompanied by lateral rectus muscle paralysis (due to proximity of abducens nucleus to the facial nucleus).

Lesions within the fallopian canal may be localized to one of the three major segments (mastoid, tympanic, and labyrinthine) based on the presentation. Loss of taste on the ipsilateral anterior two-thirds of the tongue indicates damage of the mastoid segment (which branches into the chorda tympani). Injury to the tympanic segment which serves the stapedius muscle to dampen sound waves may cause hyperacusis (sounds appear excessively loud) and loss of the stapedius reflex, as well as loss of ipsilateral taste. Impaired ipsilateral tear production (in addition to the above findings) indicates damage to the labyrinthine segment from which the greater superficial petrosal nerve originates.

Comprehensive examination of the facial nerve involves testing the five main functions of this nerve: facial expression, taste, external ear sensation, stapedius muscle function and lacrimal and salivary gland function. First, facial expression in conversation should be observed, followed by requesting performance of specific facial actions: wrinkle forehead by raising eyebrows (frontalis), close eyes tightly (orbicularis oris), press lips firmly together (buccinator and orbicularis oris), smile, and clench jaw (platysma). An enlarged palpebral fissure may be a subtle sign of facial nerve injury. Taste may be tested by using a cotton swab moistened in a sugary or salty solution. The cotton is applied to one side of the protruded tongue, taste identified, cotton applied to other side to test for side-to-side differences; mouth rinsed with

water; test repeated with the other solution. This test may be facilitated by using pre-written choices of sweet, sour, bitter, salty to which the person may point. Pain and light touch sensation is tested at the small strip of skin supplied by the facial nerve at the posteriomedial surface of the auricle, although abnormality is rarely detectable. Stapedius muscle function may be tested by having the person compare the loudness of sudden clapping behind each ear. Lacrimal and salivatory function may be assessed by asking about dry eyes, dry mouth and need for drinking water to swallow food. Lacrimal function may be formally tested using the Schirmer's test where a 5 mm by 25 mm piece of filter paper is inserted into the lower conjunctival sac for 5 minutes with less than 10 mm moisture indicating abnormal function. Because of the close proximity to cranial nerve VIII, balance and hearing should also be assessed when cranial nerve VII is found to be damaged.

Electromyography and nerve conduction studies may be helpful in providing prognostic information. In cases of complete facial nerve disruption rehabilitative surgical techniques may be helpful, such as microsurgical cranial nerve XII crossover to the cranial nerve VII. Nerve-muscle pedicle grafts from the contralateral side may offer more rapid return of nerve function without compromising neck function (35).

Misguided nerve regeneration of the salivary and lacrimal fibers may result in "crocodile tears" (tearing instead of salivation upon eating).

Inadequate lid closure may result in drying of the cornea (exposure keratitis). The problem may be further compounded by accompanying loss of corneal sensation (trigeminal nerve) (13). A topical lubricant should be used frequently to protect the eye from dryness. Additional protection may be provided by taping the lid closed with eye pad, although this is not fool proof. In severe cases, tarsorrhaphy (operation to close eye lid) may be required for protection.

### VESTIBULOCOCHLEAR NERVE (CRANIAL NERVE VIII)

Cranial nerve VIII provides special sensory functions of hearing and equilibrium/balance. Disorders of the VIII nerve may result in vertigo, tinnitus, and/or deafness. The vestibular nerve originates at the vestibular ganglion and the cochlear nerve at the spiral ganglion. In the internal auditory meatus the vestibular and cochlear nerves join and enter the brainstem at the cerebellopontine angle. Because the vestibulocochlear nerve is actually two distinct nerves that course together in close proximity through the internal auditory meatus and across the cerebellopontine angle, these two nerves are usually injured simultaneously. Once synapsing at their nuclei the nerves

take different courses, and thus, are less likely to both be injured as they run more proximally. The vestibular nuclei project through the thalamus to the somatosensory cortex providing conscious awareness of head position and balance. The cochlear nerve is represented bilaterally via fibers from the ventral cochlear nuclei.

Trauma may cause sensory and conductive types of hearing loss. *Sensory hearing loss* is caused by disruption of the transmission of auditory pathway impulses. Projections from the cochlea run bilaterally. Thus, unilateral central nervous system injury alone should not cause hearing loss. *Conductive hearing loss* results from disruption of sound transmission from damage to the tympanic membrane, ossicles, or cochlea. Hearing loss associated with TBI is more commonly sensorineural than conductive (36). Sensorineural hearing loss is reported to occur with TBI at an incidence of 85%, and 71% in the absence of temporal bone fracture (36).

Vestibulocochlear nerve injury is common with temporal bone fractures. Of all temporal bone fractures, 80–90% are longitudinal and 10–20% transverse (13). The type of temporal bone fracture, transverse or longitudinal, provides a clue as to the injury and type of hearing loss that might result. *Transverse fractures*, which tend to result from frontal or occipital blow, have been reported to result in sensorineural hearing loss in 100% of cases (37). Such injury is thought not to be amenable to surgery (13). On the other hand, *longitudinal fractures* (which occur from temporal or parietal forces) tend to result in conductive hearing loss or mixed conductive and sensorineural hearing loss (37). The incidence of sensorineural or mixed hearing loss in association with longitudinal fracture is 88%. Conductive hearing loss associated with temporal bone fractures occurs due to either ossicular chain disruption or tympanic membrane tear (13). Spontaneous recovery is reported in 80% of patients with conductive hearing loss occurring with temporal bone fractures (38). When conductive hearing loss fails to recover spontaneously, surgery should be considered. Surgical repair is associated with excellent results for all types of conductive hearing loss (37). Disruption at the incudostapedial joint occurs in 82% of cases, fracture of the stapedial arch in 30%, and malleus fracture in 11% (39). In 75% of cases of ossicular chain disruption the posterior auditory wall is also fractured (13). Although, conductive hearing loss is more common with longitudinal fractures, sensorineural or mixed hearing loss may also occur with this type of injury.

Patient examination and hospital record review may reveal important findings often associated with cranial nerve VIII injury by looking for battle's sign, mastoid fracture, otorrhea, bleeding from the ear, and hemotympanum. Hemorrhage from the ear is a common sign of longitudinal temporal bone fracture. Visualization of the tympanic membrane can be helpful to reveal tears.

Cranial nerve VIII is tested through testing eye movements, postural responses, and hearing. These assessments and how they guide lesion localization are discussed in brief detail below.

Vestibular dysfunction may manifest clinically with vertigo, nystagmus, and/or ataxia. Vertigo, the sensation of the room spinning, is a specific symptom of vestibular dysfunction. When the eyes are open, patients see the environment move; and when the eyes closed, patients feel like they are turning or whirling in space. Abnormalities in vestibular testing can be associated with lesions in the vestibular apparatus of the inner ear, the vestibular portion of CN VIII, the vestibular nuclei in the brainstem, the cerebellum, or pathways in the brainstem (such as the medial longitudinal fasciculus) that connect the vestibular and oculomotor systems. It is through observations of nystagmus and responses to provocative tests that a clinician can narrow down the origin of the problem. Thus, nystagmus elicited with extraocular movement testing, cold water caloric response testing, Dix-Hallpike Maneuver, or a rotating chair test (Ba'ra'ny Test) are key diagnostic tests in the diagnosis of vestibular pathway injury. Accompanying signs and symptoms may also provide clues to distinguish peripheral and vestibular lesions. Peripheral vestibular lesions may be accompanied by ipsilateral hearing loss and tinnitus; while central lesions may be associated with motor and sensory disturbances of the limbs, dysarthria, dysphagia or diplopia, indicating additional cranial nerve injuries.

**Nystagmus** Nystagmus is the movement of the eye in response to stimulation of the vestibular labyrinth, retrocochlear pathways, or central vestibulo-ocular pathways. To test for nystagmus, the patient is asked to follow the examiner's finger with the eyes while the examiner's finger moves through horizontal and vertical gaze. There are two components to nystagmus: slow and fast. The slow component is caused by vestibular stimulation and is mediated through the three-neuron arc from the semicircular canals to the extraocular muscles. The fast component returns eyes to the resting position and requires a functioning cerebral cortex. As a result, the fast component will not be present in coma or under general anesthesia. If nystagmus is present, record the directions of the fast-phase and slow-down phases. Nystagmus is described clinically in terms of the direction of the *fast corrective* phase, not the direction of gaze. Nystagmus is a particularly important finding because it is generally not as performance dependent as balance and coordination tests. Electronystagmography (ENG) may be used to quantify the nystagmus and provide information on the suppressive potential of visual fixation. However, ENG is not required for the diagnosis and may be considerably uncomfortable for the patient to endure.

**Vertigo** The vertigo presentation and the type of nystagmus present are important as they can help differentiate

central (CNS) from peripheral (vestibular) origin. These characteristic features are described here. *Peripheral vertigo*, commonly presenting with vertigo and emesis, is usually characterized by horizontal nystagmus with a rotary component. The fast component points away from the affected side. Duration of peripheral nystagmus is generally minutes to weeks. Some of the causes of peripheral vertigo include: benign positional vertigo, labyrinthitis, vestibular neuronitis, motion sickness, Meniere's disease, peripheral vestibulopathy, acoustic neuroma, and perilymphatic fistula. *Central vertigo* may have more insidious onset and produce mild symptoms. Central nystagmus can occur in any direction, and dissociation of movements between the eyes is possible. In central nystagmus there is no relation between the direction of the nystagmus and the location of the lesion. In general, the following types of nystagmus are central in origin: vertical nystagmus, active nystagmus without vertigo, direction changing/unipositional nystagmus, gaze paretic nystagmus, nystagmus with disconjugate eye movement, and failure of fixed suppression. Vertical nystagmus is always central in location. Central nystagmus is generally longer in duration and may be present for years. Some of the processes that present with central vertigo are: dysfunction of the vestibular portion of CN VIII, upper and lower brainstem lesions, basilar artery migraines, vertebrobasilar ischemia or infarctions, multiple sclerosis, acute cerebellar lesions (hemorrhage or infarction), cerebellopontine tumors, seizures and spinocerebellar degeneration. Metabolic causes of vertigo may be appropriate to consider which include drug toxicity, hypoglycemia, and hypothyroidism. The response to provocative tests, as described below, may also help provide such distinction. Most causes of dizziness can be determined by a complete patient history and physical examination including some of the observations described here.

**Nylen-Ba'ra'ny or Dix-Hallpike Positional Testing** This test can help distinguish peripheral from central causes of vertigo. The patient sits on the examining table, rotates the head 45 degrees with one ear down, and the examiner supports the patient's head as the patient lays back with the head extending over the edge of the table. The patient is asked to keep their eyes open and report any sensations of vertigo, while the examiner looks for nystagmus. The maneuver is then performed with the opposite ear down. The position change causes maximal stimulation of the posterior semicircular canal of the ear that is down, and of the anterior semicircular canal of the ear that is up. With *peripheral lesions*, there is usually a few second delay in the onset of nystagmus and vertigo, which then fades away within approximately 1 minute. The nystagmus is horizontal or rotatory and does not change directions (just as with peripheral nystagmus described in the above paragraph). If the same

maneuver is repeated, there is often adaptation, so that the nystagmus and vertigo are briefer and less intense each time. In *central lesions*, the nystagmus and vertigo generally begin immediately, and do not adapt. Nystagmus that persists while in this position but is not present while sitting is indicative of a central vestibular lesion.

*Vestibulo-Ocular Reflex (VOR)* This is a simple test that can be performed at the bedside and is used to determine whether or not the vertigo is vestibular in origin. Through the VOR, rapid movement of the head produces an equal and opposite movement of the eyes. This test would only be performed when there is no suspicion of spinal column instability. The patient fixates on a target while the physician quickly moves the patient's head approximately 15°. When the VOR is intact, the eyes will remain focused immediately on the target after the head is thrust. If the patient must make corrective eye movement to see the target, the VOR is decreased. Corrective eye movements (saccade) with left and right head thrust indicate vestibular dysfunction on the left and right sides, respectively.

*Head-Shaking Nystagmus* This is nystagmus that appears after vigorous horizontal head shaking for about 15 seconds, at a frequency of approximately 2 Hz. Head-shaking nystagmus occurs when there are differences in the peripheral vestibular input reaching the central velocity storage mechanism of the brainstem. Thus, a positive head-shake test is suggestive of a peripheral lesion.

*Walking with Sudden Turns Test* This test produces veering toward the side of cerebellar or labyrinthine disease. To perform this test the patient should pivot on given points on the floor.

*Fucada Stepping Test* This test is performed by asking the patient to march in place with eyes closed for 50 steps at normal walking speed. The examiner makes note of distance and angle of displacement from starting to final standing point, angle of rotation, body sway, changes in head position relative to the body, position of the arms in horizontal or vertical directions. The final standing position is regarded as abnormal if there is more than 30° of body rotation or more than 50 cm of displacement from the starting point. Individuals with unilateral vestibular pathology often turn excessively. The test is not specific to vestibular dysfunction, but may provide a supportive finding taking other findings into account.

*Caloric Stimulation Testing* For individuals in a low neurologic functioning state, assessment of the vestibular system through the above tests is not possible. In such patients, caloric stimulation testing may be particularly

helpful for this purpose. This test is performed with the head of the bed placed at 30 degrees to have the horizontal semicircular canal in a vertical plane. The external auditory canal is then irrigated with 30 degree Celsius water over thirty minutes while direction of eye deviation and nystagmus are observed. With the intact vestibular system, the eyes tonically deviate to the side of cold irrigation, and then followed after an approximate 20 second latent period by nystagmus to the opposite side that generally lasts 1.5 to 2 minutes. The procedure is repeated using 44 degree Celsius water. With warm water irrigation the nystagmus is normally to the side of the irrigation. The normal nystagmus response to caloric testing follows the mnemonic COWS (Cold Opposite Warm Same). When there is dysfunction in the vestibular pathway this response may be reduced or absent.

Hearing loss can be caused by lesions in the acoustic and mechanical elements of the ear, the neural elements of the cochlea, or the acoustic nerve (CN VIII). There are three general types of deafness: conductive, sensorineural, and central. Conductive hearing loss results from a defect in the mechanism by which sound is transformed and conducted to the cochlea as occurs with disorders of the external or middle ear. Sensorineural hearing loss results from disease of the cochlea or of the cochlear division of the eighth cranial nerve. Central hearing loss is caused by lesions of the cochlear nuclei and their connections with the primary receptive areas for hearing in the temporal lobes.

After the hearing pathways enter the brainstem, they cross over at multiple levels and ascend bilaterally to the thalamus and auditory cortex. Therefore, clinically significant unilateral hearing loss is invariably caused by peripheral neural or mechanical lesions. On the other hand, the bilaterality of the CNS connections prevents unilateral central injury from causing significant hearing loss.

Hearing may be assessed at the bedside by seeing if the patient can hear the examiners fingers rubbed together outside of the auditory canal. Similarly, the patient may be asked to cover one ear while the examiner whispers in the other ear and has the patient repeat what is heard. Testing on the two sides is compared. If hearing impairment is detected the cause may be localized and differentiated as sensorineural or conductive using the Rinne and Weber's Tests.

*Rinne Test* For the Rinne Test, a 512 Hertz tuning fork is placed over the mastoid process (bone conduction) until the patient indicates that the ringing sound is no longer heard, and then the tuning fork is placed a few centimeters from the external auditory canal (air conduction). In this second position of air conduction, sound is normally conducted through the external and middle ear to the cochlea. Normally, the tone is heard better by air conduction, and

thus, with normal hearing the ringing should be heard again in the second position. Not being able to hear the sound again by air conduction implies conductive hearing loss. That is, the problem is in the external or middle ear. With conductive hearing loss, bone conduction is heard as it bypasses problems in the external or middle ear. Rinne Test findings in sensorineural hearing loss are the same as with normal hearing, air conduction is greater than bone conduction in both ears, except hearing is decreased in the affected ear.

*Weber Test* The Weber Test is performed by placing the tuning fork over the middle of the forehead transmitting sound via bone to the cochlea and bypassing the middle ear mechanism. Normally the sound is heard equally on both sides. In sensorineural hearing loss the ringing is not as loud on the affected side, while in conductive hearing loss the ringing is heard louder on the affected side. You can replicate this increase in sound on the side of conduction block by covering and uncovering one ear with the cup of your hand while humming.

Formal audiometry may be helpful to detect and quantify hearing loss, differentiate sensorineural from conductive loss, and guide treatment decisions. In the lower neurologic functioning individual with TBI, brainstem auditory evoked potentials can be used to test the intactness of the auditory pathway. This may be particularly important in helping guide therapy towards more visual stimuli in trying to elicit reactions. Hearing loss may pose significant obstacles to the patient and treatment team in rehabilitation and community integration that should be considered in the rehabilitation program.

Treatment of cranial nerve VIII injuries can best be discussed in terms of the 2 main problems of vestibular and hearing impairment. Treatment of vestibular dysfunction is based on the vestibular system's capacity to habituate to stimuli (13). To decrease the vestibular sensitivity, labyrinthine exercises are used that incorporate equilibrium and righting reflexes (40). Referral to a physical therapists knowledgeable in the diagnosis and treatment of dizziness related to TBI can be a valuable component in the management of this disorder. Medications commonly used for vestibular problems (such as meclazine or dimenhydrinate) are generally not helpful and are discouraged due to potential sedation, cognitive side effects, and prevention of central adaptation (13).

Significant unilateral hearing loss may be improved using a CROS (contralateral routing of signal) type hearing aid which transfers sound to the intact ear (13). Surgical correction is an important consideration for conductive hearing loss that fails to recover spontaneously. For the management of tinnitus, masking sound devices and biofeedback have both been successful in some cases (13) and may be worth consideration.

## GLOSSOPHARYNGEAL NERVE (CRANIAL NERVE IX)

The glossopharyngeal nerve serves general, visceral and special sensory functions, as well as branchial and visceral motor functions. This nerve exits from the jugular foramen in close proximity to the last three cranial nerves; therefore, lesions, especially traumatic ones, tend to affect some or all of those nerves. The glossopharyngeal nerve provides general cutaneous function and taste to the posterior one-third of the tongue, and sensation to the soft palate, pharynx, faucial tonsils, tragus of the ear and nasopharynx. Its tympanic branch supplies sensation to the tympanic membrane, eustachian tube and mastoid area. Chemo and baroreceptors are also carried by the glossopharyngeal nerve from the carotid body and carotid sinus. Its motor fibers innervate the stylopharyngeus muscle and, along with the vagus nerve, the pharyngeal constrictor muscles. Parasympathetic secretory and vasodilatory fibers innervate the parotid gland.

The incidence of glossopharyngeal dysfunction following trauma is 0.5-1.6% (8). Symptoms include loss of taste over the posterior one-third of the tongue, deviation of the uvula toward the contralateral side, decreased salivation and slight dysphagia. Examination includes testing oropharyngeal sensation and gag reflex. Loss of sensation to the posterior palate with a subsequent absent gag reflex may place the patient at risk for aspiration. Treatment for an isolated glossopharyngeal nerve injury is symptomatic, as the symptoms are usually minimal. However, injury to the glossopharyngeal nerve usually involves the vagus as well, and thus, may result in severe laryngeal and pharyngeal dysfunction. Treatment of such injuries is covered below.

## VAGUS (CRANIAL NERVE X)

The vagus nerve arises from the lateral medulla, leaving the skull through the jugular foramen with the glossopharyngeal and accessory nerves. It contains motor, sensory and parasympathetic fibers. The vagus nerve supplies motor fibers to all the striated muscles of the pharynx and soft palate except the tensor veli palatini and stylopharyngeus. Through the superior and recurrent laryngeal nerves, the vagus supplies all of the striated muscles of the larynx. Parasympathetic motor fibers supply the smooth muscle of the trachea, bronchi, esophagus and gastrointestinal tract, and cause gastrin release from the antral mucosa. It also sends inhibitory fibers to the heart muscle, slowing the heart rate and reducing the amplitude of the heart beat. Sensory fibers innervate the pharyngeal plexus, larynx, and thoracoabdominal viscera.

The incidence of vagal involvement in TBI is .05 to .16% (8), usually as the result of blunt trauma associated

with occipital condyle fractures. Bilateral vagal disruption is fatal.

To examine vagus nerve function test palate elevation and gag reflex. Injury to the vagus nerve, especially the superior and recurrent laryngeal nerves, may result in: paralysis of the palate with loss of the gag reflex, dysphagia, and aphonia with unilateral paralysis of the vocal fold. Alternative feeding techniques should be identified for those at risk for aspiration. Pharyngeal exercises may improve dysarthria in individuals with mild dysfunction (40). Glottic incompetence can be treated by procedures that augment vocal cord bulk, such as the injection of Teflon, Gelfoam or fat. More aggressive surgical procedures such thyroplasty and arytenoids adduction have been reported beneficial to those with high vagal lesions (41).

### SPINAL ACCESSORY (CRANIAL NERVE XI)

The spinal accessory nerve is a pure motor nerve with two parts. The cranial part (accessory vagal nerve) arises from the medulla, exits the skull via the jugular foramen, and in conjunction with the vagus nerve, supplies all the intrinsic muscles of the larynx except the cricothyroid. The spinal part (accessory spinal nerve) arises from anterior horn cells of the first through sixth cervical cord segments. The fibers form a trunk that ascends and enters the foramen magnum, where it joins the accessory vagal nerve before exiting the jugular foramen. After joining with the vagus nerve, the fibers split off to descend in the neck to supply the sternocleidomastoid muscle and the upper half of the trapezius.

Trauma, especially from missiles, is the most common cause of spinal accessory nerve dysfunction. Symptoms include the inability to turn the head to the opposite side, and ipsilateral shoulder drooping, resulting in shoulder dysfunction and pain.

Examination includes testing trapezius function on shoulder shrug, sternocleidomastoid on contralateral head turning, and flaring of the scapula. Aggressive physical therapy should be initiated as soon as possible. Surgical repair of the accessory nerve after sectioning may be possible in some patients.

### HYPOGLOSSAL (CRANIAL NERVE XII)

The hypoglossal nerve serves somatic motor function. It emerges from the medulla, and leaves the skull via the hypoglossal canal. It innervates the ipsilateral intrinsic tongue musculature as well as the hyoglossus, styloglossus, genioglossus and geniohyoid muscles. It is responsible for tongue protrusion to the opposite side.

Injury to the hypoglossal nerve causes dysarthria and dysphagia. Injury to the hypoglossal nerve alone

most often occurs with penetrating wounds to the neck and submental region. Ipsilateral atrophy and tongue fasciculations are noted on examination. Upon protrusion, the tongue deviates toward the lesion by the unopposed, contralateral muscles. With a supranuclear (central) lesion, however, the tongue will deviate opposite the lesion due to contralateral innervation of the brainstem.

Examination of hypoglossal nerve function involves noting tongue protrusion. The tongue deviates to the side of the lesion. Exercises for the treatment of dysarthria may help to improve tongue coordination and strength. Treatment of hypoglossal nerve injuries due to penetrating wounds is surgical, and the nerve tends to recover quite well.

## Fatigue: Assessment and Treatment

*Jonathan L. Fellus  
Elie P. Elovic*

**F**atigue is a commonly reported symptom following Traumatic brain injury (TBI), yet it is both poorly understood and challenging to treat.

The word symptom is used in contradistinction to diagnosis because fatigue in general and specifically in TBI is so problematic to define and operationalize. Since TBI is a descriptive term for a heterogeneous collection of injuries to the brain that can result in physical, behavioral, cognitive or emotional dysfunction, it has been particularly vexing to determine the origin of and how to best characterize post-traumatic fatigue (PTF). As a result, the determination of its incidence has been problematic. Some attempts to quantify its incidence in TBI have placed the range between 21 and 73 % (1, 2, 3). PTF affects not only an individual's emotional well being but may also affect potential functional recovery from brain injury. Kreutzer, Seel, & Gourley (4) reported an incidence of 46% among persons in an outpatient TBI clinic and suggested that further information needs to be gathered regarding prognostication and the efficacy of treatment alternatives. However because of its multifaceted nature, the overall burden of fatigue in this population is not precisely known. However, individuals with TBI clearly suffer from fatigue with resultant diminished functioning in multiple spheres of cognition, quality of life and activities of daily living. This

functional limitation is especially problematic because the inability to sustain purposeful, goal-directed mental effort is a key requirement for independent functioning. Clinicians who attend to persons with TBI often possess few diagnostic or therapeutic resources to offer accurate assessment and treatment. Recently, however, a number of new and sophisticated neuro-imaging tools and techniques have helped to begin unraveling the underlying pathophysiology of PTF and should soon reveal more about treatment. The following discussion will review the available knowledge concerning fatigue in the TBI population. Our intent is to simultaneously educate and increase readers' interest and understanding of fatigue; to promote research in this critical area leading to productive, multi-disciplinary efforts addressing the problem of fatigue; and to facilitate the development of treatment protocols through the identification of possible fatigue generating mechanisms. Meanwhile, the state of the art approach to managing PTF is offered.

For the following discussion, TBI will be defined using the well established definition advanced by the TBI Model Systems Task Force: "damage to brain tissue caused by an external mechanical force, as evidenced by loss of consciousness, post-traumatic amnesia, skull fracture, or objective neurological findings that can be reasonably attributed to TBI on physical examination or mental status examination" (5).

## DEFINITION

Prior to embarking on a further discussion of PTF, we develop a working definition for it. It is important to recognize that no universally accepted definition or broad consensus on a conceptual framework of fatigue in general exists. Nevertheless, discussions in the fatigue literature make a distinction between *central* fatigue, which results from dysfunction of supratentorial structures involved in mentation, versus *peripheral* fatigue, which is of a more purely physical, metabolic or muscular origin. Clearly, it is the *central* type that is of greatest interest with regard to those with isolated TBI. Beyond this dichotomy, the debate over PTF or fatigue in general has moved beyond the idea of fatigue as a unitary concept and towards a belief that fatigue is multifaceted (6, 7) with components likely arising from distinct mechanisms and brain networks (8).

Lezak's reductionist, "fatigue needs no definition" (9), may be the battle cry of the lumpers in this debate; however, such a pronouncement does little to advance our understanding of this phenomenon and for the development of effective treatment strategies. On the other end of the spectrum, Chauduri and Behan (10) carefully define PTF as ". . . the failure to initiate and/or sustain attentional tasks and physical activities requiring self motivation (as opposed to external stimulation) . . ." and they lay out an elegant clinico-anatomic, pathophysiological explication of why fatigue follows acquired brain injury. Clinical experience echoes their definition in that fatigue impacts upon cognitive function (11) and the ability to perform instrumental activities of daily living.

Historically, various surrogates, markers, synonyms and clinical imitators of fatigue have been pursued in the literature, leading the casual reader astray from a purer characterization of the fatigue that follows TBI. Yet almost paradoxically, the more focused and penetrating the research on the essence of fatigue becomes, the less singular a phenomenon it appears to be. Thus, even as one measures, correlates and localizes the fundamental components of fatigue, the syndrome or symptom cannot merely be appreciated in isolation. Rather, fatigue must be appreciated in its full context, across various domains and with the understanding that the fatigue experience is not static or constant. Ultimately, the clinical picture of PTF that emerges is colored and textured by a multitude of primary and secondary, even tertiary factors that reliably engender the principle aspects of fatigue for persons with TBI. The current discussion hopes to elucidate the most likely generators of PTF and critique the current literature as well as propose an operational definition based on the most appropriate measurement tools for its assessment.

## EPIDEMIOLOGY

Currently employed methods of surveillance for disease burden due to TBI do not collect information beyond that of the total number of emergency room visits and the total number of hospitalizations. Moreover, the vast majority of TBI's are deemed *mild* and the CDC has labeled this variant the "silent epidemic" because many such cases never receive medical attention. Consequently the magnitude of the problem of fatigue among all TBI survivors or that subset "permanently disabled" is not directly known. Disappointingly even databases developed through the comprehensive Traumatic Brain Injury Model Systems are simply silent with respect to surveillance of PTF or its consequences. Thus, TBI stands as a persistent public health burden that, despite primary prevention successes, will likely continue to grow because of the increasing sophistication and effectiveness of contemporary emergency care, further resulting in a growing *prevalence* of TBI-associated problems such as fatigue. In the vast majority of studies, PTF is evaluated predominantly by self-report—in other words, subjectively. A number of investigators over the last several decades have attempted to identify the incidence or prevalence of fatigue in the TBI population, but these studies have not always been adequately controlled for such common confounds as anxiety and depression. Lezak (9) identified fatigue as one of the "subtle" sequelae of brain damage, along with distractibility and perplexity, and compared the incidence of fatigue between those patients seen in consultation, (i.e. relatively briefly), with those enrolled in detailed, longitudinal research protocols. Forty-two percent of 50 subjects reported fatigue if examined once and 60% if examined more often. Among the group in research studies ( $n = 46$ ) the reporting of fatigue reached an astounding 98%. This study exposes how a methodological flaw can seriously compromise the estimated incidence of PTF. The marked discrepancy suggests that thoroughness of assessment is essential and that without such an approach, patients are at risk for having their fatigue go unrecognized especially as TBI severity increases and with it, cognitive dysfunction such as memory and self awareness.

Middleboe (1) analyzed a cohort of 51 patients with mild TBI and noted that 21% reported fatigue one year post injury. Olver (3) studied a longer follow-up period for 254 patients at 2 years and 103 at 5 years. The majority of these patients had suffered a severe injury as reflected by a mean Glasgow Coma Score of 5.1. Fatigue was reported by 68% at two years and 73% at 5 years. Masson (12) studied a group of 231 adults five years after injury. The sample was stratified with respect to TBI severity and in addition, a lower limb injury cohort was used for comparison. Among the four groups, 30.6% of limb injured, 35.1% of mild TBI, 32.4% of moderate TBI

and 57.7% of severe TBI subjects endorsed fatigue suggesting an association between severity of brain injury and fatigue incidence. Hillier (2) examined a cohort of 67 primarily severely brain injured patients and noted a fatigue self-report rate of 37% five years post-TBI. This number may be artificially low in light of the under self-reporting noted by Lezak especially since the overwhelming majority of patients in this study were severely injured (73%) and likely to have disabling cognitive impairments. Kreutzer et al. (4) examined the epidemiology of depression in a cohort of 722 TBI outpatients on average 2.5 years after injury and with a mean duration of unconsciousness of 10 days. The self-report of fatigue in this severely injured group was 46% and fatigue was the most frequently reported problem.

From these type of epidemiological studies based on self report, PTF ranges from 2 to 98 percent (13). What remains unclear from these reports is how fatigue impacts upon mentation or on function. Limited formal neuropsychological evidence exists to elucidate the effect of PTF on cognitive performance. In addition, it is not clear what the natural history of fatigue is, or what the associations are between fatigue and a multitude of TBI-specific factors such as length of coma, duration of posttraumatic amnesia and mechanism of injury. Finally, it is unknown how the incidence and magnitude of fatigue interrelate, affect, and are affected by other common TBI sequelae.

## ASSESSMENT

To date there is no single measurement instrument that has been validated to study PTF. Nevertheless, it is important to begin the process by assessing the *impact* of PTF. Efforts at the assessment of PTF have been complicated by its multifaceted nature. Many measures that are commonly used rely on subjective reporting. Some of the more commonly employed scales used in neurological populations are the Fatigue Severity Scale (FSS) (14), Fatigue Impact Scale (FIS) (15) and the Modified Fatigue Impact Scale (MFIS). The FSS (14) is assessed by having participants rate 9 different questions rating one's fatigue from 1 (low) to 7 (high). The FSS is the average of these 9 values. The FIS (15) is a 40-item questionnaire that the person rates from 0, no problems, to 4, severe problems. These items are grouped into three separate functional categories—physical, cognitive and psychosocial. The MFIS is a 21-item derivative of the FIS that is more commonly used in the multiple sclerosis population.

In an effort to delineate both subjective and objective assessment of fatigue Lachapelle (16) evaluated thirty subjects with TBI a mean of 44.3 months after injury and compared them to an age and gender matched healthy control group. The study purported to parse fatigue into

objective and subjective components; the paradigm for objective fatigue was a continuous thumb-pressing task. Over time, normal and TBI groups demonstrated a decline in the number of repetitions per unit of time, however the difference was statistically insignificant. The subjective evaluation of fatigue was quantified by visual analogue, the FSS and FIS scales. Despite the statistical parity on the objective measure, TBI patients demonstrated significantly greater subjective fatigue scores on the FSS and FIS versus normal controls. Likewise, Walker (13) looked at the measures of quadriceps strength and physical endurance to test those complaining of PTF versus normals and found no statistical difference. Researchers trying to characterize peripheral fatigue note the significant impact upon challenging physical actions facing those with brain trauma, such as mobility, ADLs and sustaining endurance for a given task. Brain trauma often involves lesions of central pathways governing simple and complex motor function, for instance resulting in hemiplegia, spasticity, ataxia or the upper motor neuron syndrome with various well-known positive and negative signs and static and dynamic disturbances. Given the working definition of peripheral fatigue as “any reduction of maximal force output” (17), it is easily appreciated how impaired motor and sensory (modulation) centers translate into increased energy demands and reduced efficiency of ambulation, for example, quickly resulting in a fatigued individual. Thus, while we have seen above how some effort is made to distinguish *central* from *peripheral* fatigue in theory, there remains such overlap that no specific study targeting this distinction has yet been published. We are therefore left with the crude assessment tools currently available, leaving us sliding either way on a slippery slope because even purely *peripheral* fatigue must necessarily be perceived by and processed within the context of the *central* nervous system. It should thus not be surprising that so frequent a dichotomy exists between what is measured and what is perceived.

## MECHANISMS

The biological “substrate” of fatigue in normal individuals is not known. Furthermore, the study of PTF is made more difficult by the fact that in our clinical experience this symptom does not occur in isolation but rather is part of a broader array of signs and symptoms post injury. Functional neuroimaging reflects yet another level of inquiry into the morphology of the fatigued brain, attempting to correlate anatomy with task-specific activity.

### Anatomical

Given the heterogeneity and variety of lesions from TBI, a discussion of the source of fatigue should begin with a

consideration of the underlying neuroanatomy associated with known pathophysiological mechanisms. For instance, TBI may include focal or diffuse, hemorrhagic or non-hemorrhagic, coup and contrecoup, contusional, and compressive (epi- and subdural) as well as numerous secondary and clinically superimposed causes of CNS tissue damage. Because natural traumatic forces never injure the brain in exactly the same way, the various neural circuits that support optimal cognition are differentially impaired. This leads to different degrees of cognitive dysfunction from individual to individual, further permuted by the occurrence of damage within the context of each brain's unique set of premorbid strengths and weaknesses. From a strictly statistical standpoint, the generally fatigued brain may yield a potentially infinite number of specific patterns of underperformance.

The multiple structures subserving arousal are known collectively as the ascending reticular activating system (ARAS), emanating from the brainstem and represented in each of its three divisions by the following nuclei:

Medulla: raphe and reticularis ventralis (serotonergic)

Pons: parabrachialis (cholinergic), locus ceruleus (noradrenergic), reticularis pontis oralis and caudalis and the gigantocellularis

Midbrain: pedunculopontine tegmental (PPT) and laterodorsal tegmental (LDT) nucleus (cholinergic); raphe (serotonergic) and ventral tegmental area or VTA (dopaminergic)

The outputs from these structures coalesce into two pathways, the ventral and dorsal pathways of the RAS. The ventral pathway terminates in the subthalamus and posterior hypothalamus, which in turn send histaminergic fibers to a broad array of cortical end points. In addition, the ventral pathway contains a projection via the MFB to the septal nucleus and basal forebrain, which in turn send a broad array of cholinergic fibers to the cortex. The dorsal pathway projects to the interlaminar nucleus of the thalamus from which, in turn, glutaminergic tracts emerge to project across a variety of cortical and striatocortical endpoints (18).

The ARAS is a fundamental structure maintaining arousal as a prelude to alertness and bilateral injuries in the brainstem nuclei result in loss of consciousness (19). This system, however, is a part of a larger and more complex system, which maintains sensory attention and tonic arousal. When there is sufficient diffuse damage (DAI) to tracts or pathways mediating general arousal, immediate unconsciousness continues over a period of variable duration depending on the extent of damage (see Chapter 8 in this book). Therefore, a frequent and major component of TBI is a disruption in the neuro-anatomical structures maintaining arousal through shearing of

axonal connections. DAI thus results in insufficient amounts of neurotransmitters normally released by more caudal structures reaching their targets, yielding an unstable platform from which to launch desired cognitive processes and behaviors, including fundamental elements subserving cognition such as attention and processing speed.

### Basal Ganglia

In a recent review article, the investigators Chaudhuri and Behan (10) offer the hypothesis that the basal ganglia (BG) are the neuroanatomical site at which fatigue is generated following neurological injury. Specifically, they identify the disruption of two "loops", the striato-cortical fibers and the striato-thalamo-cortical fibers, as the mechanism responsible for central fatigue. Such critical pathways have been carefully delineated over the last two decades and now reveal influential and tight connections between the striatum of BG and a key component of limbic signaling, the archistriatum or amygdala. The limbic system clearly provides a route by which unconscious, spontaneous, emotionally driven motivational forces may exert influence on the motor system, thereby altering the chances that goal-directed behaviors get initiated and sustained.

In bilateral BG damage, a lack of drive, initiation and motivation is often encountered. Termed *abulia* when severe, it may be misinterpreted or overlooked altogether when more mild and is usually identified as mere apathy by rehabilitation team members. A dopaminergic pathway called the mesencephalofrontal activating system (MFAS) projects from the VTA of the midbrain to frontal regions, especially cingulate gyrus, and drives internal states towards motivated behavior. Thus, under normal circumstances, initiation and sequential performance of a task require an internally driven mechanism integrated at the level of the BG to prepare the emotive, motor and sensory apparatus responsible for the next and subsequent set of responses. Disruption of these algorithms of the sequential task processing mechanism would have the effect of not only delaying initiation, but also preventing the seamless, well-timed execution of the target task (10).

Although direct support for their theory is lacking, if it is placed within the context of the ARAS as the "substrate" for maintaining alertness, then fatigue may represent a decrease in this normal state of alertness. How this occurs is not known; however, Whyte et al. (20) have demonstrated how difficulty sustaining arousal and attention post-TBI affects cognition. They compared a cohort of 26 TBI patients with normal controls using a visual vigilance task. The results revealed "severe TBI does result in difficulties maintaining stable performance over time in an attention demanding task, independent of specific

distracting events.” While there was no formal assessment of fatigue in the TBI cohort in this study, the authors hypothesize that this inability to sustain performance reflects declining arousal or increasingly frequent lapses of attention. In a separate paper, Whyte drew a distinction between the tonic and phasic arousal. The former term is used to describe baseline alertness and wakefulness, while the latter refers to the arousal that is demonstrated in response to stimuli or as demanded by a distinct task. This runs parallel to the concept of the ARAS as not only mediating tonic activation and arousal but also playing an important role in the ability to phasically turn on cortical tissue in an efficient manner to perform upon demand.

This concept is also reflected by Heilman and Valenstein’s (21) assertion that “brain regions . . . are essentially silent unless and until activated by release of the appropriate transmitter . . .” Thus, PTF may be conceptualized as an inability not only to activate but also to efficiently sustain and recruit cortical tissue subserving cognitive tasks.

Riese et al. (22) attempted to study the impact of central (mental) fatigue on cognition. These investigators studied eight young severely injured TBI patients more than nine months post injury. All of the patients studied had suffered not only severe but also diffuse injury and in fact one inclusion criterion was “no documented focal lesions”. Fatigue was not assessed via self report. Rather, the authors assessed the ability to sustain workload via a “continuous dynamic divided attention task”. The study findings revealed no difference between control and TBI subject groups in terms of the effect of “task load” on performance but an increased amount of mental effort was required among the TBI cohort for maintaining the task. The finding of increased mental effort among the TBI cohort was corroborated through both subjective and physiological indicators of distress. It is conceivable that this increased effort may correlate with perceived fatigue.

### Neuroimaging

A recent fMRI study by Christodoulou et al. (23) examining working memory may offer one possible explanation for the findings in both the Whyte and Riese studies. This fMRI study examined the differences in cortical activation in seven controls versus nine TBI subjects while performing the mPASAT, a progressively more difficult computation task commonly used to assess working memory. Impairments in working memory among TBI subjects resulted not surprisingly in a higher incidence of error on the mPASAT test but interestingly, fMRI scanning further revealed a more regionally dispersed and more lateralized pattern of cerebral activation. In a related case report by Hillary et al. (24), the TBI participant completed the working memory task in the fMRI both pre and post treatment

with stimulant medication (methylphenidate and modafinil). Performance improvement was observed with stimulant medication, which also resulted in decreased cerebral activation on fMRI that correlated with the patient’s self-report of greater ease in performing the task.

This increased level of cortical activation for a given task likely reflects not only inefficiency in ‘phasic’ recruitment of cortical assets but also suggests that the inefficiency results in increased metabolic demands as visualized on the fMRI images. The increased amount of cortex required per task in TBI versus normal controls is accompanied by the perception of greater mental effort as well.

Therefore, informed speculation leads us to identify motor coordination centers (basal ganglia), executive and motor planning areas (frontal circuits) and internal motivational apparatus (hypothalamus and related limbic structures) as the main arbiters of fatigue-associated behavior. When one or more of these systems is affected, individuals routinely fail to complete the execution of incremental or serial tasks that demand sustained motivation and attention.

### Functional

In seeking an all-inclusive, unifying theory of the mechanism of PTF, we cannot ignore the contribution of several, clinically encountered factors. Clinicians will certainly recognize the recurring theme of one symptom or system dysfunction reflexively exacerbating another component of the index disease. For example, mood disturbances will impact upon sleep/wake cycles which, when disturbed, tend to amplify mood disorders. Pain, (frequently encountered with comorbid multi- or craniocervical trauma), puts the individual at higher risk for mood and sleep disturbance; and conversely, those with dysfunctional mood or sleep are more apt to experience magnified pain (25–27). It is easy to appreciate how these interactions pose a mounting burden that cumulatively impedes optimal cognitive function. Perhaps, at its simplest mechanistic level, PTF represents and reflects the final common pathway’s *product* of neural processing, impaired by some combination of primary damage and secondary or tertiary factors impeding cohesive, efficient and coordinated cognitive output.

### OTHER COMPONENTS OF THE FATIGUE EXPERIENCE

In addition to primary neurological injury, there are many other factors that can impact both the functional and subjective reporting of fatigue in populations other than TBI. Since they are also found in TBI, such factors can also likely impact PTF. The following sections discuss these issues.

### Psychology/Psychiatry

Depression commonly manifests as disturbances in sleep and appetite, decreased concentration, loss of interest, fatigue, and suicidal behaviors—all of which may often be found following TBI. At least two thirds of those studied describe fatigue, low energy or listlessness, making this one of the most common somatic complaints of depression (28, 29). Kreutzer (4) and Seel et al. (30) also found fatigue to be the most common symptom endorsed by depressed individuals with TBI. Statistically, depression predicts fatigue and fatigue predicts depression in the general population.

The neurobiological dysfunction in depression consistently involves 5-HT and NE systems and the limbic-hypothalamic-pituitary-adrenal (LHPA) axis (31), again demonstrating tremendous overlap with impairments following TBI (see endocrinology section below). Many attentional and cognitive deficits seen in depression are thought to be mediated by the prefrontal cortex, which receives significant NE and 5-HT input (32). Functional neuroimaging studies have recently elucidated frontal cortical-limbic pathways critical to modulation of depression and anxiety (33, 34). Given the frequency with which frontal damage occurs in TBI, one should commonly expect psychological dysfunction with its additive burden upon cognition, especially with what is known about how these internally distracting disease states interfere with cognition in those without TBI.

### Biochemical

TBI results in a cascade of events that includes biochemical and cellular derangements. The ability to make sense of these changes is limited by the complexity of neurochemical processing in the brain. At the biochemical level, it is well known that amino acid levels are altered by TBI. Aquilani et al. (35) noted that levels of tyrosine and essential amino acids are decreased after TBI and that there is a persistent decline even upon discharge from acute rehabilitation. Two especially important amino acids for CNS function are tyrosine, a precursor to brain catecholamines, and tryptophan, an essential amino acid and precursor to serotonin. The neurotransmitter serotonin has been implicated in fatigue. The relationship between TBI disruptions in neurochemistry and the sensation of fatigue is suggested by Dwyer and Browning (36) who noted that *m*-chlorophenylpiperazine (*m*-CPP), a 5HT<sub>1A</sub> agonist, induces fatigue in an animal model, and that exercise training over a prolonged period diminished the response to this agent. Bloomstrand (37) concluded that exercise-related fatigue in the CNS was correlated to 5HT because elevated levels impaired performance whereas decreased levels improved running in an animal model. One known mechanism of tryptophan regulation provides further support for its role in central fatigue, namely

that, through competitive binding for CNS transport proteins, branched-chain amino acids (BCAA) have an inverse relationship with tryptophan levels. During exercise, the ratio of tryptophan to BCAA increases and, as shown by Blomstrand (38), giving BCAA reduces perceived exertion and mental fatigue and improves cognitive performance *after* exercise.

Agents commonly used in the clinical treatment of fatigue, such as the psychostimulants methylphenidate, dextroamphetamine, pemoline and amantadine act via the dopamine neurotransmitter whereas those currently used to treat depression elevate levels of 5HT. Additional neurotransmitters to consider include histamine, which has an arousing effect on the CNS and histaminergic fibers project diffusely to cortex as discussed above with respect to the ARAS. Clinically, pharmaceuticals with an antihistaminergic mechanism of action induce sedation and fatigue. The novel agent modafinil acts, as one of its known mechanisms, as a histamine agonist. The ARAS is known to utilize cholinergic, histaminergic, glutaminergic and serotonergic neurotransmission (18).

### Endocrine

In populations other than TBI with endocrine abnormalities, especially anterior pituitary dysfunction, a wide variety of symptoms including fatigue are reported. (39–41). Of course, no one hormonal abnormality is correlated exclusively with fatigue and there are numerous other symptoms that are manifested as a result. However in other populations, the association between endocrine dysfunction and fatigue has been particularly well documented in regards to thyroid, growth hormone (GH) and cortisol deficiencies. Deficiencies in GH has been associated with decreased bone mineral densities, (42) aerobic capacity, muscle strength, lower quality of life and cognitive impairments, in addition to increased fatigue (43, 44).

Treating these deficits has been shown to be helpful in other populations. In particular, treatment of GH insufficiency has been shown to increase lean body mass and reduce body fat (45), increase exercise tolerance (46), improve quadriceps strength (47), increase energy and mood (48), increase activity and alertness (49) and an individual's sense of well being and quality of life (50).

The importance of this issue is of course dependent on the overall incidence of endocrine dysfunction associated with TBI. It has been known for nearly one hundred years that brain injury may produce endocrine dysfunction but until recently was considered a relatively rare event (51). Escamilla and Lissner (52) reported an incidence of only 0.7% (4 of 595 TBI subjects) manifesting endocrine dysfunction while Kalisky et al. (53) reported an incidence of only 4% and Edwards and Clark (54) reported a small percentage of TBI cases were associated

with hypopituitarism. However, more recently, the magnitude of the problem has become more evident. Benvenega et al. (55) documented 367 cases of head trauma associated with hypopituitarism. Among these patients, 15% were not diagnosed with pituitary dysfunction till greater than 5 years after injury.

In the past few years, posttraumatic endocrine dysfunction has been studied in a prospective manner. As a result of this work the scientific and medical communities are becoming more aware of the issue of posttraumatic endocrinopathy. Kelley et al. (56) reported that 8 of 22 individuals with TBI had endocrine abnormalities when they underwent provocative testing. Lieberman et al. (51) studied 70 patients with TBI in a postacute brain injury program and identified endocrine abnormalities in 59% of subjects: GHD in 14%, hypothyroidism in 21% and low morning basal cortisol in 45%.

These studies in TBI however only identified the presence of endocrine abnormalities. The relationship between endocrine abnormalities and fatigue in the individual with TBI is an area that is currently under study. In pilot work Doppalapudi et al. (57) have demonstrated an inverse relationship between fatigue and Insulin Growth Factor 1 (IGF1) in persons with TBI. IGF1 is commonly used as a screening measure for GH deficiency because of their correlation. In addition we have noted a direct correlation with a.m. cortisol and subjective reporting of fatigue. While still preliminary, the relationship between endocrinopathy and PTF is exciting as this may potentially lead to an effective treatment.

### Sleep

In general, disturbances of sleep may be characterized as insomnia (deficient sleep initiation or maintenance), hypersomnia (excessive sleep or what is referred to as excessive daytime sleepiness—EDS), and altered sleep-wake cycles (circadian pattern disarray). Sleep disturbances following TBI range in frequency from 36% to 70% (58,59). Several key CNS loci regulate sleep patterns, including brainstem, basal forebrain and hypothalamic nuclei—all areas commonly disrupted in brain trauma. Serotonin and acetylcholine are the two common substances involved. The comprehensive study of posttraumatic sleep disorders is complicated by the frequently encountered comorbidities of depression, anxiety, substance abuse, chronic pain and medication use, all of which independently exert negative influences upon normal sleep. Also not to be overlooked is whether one may implicate a prior (perhaps undiagnosed) sleep disorder as the proximate cause of the brain injury itself. For instance, falling asleep while driving is not uncommon, especially in persons with sleep apnea.

Controversy exists over whether severity of TBI is directly correlated with increased prevalence of insomnia.

Clinchot et al. (60) and Fitchenberg (61) showed an *inverse* relationship and Cohen (62) noted increased prevalence with increasing TBI severity. Some researchers have postulated that the reason for this counterintuitive finding lies in the fact that the severely brain injured likely underreport and the milder brain injured are more aware of their problems and therefore over report or perhaps overly attribute their fatigue to poor sleep. Clinchot et al. (60) examined 100 TBI patients during inpatient rehabilitation and followed them up again one year later. These authors reported that 50% of TBI subjects complained of difficulty sleeping. Of this sub-group 64% admitted waking up too early, 25% experienced increased sleep time, and 45% reported difficulty falling asleep. In this same cohort of 100 patients, 63% reported significant problems with fatigue. Interestingly, 80% of those admitting to sleeping difficulty also admitted to fatigue as a problem. Cohen et al. (62) have pointed to a temporally differentiated sleep disruption pattern whereby difficulty initiating or maintaining sleep tends to occur soon after TBI and excessive daytime sleeping (EDS) tends to occur more often over the months and years following TBI. Controversy also exists over whether TBI may cause a secondary narcolepsy (see Chapter 32 in this book on sleep disorders).

Several varieties of disturbed sleep-wake cycles are seen—the delayed, advanced and disorganized types—with very little literature available specific to the TBI population. Schreiber et al. (63) described sleep-wake disturbance in 15 persons with mild TBI and without history of apnea syndrome, neurological or psychiatric illness. Using polysomnography and actigraphy (activity detection device), more than half were found to have delayed-phase and the rest disorganized type.

Thus, the brain injured population experiences disruption in normal sleep physiology. Specific abnormalities discovered include reductions in REM sleep, sleep spindles, vertex sharp waves and K complexes. These electroencephalographic findings point to an overall decrease in total sleep time, a disappearance of the deeper stages of sleep as well as more frequent awakening (64). Conversely, it has been also found that as cognition improves, so too does REM sleep architecture. There also appears to be an association between cognition and sleep architecture among TBI patients across time so that as the former improves, so too does the latter (65). In addition, it has been well described in the normal, non-TBI injured population, that as sleep time declines and sleep quality worsens there is a decline in cognitive performance as well as an increase in fatigue (66).

Overall, while sleep disturbance after TBI is common, there is little work directly relating this disturbance with fatigue. However, it is likely that the relationship between sleep and fatigue observed in other populations applies to persons with TBI. While these findings are

perhaps predictable, unfortunately even in the normal population we do not know the mechanism whereby sleep reduces the self-perception of fatigue and enhances cognitive performance.

### MANAGEMENT OF PTF

As is the case for most medical conditions in general and neurological conditions in particular, complete cure remains elusive. Nevertheless, it remains critical to start on the road to cure by addressing the fundamentals, relying upon the interdisciplinary treatment team when available. Routine performance of a home exercise program not only optimizes cardiovascular health and physical well being but secondarily enhances important emotional and immune system functioning, which in turn may play important roles in the fatigue experience. Classic rehabilitation practice includes instructing the fatigued individual in compensatory strategies to conserve “energy” and can be tailored to one’s specific functional requirements as they intersect with the particular areas of cognitive functional deficit. The instruction may be as simple as the admonition to *pace* oneself. Psycho-education frequently comprises teaching the person with PTF (and involved caregiver) how the clinical sequelae of focal and diffuse injuries alter the brain’s ability to successfully perform certain tasks that consistently engender fatigue. Therefore, clients may learn how to prioritize activities to meet the goals of daily functioning. When efforts fall short, personal expectations may need to be reconciled with actual abilities and performance (see below). Attempts should be made to counsel those with PTF about dietary habits, with the goal of both weight reduction (given the frequency of post-TBI weight gain) and energy efficiency. At a minimum, obtaining a sleep history should lead to counseling about basic sleep hygiene (see Chapter 32 in this book). When appropriate, more in-depth investigation with polysomnography may reveal a treatable sleep disorder at the root of PTF. As alluded to in the endocrine section, serum hormonal screening may reveal a remediable imbalance although too few studies exist to predict how much success may be expected from a neuropharmacoenocrinologic intervention.

Formal psychiatric care or psychological counseling may be needed to minimize the influence of psychological distress upon cognition and fatigue behavior, through treatment of anxiety and depressive states. Pharmacological management by a professional knowledgeable in TBI leads to the best choice aimed at neutralizing internally distracting states while often parsimoniously addressing other sequelae of TBI such as headache, irritability, perseveration and sleep disturbance. Practically, our bias is to use the most activating of antidepressants

such as fluoxetine, bupropion (whose putative dopaminergic action may also address abulic features), venlafaxine at higher (more noradrenergic) doses, protriptyline and the latest agent, duloxetine, with a novel mechanism of selective noradrenergic and serotonergic reuptake inhibition.

Once modifiable factors have been addressed and conservative measures fail, the first practical pharmacological approach to PTF is to substitute for or eliminate those agents that cause fatigue itself or potentiate any of the common components of PTF. One of the most common obstacles to optimizing efficient cognitive function is the often inappropriately prolonged use of anticonvulsants (67–69) (see Chapter 26 in this book). If post-traumatic epilepsy exists, the least sedating and cognitively debilitating choice of drug must be pursued. Some literature even suggests that one anticonvulsant, lamotrigine, may even be *activating*. Commonly used gastric promotility, anti-spasticity, psychoactive and antihypertensive agents may also hamper optimal cognitive and behavioral (e.g. motivational) function (70).

Regarding clinical use of drugs targeting fatigue, most of the information and experience comes from their use for sequelae other than PTF and from the treatment of fatigue in other disease states. Thus, amantadine has been used sometimes with dramatic effect in TBI to improve various facets of the fatigue experience (e.g. arousal, abulia) and long ago showed efficacy in treating the fatigue associated with MS (71, 72). Numerous papers have reported on the use of methylphenidate, dextroamphetamine, and amantadine to treat cognitive deficits secondary to brain injury and fatigue in other populations. Brietbart and associates (73) demonstrated the benefit of methylphenidate and pemoline in HIV-related fatigue, whereas Wagner and Rabkin (74) reported a similar benefit of dextroamphetamine. Emonson and Vanderbeek (75) reported that dextroamphetamine was also useful for flight crews flying during Desert Shield.

The “classic” stimulants enjoy widespread use in TBI but few, if any, well-designed and powered studies have specifically named PTF as the dependent variable despite the intuitive connection. Until such studies become available, dosing remains mostly symptomatic, aimed at improving function and quality of life. We use short-acting methylphenidate (MP) and dextroamphetamine (DAA), dosed in accordance with their relatively short half-lives, to coincide with therapy sessions or periods of important activity. Long-acting preparations clearly have many advantages but cost remains a major drawback. While these drugs (including *pemoline*) enhance catecholaminergic activity in general, a newer agent, *atomoxetine* is noradrenergic-selective. With this class of stimulant drugs, clinicians should heed the typical cautions (though not seen clinically to a significant degree) (76) to monitor blood pressure and heart rate at a minimum.

The novel wake-promoting agent *modafinil* is known to less-likely cause psychomotor agitation than the classic stimulants, reflecting animal studies showing activation of more subcortical, particularly hypothalamic regions. Originally approved for the treatment of narcolepsy and, more recently, for shift work sleep disorder and under-treated sleep apnea, it does not activate dopaminergic pathways but seems to exert at least part of its action through histaminergic stimulation. Modafinil has been reported to be useful in various populations with neurological disorder including stroke, MS, depression, Parkinson disease and schizophrenia (77). It has also been shown to reduce the fatigue associated with certain medications possessing a sedative side effect.

While its use, too, is often cost-prohibitive, modafinil together with atomoxetine have the distinct advantage of being less *scheduled*, making prescription refills possible and theoretically reducing the risk of medication abuse, which is of particular concern in the largest TBI demographic.

It remains unclear whether treatment with such medications actively ameliorates dysfunction at the level of the supposed fatigue generator, at the behavioral or output level, at the perceptual level; or simply mitigates one to several of the secondary inputs to the ultimate fatigue experience. Given this lack of hard data, the therapeutic relationship may be enhanced through the suggestion that rational trials of complementary or alternative remedies (nostrums?) may, so long as they are not patently harmful, be beneficial. Examples in this category include piracetam (a non-FDA-approved nootropic widely used outside of but obtainable from certain compounding pharmacies in the US), acupuncture and various herbal preparations.

Chapter 57 in this book is dedicated to the pharmacological properties of herbal medication and the readers are referred to that section for an in depth discussion of the material. However, as these agents are becoming more widely used by the medical community (78) and being recommended for the treatment of fatigue (79) a brief discussion is warranted.

Ginkgo Biloba (80) has been suggested as a treatment for many different conditions in numerous populations with suggested doses ranging from 120 to 240 mg a day. Some evidence of its efficacy in the treatment of Chronic Fatigue Syndrome has been demonstrated (81). Ginseng is a complex alternative medication that consists of many compounds and has been suggested to exert its effect through activity on nitric oxide (82). Work by Sorensen and Sonne (83) demonstrated that a dose of 400 mg resulted in improved reaction time. Acetyl-L-carnitine in doses of 1500mg twice a day has been suggested to be beneficial in energy issues and cognitive function post TBI (84). In animal studies it has been shown to be active in the cholinergic system (85) as well as having a neuroprotective effect

on brain cells (86). Citicholine (CDP-choline), which readily crosses the blood brain barrier, dissociates to the acetylcholine precursor choline (84). It has a demonstrated neuroprotective effect and has been widely used in Europe and Asia in the treatment of patients with stroke and TBI. A study by Leon-Carrion demonstrated an improvement in both attention and vigilance (87), with suggested dosing ranging from 1–3 grams per day (84).

## FUTURE DIRECTIONS

The cause of PTF has not been demonstrated to uniquely follow from damage to one particular anatomic locus. The work of Christodoulou et al. (23) and Hillary et al. (24) suggests that neuroimaging may at sometime in the future be better able to correlate deficits in function with morphology. In addition, as neuropharmacological interventions improve and the potential to target medications to specific abnormalities becomes more developed, better treatment outcomes may be obtained. The potential for the use of imaging modalities to select pharmacologic interventions and to predict effectiveness is an exciting prospect. In addition, improved management of endocrine abnormalities, cognitive deficits, mood and sleep disorders may also lead to improved treatment outcomes.

Additional efforts to establish the relationship between fatigue and well known TBI-related deficits, particularly arousal, attention, vigilance, and memory will be critical. The future holds tremendous promise in uncovering the mechanisms of fatigue generation after TBI through a combination of neuroimaging, pharmaceutical interventions and traditional neuropsychological test batteries.

Finally, individuals with TBI have numerous medical issues that differentiate them from other patients who have fatigue. Improvements in the treatment of spasticity, endocrine abnormality, sleep disturbance and mood disorder are just some of the areas where better medical management may make a substantial difference in the nebulous area of the treatment of fatigue associated with TBI.

## Sleep Disturbances: Epidemiology, Assessment, and Treatment

*Lora L. Thaxton*  
*Amish R. Patel*

### **SLEEP DISTURBANCES IN TBI: EPIDEMIOLOGY, ASSESSMENT, AND TREATMENT**

**Objectives:** Sleep disturbances in people with traumatic brain injuries, although quite common remains a problematic management issue for caregivers. This chapter will review the epidemiology of sleep disturbances in this population, sleep architecture, sleep neurophysiology, the biochemical pharmacology of sleep, assessment measures and treatment, both nonpharmacologic and pharmacologic. This information will hopefully assist in the decision-making processes of caregivers managing individuals with traumatic brain injury and sleep disturbances.

#### **EPIDEMIOLOGY**

Sleep disturbances occur commonly in patients whom have suffered a traumatic brain injury. The patients may experience sleep disturbances during all stages of recovery. Occurrence rates for sleep disturbances following recent TBI range from 36% (1–3) to 81.2% for hospitalized patients, and 72.7% for discharged patients (4). Disorders of initiating and maintaining sleep (DIMS) were more common among hospitalized patients with recent brain injury. Disorders of excessive somnolence (DOES) were more common in post acute injured patients (4). The total

cost for treatment of insomnia in the U.S. taking into account lost productivity and insomnia-related accidents, may exceed \$100 billion per year (5). Patients whom have suffered a brain injury usually will experience difficulties in many realms of their lives including personal, professional, social, and avocational. Insomnia and sleep disturbances may compound these difficulties due to the fact that disordered sleep can have adverse behavioral and cognitive consequences. Insomnia in the absence of brain injury has been associated with increased absences from work (6), increased health care costs/utilization, and social disability (7). Mahmood et al. (206) hypothesized that TBI patients may experience sleep-related cognitive deficits even without meeting the formal diagnosis of insomnia.

#### **DEFINITIONS OF INSOMNIA**

Primary insomnia is sleeplessness that is not attributable to a medical, psychiatric, or environmental cause.

Secondary insomnia, more commonly diagnosed, is the result of an underlying medical, psychiatric, or environmental condition. Acute insomnia refers to the onset of sleep difficulties caused by emotional or physical discomforts. Acute insomnia could be considered a subset of secondary insomnia.

Sleep-onset insomnia refers to an extended time from going to bed until falling asleep. Circadian

rhythm disorders are considered a subset of sleep-onset insomnias (8).

### CLASSIFICATION OF SLEEP DISORDERS

The International Classification of Sleep Disorders categorizes sleep disturbances as dyssomnias or disorders that result in insomnia or excessive sleepiness; parasomnias or disorders of arousal, partial arousal, or sleep stage transition; and sleep disorders associated with medical or psychiatric disorders (9). An extensive review of the medical conditions that can cause insomnia is beyond the scope of this chapter. However, medical conditions should be considered in patients with sleep difficulties. Table 32-1 includes the most common disorders in each category.

Sleep related breathing disorders are commonly divided into 3 categories: obstructive sleep apnea (OSA), central sleep apnea (CSA), and mixed sleep apnea (11). Obstructive sleep apnea is characterized by periodic apnea

and asphyxia from upper airway obstruction or collapse in the pharynx that continues despite continued respiratory effort. Central sleep apnea is defined as the lack of air-flow accompanied by the lack of respiratory effort. Mixed apneas have components of both obstructive and central apneas (11). Symptoms related to sleep apnea include excessive daytime sleepiness and cognitive difficulties such as impaired memory, loss of judgment, inability to concentrate, irritability, and depression. These symptoms are often present in TBI patients in the absence of sleep apnea making clinical diagnosis difficult (200). Secondary cardiovascular morbidity associated with sleep-related breathing disorders includes systemic and pulmonary hypertension, cardiac arrhythmias, cor pulmonale, stroke, and sudden death (12). Other factors that may be present in the TBI population contributing to fatigue and excessive daytime sleepiness include: electrolyte disturbances, hydrocephalus, occult infection, seizures and endocrine disorders (200).

Webster et al. (200) is one of the first studies of sleep apnea in the traumatic brain injured population.

Restless legs syndrome (RLS) is characterized by unpleasant sensations in the legs or feet that are temporarily relieved by moving the limbs. Symptoms increase in the evening, especially when a person is lying down and remaining still. The dysesthesias cause difficulty falling asleep and are often accompanied by periodic limb movements (13).

Periodic limb movement disorder (PLMD), is characterized by bilateral repeated, rhythmic, small-amplitude jerking, or twitching movements in the lower extremities, and less frequently, in the arms. These movements occur every 20 to 90 seconds and lead to arousals usually not perceived by the patient. The patient complains of not feeling rested. The bed partner often reports these movements. This condition is more common in older individuals (14).

TABLE 32-1

#### Dyssomnias

Intrinsic sleep disorders arising from bodily malfunctions:

- Psychophysiological insomnia
- Obstructive sleep apnea
- Central sleep apnea
- Restless legs syndrome (RLS)
- Periodic limb movement disorder (PLMD)

#### Parasomnias

Group of disorders of arousal, partial arousal, and sleep-stage transition:

- Sleep-walking (somnambulism)
- Sleep talking (somniloquy)
- Sleep terrors
- Nightmares
- Teeth grinding (bruxism)
- REM sleep behavior disorder (RBD)
- Enuresis

#### Medical and psychiatric

- Anxiety
- Chronic pain
- Alcoholism
- Parkinsonism
- Dementia/delirium
- Depression
- Gastroesophageal reflux
- Chronic obstructive pulmonary disease
- Asthma
- Atherosclerotic cardiovascular disease
- Diabetes mellitus
- Thyroid disease (10)

### TREATMENT OF SPECIFIC DYSSOMNIAS OBSTRUCTIVE SLEEP APNEA

The treatment of Obstructive Sleep Apnea partly depends upon the severity of the sleep-disordered breathing. The severity of OSA is defined arbitrarily and differs among centers. The apnea-hypopnea index (AHI) has been used to grade severity of apnea. AHI of 5 to 20/hour is mild apnea; 20 to 60/ hour is moderate apnea; and greater than 60 is severe apnea (137).

Patients with mild apnea have a wider variety of options, while those with moderate to severe apnea should be treated with nasal continuous positive airway pressure (CPAP) (137, 138). CPAP works by splinting the upper airway and preventing soft tissues from collapsing resulting in improvements in apneas and normalizing oxygen saturation (138). The most common side effects of CPAP are dry mouth, rhinitis, and sinus congestion

(138). These can be treated effectively with humidification, antihistamines or nasal steroids. Unfortunately, compliance is a major problem.

Dental devices act by moving the tongue or mandible forward. They can be effective with an AHI of less than 40/hour (139). Dental devices are appropriate first line therapy in mild OSA and can be used as an alternative if the patient does not improve with CPAP (139).

Correction of the upper airway is generally recommended only for patients in whom CPAP has failed, patients who refused to consider CPAP, or those who have very mild OSA (AHI less than 10/hour) (140). The resection of the uvula and soft palate known as uvulopalatopharyngoplasty (UPPP) is effective in about 40% of patients (140). Predicting which patients will benefit from this procedure is impossible. Tracheostomy is another surgical technique that is effective by passing the obstruction. This procedure is indicated for very severe OSA especially when the patient does not tolerate CPAP or has cor pulmonale (140).

### RESTLESS LEG SYNDROME

Patients with Restless Leg Syndrome (RLS) who are sensitive to caffeine, alcohol, or nicotine should avoid these substances (141). Some patients may benefit from different physical modalities, such as hot or cold baths, whirlpool baths, limb massage, vibratory or electrical stimulation of the feet and toes before bedtime (141). Supplementation to correct vitamin deficiencies, electrolytes, or iron may improve symptoms in some patients. Patients with prominent varicose veins in the legs may benefit from TED hose.

Continuous pharmacologic treatment should be considered if patients complain of RLS symptoms at least three nights each week (142). Dopaminergic agents are first line treatment. Levodopa with carbidopa has been shown to improve sensory symptoms and periodic leg movements of sleep (PLMS) in primary RLS and in secondary RLS due to uremia (143). Other dopamine agonists such as Pramipexole, Pergolide, Ropinirole hydrochloride, have been used to treat RLS. Benzodiazepines such as Clonazepam have been shown to ease sensory symptoms and PLMS in RLS (143). Opioids have been used also successfully in decreasing symptoms of RLS (144). Gabapentin is indicated for patients whose symptoms include pain, and/or neuropathy (144).

### NARCOLEPSY

Nonpharmacologic treatment consists of sleep hygiene. Most patients improve if they maintain a regular sleep schedule usually 7.5 to 8 hours of sleep per night (145). Patients with narcolepsy should avoid heavy meals and alcohol (146). A well-designed exercise program can be

beneficial and stimulating (147). Encourage children to participate in after-school activities and sports. School personnel should have the child with narcolepsy refrain from activities if he or she appears drowsy.

Pharmacologic treatment of narcolepsy involves central nervous system stimulants to increase wakefulness, vigilance, and performance, and depressants to reduce cataplectic attacks. Modafinil, an alpha 1-agonist, has been used for several years in Europe to treat narcolepsy and was approved in the United States in 1999 (148). The mechanism of action is not well understood, but it does not appear to alter levels of dopamine or norepinephrine (148). Methylphenidate, the most frequently used stimulant, has been shown to improve sleep tendency in a dose-related fashion (148). Pemoline, the initial drug of choice in children younger than seven with narcolepsy, is a less potent amphetamine that also improves excess daytime sleepiness (EDS) and has relatively little effect on blood pressure (149, 150). Antidepressants such as clomipramine and fluoxetine have been shown to reduce the frequency of cataplexy in narcolepsy.

### TREATMENT OF PARASOMNIAS SLEEP WALKING AND SLEEP TERRORS

Sleepwalking and sleep terrors, especially in children, usually do not necessitate treatment, other than by identifying and minimizing risk factors. Risk factors include: sleep deprivation, pregnancy, menstruation, and specific medications, including psychotropic drugs (eg, lithium carbonate and agents with anticholinergic effects) (151,152). Reports of polysomnographically confirmed cases indicate that most adult cases are not causally related to a psychiatric disorder, although stress can have a contributory role (153). However, in cases involving sleep-related injury (usually in adults), pharmacotherapy is necessary and can be lifesaving. Long-term nightly treatment with a benzodiazepine has been found to be safe and remarkably effective in adults with sleepwalking, sleep terrors, and other parasomnias; the incidences of side effects and misuse or abuse are low (154). Clonazepam (Klonopin), 0.25 to 1.5 mg taken 1 hour before sleep onset, is usually effective. Alprazolam (Xanax), diazepam (Valium), imipramine hydrochloride (Tofranil), and paroxetine hydrochloride (Paxil) also may be used. Use of self-hypnosis techniques can be effective in milder cases in both adults and children. Sleepwalking and sleep terrors are not usually controlled without the treatment of a concurrent psychiatric disorder (152, 153).

### REM SLEEP BEHAVIOR DISORDER

Clonazepam (0.5 to 1.5 mg taken at bedtime) is remarkably effective in controlling both the behavioral and the

dream-disordered components of REM sleep behavior disorder. The long-term efficacy and safety of this regimen have been established (154). In addition, maximizing the safety of the sleeping environment should always be encouraged.

### NOCTURNAL SLEEP-RELATED EATING DISORDERS

Treatment of sleep-related eating is directed at controlling the underlying sleep disorder (155). For cases related to sleepwalking and restless legs syndrome with periodic limb movements, monotherapy or combined therapy with dopaminergic agents (levodopa with carbidopa [Sinemet]), benzodiazepines (clonazepam), and opiates (codeine) can be effective. Fluoxetine hydrochloride (Prozac) and bupropion hydrochloride (Wellbutrin) can also be effective as adjunctive treatments.

### BRUXISM

Psychotherapy has been used to treat bruxism. The belief that bruxism is linked to stress and other emotional and psychological factors gives rise to a variety of psychotherapeutic approaches (156). For instance, calmness and self-confidence, may be fostered by listening to progressive relaxation, visual imagery, or autosuggestion tapes just before going to sleep (157). Another psychological approach to stress reduction resorts to instrumentation. During bruxism, the relevant muscles are active, and this increased activity or tenseness can in turn be measured with an electromyograph (EMG: electro = electric; myo = muscle; graph = record). During treatment sessions at home or the laboratory, the patient sits or reclines comfortably. One or more pairs of recording electrodes are then attached to the surface of the skin, in close contact to appropriate muscles (e.g., masseter muscles). These electrodes transmit information about the level of muscle activity to a computer monitor. The patient is instructed to consciously lower that level below a threshold line (also visible on the screen). Gradually, by becoming alert to the presence of muscle tension, patients may develop techniques for reducing that tension, and hence, bruxism.

One problem with this approach is the expense of the machinery and expert guidance. Another problem is that muscles can be tense for a variety of reasons, and not simply because patients grind or clench. An unpleasant recollection, for instance, may result in a high reading, although it may have nothing to do with bruxism. Moreover, as in the case of many other psychotherapeutic approaches, the training takes place in the daytime, when the patient is awake and when his behavior is under conscious control.

It is not at all clear that such learning is transferable to the unconscious, sleeping brain.

The main problem is the lack of evidence that EMG feedback benefits the patient. In one study, for example, subjects undergoing this treatment for two weeks, along with a program of listening to relaxation tapes, seemed to brux no less than control subjects (who received no treatment) while they were receiving this treatment, or six months after treatment ceased (158).

Another controversial approach is the so-called masked negative practice, a scholarly variation of the folk principle of reverse psychology. Here the patient is told to voluntarily clench the jaw for five seconds, relax it for five seconds, and repeat this procedure five times in succession, six different times a day, for a duration of two weeks (159). Alternatively, the duration of the clenching period may be individually tailored to each patient, with each clench continuing to the point of discomfort (158). This technique involves little or no cost and it does not interfere with the patient's sleep. But, by itself, this approach damages the teeth and may aggravate other bruxism symptoms (160). Notwithstanding early enthusiastic clinical reports, at the moment the evidence for the effectiveness of this approach is meager at best. Pierce and Gales study shows that subjects undergoing this treatment performed no better than controls, while they were receiving the treatment or six months after treatment ceased (158).

Splints are by far the most common treatment regimen for bruxism. Much current research on the treatment of bruxism has been centered on the use of such dental appliances. Many other researchers insist, in fact, that the splint only provides a measure of protection for the teeth, and, in the case of grinders, a moderation of the sound. Some patients find the splint uncomfortable to wear, remove it during sleep, and it may negatively affect one's bite, cause tooth decay, and lead to degenerative joint disease of the temporomandibular joint (161).

In the treatment of bruxism, sleep feedback may involve electromyographic (EMG)-activated alarm (162). Bruxism involves tensing of certain facial muscles. This tensing causes an increase in electrical activity of the muscles, which can in turn be recorded by an electromyograph. The electrodes of this instrument are placed on the facial area where these muscles are located. When the tenseness exceeds a certain predetermined level, the alarm goes off. The loudspeaker can be free standing, or, to prevent waking others, connected to earphones that the patient wears during sleep. This approach is sensible and is fairly unobtrusive, the patient needs not insert anything into the mouth, but needs only attach electrodes externally to the face. On the other hand, this procedure may fail to correct any bruxing behavior, which is associated with muscle tension lower than the predetermined intensity or duration threshold (158, 162). Another obvious problem is that muscle tension may occur in the absence of bruxism.

## SLEEP OVERVIEW

The words sleep and somnolence are derived from the Latin word *somnus*; the German words *sleeps*, *slaf*, or *schlaf*; and the Greek word *hypnos* (15). Hippocrates suggested a humoral mechanism for sleep; sleep was induced by the retreat of blood and warmth into the inner body. Aristotle thought sleep was related to food and heat (15).

Loomis, an American physiologist, and colleagues made the discovery of different stages of sleep reflected in EEG changes in 1937 (16). Aserinsky and Kleitman discovered rapid eye movement (REM) in the 1950's at the University of Chicago (17).

A comprehensive review of sleep architecture is beyond the scope of this chapter. A brief overview is provided.

Sleep is divided into two stages based on behavioral and physiologic characteristics: rapid eye movement (REM) and non-rapid eye movement (NREM).

REM sleep accounts for approximately 20–25% of total sleep time after the age of two years (18). REM sleep is further divided into 2 stages: tonic and phasic. A desynchronized EEG, hypotonia or atonia of major muscle groups, and depression of monosynaptic and polysynaptic reflexes characterizes the tonic phase. The phasic tone is discontinuous and marked by bursts of REM (with rapid eye movements both horizontal and vertical), myoclonic twitches of the limbs and face, and autonomic lability with irregularities of heart rate and respiration with variable blood pressure (19). PGO (ponto-geniculo-occipital) spikes also occur that are not normally seen on polysomnography. PGO activity is a phasic feature of REM sleep, generated in the pons and projected through the lateral geniculate body and other thalamic nuclei to the occipital cortex. It is of 2 types: Type I PGO activity is independent of eye movements, and Type II occurs simultaneously with eye movements (18). Dreams and fragmented images have been associated with PGO spike activity (18).

During REM sleep the brain is very active metabolically, physiologically, and psychologically. This is a result of central activation because the brain neither depends on external stimuli nor expresses a motor output in response to the activation (65). Some authors believe that REM sleep is important to particular brain metabolic processes because of this central activation (65).

NREM sleep accounts for 75–80% of sleep time in adults. It is divided into 4 stages based on EEG criteria. Stage I equals 3–8% of sleep time; Stage II equals approximately 45–55%, Stage III and IV combined equals 15–20% and are described as slow-wave sleep (SWS) (20). Table 32-2 summarizes the distinct differences in the 4 stages.

K complexes are composed of an initial sharp component followed by a slow component. Sleep spindles are episodically occurring rhythmical complexes occurring

**TABLE 32-2**  
*Distinct Differences in NREM Sleep Stages*

STAGE 1

STAGE 3
Arousal threshold high
Delta waves = 20–50%
STAGE 4
Delta waves = >50%
(19,30)

with frequency of 7–14 cycles per second. They are grouped in sequences lasting 1–2 seconds and can occur alone or can be superimposed on K complexes. They usually arise from gamma-aminobutyric acid (GABA)-ergic neurons in the reticular thalamic nucleus. On scalp recordings, spindles occur maximally over the frontal and vertex areas (18). Sleep spindles may also be found in Stage 3 and 4 NREM sleep or even in REM sleep. They are most characteristic of Stage 2 NREM sleep (19).

Delta waves are high voltage waves (greater than or equal to 75 microvolts), with a frequency range of .5–4 hertz (19,30). Thalamocortical cells are most capable of generating delta or slow waves, but other areas such as the anterior hypothalamus, preoptic region, and basal forebrain are also involved (18).

## ONTOGENY OF SLEEP

Newborns spend about 2/3 of their life sleeping. When they fall asleep they immediately go into REM sleep that is accompanied by restless movements of the arms and legs. At 3 months of age, the REM-NREM cycle is established. Polyphasic sleep progresses to biphasic sleep in preschool kids, and moves to monophasic sleep in adulthood (20). REM sleep patterns remain stable in adults. However, the pattern of REM sleep seen in the young adult with progressively longer periods is not seen in the elderly. Their REM sleep is more equally distributed over the course of the night (21). The proportion of REM sleep tends to decline with deterioration in cognitive function and with specific organic mental disorders (22,23).

## PHYLOGENY OF SLEEP

Many studies have been performed to determine if other mammals have sleep stages. The purpose of these studies is to understand the physiologic and anatomic correlates

of sleep as you ascend the ladder of phylogeny. Tobler (24) concluded that sleep is homeostatically regulated, in a strikingly similar manner, in a broad range of mammals.

Mammals can be long or short sleepers. Small animals that have a high metabolic rate; also have a shorter life span and sleep longer than larger animals with slower metabolic rates (25). Smaller animals also have a shorter REM-NREM cycle. Both vertebrates and invertebrates display sleep and wakefulness (26). Birds show EEG activity of sleep but their REM-NREM cycles are very short (27).

### SLEEP NEUROPHYSIOLOGY

Effector neurons are the neurons directly leading to the production of different REM sleep components. Most of the physiologic events of REM sleep have effector neurons located in the brain stem reticular formation, with important neurons concentrated in the pontine reticular formation (PRF). As REM sleep stages are approaching the PRF neurons undergo depolarization and once reach threshold will generate action potentials. Their discharge rate increases as REM sleep is approached and the high level of discharge is maintained throughout REM sleep (28). Neurons in the midbrain reticular formation, originally described as the ascending reticular activating system, are especially important for EEG activation (28). It is also thought that cholinergic neurons (by excitation of the brain stem reticular neurons), and monoaminergic neurons (using serotonin and norepinephrine) contribute to EEG activation (28). Cholinergic compounds have excitatory actions on approximately 80% of PRF neurons, including those that are important in REM sleep (29).

The laterodorsal tegmental nucleus (LDT) and the pedunculo pontine tegmental nucleus (PPT), are two nuclei at the pons-midbrain junction where cholinergic projections arise in the brain stem. Their rostral projections are important for EEG activation of both REM sleep and waking.

### BIOCHEMICAL PHARMACOLOGY OF WAKEFULNESS

Wakefulness is maintained by the tonic activity of neurons distributed throughout the brainstem reticular formation with projections to the thalamus, hypothalamus and the basal forebrain (31). The dopaminergic and noradrenergic neurons of the ponto mesencephalic tegmentum, the posterior hypothalamic histaminergic neurons, and the cholinergic neurons of the basal forebrain, are the major neurotransmitter systems that appear to regulate wakefulness (31).

Stimulants both increase wakefulness and decrease REM sleep. Withdrawing stimulants in chronic users both

increases total sleep and REM sleep (32). The stimulating effects of amphetamines (33) and cocaine (34) on sleep are suggestive of a role for dopamine in promoting wakefulness. There is no clear-cut role for dopamine in the sleep-wake cycles. Single cell recordings of dopaminergic neurons in the substantia nigra show only minor changes in the sleep-wake cycle (35).

Noradrenergic neurons (found in the locus ceruleus) also have no clear-cut role for sleep-wake cycles. These cells have a state dependent firing rate, a high firing rate during wakefulness that decreases over NREM sleep until they are virtually silent during REM sleep (36).

Histamine has arousing effects and antihistamines have sleep-inducing effects (37–39). An ascending histaminergic pathway from the posterior hypothalamus innervates the cortex, striatum, hippocampus, and amygdala of the forebrain with cell bodies originating in the posterior hypothalamus and midbrain regions (40, 41). Studies suggest that neurons in the ventrolateral pre-optic area (VLPO) of the anterior hypothalamus are involved in the generation of NREM sleep (42). A descending histaminergic pathway extends from the posterior hypothalamus to the mesopontine tegmentum (40,43) where they intermingle with other neuronal projections that play a role in the generation of wakefulness and REM sleep (44, 45). Administrations of substances that impair histamine transmission or synthesis increase NREM, whereas enhancement increases quiet wakefulness (46–48). The role of the H1 and H2 systems is of increasing NREM sleep, and also suggested modulation of the balance between wakefulness and NREM sleep (49).

Cholinergic mechanisms play a clear role in maintaining arousal at both cortical and subcortical sites (50–53). Acetylcholine is released from the hippocampus and the cerebral cortex during REM sleep (54). 5-HT is probably not involved in NREM sleep but rather in the regulation of the stages of sleep. Jouvet et al, postulated that 5-HT, released by axonal nerve endings in the basal hypothalamus as a neurotransmitter during waking, might act as a neurohormone and induce the synthesis or liberation of hypnogenic factors that would be secondarily responsible for NREM and REM sleep (55).

### PHARMACOLOGY OF SLEEP

There are certain substances found within the nervous system that are felt to affect sleep. Since the role of these substances is not well understood, they are discussed separately in the following section.

Delta Sleep-Inducing Peptide (DSIP) is an isolate that is obtained from the blood of rabbits, when in an electrically induced sleep state that induces NREM sleep in recipient rabbits when given by intracerebroventricular infusion (56). These effects are seen with infusions in cats

and rats when given IV or subcutaneously (57). Intravenous infusions of DSIP in humans increased total sleep time regardless of administration times (58–61).

Blood plasma levels of DSIP exhibited a circadian rhythm in both humans and rats with a peak in the late afternoon and a trough in the early morning (62, 63). Not only does DSIP effect sleep but also has many physiologic activities. Graf and colleagues (64) have proposed that in addition to sleep facilitation, DSIP may also exert a chronopharmacologic action as a natural programming substance by inducing changes in cerebral neurotransmitters and plasma proteins.

Sleep-promoting substances uridine and SPS-B are both implicated in the more frequent occurrence of NREM and REM sleep episodes with normal sleep-waking behavior (65).

Muramyl peptides are proposed to induce sleep, which in turn enhances immunoreaction, serving a recuperative function in the mammalian body. A muramyl tripeptide isolated from humans is an active somnogen (66–69). Muramyl peptides are peptidoglycans that form the backbone of bacterial cell walls and exert profound pyrogenic and immunostimulatory activities in the mammalian body (70–72).

Krueger et al. (67) proposed that sleep has a reciprocal relationship with the immune system. Sleep is enhanced by certain immune modulators, and may enhance certain aspects of immune regulation. Interleukin-1 belongs to a family of polypeptides that mediate a variety of host-defense functions and possess pyrogenic activity. It is liberated by macrophages to activate T lymphocytes and induce fever by acting on hypothalamic cells. IL-1 and other immune modulators have been found to be elevated in humans during sleep (73). This peak in plasma levels occurs during SWS shortly after sleep onset (73).

A naturally occurring peptide isolated from the pineal gland, arginine vasotocin, modifies conditioned behavior, inhibits gonadotropin release, and possibly enhances NREM sleep (65).

Caffeine shortens REM latency and decreases sleep, particularly NREM sleep, presumably through its blockade of adenosine receptors. Adenosine is a naturally occurring purine nucleoside that causes sedation and inhibits neuronal firing activity (74). Extracellular concentrations of adenosine decrease with sleep. It is suggested that the duration and depth of sleep are increased by elevated concentrations of adenosine after waking (65).

The prostaglandin-dependent humoral theory of sleep regulation was developed by Ueno et al. (75,76) and Matsumura et al. (77). Two different prostaglandins: PGD<sub>2</sub> and PGE<sub>2</sub> have been shown to work reciprocally to affect sleep. When PGD<sub>2</sub> increases, PGE<sub>2</sub> decreases sleep time in a dose-dependent manner (75–77). Reciprocal activities of the PGD<sub>2</sub> and PGE<sub>2</sub> in or near the preoptic area and posterior hypothalamus may regulate the

state of vigilance (78).

Melatonin is a major hormone secretion of the pineal gland in mammals. The synthesis and release is timed by one or more biological clocks but occurs only in humans after dark. Melatonin is purported to have sleep-inducing properties (79) in cats, rats, young chickens, and humans (81–85). Its physiological actions include a phase-shifting effect on circadian rhythms, increased sleepiness when administered during daytime hours, and vasoconstriction (13). It can also be used for the treatment of jet lag and delayed sleep-phase syndrome (80). Melatonin secretion at night generally decreases as normal and pathologic aging occurs. Whether this natural process is associated with poor sleep is unknown, despite claims by numerous authors that exogenous melatonin restores natural sleep (65). It is unlikely that melatonin has any direct effects on sleep regulation secondary to the high doses needed, however it may affect sleep indirectly by altering the phase of the circadian pacemaker (86).

GABA has a role in sleep induction through the use of benzodiazepine medications, which enhance GABAergic inhibitory transmission (87). They also aid sleep through anxiolytic and muscle relaxation mechanisms.

## ASSESSMENT OF SLEEP DISTURBANCES

Patients need to be asked specific questions about their sleeping habits and difficulties at each visit. It is very helpful for both physician and patient, to have the patient keep a sleep diary for a specific period of time. A period of 2 weeks to 1 month has been suggested by various authors. The patient is to record a night-to-night history of their sleeping schedule and perception of sleep quality. This information may enable the clinician to identify modifiable causes for the sleep difficulties.

Table 32-3 provides a concise representation of the approach to sleep disturbances.

## INSOMNIA QUESTIONNAIRES

Various questionnaires have been developed to aid in the diagnosis of insomnia within the general population. Recently published examples include the Epworth

**TABLE 32-3**  
*Approach to Sleep Disturbance*

- Comprehensive evaluation of insomnia

- Pharmacological treatment

Sleepiness Scale (88), The Sleep Disorders Questionnaire (89), and the Pittsburgh Sleep Quality Index (90). The difficulty lies in correlating these questionnaires to patients who have suffered a traumatic brain injury. Few formal measures were found to be validated in a population characterized with TBI. Other helpful questionnaires when evaluating patients with TBI who report sleep difficulties include:

The Beck Depression Inventory (91) and the Multidimensional Pain Inventory (MPI) (92). The Beck Depression Inventory consists of 21 items, each of which requires the respondent to rate the presence or absence of a specific sign of mood disturbance on a 4-point scale. It provides information on the cognitive, affective, and somatic aspects of depression (91).

The MPI consists of 61 items that requires patients to rate the magnitude of various pain-related problems on a 7-point scale. It evaluates an individual's experience of pain from a psychosocial perspective and contains measures of self-perceived pain intensity and pain interference with functional activities (92).

The Sleep Disorders Questionnaire has 43 questions related to various medical conditions and symptoms as reported by the patient and the family members that are applicable in the past six months. It is very helpful to not only assess actual symptoms related to insomnia, but also the patient's perception of those symptoms.

The Epworth Sleepiness Scale evaluates daytime alertness by asking the patient to rate the likelihood of dozing or falling asleep in eight different situations, such as conversing with another person, riding in a car, resting after lunch, and reading a book. It uses a 4-point scale and has been shown to possess good sensitivity and specificity to sleep apnea, narcolepsy, and hypersomnia (88).

The Multiple Sleep Latency Test (MLST) can be ordered to determine the severity of sleepiness and give an indication of the presence or absence of the early onset of REM sleep (93). It is the only scientifically validated objective test of excessive sleepiness and is used to establish a diagnosis of specific sleep disorders or to determine the severity of sleepiness. This test is indicated for all patients suspected of narcolepsy to confirm diagnosis and severity of sleepiness; patients with mild to moderate obstructive sleep apnea syndrome who complain of moderate to severe sleepiness; in evaluation of patients suspected of having idiopathic hypersomnia, periodic limb movement disorder or when the cause of excessive sleepiness is unknown (166, 168). The MSLT is indicated in the evaluation of the complaint of insomnia when the presence of moderate to severe excessive sleepiness is suspected, and is useful in assessing the response to treatment following effective therapy for disorders that cause sleepiness to ensure occupational safety (167).

The MLST consists of five 20-minute nap opportunities, with each nap separated by 2 hours. The patient

lies in a dark room and attempts to sleep. The time before sleep is recorded for each nap, and the mean latency for all 5 naps is determined. Patients with a mean sleep latency of < 5 minutes are considered to have pathological sleepiness and those who fall asleep between 5–10 minutes are considered normal. Sleep is staged during the naps. If REM sleep occurs during 2 or more naps, the test is consistent with a diagnosis of narcolepsy, if other causes of sleep-onset rapid movements have been excluded (94).

The Pittsburgh Sleep Quality Index (PSQI) examines sleep quality and disturbances for a 1-month period. Patients provide specific sleep-related information including: usual bed time, rising time, minutes to fall asleep, and hours of actual sleep each night. They also rate a variety of sleep-related factors on a 4-point scale including: subjective sleep quality, use of sleep medications, daytime alertness and mood, and sleep disturbances such as nighttime awakenings, respiratory distress, physical discomfort, and disturbing dreams (90). Poor sleepers and insomniacs are readily identified by the PSQI and it is well suited for research examining general sleep patterns and problems (90). The PSQI was demonstrated to be a valid and useful screening tool for assessing insomnia and sleep difficulties among patients with postacute TBI (95). Steele et al. (192) have studied the effect of TBI on the timing of sleep but have concluded that the Morningness-Eveningness Questionnaire (MEQ) may not be suitable for use in a cognitively impaired patient population.

### OBJECTIVE SLEEP TESTING MEASURES ACTIGRAPHY

Actigraphy is a method utilizing a portable device, to study sleep-wake patterns and circadian rhythms by assessing movement, most commonly at the wrist. Actigraphy is reliable and valid for detecting sleep in normal healthy populations, but less reliable in disturbed sleep (163). Actigraphy is not indicated for the routine diagnosis, assessment of severity, or management of any of the sleep disorders, including the insomnias, obstructive sleep apnea syndrome and periodic limb movement disorder (163). Actigraphy may be a useful adjunct to modified portable sleep apnea testing when determining the rest activity pattern during the testing period (164). Actigraphy is an effective means of demonstrating multi day human rest-activity patterns and may be used to estimate sleep-wake patterns in the occasional clinical situations where a sleep log or diary cannot provide similar information (165). Actigraphy may also be useful in characterizing and monitoring circadian rhythm patterns or disturbances in the elderly and nursing home patients with or without dementia; newborns, infants, children, and adolescents; hypertensive individuals; depressed or schizophrenic patients; and individuals in inaccessible situations (space flight) (163).

## POLYSOMNOGRAPHY

Polysomnography (PSN), is routinely indicated for the diagnosis of sleep-related breathing disorders; for continuous positive airway pressure titration in patients with sleep-related breathing disorders; for documenting the presence of obstructive sleep apnea in patients prior to laser-assisted uvulopalatopharyngoplasty; with a multiple sleep latency test in evaluation of suspected narcolepsy; or when there is a strong clinical suspicion of periodic limb movement disorder (169, 170). Diagnosis of narcolepsy and posttraumatic hypersomnia requires a MSLT after a relatively normal night's sleep as documented by nocturnal PSN (201). Guilleminault et al. (193) found a MSLT score  $<10$  in 82.6% and sleep disordered breathing in 32% of patients with head or neck trauma. PSN is not indicated for the diagnosis of circadian rhythm sleep disorders or to establish a diagnosis of depression (170). Masel et al. (202) concluded that due to patients inability to perceive their hypersomnolence, a sleep laboratory evaluation should be considered part of their medical management.

## NONPHARMACOLOGIC MEASURES FOR TREATING SLEEP DISTURBANCE

Nonpharmacologic measures should be attempted in all patient populations, not only those with TBI and should be undertaken as quickly as possible once insomnia and sleeping difficulties have been identified. Sleep hygiene refers to health practices and environmental influences on sleep. The following suggestions should be of benefit to all patient populations affected:

- Awake at the same time daily.
- Limit total daily caffeine consumption and discontinue consumption 4 to 6 hours before retiring.
- Nicotine is a stimulant and should be avoided in all forms.
- Do not eat heavily close to bedtime.
- Sleep may be enhanced by performing a regular exercise program in the late afternoon or early evening at least 3 hours before bedtime.
- Move the clock out of view from the bed.
- Maintain the sleeping environment as comfortable as possible, minimize noise, light, and excessive temperatures (13).

## STIMULUS CONTROL INSTRUCTIONS

A set of techniques to establish sleep/wake patterns, cues for sleeping, and reduction of associations with activities that interfere with sleep:

- Lie down when feeling sleepy.

- If having difficulty with sleep, leave the bedroom. Return to bed when sleepy. The goal is to develop a positive association between the bedroom and sleep.
- Use the bedroom only for sleep and sexual activity.
- Awake at the same time each day.
- No napping (10).

## SLEEP RESTRICTION

The goal of this treatment measure is to increase the percentage of time in bed asleep. The patient limits the amount of time spent in bed to the actual time that is spent sleeping. The type of treatment often results in a mild sleep deprivation state initially that should promote more rapid sleep onset and more efficient, restorative sleep. The rising time should remain constant and the bedtime altered to maintain a regular sleep/wake rhythm. For example, if a patient only reports sleeping 4 hours a night but arises at 5 AM daily, then he should stay up until 1 AM. Each night they will go to bed 15 minutes earlier. This procedure is followed over several weeks until the desired sleep duration is achieved. This type of treatment is modified for older patients by allowing them to take an afternoon nap (13).

## ENVIRONMENTAL MEASURES CHRONOTHERAPY

Chronotherapy is a treatment measure developed primarily for circadian rhythm disorders in which the individual's sleep/wake cycle is out of phase with the bedtime (96). This treatment is very effective for patients with delayed sleep phase syndrome, who exhibit difficulty falling asleep at night and report feeling tired in the morning when awakened. The patient's bedtime is delayed by daily increments of 3 hours until sleep onset coincides with the desired bedtime (97).

## BRIGHT LIGHT THERAPY

This treatment has also been used for a number of circadian rhythm disorders. Research has shown that properly timed exposure to bright light (7000–12,000 lux) for 2–3 days can shift the phase of the sleep rhythm (98). As a frame of reference, typical indoor room light is  $<500$  lux; a few minutes after dawn, sunlight produces about 2500 lux; and at noon, sunlight is ~100,000 range (99). It is also important to have periods of darkness without bright light (98).

## CRANIAL ELECTROTHERAPY STIMULATION

CES (Cranial Electrotherapy Stimulation) is a process, which utilizes minute electrical stimulation for therapeutic treatment of anxiety, depression, and insomnia (184).

Applied through electrodes to the area between the mastoids and the jaw, the sensation felt by the individual is normally one of relaxation (184). If there is high stress or anxiety just prior to treatment, the individual may go to sleep while using CES, particularly if sitting in a reclining position (184). Sleep at the time of application is not required to benefit from CES, although individuals frequently report an improvement in the quality of their night time sleep (184). As with a number of medications, the mechanism of action of CES is not fully understood. Research has led to the hypothesis that CES has a mild effect on the hypothalamic area of the brain (185, 186). Researchers also have noticed rapid increases in serotonin, also associated with relaxation and calmness, and decreases in cortisol, one of the primary stress-related biochemicals (186,187). Interestingly, CES also increases levels of norepinephrine and dopamine, both associated with alertness and feelings of pleasure (187). No negative effects or major contraindications have been found from the use of CES to date, either in the US or other parts of the world.

### **BEHAVIORAL AND COGNITIVE THERAPIES**

Cognitive therapy involves identifying dysfunctional beliefs and attitudes about sleep and replacing them with more adaptive substitutes (13). The primary goal is to change the patients' view of the sleep problem from one of a victim, to one in which they are capable of developing adaptive coping skills. These changes in their way of thinking often helps to decrease the anxiety the patient experiences, thereby facilitating sleep. Paradoxical intention is the approach that instructs the patient who has difficulty falling asleep to stay awake as long as possible. Multiple studies have evaluated this technique with mixed results regarding its effectiveness (97).

### **RELAXATION THERAPY, MEDITATION, AND BIOFEEDBACK**

Many patients are anxious and have high levels of arousal that interfere with their ability to fall asleep. The goal of this treatment is to allow the patient to relax and fall asleep more easily. These therapies are useful for both sleep-onset and sleep-maintenance insomnia problems (97).

### **SLEEP DIFFICULTIES SPECIFICALLY RELATED TO TBI**

The emergence of insomnia after TBI concerns treatment providers, because as Zafonte et al (101) have noted, disordered sleep can have adverse behavioral and cognitive

consequences. Patients with TBI are prone to depression, particularly the mild TBI patient. Strong correlation exists between insomnia and depression in the non-TBI population. Insomnia is a common feature of depression. Both Beetar et al (103) and Fichtenberg et al. (102) find an association between insomnia and mild brain injury. It is not surprising that there is an association between insomnia and depression in the post-acute TBI patient. This follows the course of recovery after TBI. During the acute stage, dysregulation of sleep seems to be a function of the diffuse disruption of cerebral functioning in the wake of both direct physical damage to the brain and secondary neuropathological events. Sleep abnormalities are more likely to occur in patients with lesions in the pontine tegmentum located in the midpontine region (100). As brain functioning becomes reorganized and some degree of neurological stability is reestablished, sleep can be expected to normalize in the absence of damage to neural sleep structures (104). Insomnia is linked to both depression and mild brain injuries. The determinants of insomnia and depression may differ from the acute and the post-acute stage. Neurological factors may play a role in the early recovery process, and psychosocial factors may contribute later (104). When assessing insomnia in the brain-injured population, it is imperative to diagnose depression, as well as other psychiatric and emotional disturbances.

Changes in sleep patterns in patients that have suffered a traumatic brain injury are fairly common. Reports have shown decreased REM and slow wave sleep, as well as an increase in the number of times an individual awakens during sleep (105). Brain injury is believed to contribute to a shortening of the total sleep time and the disappearance of deep sleep (106). Sleep complaints of patients with brain injury are found to correlate with the presence of fatigue, higher Glasgow Coma Scale scores, better immediate memory, a positive substance abuse history, older age, and female gender (107). Sleep complaints are common in patients with recent injury, and those sustaining injury 2–3 years previously (105). Disorders in initiating or maintaining sleep (DIMS) occur more often in patients with recent injury, and disorders of excessive somnolence (DOES) occur more often in those patients with injuries sustained 2–3 years prior (105). TBI may also result in sleep apnea, which can have obvious effects on sleep maintenance (103).

### **ALTERNATIVE/COMPLEMENTARY MEDICINE TECHNIQUES**

Various methods of alternative/complementary medicine may be helpful in facilitation of sleep including: acupuncture, aerobic exercise, massage, ultrasound, cranial electrical stimulation, and reflexology. Every patient must be

questioned about the presence of pain and its interference with sleep. Aggressive evaluation, intervention and treatment of pain in both TBI and non-TBI patients is warranted. Treatment of the patient's pain may facilitate sleep.

## MELATONIN

Melatonin is a hormone synthesized in the pineal gland and, to a lesser extent, in the retina. Melatonin's excretion, which peaks after dark, follows a day/night rhythm not only in humans but also in all species studied, and is responsible for sleep induction. Physiological concentrations of melatonin can stimulate the release of opioid peptides by activated T-helper lymphocytes (180). These melatonin-induced-immuno-opioids (MIIO) mediate the immunoenhancing and anti-stress effects of melatonin and cross-react immunologically with anti-beta-endorphin and anti-met-enkephalin antisera (180). Studies have also shown the hypnotic effect ascribed to melatonin is exerted through its effect on the thermoregulatory mechanism (181). Those authors believe that by lowering core body temperature, melatonin reduces arousal and increases sleep propensity (181). Melatonin has also been shown to accelerate sleep initiation, improve sleep maintenance, decrease sleep stage 1 and increase sleep stage 2 (182). The influence of exogenous melatonin on the sleep-wake cycle was investigated. Sleep onset time and wake time were significantly earlier when using melatonin than during placebo (183). Contraindications for the use of melatonin include: heart disease, atherosclerosis and stroke secondary to vascular constriction effects. It may also negatively affect fertility (195). Fluoxetine decreases melatonin levels; TCA's and fluoxetine increase melatonin concentrations (195).

Research shows that a number of natural sleep aids may benefit anyone involved in the pursuit of a good night's rest. Valerian, kava kava, hops, passionflower have all been shown to improve sleep quality. The German government and European community sanction these herbs for the treatment of insomnia.

The active chemical constituents of valerian are primarily the valepotriates, which possess sedative activity (171). The valepotriates weakly bind GABA-A receptors. Sedation in the central nervous system is primarily controlled through these receptors. Because valerian weakly binds these receptors, its sedative actions do not result in dependence and potential addiction (171). Numerous human sleep studies have demonstrated that valerian produces a significant improvement in sleep quality, and an increase in deep REM sleep (dream phase) without producing the side effects of sleep drugs (172).

Kava kava is recognized for the ability to produce relaxation without the loss of mental sharpness (173). The active constituents of Kava consist of a group of lactones similar in structure to gamma-butyrolactone, (GBL)

a precursor to gamma hydroxybutyrate (GHB) (173). GHB produces sleepiness and depresses the dopaminergic pathway when given in high doses (173). Numerous clinical and experimental studies have documented the relaxing, sleep-promoting and anti-anxiety actions of kava extracts that contain high levels of Kava lactones. In a 1991 double-blind, placebo-controlled four-week study of patients suffering from anxiety, a group receiving kava lactone extract three times daily showed reduction in anxiety after just one week and were significantly improved at the end of the study (173). The kava group experienced a significant reduction in menopausal symptoms, anxiety and depression compared to the control group (173). A study compared the effects of a kava lactone to oxazepam (a benzodiazepine drug) in patients suffering from anxiety for four weeks. Each substance reduced symptoms of anxiety equally (174). The kava lactone produced no negative side effects and oxazepam produced side effects such as drowsiness, dizziness, headaches and vertigo (174).

Passionflower was listed in the National Formulary from 1916 to 1936 and approved as a sedative and OTC sleep drug (175). Italian researchers tested Passionflower alone and in combinations with other sedative herbs (175). They observed a synergistic effect of sedative activity from the herbal combinations. Studies have shown that oral administration and injections of passionflower into rats prolonged sleeping time, protected animals from convulsive chemicals and relaxed their muscles (175).

Hops are extensively used in botanical formulas for the treatment of insomnia because they influence relaxation in the central nervous system (176). They are recommended by herbalists to ease tension and anxiety, and may be used when tension leads to restlessness. Studies have demonstrated equivalent efficacy and tolerability of a hop-valerian preparation compared with a benzodiazepine preparation in patients suffering from sleep disorders (176). The researchers concluded that a hop-valerian preparation in the appropriate dose is a sensible alternative to benzodiazepines for the treatment of non-chronic and non-psychiatric sleep disorders (177).

Chamomile is derived from the flower heads of either of two annual plants: German chamomile (*Matricaria recutita*), or Roman chamomile (*Chamaemelum nobile*) (178). Chamomile is a popular folk remedy for digestive problems, fever, menstrual discomfort, stomachache, and anxiety. It is used to treat insomnia in children because it is a very mild relaxant and has a pleasant taste (178). Flavonoids such as apigenin as well as a distinctive blue essential oil (azulene) derived from chamomile have been found to reduce inflammation and encourage the healing of wounds (179). Apigenin may also be responsible for chamomile's anti-anxiety and sedative effects, via action on central benzodiazepine drug receptors (179). Both oral and topical chamomile

products are considered nontoxic and gentle enough for use in children or pregnant and lactating women (178).

### PHARMACOLOGIC TREATMENT FOR SLEEP DISTURBANCES

All psychosocial and physical aspects must be taken into consideration when prescribing medications to patients with traumatic brain injury. Every patient's unique and individual circumstances will affect medication choices.

#### ANTIHISTAMINES

Antihistamines are frequently purchased over-the-counter to produce or enhance sleep. When utilized by patients that have sustained a traumatic brain injury, they may produce negative cognitive effects by means of their anticholinergic actions (101). Furthermore, in studies by Roth et al. (114) and Nicholson (115, 116), it was shown that traditional antihistamines produced increased daytime sleepiness, most clearly apparent at the usual nadir in the circadian cycle of alertness. In these studies, however, antihistamines such as loratadine (in doses of 10 and 40 mg), terfenadine, and astemizole were not associated with these undesired side effects.

#### ANTIEPILEPTICS

Drowsiness and lethargy are often reported side effects of anticonvulsant medications. Caregivers using these medication(s) in patients with traumatic brain injury must keep in mind the potential undesired side effects on sleep and arousal that may be produced (101). Phenytoin administration long-term produces a decrease in sleep onset latency, a transient increase in SWS, and possibly a transient reduction in REM sleep (109, 117, 118). Carbamazepine produces a decrease in stage I sleep, an increase in SWS, and an increase in total sleep continuity (101, 109). Sodium valproate tends to increase total sleep time by decreasing total awakenings (119).

Gabitril (tiagabine) a newer, well-tolerated anticonvulsant, is rapidly absorbed after oral administration, has an elimination half-life of seven to nine hours (120).

Tiagabine significantly increased sleep efficiency by increasing SWS, caused by changes in stages 3 and 4, especially during the second and third two-hour intervals of the sleep period (121). The promotion of deep sleep was further corroborated by elevations in slow-wave activity within non-REM sleep. Tiagabine had demonstrated no effect upon sleep onset latency or total time spent in bed (121).

Pregabalin is a gamma-aminobutyric acid (GABA) analogue that binds to calcium channels, not GABA

receptors, and modulates calcium influx, resulting in antiepileptic, analgesic, and anxiolytic activity. (122, 123). It has shown greater potency than gabapentin in pain and seizure disorders (124).

Pregabalin has shown increased duration of nonrapid eye movement sleep, decreased rapid eye movement sleep, and did not affect sleep onset latency (125).

#### ANTIDEPRESSANTS

Antidepressant medications may impact sleep patterns both directly (by means of suppression of REM sleep and prolongation of REM latency) (126) and indirectly (e.g., by their effect on the underlying depression and its associated sleep disturbances (109)). Monoamine oxidase inhibitors cause the greatest suppression of REM sleep, perhaps therapeutic in that regard, because the depressed patient may be experiencing excessive REM sleep (127). The tricyclic antidepressant drugs and selective serotonin reuptake inhibitors also lead to varying degrees of REM sleep suppression. According to Arew (128), the primary indication for tricyclic antidepressants in treating insomnia is the patient whose sleep problems are secondary to depression. Nefazodone and Remeron, newer generation antidepressants unrelated to the SSRIs, tricyclics, and monoamine oxidase inhibitors, improve sleep initiation secondary to sedating side effects. Exact mechanism is unknown; however, it is presumed to be by means of serotonergic mechanisms (101). A newer agent, mirtazapine has serotonin blocking properties and has been shown to improve sleep architecture and efficiency (208).

#### SEDATIVE/HYPNOTICS

Historically, the benzodiazepine class of medications has been most commonly prescribed for insomnia and has demonstrated efficacy in short-term treatment (108).

The hypnotic agents act by means of gamma-aminobutyric acid (GABA) transmission through modulation of chloride channels to decrease phasic interruptions of sleep and increase total sleep time (101). Activation of the benzodiazepine receptor leads to an increase in GABA. This class of medications can produce a variety of side effects including physical dependence, sedation, and impairment of motor and cognitive abilities. This class is typically used for 4 weeks. Long-term use can have the potential for habituation and withdrawal symptoms. More effective long-term management of insomnia is attained if these medications are used in conjunction with behavioral therapy techniques (112). Agents with a shorter half-life should be prescribed first, since they are eliminated from the system by morning, decreasing the likelihood of

residual daytime effects. These agents may improve sleep during the first part of the night, but can lead to withdrawal-like syndromes, with REM sleep rebound and sleep fragmentation during the latter part of the night (109). Sedative and hypnotic medications can also worsen sleep apnea syndromes (109).

Zolpidem (Ambien), although not a true benzodiazepine, is often included with the class because the site of action is the benzodiazepine receptor site (110). Most hypnotic agents bind to three omega receptors; zolpidem has an affinity for the omega 1-receptor (101). It also seems to preserve stage 3 and 4 sleep and produces only minor inconsistent changes in REM sleep (111). Ambien, enhances the brain's major inhibitory neurotransmitter, gamma aminobutyric acid (GABA). GABA receptors are located in the cerebellum and cerebral cortex, but not in the spinal cord or peripheral tissues (188). Ambien in vitro preferentially binds to a subunit of the GABA receptor (also called the benzodiazepine receptor) (188, 190). Although Ambien binds to the benzodiazepine receptor, it is an imidazopyridine with chemical structure unrelated to benzodiazepines or barbiturates (189, 190). While these drugs share some of the pharmacologic properties of benzodiazepines, they differ in binding to receptor cells in the GABA complex, producing sedative, muscle relaxant, anti-convulsant and anxiolytic effects. Imidazopyridines selectively bind to just the receptor cells responsible for sedation, thereby producing less side effects and less potential for addiction (188,189).

The longer acting agents flurazepam (Dalmane) and quazepam (Doral) can cause daytime sleepiness but are less likely to produce rebound insomnia (108). Benzodiazepines are preferred to barbiturates and other agents such as chloral hydrate. Chloral hydrate is often used in TBI patients, because it affords rapid sleep induction without increasing the seizure threshold (109). It is not recommended for treatment of insomnia in the general population because of the narrow therapeutic ratio, rapid development of tolerance, systemic toxicity, potential for abuse, and the possibility of severe clinical complications of withdrawal (13). Sonata is a hypnotic agent with a chemical structure unrelated to the benzodiazepines, barbiturates, and other drugs with hypnotic properties. It has been shown to decrease the time to sleep onset. It has not been shown to increase total sleep time or decrease the number of awakenings (113). Eszopiclone, a new non-narcotic, non-benzodiazepine hypnotic, is indicated for improved sleep maintenance. It is the first and only hypnotic agent at publication approved for long-term use with no tolerance observed in a 6-month trial (209).

### ANTIPSYCHOTICS

This class of medications, have both direct effects on sleep and the ability to promote sleep by attenuating symptoms

that interfere with sleep, such as psychosis and agitation. As a group, they increase daytime somnolence, total sleep time, REM percentage of total sleep, and sleep continuity. The antipsychotic drugs also lead to decreased sleep latency and percentages of sleep in stages 1 and 2 (129–133).

### LITHIUM

Chesnik and Mendels have pointed out that lithium has multiple effects on sleep/wake patterns (134). It increases the percentage of stage 2 and SWS, the REM latency, and the total sleep time. The obvious assumption follows that it also increases daytime somnolence, a hypothesis that has proven true in most clinical cases (135).

### OPIATES

Opiates promote feelings of peacefulness, drowsiness, and pain-relief that lead to the impression they are promoting sleep. There is noted psychomotor slowing. The strong analgesic properties may permit sleep in people who would otherwise be unable to do so, such as those with chronic pain syndromes or restless legs syndrome (109). Although not borne out by polysomnographic changes in sleep, narcoleptic patients treated with codeine report better sleep (136). Patients who have suffered acute traumatic brain injury often have associated fractures and injuries. They may derive sleep benefits from treatment of their pain using opiates.

Table 32-4 organizes the medications by class and their documented effects on sleep.

### CONCLUSION

Insomnia and sleep disturbances are common complaints of both the general patient population as well as the brain injured populations. The architecture of sleep, assessment of sleep disturbances and insomnia, and treatment methods; both nonpharmacologic and pharmacologic have been reviewed. Prescription medications affecting the sleep cycles were reviewed in detail, and common effects compared and contrasted.

Once a sleep disturbance has been identified and investigated, a plan of care is formulated. The least-invasive techniques should be utilized initially and followed by prescription sleep aids if the symptoms fail to resolve. All psychosocial and physical aspects must be taken into consideration when prescribing medications for patients with TBI. It has been suggested that serotonergic agonists (trazodone, doxepin, amitriptyline) be used for sleep initiation problems. Sleep maintenance problems may be more efficiently handled with catecholaminergic agonists (nortriptyline) (137).

**TABLE 32-4**  
**Medications by Class and Their Effects on Sleep**

MEDICATION TYPE	DRUG	INCREASES OR POSITIVE EFFECTS ON SLEEP
Antihistamine	H1 antagonists: Diphenhydramine Loratadine Terfenadine	Daytime somnolence
Antiepileptics	Clonazepam Valproate sodium Carbamazepine  Phenytoin Tiagabine  Pregabalin	Stage 4% Daytime somnolence Daytime somnolence Sleep continuity in epileptics SWS% (transient) Sleep efficiency SWS Enhancement of slow EEG components Nonrapid eye movement sleep Pain-relief Somnolence Anxiolytic
Antidepressant	Selective serotonin reuptake inhibitors: Fluvoxamine Fluoxetine Tricyclic antidepressants: Doxepin Clomipramine Desipramine Nortriptyline Amitriptyline Imipramine Serotonergic agent: Trazodone  Nefazodone  Remeron	Sleep latency REM latency  Total sleep time Stage 2% Daytime somnolence REM latency  Daytime somnolence Sleep continuity SWS% REM latency Sleep initiation Sleep continuity Sleep initiation
Sedative/Hypnotic	Benzodiazepines: Triazolam Temazepam Quazepam Nitrazepam Midazolam Lormetazepam Flurazepam Zolpidem  Barbiturates: Amobarbital Secobarbital Phenobarbital Pentobarbital Chloral hydrate  Sonata	Total sleep time Sleep continuity Stage 2% REM latency  Sleep continuity SWS% Daytime somnolence Total sleep time Sleep continuity Stage 2% REM latency Total sleep time Sleep induction Sleep initiation

TABLE 32-4 (continued)

MEDICATION TYPE	DRUG	INCREASES OR POSITIVE EFFECTS ON SLEEP
Antipsychotic	Haloperidol, trifluoperazine, loxapine, chlorpromazine	Sleep continuity Daytime somnolence Total sleep time REM%
Lithium		Daytime somnolence Total sleep time SWS% Stage 2% REM latency
Opiate	Morphine, codeine, heroin	Pain-relief Daytime somnolence

Comprehensive evaluation and interpretation of the patient's symptoms combined with the information in this chapter should allow formulation of a safe and effective treatment plan for sleep difficulties in patients with traumatic brain injury.

#### ACKNOWLEDGMENT

Special thanks to Steven Mayo for his invaluable assistance with literature review in the preparation of writing and revising this chapter.

## Diagnosis and Management of Late Intracranial Complications of TBI

*David F. Long*

### INTRODUCTION

#### Purpose and Overview

*Purpose* Although many patients show excellent progress during rehabilitation from traumatic brain injury (TBI), intracranial complications occur frequently and can result in an adverse outcome. In many instances, prompt and accurate diagnosis of these complications can either be life-saving or can dramatically improve the extent of recovery which takes place.

*Overview* Complications addressed in this chapter include central nervous system (CNS) infections and the conditions predisposing to them, hydrocephalus and shunt management, and late post-traumatic vascular and mass lesions.

#### Specific Chapter Sections

*Infection and Risk of Infection* The potential risk of serious CNS infection changes the management of some patients even before an infection occurs. Topics discussed in this section include compound depressed skull fractures, penetrating injuries, basilar skull fractures, cerebrospinal fistulae, and pneumocephalus. CNS infections themselves are then discussed including meningitis, brain abscess and subdural empyema. Because specific management options,

especially antibiotic selection, are frequently subject to change, the general approach to diagnosis and management is emphasized in this section. A section on craniectomy and cranioplasty has also been added in view of the increasing recognition of the effects of these procedures on neurologic recovery.

*Hydrocephalus and Shunts* Hydrocephalus is probably the most difficult common complication to diagnose and manage during the rehabilitation of patients with TBI. Not only is it a challenge to identify which patients will benefit from a shunt, but management often becomes even more complicated after shunting. In order to optimally manage these patients, physicians need to understand the different types of shunts and their physiology, as well as common shunt complications. Programmable shunts and other recent innovations are now routinely available, and offer an opportunity for intervention to improve outcome during rehabilitation without requiring further surgery.

*Vascular and Late Mass Lesions* Although vascular lesions such as post-traumatic aneurysm and carotid cavernous fistula are relatively uncommon, physicians treating patients with TBI need to be aware of these complications in order to recognize and treat them promptly when they do occur. Finally, late mass lesions such as chronic subdural

hematoma and hygroma, late presenting epidural hematoma, and delayed post-traumatic intracerebral hemorrhage are discussed.

## CONDITIONS INVOLVING RISK OF INFECTION

### Skull Fractures and Penetrating Injuries

*Depressed Skull Fractures* Depressed skull fractures are generally considered significant if the fragment is depressed below the inner table of the skull by more than the thickness of the skull (1). Tangential skull radiographic views show these fractures most effectively. Compound depressed skull fractures are distinguished from simple depressed skull fractures by the presence of an overlying open wound or laceration, and are therefore associated with a substantial increased risk of infection. This infection risk includes subdural empyema and brain abscess, which are otherwise uncommon following closed head injury. These compound fractures account for up to 85% of depressed skull fractures (1). Both simple and complex depressed skull fractures are often elevated for cosmetic reasons and in the hope of preventing epilepsy. Compound depressed skull fractures are debrided to reduce the risk of infection. Prophylactic antibiotics are often administered to patients with compound depressed skull fractures, although this remains controversial (2–5).

*Penetrating Injuries* Gunshot wounds confer a high risk of infection for several reasons. In contrast with higher velocity military missile wounds, the bullet is retained inside the skull in about 70% of civilian gunshot wounds. The retained bullet becomes a nidus for infection, and retained bone fragments are an even greater problem increasing the risk of infection by a factor of 10 (6). Focal necrosis of tissue in the path of the bullet is also believed to be crucial in the possible development of brain abscess. For these reasons, surgical debridement has been emphasized. In contrast to cerebrospinal fluid (CSF) rhinorrhea, in which antibiotic prophylaxis remains controversial, 87% of 966 neurosurgeons reported that they use antibiotic prophylaxis in patients with gunshot wounds (7). Post-traumatic brain abscess is most common after missile injury. Other types of penetrating injury also associated with increased infection risk include knife wounds in young adults and accidental trans-orbital accidents in children, such as with pencils or wires.

*Basilar Skull Fractures* The base of the skull is comprised of five bones: the sphenoid, ethmoid (including cribriform plate), frontal, temporal (petrous and squamous), and occipital bones (1). Clues to likely basilar skull fracture include CSF leaks, pneumocephalus, hemotympanum,

Battle's sign (ecchymosis in the mastoid region), hearing impairment, peripheral facial nerve weakness, periorbital ecchymosis, fracture of the frontal sinus, and anosmia (8). Because the dura is closely adherent to the bones of the skull base, basilar fractures are frequently associated with dural tears; the resultant fistulous connection between brain and sinuses or ear provides a possible route of entry for infection. Antibiotic prophylaxis after basilar skull fracture has been controversial. A recent meta-analysis of 12 studies with a total of 1241 patients with basilar skull fracture did not find a statistically significant decrease in meningitis in patients treated with antibiotic prophylaxis (9).

### Cerebrospinal Fluid Fistula

*Cerebrospinal Fluid Rhinorrhea* CSF rhinorrhea is a definite indication of a fistulous tract from the intracranial compartment through the dura and skull base. It is therefore important to determine whether CSF rhinorrhea is present in brain injured patients. CSF rhinorrhea is typically a watery discharge with a salty taste, which does not cause nasal excoriation or stiffen bed linen (10). It may be unilateral, may increase with leaning over or prone positioning, and may be associated with a dull constant headache from low intracranial pressure (10, 11). Differential diagnosis includes vasomotor rhinitis, which is typically bilateral with sneezing and lacrimation, and pseudo-CSF rhinorrhea after surgery in the region of the pericarotid sympathetic plexus (12), with nasal stuffiness and hypersecretion, facial flushing, and absent ipsilateral lacrimation.

Glucose strips or tape are notoriously unreliable for diagnosis of CSF rhinorrhea with false-positive rates as high as 75% (13). Quantitative glucose determinations are somewhat more reliable for clear nasal fluid collected in a test tube, but not reliable when fluid is bloody. The definitive test is the beta-2 transferrin assay, which is sensitive and specific for CSF (14, 15). This form of transferrin is not normally found in serum, tears, saliva, or nasal secretions.

Common fistula sites causing CSF rhinorrhea include the ethmoid/cribriform plate region, posterior frontal sinus, roof of the orbit, and sphenoid sinus regions. When rhinorrhea is unilateral, it accurately predicts the site of the dural tear and fracture in 95% of cases. However, only one-half of patients with bilateral rhinorrhea have bilateral dural tears (1). Fractures are particularly common into the ethmoidal air cells just lateral and posterior to the cribriform plate (Figure 33-1)(10), and injury in this area is characteristically associated with anosmia (1). Rhinorrhea into the ethmoid air cells sometimes stimulates fibroblastic proliferation that may grow to close the underlying defect (10). In contrast, dural tears of the posterior wall of the frontal sinus do not tend to heal, and typically cause persistent rhinorrhea requiring surgery. Frontal sinus fracture can be associated with

FIGURE 33-1

(a) Fracture in cribriform plate, (b) Fracture through ethmoidal cells, which is the more usual type. (1) crista galli, (2) cribriform plate, (3) ethmoidal cells. (From MacGee EE: Cerebrospinal fluid fistula. In Vinken PT, Bruyn GW (eds): Handbook of Clinical Neurology, vol. 24. New York, Elsevier, 1976, with permission.)

anesthesia of the supraorbital nerves, subconjunctival ecchymosis, palpable depression over the frontal sinus region, and air in the orbit. A leak into the sphenoid sinus is particularly likely to cause profuse rhinorrhea (16).

Several diagnostic techniques are used to localize the site of a CSF leak. Radioisotope cisternography, with radioisotope injected into the CSF and measured in pledgets placed in the nose is not as precise as newer methods for pinpointing the exact location of the leak, but can be useful for lateralization of a slow or intermittent leak (17). Special MRI techniques, using images with heavy T2 weighting may highlight CSF sufficiently to show the leak (17, 18). CT cisternography, with CT scan after injection of a contrast dye, is effective in patients with an active leak but may fail to visualize intermittent leaks, and is an invasive technique. Intrathecal fluorescein with endoscopic visualization has been reported as a very effective means of precisely identifying slow leaks, especially as part of an endoscopic surgical repair procedure (17, 18). Although a high incidence of side effects was initially reported with intrathecal fluorescein, including transient paraparesis and seizures (19), others have used the technique more recently and encountered little difficulty (17, 18).

**CSF Fistula and Meningitis Risk** CSF rhinorrhea implies a 10-fold increase in the risk of subsequent meningitis (20).

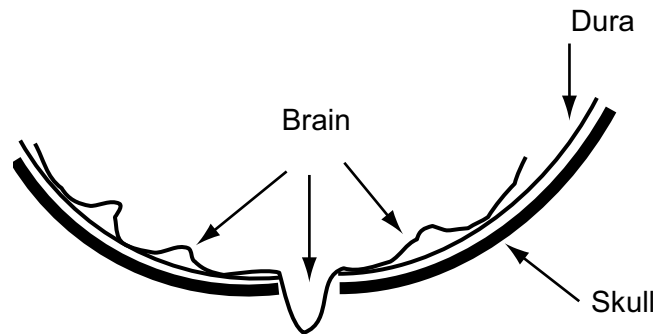

FIGURE 33-2

Fistula with brain tissue protruding through dura and skull. Even in the absence of active CSF fluid leakage, this presents a significant risk for eventual development of meningitis. Over time the plug of brain tissue may shrink somewhat with changes in brain compliance and provide route of entry for infection

However even when rhinorrhea resolves, as it does in 85% of cases within 1 week (21), there is now strong evidence of a very high (30–40% or more) risk of late meningitis (8, 17, 18, 22). In one series of 44 patients with meningitis, over one-half of the episodes occurred more than 1 year after injury (8), and cases have been reported many years later. Such late occurrences of meningitis underscore the importance of taking an aggressive approach to ensure closure of dural tears acutely and of considering a possible fistula when patients with a prior TBI present with meningitis. Rhinorrhea has also presented years after the original trauma in multiple cases (22, 23, 24, 25). Coughing, sneezing, hard work, or inverted posture may facilitate opening of the leak. Computed tomography (CT) or magnetic resonance imaging (MRI) may show evidence of encephalocele (brain protrusion through a skull defect) without clinical signs of basal fracture or CSF leak. In some late presenting cases brain tissue has been trapped in the dural defect, apparently making a temporary seal but preventing dural closure (23) (Figure 33-2). In cases presenting years after the injury the cerebral plug may become inadequate with brain atrophy or change in cerebral compliance.

Endoscopic extracranial techniques can now repair 90% of fistulae without requiring craniotomy (17). This avoids additional brain trauma and often preserves smell, which is typically lost with intracranial repair. Large defects or those associated with mass lesions may still require craniotomy. Lumbar drainage has often been used postoperatively after definitive dural repair, but it is not usually recommended as sole treatment (21, 22, 26).

Although prophylactic antibiotic use in patients with CSF rhinorrhea remains highly controversial, there is more support for prophylaxis in patients with rhinorrhea than in patients with basilar skull fracture alone (1, 9, 10, 20, 27, 28). One meta-analysis study found a statistically significant benefit by pooling studies which showed a

similar trend but individually lacked sufficient numbers to achieve statistical significance (27), while another meta-analysis came to the opposite conclusion (9).

**Cerebrospinal Fluid Otorrhea** Otorrhea occurs when petrous temporal bone fracture and dural tear are combined with tympanic membrane tear. The exact incidence of temporal bone fracture is uncertain since as many as 60% of these fractures may be missed with routine CT imaging (29). However they are believed to constitute over one third of basilar skull fractures (29). Otorrhea has been estimated to occur in approximately 7% of all patients with basilar skull fractures (30), or approximately 20–25% of those with temporal bone fractures (1). Petrous temporal bone fractures are divided into longitudinal and transverse types. Both types are associated with otorrhea. Longitudinal fractures run in the antero-posterior direction and are five times more common. Longitudinal fractures often are associated with torn tympanic membrane, ossicular disruption, and delayed transient impairment of the facial nerve. Transverse fractures run at right angles to the petrous axis and are associated with injury to the inner ear and eighth nerve, and immediate lasting injury to the facial nerve. Unlike CSF rhinorrhea, CSF otorrhea almost always resolves spontaneously in less than 1 week (1, 23). In the few cases that persist, the reported rate of cessation after a single surgical procedure is 98% (1).

**Pneumocephalus** Pneumocephalus is defined as gas within the cranial cavity. In TBI this is usually air, with the exception being gas produced in a brain abscess by anaerobic infection. Air may be present in any of the intracranial compartments, but frontal subdural or intracerebral air were most common in a series of 295 patients (31). Pneumocephalus occurs in 15% of patients with a fistula (22), and concurrent rhinorrhea is reported in 30–50% (31).

Two major mechanisms for posttraumatic pneumocephalus have been proposed, the inverted bottle mechanism and the ball-valve mechanism. Relatively early pneumocephalus in patients with rhinorrhea or otorrhea is consistent with the inverted bottle mechanism. It is similar to what happens when one drinks or pours from a bottle; as CSF escapes from the cranium, eventually air must enter to allow more CSF to exit. On the other hand, in the ball-valve mechanism, air is forced into the cranium with pressure, as by a cough or sneeze, and then cannot exit because the meninges or cerebral tissue tamponades the leak. The delayed build-up of intracranial air from this recurrent one-way valve mechanism fits the peak incidence of pneumocephalus at 1–3 months post injury.

The term “tension pneumocephalus” is used when intracranial air acts as a mass lesion, compressing the

FIGURE 33-3

CT scan showing sizeable right-sided extra-axial pneumocephalus. Patient initially had TBI with subdural hematoma, later hydrocephalus and recurrent right subdural hygroma treated with ventriculoperitoneal shunt and shunt into subdural space on right, followed by subsequent postoperative development of pneumocephalus. In this film, some fluid is now seen inferiorly in the subdural space surrounding the catheter, in addition to the air superiorly. Catheter is also seen entering the right lateral ventricle. Despite the mild mass effect seen, both the subdural air and fluid eventually resolved from this point with conservative management

underlying brain and causing headache, motor paresis, meningeal signs, and even psychosis. Sometimes this type of picture is seen postoperatively, such as after evacuation of a subdural hematoma (Fig. 33-3).

Tension pneumocephalus has been described to present with severe progressive unilateral headache as much as four years after original brain injury (32). Although this late presentation is not common, it underscores the importance of considering this diagnosis in the comprehensive assessment of the post-traumatic headache patient.

One bedside finding, the “bruit hydro-aérique (31),” or cranial succession splash, is pathognomonic for pneumocephalus. It is heard by auscultation of the head during head movement and is sometimes also described subjectively by the patient. Although reported in only 7% of patients with pneumocephalus, it is likely that many examiners have not looked for it.

Definitive treatment for pneumocephalus entails repair of the underlying dural tear and fistula. In some obtunded patients with tension pneumocephalus, the air collection is tapped via a burr hole as an initial temporizing measure (31).

## INFECTIOUS COMPLICATIONS

### Meningitis

*Presentation and Approach to Management* Trauma to the head is the most common cause of meningitis in adults (33). The classical symptoms of meningitis are well known, including headache, fever, stiff neck, and confusion. However, typical features may be lacking in 20% of patients, particularly the very young, the very old, and the immunosuppressed (34). Focal signs are typically absent in meningitis, and their presence warrants obtaining a CT scan to rule out abscess, empyema, or other mass lesion. Lumbar puncture characteristically reveals CSF pleocytosis (predominantly polymorphonuclear cells) with lowered glucose (less than one-third the blood glucose in three fourths of patients). Identification of the causative organism in the cerebrospinal fluid generally guides specific antibiotic selection, along with general principles such as ability of the antibiotic to cross the blood brain barrier, effectiveness in purulent fluid, and ability to exert a bacteriocidal effect (35, 36). Due to the changing development of drug resistant strains, availability of newer antibiotics, and the need for treatment to be tailored to the specifics of each case, only some broad guidelines are offered here, and the reader is advised to check updated resources for best management of each case.

*Common Organisms and Management* Streptococcus pneumoniae are by far the most common causative organisms causing post-traumatic meningitis, accounting for over 80% of some series (33). Whereas penicillin was previously the mainstay of treatment for these pneumococci, with the emergence of resistant strains, the use of third generation cephalosporins (such as cefotaxime, ceftazidime, or ceftriaxone) is now often suggested, sometimes accompanied by vancomycin and rifampin (35). Hemophilis is important in young children, and third generation cephalosporins have also been advocated. (35) Patients with penetrating injuries are more likely to have Staphylococcus aureus or gram-negative meningitis (20). Staphylococcus aureus can be treated with nafcillin or oxacillin, or vancomycin for resistant organisms. Adult meningitis during the first few days after nonpenetrating injury is almost always pneumococcal. Gram-negative infections usually present later, necessitating broader-spectrum coverage in late presenting meningitis. Shunt-related infections warrant special mention, because they often are indolent clinically and usually caused by Staphylococcus epidermidis. Shunt removal is generally necessitated along with vancomycin intravenously, or even intrathecally for refractory cases (see hydrocephalus section for further discussion)(37, 38). Broad spectrum coverage of posttraumatic meningitis with a combination of agents, such as vancomycin plus ceftazidime, can

sometimes be instituted when diagnostic results from cerebrospinal fluid are not available (37).

### Subdural Empyema

*Risk Factors and Presentation* Subdural empyema is most common in males under age 20, and is actually more often secondary to paranasal or ear infections than trauma (16, 20). Post-traumatic subdural empyema is usually secondary to septic compound skull fracture, comprising 77% of a series of 53 cases of post-traumatic subdural empyema. (39) Presentation is acute and fulminant with fever, headache, and obtundation (20). Periorbital swelling (40) or tenderness over the sinuses or mastoid may provide additional clues. Focal signs and seizures are common(16, 34).

*Evaluation and Management* CT scans show an extraaxial collection with medial membrane enhancement (41). MRI scans typically shows low signal on T1-weighted imaging and high signal on T2-weighted images(42). Lumbar puncture is contraindicated. Multiple organisms are usually present, including streptococci. When only one organism is cultured, it is most often Staphylococcus. In addition to appropriate antibiotics, either burr hole drainage or craniotomy is recommended (20, 34, 40, 42, 43). Although success has frequently been reported with burr holes (34, 40), large size, midline shift, parafalcine or posterior fossa location, and loculation have been identified as factors favoring craniotomy (43).

### Brain Abscess

*Risk Factors and Clinical Presentation* Trauma is a less common cause of brain abscess, compared with spread from sinusitis or middle ear infection, or hematogenous spread from pulmonary or dental infection. In fact, only approximately 10% of brain abscesses are secondary to TBI or neurosurgical procedure. Among patients with TBI, brain abscess is three times as likely after gunshot wounds, and eight times as likely with wound complications, such as hematomas, fluid collections, wound infection and cerebrospinal fistula (44). Brain abscess is rarely seen as a complication of basal fracture alone (45). Classically the presentation of brain abscess peaks at about 2–3 weeks after injury, but the mean time of presentation was actually more than 3 months post injury in one series of 36 patients (46). Presentation is frequently with signs of increased intracranial pressure rather than with acute febrile illness. In one series headache was present in 90% and vomiting in 65% (47), while as many as half of patients are afebrile at presentation (45, 47). Focal signs occur in 50–75%, with changes in mental status notable in one half of patients, and seizures in one-third (45). Table 33-1 contrasts key features of meningitis, subdural empyema, and brain abscess.

**TABLE 33-1**  
***Distinguishing Features of Different Types of Intracranial Infection***

	<b>MENINGITIS</b>	<b>SUBDURAL EMPYEMA</b>	<b>BRAIN ABSCESS</b>	<b>SHUNT INFECTION</b>
Predisposing condition	Basal fistula	Penetrating injury, Compound depressed fracture, Paranasal sinus/ear	Penetrating injury, Compound depressed fracture, Paranasal sinus/ear, Hematogenous	Recent shunt or shunt revision (70% within 2 months)
Organisms	<i>Pneumococci</i> (early) Gram negatives (late) <i>Staphylococci</i> (late)	Mixed/ <i>Streptococci</i> <i>Staphylococci</i> Gram negatives	Polymicrobial/ anaerobic <i>Staphylococci</i>	<i>Staphylococcus epidermidis</i>
Presentation	Acute Headache, nuchal rigidity, mental status change	Acute fulminant Periorbital swelling Sinus tenderness Increased ICP, Seizures, focal signs	Subacute/ progressive Increased ICP Focal signs	Indolent Malaise, nausea irritability
Fever	Yes	Yes	Only 50%	Low-grade
WBC	Elevated	Elevated	Often normal	Often normal
CT/MRI	Negative or meningeal enhancement	Extra-axial – medial rim enhancement	Intra-axial ring enhancement, especially late; MRI T2 capsule low signal	Often nondiagnostic
Lumbar puncture	Increased WBC, decreased glucose	Contraindicated (Increased WBC, normal glucose)	Contraindicated (Often negative)	LP not reliable Must tap shunt for diagnosis
Management	Antibiotics	Antibiotics Burr hole/craniotomy	Antibiotics Debridement Stereotaxic aspiration	Antibiotics, Steroids Remove shunt

Key: ICP = intracranial pressure, WBC = white blood count, LP = lumbar puncture.

**Abscess Stages and Imaging** Stages of abscess formation have been recognized pathologically and correlated with CT and MRI scan findings (45). Early on the term cerebritis is used because of the presence of inflammatory cells in a perivascular location. CT scan at this stage shows low density with little enhancement, which may be solid. MRI during cerebritis is more sensitive (34) and shows uniform signal with indistinct margins (47). Later in cerebritis both the necrotic center and surrounding edema may reach maximal size, fibroblasts and macrophages are found at the periphery, and CT scan may show a thin rim of enhancement and increasing edema. Next a capsule of collagen and reticulin begins to develop; this forms more slowly on the ventricular side of the abscess. CT scan now shows a ring-enhancing capsule (less medially) and a low-density center. MRI scan shows the capsule as low signal on T2-weighted images (47). Diffusion weighted MRI has been effective in distinguishing brain abscess from other mass lesions, such as brain tumors. On diffusion weighted MRI the central core of a brain abscess is hyperintense, whereas tumors such as glioblastoma or metastasis are typically hypointense centrally (48).

**Organisms and Treatment** Most brain abscesses are polymicrobial and include anaerobes. Gas on CT scan

may help in early differentiation from tumor and suggests anaerobic organisms. Staphylococci are found in about 10% of brain abscesses and are more frequent after trauma (45). Lumbar puncture is contraindicated in brain abscess and usually not diagnostically helpful if performed inadvertently. Therefore, choice of antibiotic reflects the anticipated polymicrobial etiology supplemented by information from aspiration of the abscess. For example, in the absence of specific culture information, a combination of a third generation cephalosporin, nafcillin or vancomycin for Staph, and metronidazole for anaerobes might be utilized. As an abscess heals, the capsule becomes more isodense on serial CT scans. Steroids are frequently used effectively in brain abscess to decrease edema, but may delay encapsulation of the abscess and make monitoring of response to therapy more difficult. Surgical management of brain abscess includes excision or CT-guided stereotactic aspiration (49, 50). Indications to the stereotactic approach include surgically inaccessible location, cerebritis stage, or poor neurologic or general medical condition. Excision is useful for removal of foreign material and necessary for posterior fossa lesions. Adverse prognostic factors in brain abscess include young or old age; large, deep abscess; coma; or rupture into the ventricular system. Mortality from brain abscess in

Vietnam was 54%, and survival was worse with gram-negative organisms. However, good recovery can occur, and 30% or less of survivors are reported to have significant residual hemiparesis.

## CRANIECTOMY AND CRANIOPLASTY

### Craniectomy and Cranioplasty

*Role of Cranioplasty in the Recovery Process* Craniectomy (skull flap left out) is performed acutely in many patients with either uncontrollable intracranial pressure or with penetrating or contaminated wounds. Traditionally cranioplasty (replacement of bone flap or prosthesis) was often delayed six months or longer to minimize risks of infection or complication (16, 51, 52), and the procedure was considered more cosmetic and protective than therapeutic. However, it now appears that many patients with craniectomy develop the so called “syndrome of the trephined” (53), and can show considerable neurologic and functional improvement with early performance of cranioplasty. The deficits shown to improve upon performance of cranioplasty have included headaches, apathy, hemiparesis (54), midbrain syndrome with eye movement disorder (55), tremor, gait, and cognitive function (53). Patients exhibiting the syndrome of the trephined have been described to show the “sinking skin flap syndrome”, where the craniectomy flap tends to be markedly ingoing (53). This is particularly likely to occur in patients with concurrent shunts for hydrocephalus (56), and because craniectomy changes the brain compliance it may actually play a role in inducing hydrocephalus (53, 56).

In those patients where marked clinical improvement occurs with cranioplasty, the improvement has correlated with cerebral blood flow improvements of up to 30% as well as improved distribution of flow. Based upon measurements of transcranial cerebral oximetry and of ratios of phosphocreatine to inorganic phosphate (sensitive to rate of oxygen depletion), it has been suggested that cranioplasty induces more energy efficient mitochondrial function (53). The practical impact of these studies is the desirability of performing cranioplasty earlier, particularly in patients with markedly ingoing skull defects or ventriculoperitoneal shunts.

*Cranioplasty Alternatives* Cranioplasty can be performed with the patient’s own bone flap, which can be frozen and stored (57), or stored in the patient’s abdomen (58). Alternatively multiple materials can be used to create a cranioplasty flap, including titanium mesh (59), hydroxyapatite, and polymethylmethacrylate (60), and computerized techniques can be used to generate a custom made cranioplasty prosthesis (61). For patients with shunts and depressed skull flaps, it has been suggested to clip the shunt

temporarily to reexpand the brain prior to cranioplasty to minimize dead space at the time of surgery (62).

## HYDROCEPHALUS

### Overview

*Importance After TBI* Hydrocephalus is the most common treatable neurosurgical complication during rehabilitation of traumatic brain injury (TBI)(63), and its treatment can sometimes have a dramatic impact on rehabilitation and outcome. One recent study estimated an incidence of post-traumatic hydrocephalus at 45% in patients with severe TBI (64). However, differentiation of dynamic hydrocephalus from central atrophy or ex vacuo ventricular dilation remains problematic(65), and the physiology relevant to the decision process in managing these patients is complex. Practical management after a shunt includes prevention and treatment of other complications such as overdrainage and subdural hematoma, and the introduction of programmable shunts now offers additional opportunity for the physician to intervene medically during rehabilitation. Therefore the pathophysiology and clinical presentation of hydrocephalus, noninvasive and invasive diagnostic studies, shunt types including newer valve innovations, and shunt complications will be reviewed in some detail.

*Types and Variants* Hydrocephalus is divided into communicating and noncommunicating types(66). In communicating hydrocephalus, the different portions of the ventricular system are interconnected, and fluid may exit the ventricular system freely to the cisterns and subarachnoid space, whereas in noncommunicating (obstructive) hydrocephalus CSF flow is obstructed either between the ventricles or in exiting the ventricular system.

Post-traumatic hydrocephalus is communicating in the vast majority of cases, and enlargement characteristically involves all components of the ventricular system. Blood products, protein, or fibrosis typically interfere with circulation of cerebrospinal fluid and its absorption into the bloodstream through the arachnoid granulations (67).

When only selected portions of the ventricular system are enlarged, noncommunicating hydrocephalus should be considered. For example, large lateral and third ventricles with a small fourth ventricle in a patient with a large head circumference is generally attributable to aqueductal stenosis (66, 68), a congenital condition which may become decompensated by TBI. Lumbar puncture is contraindicated in these patients. Endoscopic third ventriculostomy can effectively bypass the aqueductal obstruction without requiring a shunt in some cases (69). The procedure involves placing hole in the floor of the 3rd ventricle creating a connection with the adjacent cistern.

Focal ventricular enlargement frequently occurs on an atrophic or porencephalic basis in brain areas that have sustained known damage. Less often, trapping of an isolated portion of the ventricular system may produce focal enlargement with signs of increased intracranial pressure or focal deficits (70–73). Occasional cases of multiloculated hydrocephalus are encountered, usually secondary to meningitis, ventriculitis, or intraventricular hemorrhage (74). The multiple irregular intraventricular septations of the enlarged ventricular system can be effectively treated with fenestration by intraventricular endoscopy (74–76).

### Pathophysiology of Chronic Communicating Hydrocephalus Including Normal Pressure Hydrocephalus (NPH)

**Pascal's Law** Pascal's law of hydraulic systems states that  $F = P \times A$ , where  $F$  is the force against the ventricular wall,  $P$  is the intraventricular pressure, and  $A$  is the area of the ventricular wall (77). This formula implies that when the area of the ventricular wall is large, a substantial expanding force may be generated from within the ventricle without the necessity of high pressure. For example, if a certain degree of ventricular enlargement initially results from increased pressure, ongoing enlargement may take place, even though pressures are no longer elevated (78).

**Decreased Parenchymal Pressure and Compliance** Rather than the absolute intraventricular pressure, the difference between the intraventricular pressure and that of the surrounding tissue determines ventricular size (77, 79). This concept may be understood more clearly by considering that the size of a balloon is determined not only by the pressure inside the balloon, but by the pressure of the air inside relative to the air outside the balloon. Changes in the viscoelastic properties of brain parenchyma with related decrease in parenchymal pressure therefore probably contribute significantly to the development of hydrocephalus, since it is the difference between cerebrospinal fluid pressure and intraparenchymal pressure which determines ventricular size (80). A gradient of reduced blood flow has been documented in the periventricular white matter of patients with NPH, as well as altered blood flow autoregulation which likely contributes to watershed ischemia (81). Damage to myelin and axons has also been described when hydrocephalus is longstanding (82). These factors are probably among those that contribute to the decreased elasticity or compliance of the brain parenchyma which is felt to be important in the development of NPH.

**Pulsatile CSF Flow** Disturbances of pulsatile CSF flow may be more important than blockage of CSF absorption in causing chronic communicating hydrocephalus (83). According to the Monro-Kellie doctrine, the volume of

the intracranial contents including brain, blood, and CSF is constant (84). This means that arterial blood inflow during systole is accompanied by both outflow of venous blood and shifting of CSF into the spinal compartment (84). Furthermore CSF movement is not simple unidirectional flow but complex, and the basal cisterns probably play an important role in dynamic compliance. When intracranial compliance is decreased, restricted arterial pulsation and increased pulse pressure in brain capillaries have been postulated to play a causative role in chronic hydrocephalus (85).

### Clinical Presentation of Hydrocephalus

**Acute Hydrocephalus** Early post injury acute hydrocephalus can present with symptoms of increased intracranial pressure including headache, nausea, vomiting, and lethargy or decreasing mental status. Associated signs can include a tense bulging craniectomy flap, papilledema, and Cushing's triad of hypertension, bradycardia, and hypoventilation.

**Normal-Pressure Hydrocephalus** NPH is well known to present with the clinical triad of dementia, gait ataxia, and urinary incontinence. Of the three, gait impairment is the most important diagnostically and most likely to respond to shunting. The classic gait disturbance is short stepping, wide based, with a "magnetic" difficulty in lifting the feet, and characteristic of frontal or subcortical rather than cerebellar dysfunction (86, 87). The cognitive difficulties in NPH are apt to include long latency responses, decreased attention, and poor initiation rather than deficits such as aphasia or agnosia. In patients with TBI, the presentation of hydrocephalus is not limited to the classic triad of normal pressure hydrocephalus, and should be considered in any patient who worsens or fails to progress adequately. A prefrontal syndrome (88) or akinetic mutism are additional clinical syndromes that should particularly raise suspicion for hydrocephalus. Patients with meningitis or intracranial hemorrhage, especially subarachnoid or intraventricular hemorrhage, are particularly at risk for development of hydrocephalus.

### Computed Tomography (CT) and Magnetic Resonance Imaging (MRI)

**Ventriculomegaly** CT and MRI scans have been invaluable in providing information about ventriculomegaly, and multiple methods have been devised for measuring ventricular size, calculating ventricle to brain ratios, and assessing shunt function (89–93). However, ventricular size alone has not been a reliable predictor of whether a patient has shunt responsive hydrocephalus rather than cerebral atrophy (94). In fact, ventriculomegaly has been reported in as many as 72% of patients with severe TBI (95), and it is now recognized that the extent of

ventriculomegaly can be correlated with severity of diffuse axonal injury and outcome, complicating assessment for hydrocephalus in patients already known to have severe TBI (96–98). Ventricular configurations favoring dynamic hydrocephalus include enlargement of temporal horns, convex shape of the frontal horns, widening of the frontal horn radius, and frontal horn location closer to midline narrowing the “ventricular angle” (70).

**Sulcal Absence and Periventricular Lucency** Ex-vacuo ventricular dilatation or cerebral atrophy typically involves sulcal prominence. Small or absent sulci on a CT scan in combination with ventriculomegaly are predictors of a good response to shunting, although the presence of sulci does not preclude a positive response (94). Periventricular lucency has been a valuable predictor of a good response to shunting, especially when lucencies have been seen in multiple periventricular locations (see Figure 33-4) (94, 99). In hydrocephalus, fluid seeps across the ependymal lining of the ventricle and causes interstitial edema. This transependymal fluid is seen as lucency on CT and as smooth increased T2 signal on MRI. Contusion, infarction, or demyelination in the periventricular white matter can be difficult to distinguish from transependymal fluid, but are usually more irregular and asymmetric (100).

FIGURE 33-4

Hydrocephalus pre- and post shunting. In the pre-shunt scans (top) note marked periventricular lucency in the white matter consistent with transependymal fluid in addition to ventricular enlargement. There is also artifact from aneurysm clip and right hemispheric encephalomalacia, maximal in the right temporal lobe. Post shunt scans show persisting encephalomalacia of the right hemisphere including the right lateral ventricle and right temporal horn. Shunt is now seen entering the left lateral ventricle which has now normalized (including left temporal horn), and periventricular lucency has largely resolved. Surprisingly a CSF tap test (see text) had actually been negative in this patient, but after performance of ventriculoperitoneal shunt there was nonetheless marked clinical improvement

**Additional MRI Findings** MRI provides more anatomic detail about the configuration of the ventricular system than CT, including imaging of structures such as the Sylvian aqueduct and foramen of Monro. More rapid flow through the Sylvian aqueduct can be detected as decreased signal or “flow void” in the aqueduct in patients with hydrocephalus due to decreased compliance of the ventricular wall of the 3rd ventricle during systole (70, 101, 102). A series of linear measurements on MRI, essentially reflecting size and configuration of the third ventricle, can be used to distinguish obstructive hydrocephalus from atrophy, but the effectiveness of this approach in chronic communicating hydrocephalus in TBI has not been assessed (103).

**SPECT Scans** SPECT scans may be helpful in differentiating hydrocephalus from atrophy (64). Subcortical low flow improved in follow up SPECT after shunting in 10 of 11 patients who improved clinically but did not in 3 clinically unimproved patients (104). In a series of eight patients showing clinical improvement after a shunt, a “high percentage” showed improvement of previous temporal lobe hypoperfusion (64).

### Invasive Testing

**Cisternography** Radioisotope cisternography had long been a mainstay in the diagnosis of hydrocephalus. After lumbar injection of radioisotope, pooling in the ventricles rather than progression of uptake over the convexity was taken as indicative of normal pressure hydrocephalus. However, cisternogram findings may really be more of a dilution and concentration process than a true measurement of CSF flow (84), and cisternography does not improve the diagnostic accuracy of combined clinical and CT criteria (105). Cisternography based predictions were the same in 43% of patients, better in 24%, and worse in 33% (105).

**Lumbar Infusion Studies** Infusion of fluid via a lumbar or ventricular catheter with measurement of drainage at designated pressures allows calculation of the outflow resistance, a measure of the difficulty of CSF absorption (94). If the outflow resistance is low, significant volumes of CSF can be readily absorbed and a shunt is not likely to help. On the other hand, increased outflow resistance means CSF is not readily absorbed. It is related to decreased compliance of the system, and is predictive of a positive response to shunting (68, 94, 106–110). Of interest, ventricular size does not correlate well with either outflow resistance or response to shunting (84, 106). Infusion studies have relatively low risk compared with the long-term morbidity of a shunt (107, 108). Unfortunately, despite their reported value and frequent use in Europe, these studies are infrequently performed in many U.S. hospitals. The suggestion of a one-stage “test and shunt if needed” procedure may make infusion studies more practicable (68).

**CSF Tap Test and CSF Drainage Trial** A lumbar puncture with the removal of 50 ml of CSF has been widely advocated as a CSF tap test (99, 103, 112–116). If the patient shows an improvement in neurologic status after lumbar puncture, the test is viewed as positive. However, a lack of response does not preclude response to a shunt, because shunting produces more sustained ventricular decompression (67, 86). Therefore, the CSF tap test is most useful to identify patients who otherwise might not be shunted; a strong candidate would be shunted even in the face of a negative tap test. A more prolonged CSF drainage trial with a spinal catheter for 3 to 5 days has been shown to have both greater sensitivity and predictive value of shunt success than a simple tap test alone. (111, 112).

**Combined Studies** A recent patient series had both lumbar infusion testing and CSF tap tests (114). The two tests agreed in only 45% of patients, with use of both tests recommended, since each test identified patients missed by the other test. When the tap test was positive, 94% of patients had a good response to shunting, but if the test were used alone, 58% of positive shunt responders would have been missed. The lumbar infusion test was only 80% predictive of success, but false negatives were 16%. In another series, perfusion weighted MRI or SPECT were performed before and 1 day after CSF tap tests (115). Nine patients were both clinically improved and had improved blood flow after the tap, and all responded well to shunting. In addition, six patients who were not clinically improved by the tap test, but did have improved

blood flow on perfusion weighted MRI or SPECT after the tap test also showed good response to shunting.

### Approach to Shunt Decision Making.

**Establishing the Diagnosis and Therapeutic Expectations** Table 33-2 reviews multiple considerations relevant to identifying dynamic hydrocephalus. The combination of the clinical course and findings, CT and MRI appearance, and in some cases SPECT and CSF tap test (and lumbar infusion testing if available) may help establish the diagnosis. Patients with TBI are likely to show only a partial response to shunting, because deficits from hydrocephalus are superimposed on deficits from the original TBI. This should be clearly explained to family members before pursuing shunting, to prevent or minimize any unrealistic expectations. However, given the potential significant benefit to patient outcome, an aggressive approach to identification and treatment of hydrocephalus is warranted for the severe TBI patient.

### Treatment

**Treatment Without a Shunt** The definitive treatment of hydrocephalus is surgical, usually the placement of a shunt. Treatment with carbonic anhydrase inhibitors, such as acetazolamide or furosemide (116), or with serial lumbar punctures is only a temporizing measure. Similarly, external ventricular drainage may be used on a temporary basis, particularly for obstructive mass effect or

**TABLE 33-2**  
*Factors Distinguishing Dynamic Hydrocephalus from Ex Vacuo Ventricular Dilatation*

FEATURE OR TEST	DYNAMIC HYDROCEPHALUS	EX VACUO VENTRICULAR DILATATION
Antecedent history	Hemorrhage, esp IVH or SAH	Anoxia or diffuse axonal injury
Clinical deficits	NPH triad (dementia, gait impair, urinary incontinence), pretectal syndrome (loss of upgaze), akinetic mutism	Consistent with location and severity of injury
Clinical course	Worsening, intermittent, or static	Chronic slow improvement
Skull flap (craniectomy)	Bulging (increased ICP) or increasing prominence	Depressed, ingoing
Ventriculomegaly pattern	Temporal horns, 3rd ventricle, convex frontal horns	Diffuse enlargement, porencephalic dilatation in areas of focal injury
Sulci, fissures, cisterns	Decreased	Increased
Periventricular abnormality	Smooth periventricular signal on T2 MR or lucency on CT (transependymal fluid)	Absent, or frontal contusions or periventricular infarct
SPECT	Periventricular low flow	Normal or Alzheimer's pattern
CSF tap test	Positive or no response	No response
Lumbar/ventricular infusion studies	Increased outflow resistance (poor CSF absorption)	Normal (lower) outflow resistance (good CSF absorption)

Key: IVH = intraventricular hemorrhage, SAH = subarachnoid hemorrhage, NPH = normal pressure hydrocephalus, ICP = intracranial pressure, CSF = cerebrospinal fluid.

while excessive blood products are likely to clog a shunt, but conversion to a shunt is needed for treatment of persisting hydrocephalus. Third ventriculostomy, where a connection is endoscopically created between the floor of the third ventricle and the underlying cistern, is the one exception of a definitive treatment for hydrocephalus not requiring placement of a shunt. It is most commonly used to treat aqueductal stenosis (117), where the procedure can bypass the obstruction at the Sylvian aqueduct (83). More recently there has been renewed interest in the procedure for other forms of hydrocephalus as well, mainly because of the potential to improve intracranial compliance without diverting fluid from the CSF compartment (85, 118).

**Shunt Types** Ventriculoperitoneal shunts are used most commonly for post-traumatic hydrocephalus, but ventriculoatrial, ventriculopleural, and lumboperitoneal shunts are useful in certain circumstances. Ventriculoatrial shunts are used more frequently in children with obstructive hydrocephalus. Occasionally ventriculopleural shunts may be substituted in cases with abdominal infection, very high CSF protein, or rarely to drain very low pressure hydrocephalus to the negative pressure of the pleural space (119). Ventriculopleural shunts characteristically cause a small pleural effusion that disappears with shunt malfunction (66). Pleural shunts are avoided in younger children because of the likelihood of symptomatic hydrothorax with a smaller pleural cavity (75). Lumboperitoneal shunts are not commonly seen, but can be used for communicating but not obstructive forms of hydrocephalus. Lumboperitoneal shunts have also been used for pseudotumor cerebri, when ventriculoperitoneal shunt placement may be difficult because of small ventricular size (66). Placement of a lumboperitoneal shunt often obliterates the basal cisterns on CT scan of the head, and the return of previously obliterated cisterns is a reliable indicator of shunt malfunction (120). Although usually asymptomatic, cerebellar tonsillar herniation (iatrogenic Chiari malformation) has been described in as many as 70% of patients with lumboperitoneal shunts (121).

**Shunt Valves and Components** The basic components of a ventriculoperitoneal shunt are the ventricular catheter, valve, and distal tubing. A reservoir may be added proximal to the valve to facilitate access to the ventricular system. Virtually all shunt systems have some type of one-way valve to allow forward flow down the shunt when the pressure gradient exceeds a threshold range and to prevent back flow from the peritoneum. Therapy staff often ask whether a shunt contraindicates inverted position; because of the one-way valve, this is not a problem. Detailed diagrams on a variety of different past and present valve systems and components are available (122). Basic valve types include slit valves, cruciate valves, mitre valves, diaphragm valves,

FIGURE 33-5

Common shunt valve types

and ball/spring valves (see Figure 33-5) (122–124). Slit valves open and allow CSF flow when sufficient pressure develops within the tubing; setting is determined by tube thickness. Cruciate valves are similar but have two perpendicular slits instead of one horizontal slit.

Sometimes two slit or cruciate valves are housed in one unit with a pumping chamber between them. Although most shunt systems feature a valve mechanism located over the skull, it is also possible to have a slit valve in the distal tubing instead. The leaflets of a mitre valve act as springs to regulate CSF flow (123). Diaphragm valves allow movement of a diaphragm from its seat or pin as determined by CSF pressure. Reservoirs or flushing chambers are added to many shunt systems. They allow manual pumping of the shunt and potential access to sample CSF or to inject into the shunt system. It is important to know the specifics of a shunt system before injecting into it, because some shunt components (especially older components such as the Spitz-Holter valve, Coe-Schulte second bubble, or Hakim-Cordis valve) may be damaged by needle perforations (125). Most modern shunts, however, have a portion that can be injected without damage. Flushing chambers may be of either single bubble or double-bubble design (see Figure 33-6). If the chamber is proximal to all valves, compression of a

FIGURE 33-6

Double bubble reservoir

single bubble may send fluid both down the shunt and back into the ventricle. If the chamber is between valves, compression may push fluid only in the forward direction. Compression of the distal bubble of a double-bubble shunt after occluding the proximal bubble may also force fluid in the forward direction. A similar result may be obtained in some single-chamber devices by occlusive digital compression of areas of proximal tubing before compression of the flushing chamber. Alternatively, compression of distal bubble or tubing before digital compression of the proximal chamber may force retrograde flow into the ventricle (e.g., intrathecal administration of antibiotics). Of course, access to the ventricle is possible only when a chamber is proximal to all valves.

Shunt valves are also specified by the approximate pressure necessary for opening and forwarding CSF flow, and are commonly divided into low, medium, and high pressure valves (122, 123). Such valve settings are approximate and function differently depending on the compliance of the ventricular system, especially given that CSF flow is pulsatile in nature (126). In general, because of Pascal's law ( $F = P \times A$ ), larger ventricles require a lower pressure for adequate decompression (86). However, valve pressure settings have poor correlation with actual intracranial pressure, which also varies widely among patients with the same valve, and within the same patient with different head of bed positioning (127). When patients do not respond to a shunt, conversion to a shunt of lower pressure occasionally results in clinical improvement (128). Because of the obvious undesirability of reoperation to place a valve with a different pressure, programmable valves have been developed which allow changing the effective opening pressure of the valve noninvasively at the bedside with an external magnet (see further discussion below).

### Shunt Complications

**Frequency of Shunt Complications** The overall incidence of shunt complications is high. Shunt complications include shunt failure, infection, seizures, subdural hematoma, and overdrainage. In 356 adult patients over an 18-year interval, the incidence of revision was 29% (129). In a series of 1,179 patients shunted for hydrocephalus (only 312 patients over age 5 years), the probability of shunt malfunction after 12 years was 81% (130).

**Shunt Failure** Shunt failure may present with irritability, confusion, lethargy, and headache unrelieved by position change. However, shunt failure may also present in a more fulminant manner than the original hydrocephalus, requiring prompt treatment (131). Proximal occlusion of the ventricular catheter is the most common source of blockage, usually accounting for at least 30% of cases of shunt dysfunction (131). Ventricular overdrainage may predispose to proximal occlusion by abutting the catheter tip against the ventricular wall (130). Distal shunt obstruction can be caused by encystment and loculation of the peritoneal contents around the distal catheter tip (72, 75). Abdominal pain, palpable pseudocyst, and ultrasound or abdominal CT may establish the diagnosis. Disconnections of shunt components have accounted for as much as 15% of shunt revisions and often are shown by a shunt series of plain radiographs (132).

Bedside palpation of the shunt sometimes gives a clue to shunt malfunction; excessive resistance to digital compression of the shunt chamber suggests possible distal occlusion, whereas inadequate refill suggests proximal occlusion. Unfortunately, palpation was neither sensitive nor reliable for determining shunt malfunction in a consecutive series of 200 patients (133). CT scans are helpful in demonstrating increase in ventricular size in many cases of shunt malfunction.

Definitive information about shunt blockage can be obtained by performing a shuntogram, where a needle is inserted into the safely perforable portion of the shunt, a pressure recording is done, and the progression of isotope or contrast is followed down the catheter and into the peritoneum (134, 135). With distal obstruction, pressure may be elevated with rapid ventricular filling but lack of distal flow. With proximal occlusion, the distal catheter fills, but pressure is low with slow disappearance of tracer and lack of ventricular filling (135).

**Shunt Infection** Shunt infection has been described in 7–29% of cases. Most infections are acquired at the time of surgery, and 70% present within the first 2 months (136). *Staphylococcus epidermidis* is most common, accounting for approximately one-half of infections, followed by *Staphylococcus aureus* and gram-negative organisms (137). Presentation is typically insidious with low-grade fever, malaise, irritability, and nausea; meningeal irritation is usually not present (137, 138). Erythema over the shunt site, however, is a highly specific sign (136–138).

Diagnosis should be established by performing a shunt tap, not by doing a lumbar puncture. Tapping the shunt leads to accurate diagnosis in 95% of cases, whereas lumbar puncture is positive in only 7–26% of cases (136). Diagnosis is based on culture results, because CSF protein and glucose may be normal and cell count may not be much greater with shunt infection than with shunt alone.

Treatment needs to be individualized to the clinical situation, but in general, the highest overall response rate (96%) has been reported with shunt removal or externalization combined with antibiotics (136). Staph epidermidis is the most common organism causing shunt infection, and sometimes can be difficult to eradicate; intravenous vancomycin, intrathecal vancomycin or a regimen of both vancomycin and rifampin are sometimes used (139).

**Seizures** The prevalence of seizures after shunting has ranged from 5–48% (72), but in patients with posttraumatic hydrocephalus seizures may also result from the original TBI.

**Overdrainage** Overdrainage by shunts is a major clinical problem, causing acute and chronic clinical symptoms, and fostering both proximal shunt obstruction and development of postoperative subdural collections. It has been the driving force behind the development of antisiphon devices, programmable valves, and gravitational shunts. Intraventricular pressure normally becomes slightly subatmospheric when we stand. However, after placement of a shunt, orthostatic intraventricular pressure becomes markedly low (124), reflecting the additional negative hydrostatic pressure from the distal tubing (Figure 33-7). This may cause excessive siphoning of CSF and a low pressure syndrome of orthostatic headache, dizziness, nausea and vomiting, lethargy, and diplopia (131, 140–142).

Some patients with chronically overdraining shunts develop the slit-ventricle syndrome (131, 140, 141). Such patients develop severe nonpostural headaches in the face of persistently small ventricles. Slight increase in ventricular size at the time of clinical symptoms and sluggish shunt refill suggest intermittent proximal shunt malfunction with ventricular collapse against the catheter. Such symptoms develop an average of 4.5 years after shunting and are analogous to pseudotumor cerebri in the tendency toward elevated pressures with small stiff ventricles (140, 141).

**Chronic Subdural Hematoma** Chronic subdural hematomas and hygromas are recognized complications of shunting, occurring in 4.5–28% of patients, and are particularly likely when ventricles are extremely large preoperatively (72). Normally intracranial pulsatile flow and upright posture both shift CSF within the cranium and to the lumbar region, but CSF remains within the CSF compartment; however with shunting CSF exits to the peritoneum, and this can result in an underfilled CSF compartment (84, 118). Since the volume in the cranium is fixed, a loss of fluid in the ventricular compartment may result in creation of increased potential subdural space leading to development of subdural hygroma and hematoma (142, 143). Furthermore, with upright posture, low intraventricular pressures caused by standing are thought to predispose to tearing and leakage from bridging veins. The occurrence of subdural hematoma may require tying off the shunt or turning up the valve

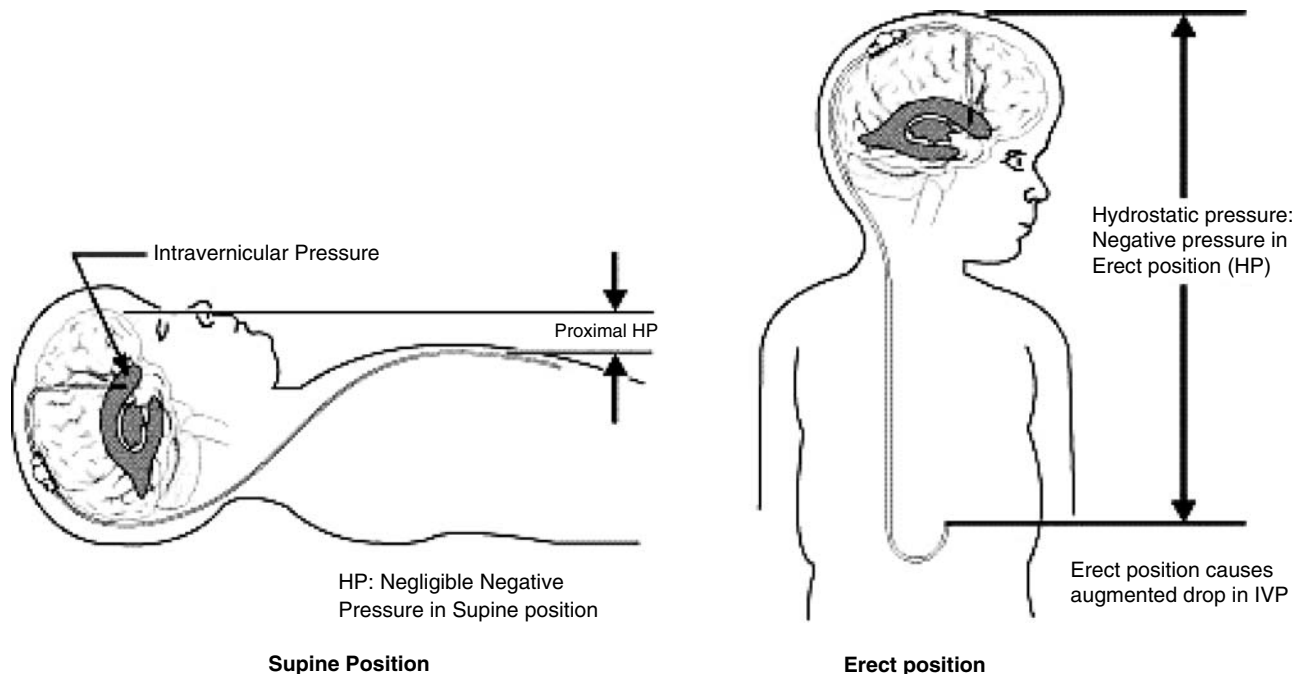

FIGURE 33-7

Positional changes in hydrostatic pressure

pressure setting if the patient has a programmable valve (72, 86, 143). Not all subdural collections are clinically significant; with MRI even very small fluid collections can be imaged (70). Post shunt meningeal fibrosis, with collagenous material in the subdural space, is distinguished from subdural fluid by its dramatic enhancement with gadolinium (70).

### Antisiphon Devices, Programmable Valves, and Gravitational Valves

**Antisiphon Devices** Problems related to overdrainage have led to the development of several special shunt components. Antisiphon devices have been developed with diaphragms that close to counteract negative standing hydrostatic pressures (124, 144). Successful prevention of the dramatic negative standing intracranial pressure has been documented (145). A less useful device is the valve with an on/off occluder bubble following the flushing chamber. Originally designed in hopes of preventing subdural development by transient occlusion, it is not used frequently today. Fortunately palpation or radiographs can determine whether the occluder has inadvertently been compressed (124). Several newer valves have been designed to assist with CSF overdrainage. The Orbis-sigma valve is a flow regulated valve, with variable resistance with three stages of flow. It initially functions like a standard low pressure valve but shows increased resistance with larger flow rates; it also has a decreased resistance safety valve to deal with higher pressures. The delta valve is similar to an antisiphon device in combination with a standard valve, but has been engineered to minimize the area of the valve diaphragm responsive to pressure effects of fluid in the distal tubing. This design was intended to increase physiologic resistance to flow in the upright position selectively (146).

**Programmable Valves** A revolutionary development in shunting for hydrocephalus has been the development of programmable valves which can have their opening pressure changed at the bedside by use of an external magnet (83, 122, 147–153). The Codman Hakim and PS Medical Strata valves (see Figure 33-8) are available in the USA, and the Sophy valve is also available in Europe.

The opening pressure of the Codman Hakim valve can be adjusted in increments of 10 mm H<sub>2</sub>O anywhere from 30 to 200, using a small bedside electromagnet. The Codman Hakim valve has a ruby ball and spring mechanism; the valve's spring tension is controlled by rotation of its spiral Cam with steps, which can in turn be adjusted by placing a small electromagnet over the shunt mechanism and dialing up the new pressure. When reprogramming the shunt, extreme care should be taken in precisely locating the active shunt mechanism by palpation, and carefully centering the electromagnetic programmer over it; otherwise the valve may program to a completely wrong setting. In cases where palpation is difficult, precise localization of the active shunt mechanism can be facilitated by a preliminary Xray with temporary placement of a radiopaque marker (beebie), which can then be removed prior to programming once the proper spot is identified. After programming the valve, one must confirm that the valve was correctly set by obtaining an Xray (see Figure 33-9); the setting can be difficult to see on Xray, and requires that the beam to pass first directly perpendicular to the shunt mechanism, then through the head, then to the Xray plate. A small dot on the right side of the device indicates proper orientation of film and placement of shunt (right hand rule); if it appears in the left, either the film was taken with the device against the Xray plate or the shunt is implanted upside down. There is a procedure for programming an upside down shunt, and the reader is advised to check with the

manufacturer in this instance. The Xray appearance is then compared with the settings template to identify the setting.

Patients with programmable valves can have MRI scans, but must have an Xray to check valve setting and may need reprogramming afterwards; valve settings were changed by MRI in 26.8 % of patients (147). Valve settings may also be changed by any very large magnets in the environment, and even by “filliping” of the shunt (abrupt manual manipulation such as flicking it with a finger)(154).

Valve pressure settings can be lowered for inadequate response to shunting, or raised for symptoms of overdrainage. Shunt settings should never be raised more than 30 mm at one time. Orthostatic headaches from overdrainage are particularly responsive to reprogramming of the valve, with headaches improving in 71% of patients (148). In some patients who develop subdural hematoma after shunting, surgical drainage of the subdural can be avoided by turning up the opening pressure of the valve(148). In two recent series reprogramming was performed in 41- 64% of patients with programmable valves at least once, and some had multiple adjustments (147–151). Based on the assumption that an adjustment of 50 mm or more would have warranted surgically changing the valve if it were not programmable, a cost benefit analysis of 541 programmable valves indicated

that the increased cost of the programmable valve was outweighed by the cost savings in avoiding additional surgeries (149). The possible benefit of reprogramming shunt valves during rehabilitation has only just begun to be explored. In one study of 114 patients, adjustments were deemed necessary in 13% of patients, and changes of 20–70 mm in steps correlated with significant functional improvement as scored on the Barthel index (151).

The PS Medical Strata valve has five settings which can be adjusted at bedside with magnetic tools. It has a ruby ball in cone with circular spring design, and includes an antisiphon component of the type found in the delta valve. Although is less flexible with regards to valve pressure settings (only 5 instead of 18 settings), the adjustment tools are easy to use, and the shunt setting can be confirmed at the bedside, making confirmatory Xray optional. One interesting aspect is that the relative positions of the Strata’s delta chamber and the ventricular tip of the catheter can substantially effect the amount of anti-siphon effect of the Strata system (83, 122, 153).

*Gravitational Shunts* Overdrainage of shunts has been particularly problematic because of the negative intraventricular pressures generated in the upright position by the column of fluid in the distal shunt tubing and the related siphon effects. In order to address this problem in a specific manner, gravitational shunts are designed with a higher opening pressure in the upright position than supine. The one used most extensively has been the Miethke Dual Switch Valve (113, 155–157). This is actually two valves in one, ingeniously designed so that the lower pressure valve opens in the supine position but is mechanically closed off by a ball in the vertical position, forcing flow through the higher pressure half of the valve when upright. A related invention is the Shunt Assistant valve (157, 158), essentially a gravitational antisiphon device which can be put in series with another valve, such as the Codman Hakim programmable valve. In the vertical position a tantalum sphere compresses a sealing ball to substantially increase the orthostatic opening pressure of the valve system specifically. At least 185 patients with normal pressure hydrocephalus have been carefully diagnosed and treated with either Meithke Dual switch valves or a combination of the Codman Hakim Programmable valves combined with the Shunt Assistant valve. Good or excellent outcome was described in 70% of patients and the incidence of overdrainage was only 4% (157). Of great interest, the patients with greatest favorable clinical response to shunting had minimal or no significant change in ventricular size post shunting (156, 157). It has been suggested that part of the reason for favorable outcome in this patient group may have been the avoidance of complications of overdrainage so commonly

seen after implantation of more conventional shunt systems.

## VASCULAR COMPLICATIONS

### Traumatic Aneurysm

*Intracranial Traumatic Aneurysms* Traumatic intracranial aneurysms are rare; they comprise less than 1% of all intracranial aneurysms (159–161) and are more common after missile injuries than closed head injury. In missile injuries direct contact of missile or bone fragments with the artery is common, whereas in blunt injuries up to 40% of cases do not have associated fracture (161). Traumatic aneurysms can be classified as true, false, mixed, or dissecting types, but false aneurysms are the most common (162–164). In true aneurysms, the adventitial wall is preserved, whereas in false aneurysms all elements of the vascular wall are disrupted and blood is contained only by the surrounding arachnoid, hematoma, or brain parenchyma. Mixed aneurysms have a combination of true and false elements. In dissecting aneurysms, blood channels within the vessel wall, effectively narrowing or occluding the vessel itself.

Common clinical presentations of traumatic intracranial aneurysms include seizures, focal neurological deficits, altered consciousness, and severe persistent headache (159, 161). Traumatic intracranial aneurysms are highly unstable and prone to rupture (162, 163); in fact, although the time interval from injury to rupture varies from days to years, 90% bleed within 3 weeks of injury (160, 163). The most common locations for traumatic aneurysms are the distal middle cerebral branches, distal anterior cerebral artery, and proximal carotid and vertebral arteries (161). Traumatic petrous and cavernous carotid aneurysms are often associated with basilar skull fracture, while supraclinoid carotid aneurysms are sometimes associated with orbital or anterior clinoid process fractures (161). Epistaxis, pharyngeal mass, and delayed cranial nerve palsy have also been described with aneurysms near the skull base (161, 165), and traumatic aneurysms should be suspected in patients with delayed subarachnoid or intracerebral hemorrhage. Although angiography remains the definitive test for diagnosis, it is now recognized that the combination of Magnetic Resonance Angiography (MRA) with perfusion weighted Magnetic Resonance Imaging (MRI) can be a very useful screening tool, especially given the difficulty of clinically identifying patients with these aneurysms (161).

Treatment of traumatic intracranial aneurysms can be problematic since they are typically false aneurysms and therefore cannot be clipped (162–164). Because the parent vessel often must be sacrificed, extracranial to intracranial distal revascularization procedures are sometimes performed at the time of definitive treatment (161).

Recently developed endovascular approaches have often been useful, including detachable balloons, detachable coils to occlude the parent vessel, or stents to exclude the aneurysm from the circulation while maintaining the patency of the parent vessel (161).

*Cervical Arterial Trauma Including Dissection* Traumatic injury to the cervical internal carotid or vertebral arteries may be seen after penetrating injuries, or after hyperextension and flexion neck injuries, as in motor vehicle accidents; many patients with blunt injuries show little or no overt external neck trauma (161). The incidence of injury to the carotid artery in patients with TBI has been estimated at 0.5% (161). When carotid injury occurs, mortality is estimated at 20–40% and neurologic deficits are seen in 80% of survivors. Presentation is typically that of infarction in the distribution of the involved vessel, either secondary to thrombosis, embolism or dissection. For example, after carotid artery trauma hemiparesis and hemisensory loss occur, but onset of these symptoms exceeds 10 hours from initial injury in half of cases, and is sometimes delayed for up to 48 hours (161). Acute headache can be a very important clue to the early diagnosis of arterial dissection, occurring in 60% of cases of carotid dissection, and slightly less often with vertebral artery dissection, where the headache tends to be occipital (166). Other important clues to possible cervical carotid injury include mandibular fracture, neck pain, pulsatile tinnitus, visual changes, lower cranial nerve palsies, and ipsilateral Horner's syndrome (161). Revascularization or direct repair is sometimes attempted for carotid dissection, but only if it can be done within 4 hours of onset in a conscious patient (162). Otherwise management is medical, with consideration of antiplatelet or anticoagulation therapy depending on clinical course and associated injuries. Anticoagulation with heparin or coumadin has been the traditional management when not contraindicated, but lacks a strong evidence base (166).

### Carotid Cavernous Fistula

*Types and Presentation* Traumatic carotid cavernous fistulas are typically direct fistulas from the internal carotid artery. Classified as type A, with fast flow and high pressure, they contrast with spontaneous carotid cavernous fistulas (types B, C, and D), which have low pressure and slow flow and typically receive dural blood supply (167, 168). The cavernous sinus is anatomically unique in that a large artery passes through a large venous space; for this reason a tear in the arterial wall alone can create an arteriovenous fistula without any additional venous anomaly (169). Visual impairment is a major presenting symptom and concern for further visual loss is a frequent management concern in patients with carotid cavernous fistula. Additional presenting signs of carotid cavernous fistula

include supraorbital bruit, exophthalmus, orbital congestion, oculomotor palsies, and trigeminal nerve involvement (167, 170, 171). Pulsatile exophthalmus is seen in carotid cavernous fistula but also has been described in a patient with orbital encephalocele and hydrocephalus (172). Pulsatile tinnitus may result from arteriovenous fistulas and malformations or from altered jugular venous flow (173–177). Onset of carotid cavernous fistula is often delayed; 43.5% are diagnosed over 1 month after trauma (170). Angiography is the definitive diagnostic test.

**Treatment** Spontaneous closure of a carotid cavernous fistula has been described in some patients; it is much more likely with a spontaneous low-flow fistula than with the traumatic high-flow fistula. Patients have been trained in intermittent manual compression of the cervical carotid artery with the contralateral hand. Although the success rate is lower with direct fistulas, 17% of patients had successful closure with this technique (178). The definitive treatment of traumatic carotid cavernous fistula has become the endovascular placement of detachable balloons (168, 179, 180). Successful fistula closure was accomplished by the detachable balloon technique in 92 of 95 cases of traumatic carotid cavernous fistula, with preservation of the internal carotid artery in over 70% of cases (168).

## LATE INTRACRANIAL MASS LESIONS

### Subdural Hematoma and Hygroma

**Differences Between Acute and Chronic Subdural Hematoma** Subdural hematoma is the most common late-presenting mass lesion. Although acute, subacute (3–20 days), and chronic (3 weeks or more) subdural hematomas

are distinguished by time of detection after injury, it is important to recognize that chronic subdural hematoma is a different pathophysiologic process than acute subdural hematoma, not simply an older blood clot (181–185). As a result, differences are also seen in the epidemiology, clinical presentation, prognosis, and treatment techniques (73, 182, 184) (Table 33-3). The incidence of chronic subdural hematoma peaks in the seventh and eighth decades, and only 60–65% of patients have known TBI (184, 186) Male predominance (70–90%) and parietal location (91%) are characteristic (181, 184). Headaches are a cardinal symptom (184, 187), sometimes following a symptom-free interval. Three major clinical presentations include hemiparesis (40%), personality or intellectual change (30%), and signs of increased intracranial pressure, including papilledema (20%) (181). In contrast with acute subdural hematoma, seizures are relatively uncommon with chronic subdural hematoma (4–7%), and ongoing anticonvulsant prophylaxis is not routinely required (188), although some authorities have recommended it in the immediate postoperative period (187). Transient episodes of aphasia or sensorimotor disturbance have also been described with chronic subdural hematomas, mimicking either transient ischemic attacks or seizures, and resolving after the immediate postoperative period following surgical drainage (189, 190).

**Scan Findings in Subdural Hematoma** CT scans characteristically show decreased density in chronic subdural hematoma. However, the isodense appearance characteristic of subacute subdural hematoma may last longer than 1 month in some instances (191). In questionable cases, contrast enhancement helps to identify isodense subdural collections (192). In other cases, a layer of isodensity or increased density is seen below a hypodense layer; this sedimentation level likely reflects interval rebleeding (192, 193). Isodensity at the medial margin

**TABLE 33-3**  
*Differences Between Acute and Chronic Subdural Hematoma*

FEATURE	ACUTE SUBDURAL HEMATOMA	CHRONIC SUBDURAL HEMATOMA
Age Peak	30–49 years	60–70 years
Known TBI	Virtually all	60–65%
Clinical Presentation	Acute mental status change, focal signs, seizures, increased intracranial pressure	Personality or chronic mental status change, headache, hemiparesis, increased intracranial pressure
Composition	Blood clot	Fluid, membrane
Pathophysiology	Venous bleeding especially from torn bridging veins	Initial subdural hygroma or initial venous bleeding, inflammatory process with leaky macrocapillaries, disordered hemostatic mechanism
Treatment	Craniotomy	Burr holes, twist drill craniostomy, or craniotomy

of a fluid collection also may represent fresher bleeding (192). Compared with CT scan density, the factors determining signal intensity on MRI are much more complex. Whereas acute subdural hematoma shows increased CT density, subacute and chronic subdural hematoma have increased signal on MRI (29, 187, 194). Subacute subdural hematoma is seen as a hyperintense collection on T1-weighted images, largely because of the presence of methemoglobin. Chronic subdural hematoma presents with more variable signal intensity on T1-weighted images but consistently shows increased signal intensity on T2-weighted images (29, 187, 194). In addition, fluid collections that are homogeneous on CT sometimes show hypointense septations and mixed intensities on MRI. In some instances, a sedimentation level of a hyperintense (fluid) upper layer and hypointense (more cellular) lower layer is seen. Such findings are consistent with the conceptualization of subdural hematoma as an ongoing process with interval rebleeding rather than a static collection of blood. As described below, an outer membrane is characteristic in chronic subdural collections; this membrane enhances significantly with gadolinium on T1-weighted imaging in many cases (29). Although CT and MRI are the definitive tests for diagnosing subdural collections, abnormalities also are seen in the electroencephalogram (EEG) and in testing of cerebral blood flow. In addition to delta slowing on the side of a subdural collection, ipsilateral suppression of voltage is seen on EEG in 25% of patients (184, 186). Diffuse reductions in cerebral blood flow preoperatively often show a recovery 1 month postoperatively (195).

*Pathology of Chronic Subdural Hematoma* On pathologic examination, the fluid of chronic subdural hematoma shows a range of color and appearance, including brown-black, dark red, amber-brown, and almost clear and watery (184, 194). Coagulated masses of blood and fibrin are sometimes present. A thicker outer membrane attached to the dura and thinner inner membrane bordering on the arachnoid are characteristic (184). Enlarged ectatic capillaries, often called giant capillaries or sinusoids, are prominent on the outer membrane and associated with inflammatory cells, fibroblasts, and hemosiderin-laden macrophages (184). With age, the outer membrane also may become calcified.

*Subdural Hygroma* Subdural hygroma has been described as a subdural collection of cerebrospinal fluid, often with a modified composition (196). The distinction between subdural hygroma and chronic subdural hematoma has often been unclear in the literature, partly because subdural fluid composition varies, sometimes exhibiting xanthochromia or containing blood products. Also the term hygroma has sometimes been used to describe low density extraaxial collections on CT scan

without mass effect (196), even when identification of cortical veins lateral to the collection on MRI might more correctly identify it as subarachnoid fluid associated with atrophy (29). It has been proposed that a tear in the arachnoid may acutely allow CSF into the subdural space, and rare surgical documentation of this process has been provided (196). More often the development of subdural hygroma may be more gradual, and in these cases subdural hygroma formation requires separation of the dura-arachnoid interface and sufficient potential subdural space (143, 197–199). Low intracranial pressure (such as orthostatic negative pressures with a shunt), an underfilled CSF compartment, and atrophy are factors in creating sufficient subdural space (84, 118, 142, 143). Many patients have slight cranial asymmetry in the occipital region, with one side flatter than the other. In the supine position the cranium tends to turn slightly to the flattened side, and subdural hygromas tend to form frontally to the opposite side, or bilaterally in patients with a more symmetrical cranium (143, 197). The time course of hygroma development, enlargement, and in most instances resolution can be plotted.

*Pathophysiology of Chronic Subdural Hematoma* Recent work has significantly clarified our understanding of the relationship between subdural hygroma and chronic subdural hematoma, and the pathophysiology of their development. Chronic subdural hematomas occasionally develop from acute subdural hematomas, but more often chronic subdural hematomas develop from subdural hygromas (143). When hygromas do not resolve, a neomembrane forms from dural border cells, followed by leakage of blood from the fragile giant capillaries in the outer membrane induced by the inflammatory process (182, 200, 201). A disordered local hemostatic mechanism has been identified in fluid from chronic subdural hematoma (182, 183) with both excessive activation of the clotting system and the fibrinolytic system. Chronic subdural collections can sometimes show increasing density on CT scans for a period of weeks to months (143). The size of a chronic subdural collection may resolve spontaneously if absorption exceeds rebleeding, or alternatively the collection may continue to enlarge (143).

*Approach to Chronic Subdural Hygroma or Hematoma Management* Management of the patient with chronic subdural hygroma or chronic subdural hematoma is largely a matter of clinical judgement. Decreasing size of the collection, stability of the neurologic exam, and a lack of mass effect or compression on the underlying brain on CT or MRI scan are all factors which mitigate in favor of observation and serial scanning. While there is no set time interval for repeat scanning, in the absence of clinical worsening and depending somewhat on the size and appearance of the collection, a period of 2 to 4 weeks

can often be utilized. Alternatively, clinical worsening, the appearance of significant mass effect or midline shift on CT or MRI scan, or serial enlargement or substantial increase in CT density consistent with significant interval rebleeding would likely necessitate a surgical approach. It has often been the author's practice to obtain neurosurgical input early on, even when the immediate management is almost certainly conservative, so that a neurosurgical plan is in place and can be enacted quickly if circumstances warrant shifting to a more aggressive approach.

**Surgery for Chronic Subdural Hematoma** Surgical removal of a certain critical mass of fluid, containing degradation products from the subdural space may be important in interrupting the vicious cycle of disordered hemostasis and facilitating the recovery from chronic subdural hematoma (182, 183). Successful surgery, therefore, may reduce the residual volume to a degree that allows further resorption rather than fully removing the blood clot. Twist drill trephination or burr holes are the first line treatments for chronic subdural hematoma (181, 184, 202–204). Occasionally the presence of sizable clots or loculation may necessitate craniotomy, as is commonly done for acute subdural hematoma (182, 205). Postoperative drainage has been advocated to assist with brain reexpansion (182, 202). The hematoma cavity is commonly washed out with saline, and it has been suggested that continuous irrigation (to remove coagulation degradation products) may decrease the duration of drainage or frequency of recurrence (206, 207). Persisting subdural fluid was described postoperatively in 78% of patients, but had returned to normal by 40 days postoperatively in 27 of 32 cases, leading to the suggestion that reoperation should be avoided until at least 3 weeks postoperatively unless marked clinical deterioration occurs (208). Because of the active inflammation in the dural border cell layer and associated inflammatory cytokine production, postoperative anti-inflammatory medication/steroids have been suggested by some (182, 204). The overall prognosis from chronic subdural hematoma is much more favorable than the prognosis for acute subdural hematoma (184), although the residual deficits in the areas of personality and memory may be problematic (207). Patients with even severe neurologic deficits preoperatively may have successful outcomes (181), although the extent of preoperative deficit has been a useful predictor of outcome in some series (207).

### Epidural Hematoma

**Presentation** Although epidural hematoma is usually considered the most acute posttraumatic mass lesion, it presents more than 5 days after injury in 10% of cases (209) and may present as late as the second or third week after injury (210). Although epidural hematoma most

often presents in the temporal fossa (57–83% of cases) due to injury to the middle meningeal artery, delayed presentation is more common with extratemporal location, especially frontal or posterior fossa lesions (209, 211). Clouding or decreased level of consciousness is considered the most important sign of epidural hematoma (209). Onset is slowest with frontal lesions, and symptoms may be vague. Unilateral exophthalmus is an unusual sign that has been described with subfrontal epidural hematoma (211).

**Posterior Fossa Epidural Hematoma** Posterior fossa epidural hematomas are unique among epidural hematomas in that they are of venous rather than arterial origin. An occipital bone fracture is seen in 84.2% of cases and characteristically crosses the venous sinus, causing this venous bleeding (212). The venous origin helps explain why a slower clinical presentation may occur. A lucid interval is common, and progressive decrease in the level of consciousness is characteristic. Battle's sign is often seen, and neck stiffness, occipital headache, and vomiting may be prominent. Symptoms and signs of increased intracranial pressure as well as brainstem, cranial nerve, and cerebellar dysfunction are common (212, 213). Posterior fossa epidurals are not common; they are seen in only 0.3% of patients with TBI (212). However, they have the highest mortality rate (209) and are notoriously difficult to diagnose (211).

### Intracerebral Hemorrhage

Delayed traumatic intracerebral hemorrhage is defined as an intracerebral hematoma that is not visualized on initial CT but is seen on a follow-up study. It occurs in 5.6–7.4% of patients with severe TBI (214). Time of onset is typically about 24 hours after original injury (214), and 80% of cases occur within 48 hours of injury (187). Cardinal signs of delayed traumatic intracerebral hemorrhage include decreased level of consciousness, focal signs, or seizures (215). Factors postulated to play a role in the pathogenesis include dysregulation of blood flow, coagulation disorders, and removal of tamponade effect by evacuation of another mass lesion, such as an epidural or subdural hematoma. Outcome is worse with temporal lobe location, which shows an increased incidence of herniation (216).

## SUMMARY AND FUTURE DIRECTIONS

### Risks and Infections

**Risks** Conditions associated with increased risk of infection have been discussed including skull fractures and penetrating injuries, and cerebrospinal fluid (CSF) fistula. With the exception of penetrating wounds, where

antibiotic prophylaxis is almost universal, the approach to prophylaxis remains controversial. A large well controlled study would be helpful to resolve the indications for antibiotic prophylaxis. It appears that the ongoing presence of a fistulous connection between the atmosphere or sinuses and the intracranial compartment (through the skull and dura) implies a very substantial risk for development of meningitis, even in the absence of overt CSF drainage, and sometimes even years after injury. Therefore an aggressive approach to identification and closure of a CSF fistula is warranted. Glucose testing is not reliable in suspected CSF rhinorrhea, but assessment of beta-2 transferrin assay is reliable.

Cranioplasty was often delayed in the past partly because of concerns of complications including infection if performed early. However it has recently become clear that some patients with craniectomy exhibit the syndrome of the trephined with a markedly ingoing flap in the area of missing bone. These patients not only tolerate having cranioplasty performed earlier, but sometimes actually show significant neurologic improvement after cranioplasty is performed.

**Infections** Meningitis typically pursues a fulminant course. The exception is infection of a ventriculoperitoneal shunt, which tends to pursue a very indolent course without overt signs of acute infection. Shunt infection can only reliably be diagnosed by tapping the shunt, not by lumbar puncture, and *Staphylococcus epidermitis* is the most common organism and in this setting is usually real rather than a contaminant.

Subdural empyema and brain abscess are rare complications of TBI except with compound depressed skull fracture, CSF fistula or penetrating wounds. Subdural empyema typically presents with acute signs of infection, while brain abscess often presents as a mass lesion without evidence of acute infection. Lumbar puncture is contraindicated for both, while newer imaging modalities such as diffusion weighted MRI are proving useful in establishing the diagnosis in some cases.

### Hydrocephalus

**Diagnosis** Ventriculomegaly is common after severe TBI, but it remains difficult to distinguish dynamic hydrocephalus from ex-vacuo ventricular dilatation. Both the CSF tap test and lumbar infusion studies, possibly combined with SPECT studies, appear to have utility in sorting difficult cases. Further research on CSF drainage trials and lumbar infusion testing in TBI patients with possible hydrocephalus would be valuable, and might spur increased routine use of these studies.

**Shunts** The mechanisms, complications and innovations in shunt technology have been reviewed at length. Pro-

grammable shunts may offer significant promise specifically for the patient with post-traumatic hydrocephalus, given the frequency of communicating hydrocephalus without high pressure, difficulty in predicting appropriate pressure settings, and uncertain magnitude of clinical response. However further research demonstrating proven superiority over standard shunts in this population is still needed, especially as use of these shunts is complex and can be labor intensive on the part of the physicians managing them. Overdrainage has been a major complication with ventriculoperitoneal shunts, and the recent development of shunt systems which effectively drain at a higher opening pressure standing than supine could be a major advance.

### Late vascular and mass lesions

**Vascular Complications** Traumatic intracranial aneurysms are uncommon, but are often false aneurysms and extremely prone to rupture. Clinical features to aid diagnosis are discussed, and MRA and perfusion weighted MRI may be helpful for screening. Endovascular approaches including coils and stents have recently changed management considerably. Carotid cavernous fistula is the most common post-traumatic arteriovenous malformation, and often presents with visual symptoms along with localizing signs of cavernous sinus involvement. Endovascular approaches with balloons have proven effective. Trauma to the cervical carotid and vertebral arteries can induce thrombosis or dissection. Presentation with severe head and neck pain can be a diagnostic clue prior to development of cerebral infarction, and anticoagulation is often utilized.

**Late Mass Lesions** Subdural hygroma and chronic subdural hematoma are frequently encountered, whereas delayed epidural and intracerebral hematomas are less commonly seen. Posterior fossa epidural hematoma is of venous origin, typically in association with occipital fracture, and a rare but serious complication. Chronic subdural hematoma is a clinically distinct entity from acute subdural hematoma, both in terms of epidemiology and management. It now appears that many chronic subdural hematomas develop from a subdural hygroma. The approach to management of chronic subdural collections is discussed at length.

## Complications Associated with Immobility after TBI

*Kathleen R. Bell*

### INTRODUCTION

Immobilization of the human body has long been known to affect physiology in ways detrimental to normal function, even in the time of Hippocrates (1). Despite this knowledge, prolonged bedrest was used for many years in the treatment of medical disorders. However, studies emanating from the manned space program since the 1960's defining the effects of a gravity-free environment have clarified many of these effects in healthy humans. Most of the studies performed on animals, however, rely on hindlimb suspension models of immobilization and many studies on humans rely on the head down tilt position in bed to mimic microgravity. None of these conditions precisely reproduces the conditions of prolonged bedrest in a medical situation. Nonetheless, general principles regarding the effect of inactivity on the body can be derived from these experiments. As an additional complicating factor in severe traumatic brain injury (TBI), the effects of immobilization may be prolonged and worsened by a number of disorders stemming from the brain injury itself such as posturing, spasticity, dysautonomia, endocrine abnormalities, and other body system injuries. Thus the importance of prevention and prompt management of these disorders is highlighted in addition to early mobilization of the patient with TBI.

Prolonged bedrest brings about reduced function in multiple body systems simultaneously. For example,

deconditioning is a diagnosis in its own right (2). Deconditioning results from reduced functional capacity of both the musculoskeletal and cardiovascular systems; changes to one system are unlikely to be significant without accompanying decrements in the other system. The effects of deconditioning can be studied in young, healthy experimental subjects, eliminating the effects of pathology. The effects of mobilization and exercise on this group emphasizes the importance of early mobilization for those with illness or injury (2).

This chapter seeks to address those general aspects of immobility that may be seen in any situation where prolonged bedrest occurs and to discuss the impact of traumatic brain injury on related causal factors and treatment (Table 34-1). There are very few studies that actually examine the specific effects of immobility on persons recovering from TBI (or any other illness or injury) so associations and recommendations are made derived from literature on healthy individuals or those with other disorders.

### EFFECTS OF IMMOBILITY ON THE PERSON WITH TRAUMATIC BRAIN INJURY

#### Musculoskeletal System

Significant changes occur in the musculoskeletal system in the first 4–6 weeks of immobilization affecting all

**TABLE 34-1**  
***A Summary of the Effects of Immobility on Organ Systems with Associated TBI-Related Physiological Stressors***

ORGAN SYSTEMS	POSSIBLE EFFECTS	TBI RELATED DISORDERS
Musculoskeletal	Muscle weakness, osteopenia, muscle and joint contracture	Spasticity and other movement related disorders, paresis, associated trauma
Respiratory	Hypoventilation, pooling of secretions	Tracheostomy, altered immune function
Cardiovascular/Hematologic	Deconditioning, postural hypotension, thromboembolic disorders	Autonomic instability, hyperhidrosis, paresis, fluid and metabolic disorders
Dermatological	Pressure ulcers	Paresis, catabolism, dysphagia
Neurological/Psychological	Sensory deprivation, balance disorder	Special senses disturbances, cognitive impairment, vertigo
Metabolic/Neuroendocrine	Volume contraction, hypercalcemia	Sodium disorders, hyperhidrosis, paresis
Gastrointestinal and Urologic	Constipation, reflux, and urinary stasis	Dysphagia and impaired cognition requiring enteral feeding

components of the system, including up to 40% loss of muscle strength, decrements in bone density, and shortening of collagen-containing tissues. These changes are the results of a lack of the usual weight-bearing forces acting in the vertical position and the decrease in muscular contraction especially in the postural muscles (3). While these types of changes occur in even healthy young people, the effects are magnified in populations such as the elderly with baseline alterations in muscle strength and bone density. One concern is whether persons subjected to prolonged periods of bedrest will be at higher risk of osteoporosis as they age if stores are not recovered (3). As we will see, persons with TBI are likely to be more profoundly affected as well, because of associated conditions.

**Bone Density Loss** Bone is constantly undergoing alteration and remodeling during normal activities. The activity of osteoclasts that reabsorb mineralized bone matrix and osteoblasts which are responsible for the synthesis and mineralization of bone is governed by mechanical stresses and systemic stimuli. Participants in the regulation of bone density include mechanical stresses, hormones, growth factors, and cytokines. In addition to osteoclasts and osteoblasts, chondrogenitor cells may become either chondrocytes covering the joint surface of bone or growth plate chondrocytes that are the basis for metaphyseal bone formation. These cells form bone modeling units (BMUs) whose activity is altered by physical activity or immobility, nutrition, aging, and illness (4). Specifically, skeletal muscle activity at least partially regulates bone density maintenance via growth factors (e.g., IGF-1) even during periods of disuse (5).

Chronic illness or prolonged recovery from trauma such as that seen in TBI is most likely associated with the

growth hormone/IGF-1 axis, along with impaired thyroid and gonadal function (4, 6). Immobilization specifically is associated with a moderate decrease in bone resorption but an even larger decrease in mineralization of bone matrix (7, 8). A negative calcium balance occurs within a week of bedrest, and 20 weeks of bedrest in healthy, young men results in a 60% increase in urinary calcium. Fecal calcium loss also occurs in conjunction with reduced intestinal absorption (3). There is decreased bone mineral density in the lumbar spine, femoral neck, tibia, and calcaneus but not the radius noted in young men on 4 months of bedrest (9). There are no significant changes in serum parathyroid hormone or in serum 1,25-dihydroxyvitamin D during bedrest in healthy men, but persons with spinal cord injury have been shown to have decreased levels of both (10). In persons with TBI, an additional factor to consider in factoring the degree of bone loss is the frequent presence of hemiplegia or other patterns of paralysis. Data from persons recovering from stroke and other neurologic disorders offer some insight although not directly applicable to the brain-injured population because of the differences in average age and degree of paralysis and immobility. Bone loss early after stroke appears to be primarily due to increased bone resorption while later bone loss is more clearly related to the degree of paresis and vitamin D levels (11). 1, 25-dihydroxyvitamin D production appears to be inhibited (12). Nearly all fractures after falls occur on the hemiparetic side in stroke patients (13). Bone mineral density was significantly lower in both femurs in stroke patient who were non-ambulatory after stroke. The difference in bone loss only on the hemiparetic side between the non-ambulatory and ambulatory patients was also significant. Most of the loss occurred within the first seven months

after stroke (14). Bone density loss in the limbs is even more striking after spinal cord injury; however, vertebral bone density is not significantly compromised because of continued weight-bearing in the seated position (15).

Recovery of bone mineral density after loss is quite slow for longer periods of immobilization. Although dogs recover to baseline in 12 weeks after 12 weeks of immobilization, for longer periods of immobility, bone did not recover even after 7 months (16). Calcaneal bone density deficits have been noted in astronauts even 5 years after space flight (3, 17). There are few studies of reversing or minimizing bone loss after neurologic insults. Vitamin D and calcium supplementation have been demonstrated to be helpful in preventing fracture in elderly patients but caution should be used after stroke in the presence of hypercalcemia (18, 19). Etidronate which inhibits bone resorption has been studied in spinal cord injury and stroke and may be effective in preventing bone resorption (20, 21). Clenbuterol, a beta-2-agonist, has been tested to prevent muscle and bone loss in rats with a significant prevention of muscle atrophy and accompanying lessening of bone mass loss (22).

*Muscle Weakness and Atrophy* There is no doubt that muscle strength and size are affected after prolonged bedrest. As might be predicted, the weight-bearing muscles of the lower limb are affected to a greater degree than the muscles of the arm (23). There are even more local differences in the degree of muscle atrophy. The knee extensors lose more mass than do the knee flexors (24). There are a number of possible mechanisms that result in muscle weakness and atrophy that are further discussed below.

*Protein Breakdown* By the fifth day of bedrest, there is a significant increase in the urinary excretion of nitrogen, peaking in the second week of bedrest. This reflects protein degradation and is an early marker of muscle atrophy (25–27). The cross sectional area of muscles is reduced 7–14% in 4–6 weeks of immobilization, especially in muscles responsible for resisting gravity such as the knee extensors (28, 29). Lower limb muscles are affected more than upper limb muscles.

*Decreased Protein Synthesis* Shortly after a limb is immobilized, decreases in total RNA and protein synthesis can be seen in muscles (30). Some alterations in pre-translational and translational mechanisms for protein production begin within six hours of immobilization, reflected in decreased alpha-actin and cytochrome c protein synthesis and decreased cytochrome c mRNA in rats (31–33).

Regrowth after inactivity-induced atrophy involves a number of mechanisms including 1) increased protein synthesis, 2) continued elevations of protein degradation,

3) increased proliferation of muscle precursor cells, 4) and increases in myonuclear number (myonuclei per 100 myofibers) (30). Unfortunately, muscle regrowth after atrophy is not always complete, especially in the elderly (34, 35). As a clinical example, muscle wasting in 64-year-old patients after total hip arthroplasty persisted 5 months postoperatively (36). This limited regrowth may be due to low satellite cell numbers and lower levels of growth factors (such as IGF-1) (30).

*Disruption of Antioxidants in Skeletal Muscle* In pathological conditions, such as post-trauma catabolism, other mechanisms may be at play in the volume of muscle loss during bedrest and immobilization. Typically, antioxidant protein and scavenger protection protect skeletal muscle against oxidative stress. However, during hindlimb unloading in rats, there has been demonstrated large shifts in superoxide dismutase activity with impaired antioxidant activity (decreased catalase, glutathione peroxidase, and nonenzymatic antioxidant scavenging capacity) (37–39). This disruption of protection can result in muscle fiber damage and loss that, when combined with a state of protein loss after severe trauma, is accelerated.

There is disagreement between animal and human experiments on which muscle fibers appear to be most affected by this loss of volume induced by immobilization. Generally, in animals, slow-twitch fibers are predominantly affected. In humans, however, fast-twitch fibers appear to be most affected. It is possible that this may be somewhat misleading as the relative sizes of slow- and fast-twitch muscle are different in rats and humans (3).

There is some evidence that some of this muscle atrophy and loss of oxidative capacity can be prevented by isometric exercise during the period of immobilization (40, 41). Isometric exercises appear to be more effective in slow tonic muscles like the soleus as compared to the fast-twitch muscles such as the gastrocnemius (40). In addition to having a salutary effect on bone density, clenbuterol also appears to reduce muscle degeneration in dystrophic or denervated muscle (42). In addition, there is some evidence that oral creatine supplementation enhances the muscle hypertrophy response to exercise after a period of immobilization (43).

Not unexpectedly, these findings suggesting protein breakdown and a loss of muscle mass would lead one to predict an accompanying decrease in muscle strength. Microgravity studies have demonstrated that 30 days of bed rest will result in an 18–20% decrease in knee extensor strength (44, 45).

Endurance is also decreased after prolonged immobility. Decrements up to 17% are noted in torque production in limbs unloaded for 4 weeks; this does not recover to baseline even after 7 weeks of recovery (46). These findings may be due to changes in muscle oxidative

enzymes as well as decreased oxygen delivery to muscle after disuse (3).

Part of the loss of muscle strength observed after prolonged bed rest is the result of decreased efficiency in motor neuron recruitment. While electromyographic activity is reduced by half in muscles that are shortened, there does not appear to be a relationship between the electrical activation of muscle and the relative decrease in muscle mass (47). However, there is evidence for reduced motor neuron activation after immobilization and a subsequent need for increased neuronal activation to produce the same degree of muscle force output (48–50). These neuromuscular inefficiencies can be totally reversed with training after the cessation of bedrest (49). This type of data also supports the notion of early movement and weight-bearing, as much of the muscle loss seen in the first 2 weeks of bedrest can be easily restored.

*Joint Contractures* There are a number of changes in connective tissue and muscle during immobilization of a limb that can result in a loss of passive range of motion in a joint. For instance, studies have demonstrated reductions in both the length and diameter of muscle fibers and in muscle extensibility (51–53). Additionally, there is an increase in intramuscular connective tissue and reduced capillary density in muscle (54, 55). In addition to these muscle changes, there is a significant increase in endomysial and perimysial connective tissue. More fibers are deposited perpendicularly to the adjacent muscle fibers. The network of collagen fibers become indistinguishable from each other (56).

Patients with TBI have an assortment of risk factors associated with their injuries that may contribute to the formation of joint contractures. Spasticity and rigidity may be extremely difficult to control in the acute stages of TBI. In examining the patient with TBI for contractures, it is important to assess the contribution of dynamic (spasticity dependent) aspects of joint movement limitation. It may be useful to perform a peripheral nerve block for this purpose. In later stages of TBI, postural control, especially of the axial skeleton, may lead to contractures of the neck and spine that are challenging to address. Weakness and prolonged maintenance of any posture will also contribute to joint contracture. Other general risk factors include age, edema, and diabetes mellitus. Reported incidence of ankle plantar flexion contractures in persons with acute moderate to severe TBI has ranged from 16–76%, depending on the definition of contracture (57, 58).

Prevention of joint contracture depends on the maintenance of proper joint position with the use of splints, adequate treatment of spasticity, and active and passive range of motion exercises to the joint several times daily. Standing is the optimal method of maintaining ankle range of motion and prone lying is very helpful to prevent hip flexion contractures. Serial casting is one option to

treat mild to moderate equinovarus deformities of the ankle and contractures of the upper limb (59, 60). Short changing intervals of 1–4 days were more effective than intervals of 5–7 days in restoring range of motion (60).

### *Respiratory System*

Many patients with severe TBI have tracheostomies for assisted ventilation and respiratory toilet in the acute stages. In addition, impaired alertness will result in a decreased drive for deep inspiration. Therefore, TBI patients are already at risk for pulmonary complications during their rehabilitation. Prolonged bedrest adds to that risk. Simulated weightlessness with a head-down tilt in healthy individuals demonstrates that the functional residual capacity of the lungs falls by 33% during this period with insignificant changes in lung tissue volume. Diffusing capacity decreases gradually to 4–5% below baseline values. Pulmonary blood flow also decreases by 16% (61). All of these changes result in higher risk for atelectasis and pulmonary infection. Treatment consists of early mobilization of the patient and aggressive pulmonary toilet with suction and the use of equipment such as the in-exsufflator to assist in the management of secretions.

### *Cardiovascular System*

Research on cardiovascular effects of immobility is drawn both from microgravity experiments during space flight and from experiments utilizing a head-down tilt position to mimic weightlessness. Obviously, these studies seek to maximize the effects of bedrest. Normal head-up positioning of patients in bed after TBI will mitigate the severity of cardiovascular effects.

*Reduction of Cardiopulmonary Functional Capacity and Postural Hypotension* Functional efficiency of the heart depends on both intravascular volume (hydrostatic forces) and coordinated filling and emptying of the ventricles (hydrodynamic forces). Normally, arterial pressures and certain levels of intravascular volume interact to maintain adequate body and cerebral perfusion in the face of gravity. However, when the body is placed horizontally for a prolonged period of time, about a liter of fluid is relocated from the legs to the chest area. Initially, this increases diastolic filling and increases the stroke volume of each cardiac contraction (i.e., the Frank-Starling mechanism). However, baroreceptor responses eventually result in a diuresis and loss of plasma volume within 24–48 hours (62). When a normal upright position is resumed, there is a sudden decrease in both ventricular filling and stroke volume that results in orthostatic symptoms (63). Cardiovascular baroreflex responses become attenuated without the challenges of baroreceptor unloading that comes from upright standing (64). Other factors

may include disordered sympathetic activation in combination with hypovolemia and diminished baroreceptor reflexes (65). Particularly interesting in the context of TBI is the involvement of brain autonomic nuclei such as the paraventricular nucleus of the hypothalamus that includes basal and reflex control of the sympathetic nervous system vasopressin and oxytocin release and secretion of corticotrophin releasing factor (66).

Other changes in cardiac function have been noted. After immobilization, the maximal oxygen uptake ( $\dot{V}O_{2\max}$ ) is reduced and the heart rate is increased in response to submaximal exercise (67). This equates to a loss in aerobic capacity of 0.9% per day over thirty days of bedrest (2). The heart rate during prolonged bedrest is higher for the same oxygen requirement (68). Part of this is related to the fluid changes noted above; these effects are much less during supine submaximal exercise (67). The heart rate is probably increased due to increased beta-adrenergic receptor sensitivity (68).

Simple replacement of volume does not abolish the orthostatic response (69). It appears that there are some alterations to the ventricles themselves during a period of prolonged bedrest leaving them less distensible (70). This appears to be an effect on cardiac muscle similar to the loss of muscle volume seen in skeletal muscle during prolonged immobilization (63). Actual muscle contractile properties seem to be preserved (71). The effects on stroke volume and cardiac output after prolonged bedrest will persist for at least a month (71). These effects are partially masked by an increase in peripheral volume and retention of sodium and, at least initially, an increase in sympathetic nerve activity (72).

Other peripheral mechanisms also come into play during prolonged bedrest. Deconditioning causes a reduction in red blood cell mass by 5–25% that may compromise blood oxygen-carrying capacity. However, the hematocrit generally remains stable during bedrest. Therefore, the effect of reduced blood cell mass is still unclear (68). As noted elsewhere in this chapter, there is a significant decrease in resting blood flow to the leg muscles and a reduction in capillarization. This is correlated with fatigability in calf muscles (73, 74) (See Figure 34-1 (68)). Interestingly, the role of the nervous system as another contributor to orthostatic intolerance has been recently promulgated. A subset of neurons in the paraventricular nucleus may be part of the puzzle in determining sympathetic nervous system excitation in response to blood volume and baroreflexes (66).

Reversing these effects requires not only the upright position and adequate fluid volume but also exercise that induces arterial baroreceptor loading (64). In animals, daily standing for only 1 hour per day prevented depression of myocardial contractility (75).

**Thrombogenesis** Thromboembolic disease is a well described risk in the setting of immobilization. In the

FIGURE 34-1

Model of cardiovascular mechanisms controlling maximal oxygen uptake during bed rest. (Permission requested: Convertino VA. Cardiovascular consequences of bed rest: effect on maximal oxygen uptake. *Med Sci Sports Exerc* 1997;29(2): 191–196.)

brain injured patient, this risk remains present with significant complicating factors for diagnosis and treatment. Often after significant trauma, each of the factors of Virchow's triad (stasis, endothelial damage and hypercoagulable state) is present on admission to the emergency room. In the TBI patient, one sequela of the injury may be hemiparesis which contributes to stasis in a more discrete and prolonged manner. Patients with TBI may also present with bleeding in the subdural or subarachnoid space, limiting the choice of treatment modalities. The TBI patient may also be impulsive and have considerable fall risk which may limit pharmacologic prophylaxis and treatment options. Identification and treatment of venous thromboembolism is therefore of increased complexity but of great necessity in the traumatic brain injured population (76).

Initial traumatic injury inherently carries with it risk for hypercoagulability when multiple organ systems are involved and bleeding is present at one or more sites. When bleeding occurs, the body initiates the coagulation cascade, a response that may be prolonged when blood remains present acting as a nidus for continued production of coagulation factors. In traumatic brain injury, bleeding may occur at any site in the body due to concomitant trauma, but is of particular concern in the subarachnoid or subdural space. The patient may require prolonged monitoring to ensure resorption or neurosurgical intervention to reduce mass effect due to bleeding, contributing to further stasis. A functional limitation of TBI may be hemiparesis or bilateral weakness which may persist following the acute period of immobility after trauma. Thrombi are noted to occur most frequently in the paralyzed limb of hemiparetic patients and more likely to occur in the proximal segment of the limb placing them at higher risk for

propagation (77). In a similar setting, DVT risk has been found to be comparable following brain tumor surgery as in the orthopaedic hip replacement population (78). The traumatic brain injury patient is also likely to have suffered endothelial damage with the initial inciting injury.

Identification of thromboembolism may be suspected clinically by the presence of a warm, edematous and painful limb. Unfortunately, the affected limb often exhibits no signs at all of thrombophlebitis therefore physical exam is unreliable for venous thrombosis diagnosis (79). The venous duplex exam is the mainstay of diagnosis. Testing carries high accuracy, is non-invasive and often readily available at the bedside (80). If pulmonary embolism (PE) is suspected by clinic findings of decreased oxygen saturation, tachypnea and pleuritic chest pain, studies to assist in diagnosis for PE should be employed as well as the above mentioned venous duplex to identify the potential source of the embolus. The D-dimer assay, spiral computerized tomography (CT) and ventilation-perfusion studies are all well accepted means to assist in diagnosis of pulmonary embolism. In the TBI patient, there are noted limitations to the use of these means of diagnosis. Following trauma, it is anticipated that D-dimer levels will be unspecifically high and therefore are not as helpful in diagnosis. Using D-dimer levels has not been shown to be useful in predicting deep venous thrombosis after acute TBI (81). However, a low D-dimer level may assist to rule out a pulmonary embolism if this be the goal. A ventilation-perfusion scan may be limited by any other concomitant pulmonary conditions such as pneumonia, secretions or atelectasis. The spiral CT is the most readily available tool for reliable diagnosis, albeit at a higher initial cost.

Treatment for identified thromboembolism is primarily pharmacologic by using unfractionated or regular heparin. Heparin acts initially by enhancing antithrombin III activity. In high doses, heparin also acts to inhibit prothrombin and platelet aggregation. This constitutes its efficacy in meeting the key treatment goals for PE and thromboembolism by inducing a hypocoagulable state and decreased potential for clot propagation (79). However, the TBI patient may have co-morbidities limiting the use of anticoagulation in their pharmacologic regimen. In the setting of TBI, the patient may have suffered a subarachnoid or subdural hemorrhage making anticoagulation undesirable. Further, impulsivity and significant fall risk may instill hesitation for use of anticoagulation in this population. In this setting, the use of retrievable inferior vena cava filters is increasing as a means to disrupt the clot pathway to decrease risk of pulmonary embolism. These filters are generally used in patients in whom recurrent PE has occurred despite treatment with anticoagulants or those in whom anticoagulant therapy is contraindicated (82). A review of multiple case series has indicated that these filters are successfully removed in 91% of cases; 9% of filters could not

be removed because of large trapped thrombus (83). It is important to note that these filters are associated with a 2-fold increase in the incidence of recurrent deep venous thrombosis. If it is safe to anticoagulate a patient, they should remain on therapeutic anticoagulation even with a filter in place for the recommended length of time (84).

Prophylaxis of thromboembolism to decrease the risk of a potential pulmonary embolism is the single most effective means of decreasing morbidity and mortality from venous embolic disease. Often patients are placed on mechanical and pharmacologic means of prophylaxis. The mainstays of mechanical means, compression stockings and sequential compression devices, may be appropriate in the TBI patient when in bed; however their use may be limited as they may interfere with ambulation and the rehabilitation process. The TBI patient may be appropriate for heparin or unfractionated heparin therapy if no contraindications exist. However, in the setting of intracranial hemorrhage, inferior vena cava filters may assist in limiting pulmonary embolism if initiated as a means of prophylaxis acutely after injury.

### *Integumentary System*

Pressure ulcers are a well-known complication of bedrest, particularly when complicated by paresis of any kind. Pressure ulcers are associated with increased mortality, morbidity, length of stay, and cost of treatment (85, 86). While TBI patients have not been specifically examined, immobility and decreased body weight are both independent risk factors for the development of pressure sores (87). After acute TBI, inadequate tissue perfusion because of unrelieved pressure at bony prominences is chiefly responsible for the development of pressure ulcers (88, 89). Pressure wounds heal best when kept moist with occlusive dressings. Other methods used to improve healing have included serial casting in patients with spasticity; the casts are thought to reduce friction associated with repetitive movements.

### **Neurological Systems**

*Effects of Bedrest on Cognitive and Psychiatric Function*  
Confinement to bed has been associated with a number of undesirable psychological and cognitive effects. Much of the data has come from studies on healthy young men as part of the space program research projects. These studies have used a 6-degree head-down tilt that more closely reproduces microgravity conditions than normal bedrest. Nonetheless, these studies have some application to medically-driven bedrest. These studies have noted enhanced levels of depression and emotional distress. In addition, impairments in overall cognitive capabilities have been described as well with self-reported confusion and depressed scores on cognitive testing (90, 91).

An additional area that may be affected by prolonged immobilization in bed is sleep. Chronic insomnia can be perpetuated by increased time spent in bed (92). Studies on elderly hospitalized patients on bedrest in poorly lit rooms have demonstrated that patients report poor sleep quality and that phase shifts for sleep are noted (93). Although these conditions have not been evaluated in patients with brain injury, it is reasonable to assume that worsening of confusion and sleep disorder can result from prolonged bed rest.

**Balance Disorder and Incoordination** Neuromuscular changes associated with inefficient recruitment of motor neurons may be partly responsible for the findings of increased postural sway, gait changes, and impaired kinesthetic sense after prolonged space travel (3, 94, 95). These changes in response to immobilization and bedrest may occur at multiple levels of the nervous system (96). For instance, it has been demonstrated that training can enlarge the size of the cortical area involved in the task. Conversely, it appears that there are reduced cortical responses after immobilization of a joint that are proportional to the length of time of immobilization. The amplitude of motor evoked potentials decreases after joint splinting during motor imagery tasks but not motor activation tasks (97). Other changes have been noted in the motor strategies used to perform a static muscle contraction after immobilization; some people were noted to produce a bursting pattern with reduced EMG amplitude in contrast to the pre-immobilization pattern of progressive increase in the amplitude of EMG activity (98, 99). The organization of neurons to provide maximal voluntary contraction appears to be diminished after 6 weeks of immobilization of a limb; peak force produced voluntarily during a maximum contraction was lower than that produced by electrical stimulation (100). Although the specific effects of immobilization on sensory inputs on control of movement have not been studied, there is evidence that sensory feedback such as vibration can evoke a cross-training effect and increase the power production capability of muscles (49,101).

### **Endocrine and Metabolic System**

There is no literature that directly addresses the influence of bedrest on the endocrine system or metabolism after TBI. A few points, however, may be interesting to review with an emphasis on how these factors may be affected by conditions after TBI such as hyperhydrosis (resulting in volume loss) and intrinsic damage to the pituitary-adrenal axis. Growth hormone resistance has been observed in chronic illness and/or malnutrition resulting from resistance at the hepatic growth hormone receptor leading to impaired hepatic IGF-1 generation and decreased growth hormone bioactivity. Growth hormone and thyroid hormone have synergistic actions and potentiate the effects

of each other on normal skeletal growth while acting on osteoblasts to stimulate bone remodeling. Involvement of growth hormone/IGF-1 and thyroid hormones can result in decreased skeletal growth, low bone mass, and low serum concentration of osteocalcin (4). Prolonged immobilization can be seen as a physiological stress and, as such, has been associated with elevated corticosterone levels and decreased plasma ACTH levels (102).

Hypercalcemia has been noted to be a particular problem in young adolescents who are immobilized for prolonged periods of time, particularly after spinal cord injury. However, there has been noted suppression of the parathyroid—1,25-dihydroxyvitamin D axis resulting in calcium loss as well as increased serum phosphorus and an elevated phosphorus renal threshold (103). Additionally, losses of magnesium in both feces and urine during immobilization in rats have been observed, resulting in a negative magnesium balance despite replacement (104). Nitrogen loss has been studied for many years; urinary nitrogen excretion peaks in the second week of bedrest at 20–43% above baseline (25).

Volume-regulating systems are affected by head-down bedrest (HDBR) and likely, by extension but to a lesser degree, to bedrest. Sodium and chloride are excreted as volume is lost, reflected by weight loss. Potassium excretion is delayed but then is elevated for the duration of HDBR experiments. An elevation in plasma renin activity accompanied these changes as well as a decrease in autonomic responses, with a shift towards sympathetic control (105). A high sodium diet does not seem to stabilize this loss of plasma volume (106).

### **Gastrointestinal and Urologic Systems**

**Constipation and Abnormal Absorption.** Intestinal absorption in general is decreased during the period of bedrest (3). More specifically, calcium absorption decreases from 31% to 24% of dietary intake over 17 weeks of bedrest (107). However, bone resorption accounts for a large proportion of the hypercalciuria seen after prolonged bedrest.

**Gastroesophageal Reflux** After severe traumatic brain injury, there are many issues that interfere with normal ingestion and digestion of food. Both neurologically based and cognitively based dysphagia predispose the patient to aspiration and almost always result in the use of parenteral feeding via a gastric or jejunal feeding tube. There has been little study of gastroesophageal reflux in patients on bedrest and none on patients with TBI or stroke, but it seems likely that the combination of dysphagia, tube feeding and related gastroparesis, and bedrest would increase the risk. One study of all patients admitted to a hospital via the emergency department found that, while symptoms of reflux were reduced in the whole population, those on bedrest or who received non-steroidal

anti-inflammatory drugs had increased risk of reflux-like symptoms (108). Patients with prolonged nasogastric tube feeding have demonstrated increased rates of esophageal damage (108).

**Urinary stasis** The recumbent position is associated with a reduced urinary flow rate and, although the difference in post-void residuals does not reach the level of significance, there is a trend toward higher volumes in recumbent voiding (109).

## PREVENTION OF COMPLICATIONS

In general, it can be said that any mobilization is beneficial in ameliorating the effects of prolonged bedrest. From the limited work done on the effects of exercise during prolonged bedrest, it is apparent that both isotonic and isokinetic exercises help to maintain cardiac functional capacity (peak  $\dot{V}O_2$ ), and help to preserve the red cell volume and positive body water balance. However, these two types of exercise had varying effects on quality of sleep and mental concentration (isotonic exercise surprisingly seemed to impair both) and had no effect on orthostatic tolerance when the experimental subjects were remobilized (110).

Remobilization after prolonged bedrest of the elderly patient with TBI should be done cautiously because the effects on bone density will be magnified in this population. Exercise directed at the weight-bearing trunk and lower limbs should be approached in a graduated basis.

Adequate hydration and nutrition are extremely important in maintaining bone, skin, and muscle integrity during rehabilitation after TBI, especially while the patient is on bedrest. Hydration is often difficult to maintain in patients with spasticity, dysautonomia, and hyperhydrosis. Range of motion and good positioning of the limbs, trunk and head are essential in preventing contractures and preserving the ability of the patient to utilize neurological recovery effectively at a later date.

## Assessing and Treating Muscle Overactivity in the Upper Motoneuron Syndrome

*Nathaniel H. Mayer*  
*Alberto Esquenazi*  
*Mary Ann E. Keenan*

### INTRODUCTION

A lesion of the corticospinal tract produces an *upper motoneuron* syndrome (UMNS) (1, 2). Since the 19th century days of Hughlings Jackson, clinicians have classified UMN phenomena as positive or negative signs. Negative signs signified loss of voluntary motor behaviors (e.g. force production or dexterity of movement) that reflected *phenomena of underactivity or absence*. In contrast, positive signs such as increased stretch reflexes, spasms or co-contraction signified *muscle overactivity or phenomena of presence*, whether entirely new or merely enhanced beyond their normal presence. “Spasticity” was often used as a collective term for positive signs but, strictly speaking, spasticity is only one of many positive signs seen in UMNS (3).

In this chapter, we use “muscle overactivity” as a collective term for positive signs in UMNS because it captures the dynamic quality of excessive muscle contraction that is characteristic of the positive signs of the UMNS. The issue is not semantics. The pathophysiology of positive signs varies and so will their treatment. For example, co-contraction, likely of supraspinal origin, will differ in its treatment from clonus, a phenomenon of the segmental stretch reflex loop.

Studies have suggested that UMN muscles stiffen and develop contracture after being subjected to prolonged overactivity (4–6). Some have argued that such

viscoelastic and plastic changes, termed *rheologic* changes, can be more dysfunctional for the patient than many of the classic positive and negative signs (7). We agree with this perspective because we view the ubiquitous presence of stiffness and contracture, commonly responsible for disability in UMNS, as a third sign of UMNS. Negative signs represent the broad issue of impaired voluntary control and, when control is absent, muscle overactivity creates unbalanced forces across joints that restrain range of motion and promote stiffness and contracture. In our view, clinical problems seen in UMNS result from a combination of impaired production and control of movement (‘negative signs’), various forms of muscle overactivity (‘positive signs’) and a third sign of muscle stiffness and contracture (rheologic change). Moreover Herman has shown that muscle overactivity can be influenced by the stiffness characteristics of muscle. He studied 220 hemiplegic patients, divided into four clinical groups based on stretch reflex activity and physical extensibility of the calf muscles (4). Groups varied from an early hypotonic stage (group I) to a late “burned out” stage (group IV) that was characterized by increased tissue stiffness, lost range of motion and fixed contracture. For Group IV, Herman found reduced tissue extensibility to be linked with reduced tonic stretch reflexes. Increased resistance to passive stretch was due to changes in the physical stiffness of the triceps surae muscle. Patients with calf muscle contracture typically

walk with difficulty. From a therapeutic perspective, treatment of contracture is very different from treatment of negative signs of muscle underactivity and positive signs of muscle overactivity.

### POSITIVE SIGNS: 1. SPASTICITY

Spasticity is a term linked to stretch reflexes (8). It has a specific definition with respect to stretch reflexes but it has often been used confusingly as a collective term for all positive signs, many of which are not based on stretch reflexes. Strictly speaking, the term “spasticity” refers to an increase in excitability of muscle stretch reflexes, both phasic and tonic, that is present in most patients with an UMN lesion (9). Clinically, the defining characteristic of spasticity is excessive resistance of muscle to passive stretch. It is the nature of that resistance to increase as the examiner increases the velocity of stretch (10). Faster rates of stretch result in a sudden increase in resistance felt by the examiner after stretch has commenced. The afferent-efferent character of the stretch reflex was first identified in Sherrington’s seminal studies (11, 12) on the cat’s myotatic reflex which provided strong physiological underpinnings for later clinical descriptions of spasticity. The clinical character of spastic stretch reflexes is succinctly described by Peter Nathan (8): “Spasticity is a condition in which the stretch reflexes that are normally latent become obvious. The tendon reflexes have a lowered threshold to tap, the response of the tapped muscle is increased, and usually muscles besides the tapped one respond; tonic stretch reflexes are affected in the same way.” The quick whack of a tendon tap resembles an engineering impulse function and the resulting brevity of the jerk response aptly classifies it as a *phasic* reflex, based on its phasic (transient) output response. In contrast, longer duration passive stretch of a spastic muscle induces sustained tension for the duration of stretch and reflects underlying stretch reflex activity of the *tonic* type. Resistance perceived by the examiner is elevated in the spastic state and varies with the velocity of stretch. If resistance develops suddenly during rapid passive stretching, the act of passive stretch may be interrupted for an instant and the examiner will feel a “spastic catch” phenomenon. Clonus develops under similar circumstances.

Physiologically, afferent information regarding stretch of the muscle and its muscle spindle is signaled to the central nervous system by group Ia and group II afferents. However, there has been no evidence to suggest that spindle afferent activity is increased in spastic patients (13). Rather, the central excitatory state of the cord appears to be high (14). A number of theories of spasticity emphasize the concept of signal “mishandling” at the level of the spinal cord. For example, Delwaide points out that the normal mechanism of pre-synaptic inhibition in the spinal

cord is altered for patients with hyperreflexia (15). Ia afferent activity from the muscle spindle is normally adjusted at a pre-motoneuronal level depending on supraspinal facilitatory influences and preeding Ia discharges. In spasticity, according to Delwaide, the interneuron responsible for pre-synaptic inhibition becomes less active due to a reduction of supraspinal facilitatory influences. Accordingly, the stretch reflex of the patient with hyperreflexia is no longer subject to tonic inhibitory control by the mechanism of pre-synaptic inhibition. Instead, all proprioceptive afferent impulses are able to gain direct access to alpha motor neurons and hyperreflexia results. Other theories of signal “mishandling” at the level of the spinal cord include Veale, Mark and Rees’ work on Renshaw system disinhibition (16) and Jankowska’s work on abnormal handling of group II afferent activity from the muscle spindle by a specific interneuronal system in the spinal cord (17). What is common to these theories is an enhanced central excitatory state that promotes exaggerated motor responses to ordinary cord input.

Lance characterized spasticity as an increase in velocity-dependent *tonic* stretch reflexes along with exaggerated (*phasic*) tendon jerk responses (18). The term “phasic” means time varying. “Tonic” has a time invariant quality, though time scales are always relative. However, the literature’s use of ‘phasic’ and ‘tonic’ can be confusing because some authors describe the input stimulus as ‘phasic’ or ‘tonic’ while others describe the output response as ‘phasic’ or ‘tonic’. *Tonic* stretch reflexes discussed by Lance referred to the output response of a muscle group that was being stretched at different rates of stretch. The output jerk response of a tendon tap was an example of a *phasic* stretch reflex. At the bedside, phasic stretch reflexes are tested by tendon taps while tonic stretch reflexes are tested by passively stretching a muscle group through the full (available) range of motion, repeating this manouver a number of times in order to vary the velocity of stretch for each repetition. When a patient is spastic, resistance to stretch experienced by the examiner will increase as the rate of stretch is increased. Physiologically, an increase in electromyographic (EMG) activity generated by the stretched muscle is observed, producing tension that opposes the stretching force of the examiner. Figure 35-1 illustrates stretch reflex activity in a patient with traumatic brain injury (TBI) undergoing passive stretch of the elbow flexors at different rates of stretch. Although the examiner, as he stretches, feels a unitary resistance, the reader can see that different muscles may respond differently to the same input stretch. The reader may infer that differential muscle responses may have different treatment requirements.

Stretch reflex activity of antagonist muscles may also be triggered during voluntary movement when a shortening contraction produced by agonist muscles on one side of a joint is necessarily accompanied by lengthening

(stretching) of antagonist muscles on the other side of the joint. Paretic patients often move slowly so that velocity of stretch during voluntary effort is low enough to minimize spastic reactivity in antagonist muscles. In this regard, co-contraction is a phenomenon that can be confused with spasticity. Co-contraction is characterized by *simultaneous* activation of agonist and antagonist muscles during voluntary movement (19). Spasticity depends on muscle stretch and its onset occurs after movement has begun after some stretch displacement has already taken place. Simultaneous activation of agonists and antagonists is more easily observed on EMG records. (Figure 35-2)

## 2. CLONUS

Clonus is a low frequency rhythmic oscillation in one or more limb segments. (Figure 35-3) Clonus is generated by rapid stretch and hold of a muscle group. It may also be triggered by a patient who unintentionally stretches a

FIGURE 35-1

Passive stretch of elbow flexors performed by an examiner at different rates of stretch in a patient with TBI and UMN. As the velocity of stretch increases, more EMG is generated. Note, however, that different muscles respond differently to the same input

FIGURE 35-2

Co-contraction of elbow flexors and extensors during voluntary alternating movements at the elbow. The patient complained of fatigue and she felt as if she were "fighting herself" when she made these movements

muscle group during limb positioning (e.g. by mechanically stretching the calf when placing the foot on a wheelchair's footpedal). Clonus may be triggered during voluntary movement, for example, during a reaching effort when voluntary elbow extension triggers clonus in elbow flexors. Electromyographically, clonus is characterized by repetitive, rhythmic bursts of short duration electrical activity. Clonus occurs at typical frequencies of 6 to 8 Hz. Clonus can appear synchronously in one or more muscles. Clonus can also alternate between agonist and antagonist muscles. Figure 35-4 shows a patient with hemiparesis who was

FIGURE 35-3

Illustration of clonus during extension phase of voluntary alternating movements of the elbow. Clonus is a low-frequency rhythmic oscillation, approximately 6-8 Hz, in one or more limb segments. This patient illustrates clonic bursts of EMG in brachioradialis, extensor carpi radialis, and pronator teres. The displacement trace reveals clonic oscillations of the elbow 'sitting atop' the extension phase of the movement

FIGURE 35-4

A patient with hemiparesis (gunshot wound of the brain) extends his elbow. Alternating bursts of clonic EMG activity are seen between medial triceps and brachio-radialis. Spread of activity to distal muscles (e.g., first dorsal interosseous) is also observed

asked to extend his elbow. Bursts of EMG can be seen to alternate between medial triceps and brachioradialis. In addition, spread of activity to more distal muscles (extensor carpi radialis and 1st dorsal interosseous) is also observed. Clonus may be sustained or unsustained and it can be stopped by re-positioning clonic muscles at shorter lengths. Clonus is usually associated with other hyperexcitable phasic stretch reflexes. In addition to rapid stretch, various cutaneous stimuli, especially cold or noxious stimuli, may give rise to ipsilateral or even contralateral clonus (20). Clonus may represent auto-oscillation of a hyperexcitable stretch reflex loop (21). Rack et al. viewed clonus as a self-sustaining oscillation of the stretch reflex pathway but they felt that the frequency of clonus was determined by physical parameters such as load rather than central neurological mechanisms (22). Dimitrijevic et al. were of the opinion that a central oscillator produced clonus (23). Therapeutically, dantrolene sodium, an agent that acts directly on skeletal muscle and muscle spindle fibers, is particularly effective for damping the low frequency ('low tone') oscillations of clonus. Unfortunately, it is not very effective in 'high tone' situations such as the high frequency drive of decerebrate rigidity after TBI.

### 3. CO-CONTRACTION

Co-contraction is another form of muscle over-activity seen in UMN that may be described as simultaneous activation of agonist and antagonist muscles during voluntary movement. Co-contraction can be activated and deactivated at a cortical level and is related to the switching mechanism of reciprocal inhibition in the cord (24). Abnormalities of Ia reciprocal inhibition have been reported for patients with UMN and co-contraction in such patients may represent an impairment of supraspinal control of reciprocal inhibition (25–27). Co-contraction may occur during isometric effort so that it is not necessarily related to muscle stretch. Figure 35-5 illustrates co-contraction during forward reach by an adult with UMNS. Simultaneous activation of flexors and extensors of the elbow is observed in the record. The movement trace reveals slow, unsmooth extension. Though co-contraction can be a normal mechanism to provide joint stability, in this case, the patient's elbow flexors appear to be exerting an unwanted restraining action because the patient struggled to extend his elbow clinically during reaching. Figure 35-5 reveals that brachioradialis and biceps activity occurred at the very onset of movement, indicating that early activity in these muscles was not stretch induced but was likely linked to the supraspinal reach "command". A key feature of co-contraction is that it is generated by simultaneous motor drive to agonist and antagonists during voluntary effort (28). When a co-contracting antagonist, undergoing stretch, develops superimposed spasticity, the combination has been called spastic co-contraction.

FIGURE 35-5

Co-contraction during forward reach by an adult with UMNS. Simultaneous activation of flexors and extensors of the elbow is observed in the record. The movement trace reveals a slow, nonsmooth extension trajectory (flexors restrain extensors)

Clinically, patients with co-contraction make slow, effortful movements. Speed of 'back' and 'forth' or alternating movement is often asymmetrical. For example, when a patient is asked to alternately flex and extend a limb, co-contraction of flexors during extension phase may prolong extension phase compared with flexion phase. We typically test for antagonist restraint by asking the patient to perform voluntary alternating movements about a joint for the full available range. Normally, alternating 'back' and 'forth' movements are symmetrical in time ('back' duration = 'forth' duration) and amplitude (endpoints or 'back' and 'forth' movements are at full range, respectively). Patients with restraining co-contraction, however, exhibit temporal and range asymmetries. Therapeutically, co-contracting antagonist muscles may respond to a weakening strategy (chemodenervation, tendon lengthenings). Among central muscle relaxants, only tizanidine has been described as having a potential effect on Ia reciprocal inhibition (29).

### 4. FLEXOR AND EXTENSOR SPASMS

According to Lance, a characteristic feature of UMN, both physiologic and clinical, is release of flexor reflex afferents (30). The flexor reflex, a polysynaptic reflex that results in flexor muscle contraction, is elicited by afferent stimuli collectively known as flexor reflex afferents. Among others, these afferents include exteroceptive cutaneous receptors responding to touch, temperature and pressure, nociceptors responding to painful stimuli, secondary endings from muscle spindles (group II afferents) and free nerve endings scattered ubiquitously over muscles that generate slowly conducting afferent activity in group III and IV axons. The polysynaptic flexor reflex has a prolonged latency (more than twice that of a monosynaptic tendon jerk) due to slow afferent conduction to the

cord and also to central delay. In the cord, flexor reflex afferent activity travels up and down to synapse in the internuncial pool, a system of spinal interneurons that is influenced by inputs coming from peripheral as well as central sources including the brainstem. Compared to segmental stretch reflexes, the time course of polysynaptic flexor reflexes is slower and, unlike segmental stretch reflexes, flexor reflexes represent coordinated activity of motoneuron pools spanning many segments, resulting in muscle contraction across several joints, sometimes bilaterally. By typically recruiting flexor muscles across several joints, the flexor reflex is an example of an interjoint reflex that has tissue protective value such as enabling quick withdrawal from a noxious stimulus. Extensor reflexes are also polysynaptic and interjoint in nature and may serve certain support functions. Flexor and extensor reflexes may be core substrate for more complex coordinated patterns such as locomotor stepping generators.

After UMN, particularly after spinal cord lesions, release of inhibitory descending influences makes reflexes such as the flexor reflex more pronounced. When complaints are traced to flexor and extensor spasms, it is likely that spasms represent disinhibited flexor and extensor reflexes. A variety of overt stimuli can trigger flexor and extensor spasms or they may be set off by covert stimuli such as a full bladder, a stool distended bowel, a tight diaper, unseen skin ischemia from sitting or lying in one position too long and other unobserved or masked sensory sources.

Clinically, flexor reflexes can range from the familiar toe response of the Babinski sign to a mass flexor reflex characterized by intense, often painful interjoint flexion with spread to the abdominals. Patients may call them a muscle spasm but they mean whole limb involvement rather than focal spasm of a single muscle group. In UMN lesions, the elicitation threshold of the flexor reflex is reduced, the intensity of muscle contraction for the same stimulus input is increased and interjoint components of the reflex are often expanded (i.e. more muscles and more joints are recruited). Drugs such as baclofen and diazepam can inhibit polysynaptic activity in the cord and reduce the frequency and intensity of flexor spasms (but in TBI they may sedate (baclofen and diazepam) or affect memory (diazepam)). Excessive flexor withdrawal on ground contact can impair stance phase of gait for patients with TBI. Excessive flexion during swing phase can mimic steppage and impair advancement or subsequent foot placement on the floor.

## 5. SPASTIC DYSTONIA

The term 'spastic dystonia' originated with Denny-Brown (31). He examined postural reactions of monkeys after cerebral cortex ablations. Lesions were independent of,

or in addition to, damage to the pyramidal tract. When the bodies of animals with cortical ablations were held in different positions, their limbs developed fixed positions or postures. For all postures, any attempt by the examiner to pull the limb away from its fixed position was met by an increasing resistance of spring-like quality. The limb would 'fly' back to its original posture when released. Denny-Brown called this fixed attitude *dystonia*, meaning that the fixed limb posture was maintained by *active muscle contraction*. The continuous nature of muscle contraction that maintained cortical dystonia was present without the monkey making limb or body movements elsewhere and the dystonia did not depend on afferent input from the limb, since it persisted even after the relevant dorsal roots were cut. Moreover, EMG recordings of dystonic monkey muscles revealed sustained or tonic EMG activity and Denny-Brown thought that dystonia of this kind represented release of motor mechanisms that had direct access to alpha motoneurons. What seems clear, therefore, is that these dystonic postures were mediated efferently from above and had nothing to do with spinal reflex activity. However, what is not clear to these authors is the exact meaning of the term: 'spastic dystonia'. Denny-Brown himself pointed out that there were dystonic monkeys without spastic features such as increased tendon jerk reflexes. Nevertheless, he indicated that dystonia may occur in the presence of spasticity (enhanced phasic and tonic stretch reflexes) He referred to such a combination as "spastic dystonia". Many clinicians seem to use the term 'spastic dystonia' when they see a UMN patient with fixed limb postures (e.g. flexed elbow, clenched fist) in the absence of obvious stretch or voluntary effort. It is not clear, however, just from visual observation that a fixed posture is driven by sustained, supraspinal efferent activity—a necessary requirement of the term 'spastic dystonia'. We prefer to use the term when such a patient has tonic muscle activity, demonstrated by EMG, that maintains the limb in a fixed posture in the absence of phasic stretch or voluntary effort. Spastic dystonia is primarily due to abnormal supraspinal drive, characterized by an inability to inhibit muscle activity despite efforts to do so. Gracies et al. state that spastic dystonic muscles are sensitive to the degree of tonic stretch imposed on them (32). Figures 35-6 and 35-7 show a patient with right hemiparesis due to a brain gunshot wound who was asked to stand quietly 'at rest'. EMG recordings showed tonic activity in biceps and occasional activity in brachioradialis. Flexion posture of the elbow was persistent, the patient was not making a voluntary effort to hold the position nor was he undergoing phasic (time varying) stretch. Clinically, the patient had signs of spasticity. One might describe this patient as having 'spastic dystonia'. In Denny-Brown's sense of mechanism for this phenomenon, tonic biceps activity comes from supraspinal drive of alpha motoneurons. This is not so easy

FIGURE 35-6

Spastic dystonia. This patient with an upper motoneuron syndrome and left hemiparesis was asked to stand quietly "at rest." The flexed posture of the elbow was persistent, and the patient readily acknowledged that she was not making any voluntary effort to hold this position. Persistent elbow flexion was her chief complaint. An EMG record during "rest" revealed persistent activity in many muscles about the elbow and forearm

FIGURE 35-7

Passive stretch of the elbow flexors of the patient in Figure 35-6 revealed that her dystonic activity was stretch-sensitive. According to Denny-Brown, the dystonic phenomenon (activity at rest) is of supraspinal origin and is mediated efferently, not afferently. However, the presence of stretch sensitivity suggests that some patients may also have a component of spasticity

to prove, yet its assertion has therapeutic implications. For example, one would not expect central agents such as diazepam and baclofen, known to suppress spinal reflex activity, to be very useful for treating 'spastic dystonia'. Focal chemodenervation by botulinum toxin, neurolysis by phenol or direct contraction inhibition by dantrolene would seem to have stronger therapeutic rationales.

EMG equipment, if available, can help identify persistent muscle activity that may be consistent with a dystonic form of muscle overactivity. Without such study, clinical assumptions about the mechanism of a limb posture may be risky. A net balance of force created by passive tissue stiffness may be sufficient to maintain limb posture. Contracture can hold a limb in fixed position

as can heterotopic ossification. Finally, associated reactions can generate limb muscle activity that ends in postures reflecting a net balance of muscle forces acting across various joints.

## 6. ASSOCIATED REACTIONS

Associated reactions were first described by Walshe in 1923 as 'released postural reactions deprived of voluntary control' (33). 'Synkinesis' is a term used by Bourbonnais more recently (34). An associated reaction refers to involuntary activity in one limb that is associated with a voluntary movement effort made by other limbs. Associated reactions may be due to disinhibited spread of voluntary motor activity into a limb affected by a UMN lesion. Figure 35-8 shows a patient with left hemiparesis due to a brain gunshot wound attempting to readjust his sitting position by pushing down on the wheelchair's armrest with his right arm. The patient was unable to use the left upper extremity in this task because voluntary control was severely impaired. Dynamic EMG of elbow musculature during this activity revealed high EMG recruitment in flexor and extensor muscles about the elbow (figure 35-9). Despite elbow extensor activity, the photograph reveals *flexed* elbow posturing indicating that a net balance of muscle forces about the elbow favored flexion. The intensity of an associated reaction may depend upon how much voluntary effort is made. Dewald and Rymer thought that impaired descending supraspinal commands were involved in generating associated reactions (35). They hypothesized that unaffected bulbospinal motor pathways may have taken over the role of damaged UMN tracts during the transmission of descending voluntary commands.

Assuming that associated reactions are supraspinal in origin, one would not expect efficacy from central relaxants such as baclofen and diazepam. Depending on the contractile intensity of an associated reaction, dantrolene sodium, an inhibitor of muscle contraction, might have some therapeutic value. Tizanidine has known effects at spinal levels, but it may also act supraspinally by influencing activity in descending coeruleospinal pathways. Reports of depressed neuronal activity in the locus coeruleus by alpha-2 adrenergic agonist drugs have emphasized their impact on cord mediated reflexes such as flexor reflexes but not on supraspinally mediated behaviors such as associated reactions (36). The authors are not aware of reports regarding tizanidine and associated reactions in man.

The 'real life' impact of spasticity, strictly defined, may be less than advertised when one reflects on how often patients and caregivers might actually stretch spastic muscles at rates that would elicit intense spastic responses. We have commonly observed patients and

FIGURE 35-8

An “associated reaction” refers to involuntary activity in one limb that is associated with a voluntary movement effort made in other limbs. This figure illustrates an associated reaction in the left arm of a patient with left hemiparesis (gun-shot wound of brain) who is readjusting his sitting position in the wheelchair by volitionally pushing down on the arm-rest with his right arm. The patient was unable to use the left upper extremity in this task because voluntary motor control was severely impaired on the left

caregivers performing limb manipulations at slow rates of stretch in order to avoid or minimize rate sensitive spastic resistance. In addition, what frequently passes for dynamic spastic resistance may be, in large measure, an increase in static stiffness due to intrinsic changes in the physical properties of muscle tissue. By contrast, frequent occurrence of associated reactions may be unavoidable in ‘real life’ situations because voluntary movement made by ‘uninvolved’ limbs happen all the time. High intensity voluntary efforts required during transfers, gait and activities of daily living might be expected to promote associated reactions as a high frequency form of muscle overactivity. For patients with UMN, it is conceivable that the everyday potential for generating associated reactions may contribute to the development of muscle stiffness and contracture more than spasticity does. More studies along this line would help.

FIGURE 35-9

Dynamic EMG study of elbow musculature in the patient of Figure 35-8 was performed during the same manoeuvre of re-adjusting position in the wheelchair. Findings revealed high EMG recruitment for flexor *and* extensor muscles about the elbow. Despite elbow extensor EMG activity, the photograph in Figure 35-8 reveals *flexed* elbow posturing indicating that, despite extensor muscle contraction, a net balance of muscle forces about the elbow favored flexion posturing. The intensity of a limb’s associated reaction may depend on the magnitude of voluntary effort made by the patient elsewhere

## 7. MUSCLE STIFFNESS AND CONTRACTURE

Muscle contracture refers to physical shortening of muscle length and it is often accompanied by fixed shortening of other soft tissues such as fascia, nerves, blood vessels and skin. Muscle *contracture*, an invariant physical state of fixed shortening, should not be confused with muscle *contraction*, a dynamic, variable state of internal shortening produced by sliding action of actin and myosin filaments within a muscle fiber. The development of contracture is promoted by a number of processes that start when an acute UMN lesion occurs: paresis impairs cycles of shortening and lengthening of agonist and antagonist muscles promoted by everyday muscle usage, the force of gravity generates positional effects on limb segments and joints, positional effects are created by a net balance of static rheologic forces across joints, and, as preferential muscle overactivity develops in particular muscle groups, a net balance of dynamic contractile forces promotes positional effects leading to contracture. Contracture implies that even if one blocked all muscle *contraction* by local or general anesthesia, physical shortening of muscle would still remain. Since central muscle relaxants such as tizanidine and baclofen, peripheral agents such as dantrolene, chemodenervation/neurolytic agents such as botulinum toxin/phenol affect dynamic muscle contraction only, a clinical picture dominated by contracture will not respond to these types of interventions. Physical and surgical methods are necessary to undo contracture.

**TABLE 35-1**  
***Common Patterns of Upper Motoneuron Dysfunction, Potential Muscles Involved and the Authors' Botulinum Toxin Dose Ranges***

	Extensor hallucis longus	20-50	1

After a UMN lesion, paralyzed muscles immobilized for long periods in a shortened position became shortened and stiffer. When muscle overactivity develops in these shortened muscles, tension is generated at shorter lengths. A lack of voluntary contraction in the antagonists of these shortened muscles prevents their natural re-extension, leading to a continuation of the process of stiffness and fixation. In the upper limb, for example, muscles that typically shorten include shoulder adductors and internal rotators, elbow flexors, forearm pronators, wrist, finger and thumb flexors and thumb adductors. However, other patterns are possible and observed. Familiar UMN patterns of deformity develop in both the upper and lower limbs (Table 35-1) (figures 35-10 and 35-11). The position of a given joint results from a net balance of static and dynamic muscle forces acting across one or more joints. Literature support of this idea comes from many studies. Herman described changes in the rheologic properties of spastic muscles in a large number of hemiplegic patients (4). Patients with contracture often had *reduced* reflex activity, yet resistance to passive stretch was high because muscle tissue had become physically more stiff. His study indicated that a description of muscle tone must consider the complex interaction between rheologic and reflex properties of muscle because stretch reflex properties of spastic muscle may be influenced considerably by alterations in the physical properties of muscle. Along similar lines, Dietz et al. (5) (stroke, cerebral palsy) and Thilmann et al. (37) have argued that hypertonia might not be related to exaggerated reflexes but rather to changes in soft tissues. Hufschmidt and Mauritz (38) proposed that abnormal cross-bridge connections could contribute to the resistance of passive movement and that these changes would very likely occur in muscles subjected to prolonged positioning. Akeson (39) demonstrated in animals that immobility led to stiffness associated with water loss and collagen deposition and Gossman (40), Herbert (41), Carey and Burghardt (42) have suggested that immobility imposed on a patient by the negative signs of UMN can result in soft tissue contracture. Other animal studies have suggested that when muscles are immobilized in a shortened position, some sarcomeres are lost and others become shorter and stiffer (Tabary (43); Williams and Goldspink (44); Witzmann (45)). Soft tissues other than muscle become less compliant in chronically shortened positions. It is for this reason that surgery for a severe contracture should not corrected for more than about half the lost range for fear of snapping nerves and occluding blood vessels. These soft tissues will require gradual physical stretching techniques postoperatively to achieve reversal of the second half of the range. Special surgical intervention for skin contracture may also be required.

Human biopsy studies of muscle with contracture have shown shorter fiber lengths for patients with cerebral

FIGURE 35-10

A familiar UMN pattern of upper limb deformity: adducted/internally rotated shoulder; flexed elbow; pronated forearm; bent wrist; clenched fist; thumb-in-palm. The position of a given joint results from a net balance of static and dynamic muscle forces acting across one or more joints that are promoted by a variety of UMN phenomena that are triggered frequently, likely every day (e.g., spasticity, co-contraction, flexor and extensor spasms, associated reactions)

FIGURE 35-11

A familiar UMN pattern of lower limb deformity: flexed hip, adducted (scissoring thighs); flexed knee; stiff knee; equinovarus foot

palsy compared to normal (46). Shorter fiber lengths would have fewer sarcomeres in series. When antagonist muscle fibers with fewer sarcomeres are stretched during normal agonist concentric contraction, stretched sarcomeres become longer, compared with sarcomeres of normal fibers. During stretch, these longer than normal sarcomeres are thought to be the main reason that many patients with cerebral palsy have excessive passive tension in their muscles. A similar process might conceivably account for elevated passive tension in adults with UMN lesions. A different finding was recently described by Friden and Lieber (47) who found that single fibers taken from spastic subjects with cerebral palsy developed

passive tension at significantly shorter sarcomere lengths than fibers taken from subjects without spasticity. Patient fibers were almost twice as stiff as controls and resting sarcomere lengths were shorter. Friden and Lieber found that the force borne by spastic fibers was similar to normal fibers, even though the cross-sectional area of spastic fibers was less than one third of normal fibers. Greater stress resulted when spastic fibers were passively stretched. Their study suggested that sarcomeres in subjects with cerebral palsy do not have to be stretched beyond normal lengths to develop excessive passive tension. From this perspective, their study challenged the assumption that tendon lengthenings or even stretching exercises that aim to allow a muscle to relax to normal sarcomere lengths will lessen passive tension to normal levels. Their study challenges the current theoretical framework which suggests that when muscle-tendon length is adjusted appropriately, sarcomeres will operate over a more normal range of lengths and there will be a reduction in passive tension and an increase in active force potential. Their study of chronic spastic muscle fibers (during childhood development) points to a process of considerable intrinsic structural remodeling of muscle tissue components that may not be easily reversed by current surgical or physical manipulations.

#### GENERAL COMMENTS ON THE APPROACH TO EVALUATION

*Clinical Aspects of Evaluation* In broad terms, evaluation of muscle overactivity focuses on three issues: (1) identifying the clinical pattern of motor dysfunction; (2) identifying the patient's ability to control muscles involved in the clinical pattern; and (3) identifying the role of muscle stiffness and contracture as it relates to the functional problem. In Table 15-1, we identify fourteen common patterns of motor dysfunction, organized by joint or limb segment, that are typically found in patients with TBI who have upper motor neuron lesions. For each pattern, a number of muscles may be involved in motor dysfunction. Evaluation focuses on the characteristics of these muscles in terms of their voluntary or selective control, type of muscle overactivity, rheologic stiffness and contracture. Does the patient have voluntary control over a given muscle? What is the nature of a muscle's overactivity? (e.g. Is the muscle spastic? Does the muscle co-contract? Is it dystonic? Is it part of an associated reaction?) Does the muscle have increased stiffness when slowly stretched? Is contracture present? There are two or more muscles that cross each axis of most limb joints and each muscle can vary in its UMN characteristics. Since each muscle may contribute to movement of its joint, information about each muscle's contribution is useful to the assessment as a whole. We use dynamic electromyography to identify the characteristics

of muscle overactivity and voluntary control during upper and lower limb movements. We use anesthetic nerve blocks to identify properties of stiffness and contracture in particular muscle groups.

*Technology Aspects of Evaluation* Laboratory measurement of upper and lower extremity motion is a cornerstone of modern analysis of muscle overactivity and impaired voluntary control of movement. Gait and motor control analysis of movement is capable of measuring specific contributions of muscles to movement by means of multi-channel electromyography (dynamic EMG). Dynamic EMG is measured simultaneous with joint motion (kinematics) and ground reaction forces (kinetics). Force platforms enable the measurement of ground reaction forces during walking and standing and permit force vector analysis. Computations based on photo marker systems allow collection of three-dimensional quantitative motion data that provide information regarding range, direction, velocity and acceleration of limb movements. Clinical correlations and interpretations are significantly enhanced by slow-motion video that provides frame-by-frame display of walking and other limb movements. Measurement of passive movement responses combined with pre- and post-nerve block data allow for clinical interpretations of tone and contracture. What is abundantly clear, especially after TBI, is that clinical examination alone may be insufficient to identify voluntary and muscle overactivity characteristics of the many muscles impaired by UMN. Combined with clinical information, laboratory measurements provide the degree of detail necessary to generate practical hypotheses about findings that lead directly to the formulation of rational treatment interventions.

*Considerations Related to Time Course of Motor Recovery* Evaluation and treatment will also depend on a clinician's expectation for motor recovery. We arbitrarily divide neurological recovery into two periods: an early period during which neurological motor recovery may be expected and a late period when motor recovery for all practical purposes has ended. In our experience, practical UMN motor recovery after head injury winds down significantly between six and twelve months after injury. Functional recovery is a different story. Even if many years have elapsed after a head injury, interventions aimed at improving function can produce practical changes. For example, a non-ambulatory patient whose base of support is severely compromised by equinovarus deformity during stance phase may regain ambulation through neuro-orthopaedic re-balancing of muscles crossing the ankle joint that change the base of support. Functional recovery may occur at any time after head injury provided that compensatory interventions are feasible and the patient has sufficient motor control to take advantage of the changes in biomechanical conditions.

*Clinical Commentary on Treatment Perspectives* Before 1980, little heed was given to cognitive, behavioral and psychosocial aspects of head injury. Patients with severe disability after TBI were not considered candidates for rehabilitation. Those with lesser disability who were admitted to a rehabilitation center were given physical rehabilitation, based on approaches used for patients with stroke and spinal cord injury. The pendulum shifted in the next decades toward cognitive and behavioral aspects of TBI as professionals began to recognize that families were more vulnerable to the burdensome effects of impaired behavior and cognition than they were to the effects of physical impairment (48). With a relatively reduced emphasis on physical rehabilitation, treatment of muscle overactivity was approached less aggressively. Drugs used in spinal cord injury and multiple sclerosis such as diazepam, baclofen and dantrolene were looked upon cautiously because of their sedating, fatiguing and weakening side effects. Surgery was typically based on inferences made from physical examination alone and was considered an option of last resort, often focused on reduction of severe deformity rather than increasing functional performance. Surgeons were not well acquainted with cognitive and behavioral issues that might affect their pre-operative decisions and post-operative care. Rehabilitation staff who dealt with cognitive and behavioral issues generally thought that surgery was an aggressive choice of last resort. Many nonsurgical physicians thought so too — especially since the experience of local surgeons with an interest in neurological problems varied greatly.

We believe that good conservative and surgical methods are available for improving function of patients with muscle overactivity. Psychosocial considerations and time course of motor recovery are important in the planning process. Most importantly, we emphasize focal analysis of muscles, joint by joint, that exhibit positive and negative signs of UMN because UMN pathology is highly variable. When TBI produces UMNS, the degree of voluntary function that remains varies greatly from muscle to muscle, even in the same limb segment. Factors related to poor production and regulation of movement need to be distinguished from those that reflect different forms of muscle overactivity along with rheologic changes. These distinctions may be based on physical examination alone but technology-based evaluations provide increasingly useful and objective support to complement clinical analysis. Treatment of motor dysfunction associated with UMNS is linked not only to muscle overactivity but also to concepts of voluntary production and control of movement along with rheologic change.

## PATTERNS OF UMN MOTOR DYSFUNCTION

The varied forms of muscle overactivity in UMN lead to familiar postures of upper and lower extremity joints by

virtue of a net balance of contractile and rheologic forces generated in time. Many common patterns have been presented in Table 35-1. We now expand them in bullet format below. The remainder of the chapter adds discussion of central muscle relaxants, chemodenervation and neurolysis. Finally, a special section on neuro-orthopaedics allows the reader to gain greater familiarity with this approach through details of the operative techniques it employs.

### The Adducted, Internally Rotated, Flexion Restricted Shoulder

#### *Description, Functional Consequences and Penalties*

- S&S (signs and symptoms): shoulder adducted and internally rotated; some patients have hyperextension as their main problem; painful passive stretching of adductors is a common complaint
- PF (passive function): axillary redness, maceration and skin breakdown may be present; restriction of access to axilla for washing and hygiene is problematic for caregivers and patients
- AF (active function): some shoulder adductors are also shoulder extensors so, depending on the net balance of shoulder muscle forces, impaired voluntary flexion, abduction and rotation of the shoulder can make whole limb actions such as reaching, pushing, stabilizing and otherwise placing the hand in space problematic; difficulty raising the arm and placing the hand behind and on top of the head is common

#### *Differential Diagnosis and Diagnostic Work Up*

- Muscles that may contribute: adduction &/or internal rotation: pectoralis major (PM), teres major (TM), latissimus dorsi (LD), anterior deltoid (AD), subscapularis (SC); hyperextension or flexion restricting: long head of triceps (LHT), teres major, latissimus dorsi, posterior deltoid (PD)
- Taut tendons of PM, TM and LD palpable in the axilla; resistance to passive abduction, external rotation and extension of shoulder is typically high and often painful
- Restricted motion from capsular tightness needs to be distinguished from increased muscle resistance; examine passive internal and external rotation with humerus at side of thorax and with humerus abducted
- Single voluntary movements: when passive exceeds active range for abduction, abductor weakness or adductor over-activity is suggested; when passive exceeds active flexion range, flexor weakness or extensor over-activity is suggested; when passive

exceeds active external rotation range, external rotator weakness or internal rotator over-activity is suggested

- Alternating (to and fro) movements: if voluntary abduction is slower than adduction, voluntary flexion is slower than extension, voluntary external rotation is slower than flexion, then weakness of abductors, flexors, external rotators and/or over-activity of adductors, extensors, internal rotators may be present
- With so many muscles potentially weak or overactive, dynamic EMG helps supplement clinical exam
- Radiographs should be obtained to rule out restricted motion caused by heterotopic ossification
- Local anesthetic blocks may clarify sources of restriction (muscles, over-activity, contracture): motor point blocks for PM, TM, LHT AD, PD; thoracodorsal nerve block for LD; access to SC is very difficult

### *Findings and Treatment Options*

- Unmasked voluntary shoulder flexion and/or abduction and/or external rotation after diagnostic blocks improves prospects for placing the hand in space, especially for reaching
- Consider chemodenervation with botulinum toxin and/or neurolysis with phenol
- Use of phenol for large muscles (e.g. LD, PM) offsets the need to use large doses of botulinum toxin in such muscles, thereby preserving the use of toxin for many smaller, more distal muscles; PM, TM, LHT, AD, PD are amenable to both chemodenervation and neurolysis
- Limited change in range of motion after local block suggests muscle contracture and/or capsular tightness
- Drugs for pain and blocks for over-activity may help an aggressive range program for focal contracture

### **The Flexed Elbow Deformity**

#### *Description, Functional Consequences and Penalties*

- S&S: riding up during standing and walking; fist and fingers may contact throat or face; pain on passive stretching
- PF: reddened, macerated elbow crease, skin breakdown; caregiver has difficulty with dressing, bathing; impact on balance during gait
- AF: restrained elbow extension during forward reaching; bringing objects to and from body is impaired

#### *Differential Diagnosis and Diagnostic Work Up*

- Muscles that may contribute to this deformity include: biceps, brachialis, brachioradialis and pronator teres and extensor carpi radialis

- Resting posture: elbow flexed, forearm more often pronated than supinated; ECR and PT may contribute when wrist is flexed, forearm pronated; an acutely flexed elbow can lead to stretch injury of ulnar nerve
- Very slow passive stretch establishes the available range of motion and the likely presence of contracture (fixed shortening)(Figure 35-12). Changing the velocity of stretch from slow to fast helps identify presence of spasticity. Ashworth test for spasticity: take joint through fully available passive extension in about one second. Brachioradialis and biceps contractions, when present, are easily observed. Much more difficult to ascertain brachialis contribution. Dynamic EMG is useful
- When “single” joint voluntary extension movements fall short of the available passive range of motion, flexor overactivity is likely but extensor weakness and changes in physical stiffness of flexors must be considered
- When patient is able to do alternating voluntary movements of flexion and extension, timing and amplitude asymmetries can be identified. When extension movements are visibly longer in time than flexion movements, overactivity of flexors is likely, but extensor weakness and flexor stiffness may be factors. Amplitude asymmetries have similar implications. In addition, contracture may be present
- An effort to move the limb as a whole as in reaching for an object or pushing a door may exhibit flexor or extensor synergy (pattern overlay), either partly or fully. Pattern overlay, a centrally generated phenomenon, may be less amenable to relief by peripheral interventions

**FIGURE 35-12**

Example of an elbow flexion contracture. Very slow passive stretch establishes the available range of motion and the likely presence of contracture (fixed shortening). Contracture is a physical phenomenon and requires physical methods of treatment such as aggressive stretching, serial casting or surgical lengthening

- Radiographs are obtained when bony block and heterotopic ossification is suspected
- Musculocutaneous nerve block in the axillary region can help differentiate role of muscle over-activity versus contracture of biceps and brachialis. A separate motor point block of brachioradialis is required to determine its role. Flexor blocks may unmask voluntary extension

### Findings and Treatment Options

- If range of motion improves completely after nerve blocks, muscle over-activity without contracture is likely the cause of the posturing
- An x-ray positive form H.O. establishes a mechanical block as likely source of motion impairment. Underlying motor control may be established using dynamic EMG (even if motion is not present) because the patient can produce alternating voluntary recruitment patterns in flexors and extensors respectively if they have good motor control
- Partial improvement in range or no improvement suggests contracture
- Serial casting may be considered, preceded by local anesthetic block or phenol block if a dynamic component has been established by maneuvers described above
- In the early period of recovery, serial casting, phenol blocks of musculocutaneous nerve and motor point of brachioradialis may be considered. Botulinum toxin is useful for biceps, brachioradialis and brachialis, even pronator teres and ECR can be elbow flexors by reverse origin and insertion
- Treating elbow muscular should be accompanied by treatment of shoulder, wrist and finger muscles, as necessary, as the limb should be thought of as a whole

### The Pronated Forearm

#### Description, Functional Consequences and Penalties

- S&S: forearm pronates excessively at all times; passive stretching may be painful
- PF: may be difficult to passively supinate palm for washing, fingernail clipping due to tight pronators
- AF: impaired voluntary underhand reaching; patient has difficulty orienting hand to objects

#### Differential Diagnosis and Diagnostic Work Up

- Muscles that may contribute: pronator teres (PT) and pronator quadratus (PQ)

- Resting posture: forearm is pronated, elbow typically flexed by flexor muscles including pronator teres
- Very slow passive stretch establishes the available range of motion and the likely presence of pronator contracture. Since PT crosses the axis of rotation of the elbow, an extended elbow may increase tension in pronator teres. Stretching the pronators by passive supination at different velocities helps identify presence of spasticity. Tension in PT is clinically palpable but PQ is not palpable. Dynamic EMG is useful (Figure 35-13)
- When voluntary supination movement falls short of the available passive range, pronator over-activity is likely but supinator weakness and changes in physical stiffness of pronators must be considered
- When a patient is able to do alternating voluntary pronation and supination movements, timing and amplitude asymmetries can be identified. When supination movements are visibly longer in time than pronation movements, over-activity of pronators is likely, but supinator weakness and pronator stiffness may be factors. Amplitude asymmetries may also suggest pronator contracture
- Radiographs are obtained to rule out bony block, especially if forearm fractures have occurred
- MP blocks of PT and PQ (through the interosseous membrane) can be performed to distinguish between intense muscle over-activity and contracture but not usual to do so

FIGURE 35-13

Dynamic EMG study of pronation/supination of the forearm. This patient with TBI complained of difficult reaching underhand. The record shows good reciprocal innervation of biceps and pronator teres. When the biceps is active as a forearm supinator, pronator teres is inactive. When the pronator teres is active as a forearm pronator, the biceps is inactive. The same cannot be said of pronator quadratus, which is active during pronation *as well as* supination. These findings are consistent with co-contraction phenomenon in pronator quadratus but not pronator teres. Treatment implication: focal chemodenervation or surgery should be aimed at pronator quadratus, not pronator teres

- Dynamic EMG helps identify patterns of weakness in supinators and overactivity in pronators

#### *Findings and Treatment Options*

- When dynamic EMG suggests overactivity in PT and/or PQ and contracture is mild or absent, consider chemodenervation with botulinum toxin
- When contracture is present, chemodenervation combined with serial casting can be used but casts must go above elbow and include the wrist
- When neurological recovery is no longer expected, consider surgical lengthening of PT and PQ

### **The Flexed Wrist Deformity**

#### *Description, Functional Consequences and Penalties*

- S&S: wrist flexed excessively; passive stretching may be painful; pressure in carpal tunnel may lead to carpal tunnel syndrome
- PF: redness and possible skin breakdown in wrist crease; may create difficulty for caregivers during dressing
- AF: impaired wrist extension during reaching; ulnar deviation may be present

#### *Differential Diagnosis and Diagnostic Work Up*

- Muscles that may contribute: flexor carpi ulnaris (FCR), palmaris longus (PL), flexor carpi ulnaris (FCU), flexor digitorum sublimis and profundus, extensor carpi ulnaris (ECU) (consider when ulnar deviation is present), wrist extensors (weak)
- Wrist range examined with elbow extended to maximize flexor stretch (& simulate what would occur during a full reach)
- Since extrinsic finger flexors as well as wrist flexors can provide stretch activated flexion forces across the wrist, their respective contributions are sorted out by passive extension of the wrist with fingers held flexed by the examiner and with fingers held extended
- Passive stretch: bowstringing of FCR is common, PL often involved as is FCU; resistance to stretch is enhanced by holding elbow in maximum available extension; passive abduction with wrist in neutral reveals stretch activity in ulnar deviators (FCU and ECU); when resistance to passive extension of the wrist is enhanced by simultaneous finger extension, extrinsic finger flexor spasticity also contributes to the wrist flexion deformity
- Dynamic EMG is helpful in identifying whether wrist flexor overactivity and/or wrist extensor

under-activity is present during reaching and whether overactivity is present in superficial or deep finger flexors or in both

- When selective voluntary extension of the wrist falls short of the available passive range of motion, flexor over-activity is likely but extensor weakness and flexor physical stiffness may be factors
- When a patient is able to do alternating voluntary flexion and extension, timing and amplitude asymmetries can be identified. When extension movements are visibly longer in time than flexion movements, over-activity of flexors is likely, but extensor weakness and flexor stiffness may be factors. Amplitude asymmetries have similar implications. In addition, contracture may limit extension amplitude
- Motor point block of FCU and/or ECU can help sort their contributions to ulnar deviation

#### *Findings and Treatment Options*

- Consider chemodenervation with botulinum toxin for overactive wrist flexors and finger flexors without significant contracture
- When contracture and overactivity are both important limiters of range, chemodenervation and serial casting are considered. When chemodenervation is used, some delay before cast application may be necessary to allow for chemodenervation to take hold. Alternatively, proximal median nerve infiltration with local anesthetic can block not only most of the major wrist flexors but also most of the extrinsic finger flexors. Proximal ulnar nerve block can be added, if needed
- When additional neurological recovery is not expected, consider surgical tendon lengthenings and carpal tunnel release as indicated

### **The Clenched Fist Deformity**

#### *Description, Functional Consequences and Penalties*

- S&S: fingers clenched into the palm, wrist most often flexed but some patients have an extended wrist that will exacerbate finger flexion by tenodesis: malodor and maceration are common; skin breakdown occurs when fingernails dig into the palm
- PF: washing, and maintaining a dry, clean palm, donning splints and gloves, filing and painting fingernails all pose problems for patients with a clenched fist and for their caregivers (Figure 35-14)
- AF: impaired finger extension during reaching; individual fingers or groups of fingers may be flexed; flexed index and long fingers impair object acquisition by web space on radial side of hand (Figure 35-15)

**FIGURE 35-14**

An example of passive dysfunction of the hand reflected by poor cleanliness and hygiene of the hand. A clenched fist reduces access to the palm for cleaning and leads to moisture retention, malodor, and tissue maceration

#### *Differential Diagnosis and Diagnostic Work Up*

- Muscles that may contribute: flexor digitorum sublimis (FDS), flexor digitorum profundus (FDP); intrinsic overactivity may be masked by strength of extrinsics; extensor digitorum communis (EDC) (weakness)
- Resting position: When FDP is overactive, fingernails are not easily seen as they dig into the palm; when FDS but not FDP is involved, the distal interphalangeal joint (DIP) is extended, the fingernails are visible and the proximal interphalangeal joint (PIP) is flexed
- Passive stretch: we examine with elbow relatively extended and wrist in neutral (when possible) so as not to be fighting overly tight wrist flexors; finger flexor tension is reduced by flexing the wrist and this allows assessment of intrinsic musculature (interossei and lumbricales) as well as finger joints for contracture; though many examine the group of extrinsic finger flexors as a whole, we prefer to examine FDS and FDP for each finger individually,

**FIGURE 35-15**

This photo reveals that individual fingers can be differentially involved in the clenched fist deformity. The flexed index finger and flexed thumb of this patient narrowed the web space opening on the radial side and limited the size of objects that could be acquired by the hand. Focal chemodenervation applied solely to the muscle slip of flexor digitorum of the index finger and to flexor pollicis longus is indicated

keeping in mind that FDP flexes the DIP joint while FDS flexes the PIP joint

- Dynamic EMG with wire electrodes helps distinguish behavior of FDS and FDP during voluntary tasks such as reaching. Dynamic EMG is also useful in determining intrinsic muscle behavior, especially when the stronger extrinsics dominate the clinical picture; wire electrode recordings reveal voluntary behavior of EDC
- When selective voluntary extension of the fingers falls short of the available passive range, flexor overactivity and weakness of extensor digitorum communis are likely. Contracture of finger flexors is also common
- When a patient is able to do alternating voluntary flexion and extension, timing and amplitude asymmetries can be identified. When extension movements are visibly longer in time than flexion movements, overactivity of flexors is likely, but extensor digitorum communis weakness is typical and flexor stiffness may be a factor. Amplitude asymmetries have similar implications. In addition, contracture may limit extension amplitude

#### *Findings and Treatment Options*

- Consider chemodenervation with botulinum toxin for overactive finger flexors without significant contracture.
- When contracture and muscle overactivity limit range, chemodenervation followed by aggressive ranging and serial splinting may be considered.
- FDS can be chemodenervated separately from FDP. Individual muscle slips of FDS and FDP can be identified by electrical stimulation through the injecting

hypodermic needle. We use electrical stimulation to guide chemodenervation of FDS and FDP because EMG guidance is less certain for these deep muscles.

- When additional neurological recovery is not expected, consider tendon lengthenings. A superficialis to profundus transfer is considered for a non-functional hand with major hygiene problems.

### The Thumb-in-Palm Deformity

#### *Description, Functional Consequences and Penalties*

- S&S: thumb flexed into the palm at rest or with effort (Figure 35-16); thumbnail digs into skin
- PF: impaired access to palm for washing, donning gloves; psychologically bothersome appearance
- AF: impaired 3 jaw chuck, key pinch, other types of grasp; small web space limits size of objects that can be acquired by the radial side of the hand

#### *Differential Diagnosis and Diagnostic Work Up*

- Muscles that may contribute: flexor pollicis longus, and brevis, adductor pollicis, 1st dorsal interosseous
- Thumb range, tone examined with wrist extended and flexed; thumb intrinsics examined with wrist flexed
- Flexion of distal interphalangeal joint (DIP) suggests FPL involvement; carpometacarpophalangeal joint flexion with a flexed wrist points to potential involvement of FPB; a narrowed web space and adducted thumb suggests potential involvement of AP and/or 1st DI
- Voluntary thumb extension is tested with the wrist flexed in order to minimize FPL tightness
- Ulnar nerve block in Guyon's canal eliminates overactivity in AP and 1st DI, opening the web space
- If the web space remains narrow, muscle contracture is suggested; examine for skin contracture as well

**FIGURE 35-16**

Example of a thumb-in-palm deformity. Flexor pollicis longus is clearly involved. Flexor pollicis brevis must also be considered because of flexion of the metacarpophalangeal joint

- Median nerve block in carpal tunnel eliminates median innervated intrinsics of the thenar eminence
- Dynamic EMG of thumb intrinsics and extrinsics may be useful in localizing muscle overactivity

#### *Findings and Treatment Options*

- If diagnostic block of ulnar nerve in Guyon's canal opens the web space, muscle overactivity without contracture is the likely cause of an adducted thumb
- Consider botulinum toxin for muscle overactivity without contracture
- If web space remains tight after block, muscle contracture is likely; examine for joint contracture as well
- During early recovery, stretching exercises, dynamic splinting, serial casting may be considered
- If FPL is overactive, consider botulinum toxin injection; stretch FPL contracture after toxin injection
- When further neurological recovery is not expected, skin, muscle and joint contractures may be handled surgically
- When thumb flexion is weak, fusion of the DIP joint may enhance pinch power; when thumb flexion is adequate, thumb extension by an orthosis with elastic properties is theoretically desirable but often difficult to fabricate
- Chemical or surgical relief of the thumb-in-palm (TIP) deformity can enhance 'hand as a holder' function i.e. the insertion of objects into the TIP hand for useful holding (without manipulation)

### The Flexed Hip Deformity

#### *Description, Functional Consequences And Penalties*

- Flexed hip deformity during stance phases with forward flexed trunk. (Figure 35-5)
- Other findings include compensatory knee flexion during stance phase and relative leg length discrepancy with increased energy consumption. Limited hip extension with shortening of the contralateral step length. Hyperlordosis in an attempt to keep upright posture.

#### *Differential Diagnosis and Diagnostic Work Up*

- Muscles, which can contribute to this deformity, include the iliopsoas, rectus femoris and in some cases the hip adductors and pectineus.
- Hip range of motion should be examined with the Thomas test reducing spine motion. The Eli test will help elucidate the contribution of the rectus femoris to the deformity.
- The hip flexion may be caused as a compensation for equinus deformity and will be evident only during

walking but not confirmed by passive range of motion examination of the hip. Involvement of the rectus femoris may be clinically elucidated by observation of gait with knee extension and hip flexion occurring always together.

- Dynamic EMG is helpful in clarifying the contribution of rectus femoris vs. hip adductors and iliopsoas.
- Radiographs should be obtained to rule out bony deformity of the hip.
- Obturator nerve block or a motor branch block to the rectus femoris with local anesthetic can help differentiate the role of the hip adductors vs. iliopsoas or rectus femoris vs. iliopsoas.
- Increase stance phase hip extension following a diagnostic block helps to determine contribution from other muscles.
- Persistent hip flexion post block will point to the iliopsoas as the deforming force.
- Hip adduction deformity may be present in conjunction with flexion.

#### *Findings and Treatment Options*

- If a temporary nerve or motor branch block results in increased hip extension, muscle overactivity without contracture of the hip adductors or rectus femoris is the likely cause of the deformity.
- If the hip flexion persists and no radiographic evidence of bony involvement is evident, iliopsoas is the source of the deficit.
- Botulinum toxin could then be injected into the iliacus followed by stretching. If there is no change in the hip range of motion a contracture is determined.
- In the early period of recovery, stretching and botulinum toxin to control hip flexion is considered.
- If EMG studies or blocks demonstrate static origin to the deformity or sufficient time has elapsed for further neurological recovery, surgical intervention should be considered.
- Stretching of the hip flexors and strengthening of the hip extensors should be undertaken.

#### **The Adducted Hip Deformity**

##### *Description, Functional Consequences And Penalties*

- Adducted hip deformity during swing phase with narrow base of support. (Figure 35-17)
- Other findings may include associated hip flexion and relative leg length discrepancy with decrease stability in stance phase. Limited hip extension with shortening of the contralateral step length and difficulty with limb advancement in swing phase.

**FIGURE 35-17**

The consequence of an adducted hip is a narrow base of support

#### **DIFFERENTIAL DIAGNOSIS AND DIAGNOSTIC WORK UP**

- Muscles, which can contribute to this deformity, include the adductor magnus, adductor brevis and adductor longus, in some cases the iliopsoas and pectineus may be involved.
- Hip range of motion with hips in flexion and extension should be examined.
- Limitation in hip extension may be secondary to the limitation in hip abduction.
- Dynamic EMG is helpful in clarifying the contribution of the adductor magnus, adductor brevis and adductor longus and the lack of activation of the gluteus medius.
- Radiographs should be obtained to rule out bony deformity of the hip.
- Diagnostic Obturator nerve block with local anesthetic can help differentiate muscle overactivity from contracture.

- Increase hip abduction with widening of the base of support following a diagnostic block helps to differentiate muscle overactivity from contracture.
- Persistent hip flexion post block will point to the pectineus or iliopsoas as deforming forces.
- Hip flexion deformity may be present in conjunction with adduction.

#### *Findings and Treatment Options*

- If a temporary nerve block results in increased hip abduction, spasticity without contracture of the hip adductors is the likely cause of the deformity.
- If the hip adduction persists and no radiographic evidence of bony involvement is evident a contracture is the likely source of the deformity.
- Phenol or botulinum toxin can be used to achieve longer term relief of over-activity in the early period of recovery, stretching of the hip adductors and strengthening of the abductors should follow these interventions.
- If over-activity is severe, obturator neurectomy can be entertained.
- If blocks demonstrate a static origin of the deformity or neurological recovery has lapsed, hip adductor tenotomy should be considered.
- Stretching of the hip flexors and strengthening of the hip extensors should be undertaken.

### **The Stiff Knee Deformity**

#### *Description, Functional Consequences And Penalties*

- Stiff knee deformity during swing phase with impairment of limb clearance. (Figure 35-3)
- Limited limb advancement in swing phase.
- Other findings include pelvic hick and trunk lean during stance phase and relative leg length discrepancy with increased energy consumption. Ipsilateral circumduction and contralateral vaulting as compensatory mechanisms in swing phase.

#### *Differential Diagnosis and Diagnostic Work Up*

- Muscles, which can contribute to this deformity, include the quadriceps, hamstrings, iliopsoas and gastrocnemius.
- Knee range of motion should be examined with the hip extended and flexed.
- The knee extension caused by the quadriceps is often noted by inspection during ambulation. Hip extension reduces the stiff knee deformity.
- Dynamic EMG is helpful in differentiating the contribution of muscles such as the vastii from the rectus femoris.

- Radiographs should be obtained to rule out bony deformity at the knee or hip.
- Femoral nerve motor branch block in the anterior thigh with local anesthetic can help differentiate the role of overactive knee extensors vs. hip extensors.
- Increase swing phase knee flexion following a diagnostic block helps to determine ambulatory potential.
- Persistent knee extension post femoral motor branch block will point to the hip extensors or ankle plantarflexors as the deforming force.
- Ankle plantarflexion deformity may be present in conjunction with stiff knee.

#### *Findings and Treatment Options*

- If a temporary diagnostic femoral nerve motor branch block results in increased knee flexion, spasticity without contracture is the likely cause of the deformity.
- If the knee extension persists hip extensors may be the cause of the deformity.
- If EMG studies or blocks demonstrate dynamic origin to the deformity, botulinum toxin injection or motor branch block with phenol should be considered.
- Botulinum toxin injection of the hip extensors should be considered.
- Stretching of the knee extensors and strengthening of the knee flexors should be undertaken.
- Surgery in the form of a transfer of the rectus to the gracilis and lengthening of the vastii is considered in late recovery.

### **The Flexed Knee Deformity**

#### *Description, Functional Consequences And Penalties*

- Flexed knee deformity during stance phase with knee instability with weight bearing. (Figure 35-2)
- Limited knee extension in the terminal swing phase
- Other findings include pelvic drop and trunk lean during stance phase and relative leg length discrepancy with increased energy consumption. Limited knee extension with shortening of the step length.

#### *Differential Diagnosis and Diagnostic Work Up*

- Muscles, which can contribute to this deformity, include the hamstrings, gracilis, gastrocnemius and adductor longus.
- Knee range of motion should be examined with the hip extended and flexed.
- The knee flexion caused by the hamstrings is often noted by inspection during ambulation. Hip extension reduces the flexed attitude of the knee.
- Dynamic EMG is helpful in clarifying the contribution of muscles such as the medial vs. lateral hamstrings or the adductor longus.

- Radiographs should be obtained to rule out bony deformity at the knee.
- Sciatic nerve motor branch block in the gluteal fold with local anesthetic can help differentiate the role of dynamic spasticity with respect to contracture in this deformity.
- Increase stance and swing phase knee extension following a diagnostic block helps to determine ambulatory potential.
- Persistent knee flexion post sciatic nerve block will point to the hip adductors as the deforming force.
- Hip adduction deformity may be present in conjunction with flexion.

#### *Findings and Treatment Options*

- If a temporary diagnostic sciatic nerve motor branch block results in increased knee extension, spasticity without contracture is the likely cause of the deformity.
- If the knee flexion persists hip adduction may be the cause of the deficit.
- If there is no significant change in the knee range of motion after a sciatic nerve block, a static deformity i.e., knee contracture is determined.
- In the early period of recovery, orthotic management to control knee flexion is considered.
- If EMG studies or blocks demonstrate dynamic origin to the deformity, Botulinum toxin injection or motor branch block with phenol should be considered.
- Stretching of the knee flexors and strengthening of the knee extensors should be undertaken.
- Surgery in the form of distal hamstrings lengthening is considered for a static deformity in late recovery.
- A capsular release is considered if knee flexion is present while under general anesthesia.

#### **The Equinovarus Foot Deformity**

##### *Description, Functional Consequences and Penalties*

- Abnormal base of support during stance phase with weight bearing applied to the lateral border of the foot with pain and ankle instability with antalgic gait pattern.
- Equinovarus posturing in swing phase
- Other findings include hyperextension at the knee with recurvatum thrust (Figure 35-18), impaired forward progression of the center of gravity and relative leg length discrepancy with increased energy consumption.

##### *Differential Diagnosis and Diagnostic Work Up*

- Muscles, which can contribute to this deformity, include the gastrocnemius, soleus, tibialis anterior,

**FIGURE 35-18**

This patient has plantarflexor overactivity and contracture leading to hyperextension at the knee with recurvatum thrust and impaired forward progression of the body over the stance phase limb

tibialis posterior, extensor hallucis longus, extensor digitorum, flexor digitorum and foot intrinsics (Figure 35-19).

- Ankle range of motion should be examined with the knee extended and flexed.
- The inversion pull of tibialis anterior is often noted by inspection during ambulation. Hind foot inversion is often generated by spastic tibialis posterior.
- Dynamic EMG is helpful in clarifying the contribution of muscles such as the tibialis posterior and anterior.
- Radiographs should be obtained to rule out bony deformity at the ankle.
- Tibial nerve block in the popliteal fossa with local anesthetic can help differentiate the role of dynamic spasticity with respect to contracture in this deformity.
- An improved base of support following a diagnostic block helps to determine ambulatory potential.
- Persistent ankle inversion post tibial nerve block will point to the tibialis anterior as the deforming force.
- Curled toes may be associated with the equinovarus deformity and worsened by increase ankle dorsiflexion.

**FIGURE 35-19**

Two feet with equinovarus deformities in the same patient. As confirmed electromyographically, left foot varus was attributable to tibialis anterior overactivity. Right foot varus was driven by tibialis posterior overactivity. Note bilateral great toe hyperextension, variously termed: striatal toe or hitchhiker's toe

#### *Findings and Treatment Options*

- If a temporary diagnostic tibial nerve block results in increased ankle dorsiflexion, spasticity without contracture is the likely cause of the deformity.
- If varus persists in swing phase, the most likely cause is tibialis anterior and/or extensor hallucis longus.
- If there is no significant change in the range of motion after a tibial nerve block, a static deformity i.e., contracture is determined.
- In the early period of recovery, orthotic management to control equinus is considered, with appropriate components to control ankle inversion and toe flexion.
- If EMG studies or blocks demonstrate dynamic origin to the deformity, Botulinum toxin injection or percutaneous motor point blocks with phenol should be considered.
- Stretching of the ankle plantar flexors and strengthening of the ankle dorsiflexors should be undertaken.
- Surgery in the form of tendo Achilles lengthening or intramuscular lengthening is considered for a static deformity in late recovery.
- A SPLATT (Split Anterior Tibialis Tendon Transfer) is considered if ankle inversion is present during swing phase and is caused by tibialis anterior. If inversion is caused preferentially by tibialis posterior, a lengthening of this muscle is indicated.

#### **Concepts in Pharmacological Intervention**

Pharmacological reduction of muscle overactivity may be beneficial in selected clinical problems. However, drug

treatment of overactivity is often a trade off against side effects. Three drugs, dantrolene sodium, baclofen and diazepam are commonly used to treat spasticity. Their use in TBI must be considered carefully because the side effect of sedation, though typically different for each drug, can be problematic for patients with arousal or cognitive dysfunction. It is ironic and sobering that patients with TBI, who often need help for muscle overactivity more than most, are also among the most sensitive to the side effects of these agents with respect to functions such as attention and cognition.

*Dantrolene Sodium* Dantrolene sodium exerts its effect directly on skeletal muscle fibers. Physiologically, a neural signal to a muscle triggers a motor unit action potential that causes release of calcium from sarcoplasm storage sites within the muscle fiber itself. Calcium ions initiate cross-bridging of myofilaments and build-up of contractile tension. By inhibiting release of calcium from the sarcoplasmic reticulum, dantrolene sodium reduces the force of muscle contraction and, thereby, has the potential for reducing tension in overactive muscles. It should be noted that tendon jerk responses and electrically induced twitch tensions of muscle are reduced much more effectively than tetanic stimulation or sustained volitional contraction. In the latter conditions, the amount of calcium released into the sarcoplasmic reticulum over the course of continued stimulation of muscle by nerve activity (whether through volition or through electrical stimulation) tends to accumulate and overcome the inhibitory effects of the drug. This latter observation is important in understanding the utility and limitations of dantrolene sodium as a clinical agent. Dantrolene sodium may be useful in treating short duration, low frequency spastic phenomena such as clonus or brief spasms (49) (Figure 35-4). Phasic, small tension overactivity rather than tonic, large tension overactivity is favored for treatment with dantrolene sodium. Patients with TBI who have severe overactivity are not typically responsive to dantrolene sodium. Though its influence on treating spasticity is peripheral, dantrolene sodium apparently has a number of side effects that are central in nature and it can be sedating to patients with arousal dysfunction. Nevertheless, it may be a reasonable choice for mild to moderate overactivity, especially for clonus or other phasic behaviors involving many different muscles. Clonus often remits at a dose level of 50 mg q.i.d. though doses of up to 400 mg a day may be used. Cases of hepatotoxicity have been reported and liver function tests should be monitored, especially in those at risk for liver toxicity for other reasons.

*Diazepam* This agent, centrally acting and highly sedating, increases the central inhibitory effects of gamma amino-butyric acid (GABA) (50). Diazepam appears to bind to receptors located at GABA-ergic synapses and

increases GABA-induced inhibition at those sites. Antispastic characteristics of diazepam appear to arise from GABA-related inhibitory effects on alpha motor neuron activity in the spinal cord. Since diazepam also exerts sedative effects in the brain, some of its muscle relaxant properties may be due to diazepam's ability to produce a more generalized state of sedation. Although it is often successful in reducing spasticity of skeletal muscle, the primary problem with diazepam is sedation. Diazepam is not a suitable drug for persons with TBI who have attention or cognitive dysfunction. For patients who have persistent phasic flexor spasms that disturb activities of daily living or nighttime sleep, small doses of diazepam may be effective in reducing the frequency and intensity of these spasms with tolerable sedation.

**Baclofen** This drug, a derivative of GABA, appears to act as a GABA agonist inhibiting transmission at specific synapses within the spinal cord (51). When used as an antispastic agent, baclofen ultimately appears to have an inhibitory effect on alpha motor neuron activity. It is unclear whether this inhibition is presynaptic (through inhibition of other excitatory neurons that synapse with the alpha motor neuron), or whether it is postsynaptic on the alpha motor neuron itself. Nevertheless, the net result of baclofen's action is to inhibit the firing pattern of the alpha motor neuron pool in the spinal cord with subsequent reduction of muscle overactivity in skeletal muscles.

Clinical research studies using baclofen for overactivity have primarily addressed the problems of patients with multiple sclerosis or spinal cord injury (52). Baclofen has been effective in these populations, especially when the clinical problem has related to flexor spasms. Oral baclofen is generally initiated at 10 mg a day in divided doses and increased to 80 mg or more as needed. Such high doses will invariably lead to side effects in many patients that can overshadow any benefits. In patients with TBI who are in a persistent vegetative state and are not expected to recover, high doses may be considered since cognitive and arousal function are not an issue. Nevertheless, on the remote possibility that the patient might be making some recovery, it might be wise to taper the drug periodically and observe.

Oral baclofen has been little studied in spasticity of cerebral origin (53). Meythaler et al. performed a retrospective review of 35 adult patients with acquired brain injury before and after starting treatment with oral baclofen. Twenty two patients had TBI and were found to have a change in Ashworth grade and deep tendon reflexes in the lower limbs. For the upper limbs, no significant change in Ashworth grade or deep tendon reflexes and spasm frequency didn't change in upper or lower limbs. The average dosage at follow-up was 57 mg baclofen (range: 15–120 mg/day). For the group as a whole, a 17% incidence of somnolence limited the maximum daily

dosage. The authors speculated that the lack of effect of oral baclofen on Ashworth scores and tendon reflexes may have been related to their observation that systemic delivery may have profound central side effects at brain level before it reaches adequate concentrations at cervical cord level necessary for affecting upper limb spasticity. Drowsiness, confusion and memory impairment are known side effects of oral baclofen and can be particularly troublesome for patients with TBI who already have impairments of arousal, attention and cognition (52, 54). A potential method for reducing central side effects is the intrathecal delivery of baclofen (ITB)(55), an approach for controlling hypertonia in ABI that has more extensive literature than oral ingestion. A drug pump is implanted subcutaneously to infuse baclofen into the lumbar subarachnoid space. Compared with oral administration, the pump allows much smaller doses of baclofen to be used (56–58). Side effects are reduced and effectiveness in refractory cases is enhanced (53). The pump has an eighteen milliliter reservoir, connected to an intrathecal catheter, that is refilled periodically by percutaneous puncture. The rate of baclofen infusion is adjusted by an external computer. The most common adverse effects of ITB include hypotonia, drowsiness, dizziness, nausea, vomiting, hypotension and headache (59, 60). Life-threatening complications associated with overdose or withdrawal have occurred, linked to mechanical failure or human error. (61–64) Intrathecal overdose can cause coma and respiratory depression. Sudden withdrawal of the drug (e.g. by unrecognized pump failure) can cause an exaggeration of spasticity along with hallucinations and seizures. The system is expensive and potentially hazardous when technical problems arise. However, the pump system may be useful for patients who have regional muscle over-activity distributed across many lower extremity muscle groups, especially bilateral hip flexor, adductor and hamstrings groups. Most studies with ITB (as with oral baclofen) have focused on the evaluation of stretch reflexes and spasms and active function has not been systematically investigated (53, 65). In a pilot study, Francisco and Boake reported an improvement in walking speed in 10 patients with poststroke spastic hemiplegia after ITB in combination with physical therapy.

**Tizanidine** Tizanidine has muscle relaxant properties, acting as an agonist at alpha-2 adrenergic receptor sites both spinally and supraspinally. Placebo-controlled studies have shown that tizanidine reduces muscle response to passive stretch in both the spinal and cerebral forms of spasticity including patients with TBI (66–68). Tizanidine does not appear to confer functional changes (67, 69). Adverse effects have included hypotension, sedation, generalized fatigue, falls, dry mouth, reduced renal clearance and the potential for hepatotoxicity and

hypotension (70). Sedation, a particular problem for patients with TBI, is the commonest adverse effect, occurring in almost 50% of patients who use it (71). The amount of tizanidine that a clinician can use for patients with TBI is necessarily curtailed by its side effects, particularly drowsiness. Hence, its therapeutic effect for muscle overactivity is often limited. In addition to spastic stretch reflexes, tizanidine has been shown to have a physiologic effect on co-contraction, a common positive sign of UMN activity that hampers voluntary movement (29).

### Botulinum Neurotoxin (BoNT)

Pharmacological management of muscle over-activity often requires a balance between acceptable reduction in over-activity and acceptable side effects. From this perspective, botulinum neurotoxin (BoNT) is an excellent therapeutic agent because of its focal action without significant side effects. A number of double-blind, placebo-controlled studies have reported significant reductions in muscle tone for patients with acquired brain injury, primarily stroke (72–74). Yablon et al. performed an open-label study of 21 patients with TBI who had severe wrist and finger flexor spasticity (75). Improvements were seen in range of motion at the wrist and in the modified Ashworth scale. There were no significant side effects. Brashear, Gordon, Elovic et al. performed a large scale multi-center trial that was a randomized, double-blind, placebo-controlled study of BoNT A in persons with spasticity of the wrist and finger flexors after a stroke (76). The study assessed efficacy and safety of BoNT A in 126 subjects who received a one-time injection of 200 to 240 units. The primary outcome measure was self-reported disability in four areas: personal hygiene, dressing, pain and limb position at six weeks. At base line, each subject selected one of these areas as the principal target of treatment. Based on Ashworth scores, they found significantly greater improvement in subjects treated with BoNT A in wrist and finger flexor tone at all follow-up visits through 12 weeks than did subjects who received placebo. In addition, subjects treated with BoNT A had greater improvement in the principal target of treatment at weeks 4, 6, 8 and 12. There were no major adverse events associated with injection of the neurotoxin. Brashear, Zafonte, Corcoran et al. demonstrated inter- and intrarater reliability for the the Disability Assessment Scale as well as for the Ashworth Scale applied to elbow, wrist, finger and thumb flexors of poststroke patients (77). Brashear et al. have reported results of an open-label, single-treatment session using BoNT B (MyoBloc; Elan) in 10 patients with upper limb spasticity (elbow, wrist, fingers) (78). Improvements in Ashworth scores as well as global assessment changes by investigators and patients were obtained. Nine of 10 subjects reported dry mouth at week 4 of the study with resolution by week 12. No changes were seen on functional measures.

BoNT type A (BoNT A) is injected directly into affected muscle groups, usually under electromyographic or electrical stimulation guidance, causing reversible, dose-dependent muscle relaxation by blocking acetylcholine release at the neuromuscular junction (Figures 35-20 and 35-21). The purpose of toxin injection is to reduce force generated by UMN muscle over-activity in order to create a more favorable net balance of forces acting across joints (Figures 35-22 and 35-23). When target muscles are identified, the toxin's localized inhibitory effect makes it a very useful agent for carrying out focal strategies for managing muscle over-activity. A reduction in excessive tension can lead to improvement in passive and active range of motion and allows for more successful stretching of dynamically and statically tight musculature. More subtly, and more importantly, a patient's improved control over movement and posture may allow for compensatory behaviors during functional activities that rely on active as opposed to passive movement. A reduction in muscle over-activity in one muscle group may have consequences for tone in other muscle groups of the limb through a reduction in the overall effort required to perform movement and/or possibly through changes in sensory information going to the central nervous system from that limb.

In contrast to phenol or alcohol, exposure to the toxin causes reversible denervation atrophy without fibrosis. There are seven serologically distinct toxins produced by *Clostridium botulinum* that are potent

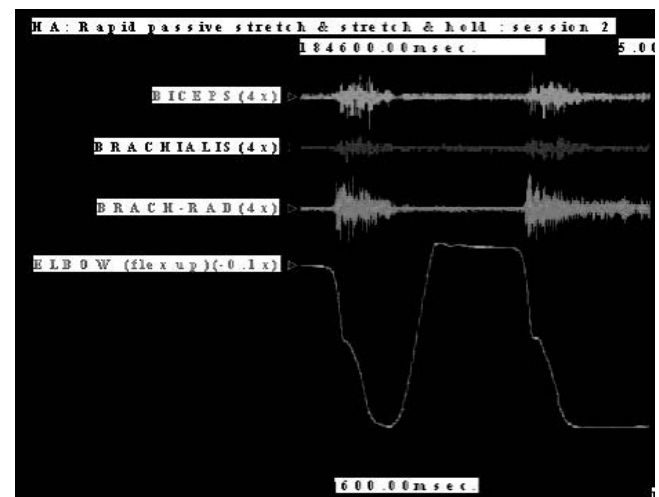

FIGURE 35-20

Prior to injection of BoNT A: Rapid passive stretch of elbow flexors followed by rapid passive stretch and hold in a patient with TBI and hemiparesis reveals spastic reactivity in all three elbow flexors during dynamic stretch. Tonic activity is also seen in brachioradialis during static stretch (“hold” phase). Bottom movement trace shows a “spastic catch” midway during displacement

FIGURE 35-21

Biceps was injected with 120 units BoNT A (Botox®); brachioradialis was injected with 80 units. The figure is a 22-day follow-up study: Note marked reduction in stretch reflex activity and absence of “spastic catch” in the movement trace, as reflected in EMG of all flexors during stretch. BoNT A inhibits muscle contraction by blocking acetylcholine release at the neuromuscular junction

FIGURE 35-22

Flexed index finger during reach to grasp in a 22-year-old woman two years after TBI. Muscle overactivity on the radial side of the hand impairs access of objects into the webspace of the hand

neuroparalytic agents and these are designated as BoNT A, B, C, D, E, F and G. Only two types (A and B) are available for therapeutic human use. BoNT type A is synthesized as single chain polypeptides with a molecular mass of approximately 150 kDa. Neurotoxin activation

FIGURE 35-23

Twenty-two days after injection of 20 units BoNT A (Botox®) into isolated muscle fascicles of flexor digitorum profundus and flexor digitorum sublimis of the index finger. Access to the webspace was improved and objects were more easily grasped

requires a two-step modification in the structure of the protein. In the first step, the parent chain is cleaved. The result is the formation of a heavy chain tethered by a disulfide bond to a light chain that is associated with one atom of zinc. The second activation step, disulfide reduction requires internalization by the target cell. The toxin must enter the endplate zone to exert its effect. The process is partially dependent on nerve stimulation and independent of  $Ca^{2+}$  concentration. A commercial form of BoNT A in the United States (US) is Botox® [Allergan] which is currently approved by the US Food & Drug Administration (FDA) for the treatment of blepharospasm, facial spasm, strabismus, cervical dystonia and torticollis and certain cosmetic uses. BoNT B is branded as MyoBloc [Solstice] and is approved for the treatment of cervical dystonia in the US. Dysport is a different (non-interchangeable) version of BoNT A that is available in Europe and elsewhere but not the US. In Europe and Canada, BoNT A is also approved for the management of spasticity secondary to cerebral palsy and stroke.

Patients may begin to experience benefits three to seven days after injection. The duration of action in the management of muscle overactivity is about three to four months, after which re-injection is indicated. Reported adverse effects have included excessive weakness of injected muscles, pain at injection site, local irritation, headache, fatigue and flu-like symptoms. No anaphylactic response has ever been reported due to BoNT A injection. Treatment success, in part, depends on the skill of the injector. Muscle selection, injection technique and dose must be individualized. (see Table 35-1)

**Nerve Blocks** Nerve and motor point blocks are very useful in targeting specific muscles or muscle groups for diagnostic and therapeutic maneuvers. The purpose of the nerve or motor point block is to reduce force produced by a contracting spastic muscle or muscle group. A reduction in spastic tension can lead to improvement in passive and active range of motion and allows for more successful stretching of tight musculature. More subtly, and more importantly too, a patient's improved control over movement and posture may allow for compensatory behaviors during functional activities. A reduction in spastic activity in one muscle or muscle group may have consequences for tone in other muscle groups of the limb through a reduction in the overall effort required to perform movement and/or through changes in sensory information going to the central nervous system from that limb. Finally, the application of external devices such as braces, casts, even shoes, can be facilitated by nerve and motor point blocks.

Blocks may be classified broadly as diagnostic or therapeutic in nature. Diagnostic blocks are typically performed with short acting local anesthetics such as lidocaine or bupivacaine. These quick acting, short duration agents allow the examiner to evaluate factors described above such as passive range of motion, muscle stiffness unrelated to overactivity, changes in active range of motion when dynamic resistance is blocked, and enhanced motor control during functional movements. For example, a patient with overactive adductors causing scissoring during gait may be prone to fall because of the narrow base of support. A temporary block of the obturator nerve with 2% lidocaine will allow the examiner to observe whether the base of support widens and stability improves. The key to understanding the use of a diagnostic nerve block is that it be used to test a hypothesis. In the given example, the hypothesis behind the obturator nerve block is that the base of support was narrowed by excessive adduction of the leg caused by spastic adductors. It was further postulated that a wider base of support would lead to greater stability during dynamic gait. After the nerve block is performed with a quick-acting local anesthetic, the patient is ambulated in order to test the hypotheses about widening the base of support and improving stability during ambulation. If improved ambulation results, then more permanent (i.e. less reversible) types of intervention may be contemplated with a greater sense of outcome prediction. Therefore, the prediction of a likely outcome for an intervention is an important feature of temporary nerve or motor point blocks. In the given example, it is possible that the base of support might not widen. For example, a severe adductor contracture will not remit after a nerve block. However, this information is useful in designing the next step in the treatment program. Similarly, it is possible that the nerve block may be physiologically successful, spasticity

of the adductors are blocked, and the base of support widens. Yet the overall gait pattern is only partially improved because instability was coming from other sources of neuromuscular neurological impairment. Again, this kind of information can lead to further diagnostic testing of other hypotheses relevant to why the patient has an ambulation dysfunction.

Therapeutic nerve and motor point blocks are primarily performed with aqueous solutions of phenol. When it is injected in or near a nerve bundle, phenol denatures protein in the myelin sheath or cell membrane of axons with which it makes contact. When administered in the operating room under direct nerve visualization, phenol is instilled directly into the nerve bundle in a glycerin solution to minimize leakage. Related to this technique, the desired motor nerves are identified by electrical stimulation prior to injection, mixed nerves with sensory and motor fibers are avoided because of consequent dysesthesias, and the duration of effect is often six months or more because the injection of the nerve is so direct. An aqueous solution of phenol, on the other hand, is the medium used for percutaneous injection in the laboratory or at the bedside and the location of the nerve is approximated by an electrical stimulation technique which typically results in variable contact of phenol with axons (Figure 35-24). This variability is a key factor in the duration of effectiveness of a percutaneous phenol nerve or motor point block. As Glenn has indicated, a peripheral

**FIGURE 35-24**

Phenol injection into a motor point of pectoralis major. A motor point is defined electrophysiologically rather than by anatomy. It is the most distal location of a motor nerve at which electrical current produces a visible or palpable contraction of muscle. The hypodermic needle in the photo is insulated on the outside and has a conductive core on the inside. When connected to an electrical stimulator, the needle is used to find a motor point and, when found, to inject phenol into the region of the motor point

nerve block is more likely to last longer than a block of a motor point [a motor nerve branch located much closer to a muscle than the more proximal peripheral nerve]. Phenol neurolysis of peripheral nerve may result in Wallerian degeneration. Re-innervation probably takes longer for the proximally blocked peripheral nerve because it has a longer distance for axoplasm to advance in order to reach muscle compared with the re-innervation distance of nerve blocked at the more distal motor point. The smaller size of the nerve involved in a motor point block may also make it harder to localize percutaneously. In addition, if a mixed sensory-motor nerve is selected for phenolization [typically in a low level patient where there is less concern about consequent dysesthesia], a reduction in afferent drive of spasticity may add to the effectiveness of the block as well. It is our impression that a motor point block with phenol can influence over-activity for three to five months. Nevertheless, reports on duration effectiveness in the literature have varied over a vary broad range from several days to three years. The reader should glean from this that phenol blocks are a temporizing measure and are most effectively used in the period of expectant neurological recovery. The rationale for the other injectable agents such as alcohol and botulinum toxin, is in our view, essentially the same.

The strategy of performing a block is as follows: a surface stimulator is used to locate the selected peripheral nerve or motor point. The skin is then prepared with an antiseptic iodine solution, swabbed with alcohol and subcutaneously anesthetized with lidocaine prior to insertion of the teflon coated, 22 gauge injecting needle (see Figure 35-24). The electrically conductive inner core of the tip of the needle is used to pass current to the tissues. As the needle is advanced closer to the nerve, less current is required to produce similar amounts of muscle contraction. When a minimal current producing a visible or palpable muscle contraction is reached, we typically inject 3–5cc of aqueous phenol in concentration of 7%. When injecting multiple nerves or motor points, we usually do not exceed a total volume of 15cc and we generally avoid injecting patients taking anticoagulants where the risk of systemic absorption of phenol is greater. [In very large quantities, systemically absorbed phenol can cause seizures, central nervous system depression and cardiovascular collapse]. The essence of the technique is in the clinical manipulation of needle advancement towards the nerve. Depth of penetration and directional orientation of the needle tip require a steady hand, competent knowledge of anatomy and a good assistant. Morbidity is typically benign. Local irritation at the site of the block is treated symptomatically with ice, compression or mild analgesics. We avoid mixed sensory-motor nerves so as not to induce painful dysesthesias and we will substitute motor point blocks that involve motor branches only. The injection technique is a good temporizing measure during

the period of expectant neurological recovery and facilitates serial casting, range of motion exercises, passive ADL functions and active movements and function as well.

Borg-Stein et al. have made an initial comparison of phenol and botulinum toxin injections (79). They indicated that a reduction in over-activity after phenol motor point block tends to diminish after several months, but may last as long as several years. The effect of botulinum toxin appears to last for about three to four months with a more complete return to baseline than is generally seen after phenol injection. Botulinum toxin is not associated with dysesthesia, but neither is motor point block with phenol. Only injection of phenol into a mixed sensory/motor nerve may produce such an effect. The cost of the toxin compared with the cost of phenol is large and the cost will escalate if multiple injections are required to titrate a desired clinical effect. Second, it is not clear how to control the titration process for an overactive muscle that also has volitional capacity. An ideal agent would eliminate a muscle's over-activity while preserving its voluntary capacity. Third, the technique for injecting deeper muscles with toxin requires electrical stimulation to verify the muscle's identity. This requires searching skill akin to the skill of advancing toward a motor nerve using the phenol technique. For deep muscles, EMG guidance does not really specify which muscle is being injected. Such a technique may be useful in dystonia, but is riskier in UMN muscle over-activity. Phenol has local anesthetic properties so that one can see an immediate result after injection (Figures 35-25 and 35-26). Botulinum toxin effects are variably seen after 5–14 days. On the whole, injecting botulinum toxin into a single superficial muscle under EMG guidance is quicker than injecting

**FIGURE 35-25**

Phenol has local anesthetic properties so that one can see an immediate result after injection. In this photo, a prominent biceps tendon is observed when the biceps is stretched

**FIGURE 35-26**

This photo was taken 5 minutes after phenol block of the musculocutaneous nerve was performed with 4 cc of 7% aqueous phenol. The biceps tendon is no longer prominent because the local anesthetic effect of phenol has eliminated stretch reflex activity in the biceps (and brachialis). Beginnings of the longer-term denaturation effect of phenol is not expected for 48-72 hours after phenol injection

phenol but more individual muscles are injected with the toxin so that total work time may turn out to be a wash. To inject phenol, we typically utilize an assistant. Botulinum toxin can be managed entirely by the physician. Finally, BoNT and phenol can be used together in situations where large proximal muscles receive phenol blocks and smaller distal muscles receive toxin. Since the current upper range of toxin use is 600 units, large muscles would absorb most if not all of the prescribed toxin leaving little left over for many smaller distal muscles. Hence, phenol applied to proximal musculature spares toxin for use elsewhere.

### **Special Section on Neuro-Orthopaedic Principles, Selected Procedures and Post-Operative Rehabilitation for UMN Muscle Overactivity After TBI**

*Neuro-orthopaedic Principles and Perspective* Six or more months after TBI, when the patient is neurologically stable and a majority of motor recovery has occurred, decisions can be made regarding neuro-orthopaedic surgery to correct limb deformities and rebalance muscle forces. It is at this time that a neuro-orthopaedic surgeon can make the greatest contribution to a patient's functional recovery. When evaluating patients with brain injury, questions commonly arise regarding indications for surgery, cost, expected outcome, and practicality of this approach. These issues should be considered on an individual basis for each patient. We have delineated

general principles that serve as our guidelines for decision making.

*Operate Early — Before Deformities Are Severe and Fixed* Orthopaedic surgery is a powerful rehabilitation tool. It is often the only treatment that will correct a limb deformity or improve function. Surgery should not be considered a treatment of last resort when “conservative” measures have failed. The choice of treatment technique, surgical or non-surgical, should be predicated on which one will provide the most optimal result.

*Better Underlying Motor Control Means Better Function for the Extremity* Orthopaedic surgery cannot impart control to a muscle. Lengthening a spastic muscle can improve its function by improving joint range of motion, by diminishing unwanted force generated by muscle overactivity, unmasking volitional strength of agonists when antagonists are modified by lengthening and uncovering any latent motor control that was present. Successful surgery depends on a careful evaluation preoperatively to determine the amount of volitional control present in each individual muscle that is affecting limb posture and movement.

*Distinguish Between the Function of the Extremity and the Function of the Individual* We think of active function and passive function of the extremity. These terms refer to the expected outcomes for a limb but do not indicate the outcome for the person as a whole. Surgical releases of an arm contractured in a flexed and internally rotated position in a hemiplegic patient often allows the person to become independent in dressing even though the arm itself does not have volitional movement.

*Consider the Cost of Not Correcting Limb Deformities* Allowing limb deformities to occur or persist is detrimental to well being and quality of life of the person with brain injury. Likewise, the cost of laboratory based motor control evaluation using dynamic electromyography (EMG); video and motion analysis is relatively modest for the benefits it provides. Dynamic EMG is a one-time expense. The cost of performing an incorrect surgical procedure that fails to correct or worsens a limb deformity is much greater. The cost of performing a surgical procedure is likewise limited when compared to a lifetime of attendant care, spasticity medications, repeated blocks, orthotics to control limb position, complications such as skin ulceration and infection and lost productivity for the patient and caregivers.

*Perspective on Neuro-Orthopaedic Treatment of Muscle Overactivity* Treatment of muscle overactivity is most effective when functional problems are formulated in focal rather than diffuse terms. For example, a patient may have muscle overactivity across all joints of the upper

extremity that some might consider sufficient justification for the use of a systemic agent to reduce tone in the arm as a whole. A closer examination of the patient might reveal that function of one joint in particular is most important. Treatment of focal problems lends itself well to surgical intervention that can target particular muscles. Surgical lengthening, transfer or release of targeted muscles can provide very effective solutions to problems of function that are clearly identified from the outset. The localizing approach is useful because it forces the clinician to indicate the desired outcome in advance since the outcome is based on an analysis that identifies the specific muscles responsible for the problem. For example, if the clinical problem is an adducted shoulder that hinders access to the axilla for purposes of bathing and hygiene, blocking the pectoralis major or surgically releasing it will not solve the problem if the teres major and latissimus dorsi are really the culprits responsible for the problem. Identifying the specific offending muscles by using the technique of dynamic electromyography is critically important to localized strategies of intervention.

In a neurologically impaired patient, it is frequently difficult to distinguish between the many potential causes of limited joint motion. The possibilities include increased muscle tone, myostatic contracture, the presence of peri-articular heterotopic ossification (HO), an undetected fracture or dislocation, joint subluxation, pain, or the lack of patient cooperation secondary to diminished cognition. Bony deformities may not exhibit an obvious clinical deformity but can be detected by radiography. Various muscles may contribute to motor dysfunction across joints and limb segments in these clinical patterns. Evaluation focuses on the following characteristics of the involved joint and limb segment: (1) the extent of voluntary or selective control, particularly within the context of whole limb movements; (2) the nature and intensity of muscle overactivity; (3) the degree of rheologic stiffness; and (4) the severity of contracture. When many muscles cross a joint, the characteristics of each muscle may also vary. Because each muscle may contribute to motion and movement of the joint, information about each muscle's contribution is useful to the assessment as a whole. Treatment depends on information that is obtained from a variety of sources including a history of signs and symptoms, a history of passive and active dysfunction with everyday usage, clinical examination, radiography, multi-channel dynamic EMG studies, kinetic and kinematic measurements, videography and photography, temporary nerve blocks, casting and splinting and even empirical trials with longer term blocking agents.

### **Technique and Post-Operative Rehabilitation of the Shoulder**

*General Comments* Shoulder problems are most often the result of a combination of both neurogenic and

mechanical factors. The mechanical problems include fracture malunions, joint subluxation, adhesive capsulitis, heterotopic ossification (HO), and soft tissue contractures. Together these cause the static component of the deformity. The dynamic component of the deformity or dysfunction is the result of neurogenic factors such as weakness, impaired motor control and the various forms of muscle overactivity. Extremity impairments are also classified as to whether they are symptomatic, cause problems of active function or passive function. Active function implies that the person has some capacity or potential to move the extremity volitionally. The shoulder places the hand in space, enabling a person to access and control tasks performed in a large sector of three-dimensional space. Problems of active shoulder function are characterized by impaired reaching, pushing, pulling, wiping, stabilizing and many other actions that depend on proximal strength, dexterity and control. Passive function indicates that little or no active movement of the extremity is possible. Problems of passive shoulder function in an immobile extremity include pain, skin maceration, malodor, ulceration, and contractures that impair passive mobility needed for hygiene, dressing and comfortable positioning.

*Anterior Shoulder Release for Contracture* An incision is made on the anterior shoulder beginning at the coracoid process and extending distally. The tendinous insertion of the pectoralis major tendon is identified and released near its insertion with electrocautery. The subscapularis is exposed and isolated from the shoulder capsule near its insertion on the humerus. Release of the subscapularis muscle is performed without violating the glenohumeral joint capsule. The joint capsule should not be opened because instability or intra-articular adhesions may result. The latissimus dorsi and teres major muscles are identified through the interval between the short head of the biceps and deltoid musculature. Release of these deforming muscles can then be performed in a non-functional extremity. A drain is placed deep into the wound prior to closure. Post-operatively, an aggressive mobilization program is instituted following skin healing. Gentle range of motion exercises are employed to correct any remaining contracture. Careful positioning of the limb in abduction and external rotation is necessary for several months to prevent recurrence.

*Selective Shoulder Lengthenings* Muscle overactivity in shoulder extensors and adductors commonly restricts shoulder movement important for reaching. Selective lengthenings to improve reaching are based on clinical examination and dynamic EMG studies. When pectoralis major is involved, an incision is made on the anterior shoulder beginning at the coracoid process and extending distally. The tendinous insertion of pectoralis major

is identified. The pectoralis is lengthened by transecting the tendon where it overlaps with the muscle belly. This junction can be found on the undersurface of the muscle. The tendon must be transected proximally to avoid complete rupture of the muscle tendon unit. The degree of muscle overactivity in the muscle ultimately determines the amount that the muscle tendon unit will lengthen. A new tendon forms within 3 weeks of surgery. When latissimus dorsi and teres major are known to be involved, they are identified through the interval between the short head of the biceps and deltoid musculature and lengthened at the musculotendinous junction. When the long head of the triceps is overactive, it is also lengthened. The long head of the triceps can be exposed and lengthened through the same incision.

After surgery the patient does not need immobilization. Therapy is started on the first post-operative day and consists of active and active assisted movement of the shoulder. No passive stretching or resistive exercises are permitted until 3 weeks after surgery to avoid over lengthening or rupture of the lengthened muscles.

**Supraspinatus Slide** Overactivity of the supraspinatus muscle can cause abduction posturing, making balance while ambulating difficult. The supraspinatus may be effectively lengthened by means of a slide procedure. The patient is placed in the lateral decubitus position with the affected extremity uppermost. An incision is made parallel to the scapular spine. The trapezius insertion is detached from the spine of the scapula, leaving a cuff of fascia for later reattachment. The deltoid is retracted laterally. Using a small periosteal elevator, the origin of the supraspinatus is elevated subperiosteally from the medial border of the scapula. The dissection is continued laterally, with care being taken to avoid injury to the neurovascular pedicle at the suprascapular notch. The muscle is then allowed to slide laterally. The trapezius is reattached to the scapular spine. The patient is allowed full, unrestricted postoperative motion.

### Technique and Post-Operative Rehabilitation of the Elbow

**Selective Flexor Lengthening for Active Function** Elbow extension is an important component of reaching and patients with a flexed elbow pattern have difficulty with reaching and placing the hand in space. When the biceps is involved, a longitudinal incision is made over the proximal anterior arm starting at the lower edge of the pectoralis major tendon. The muscle tendon junctions of both the long and short heads of the biceps are exposed. Tendon tissue that directly overlies muscle belly is then sharply transected, allowing the muscle tendon unit to lengthen (Figure 35-27). When brachialis is involved, an incision is made on the lateral aspect of the elbow. The

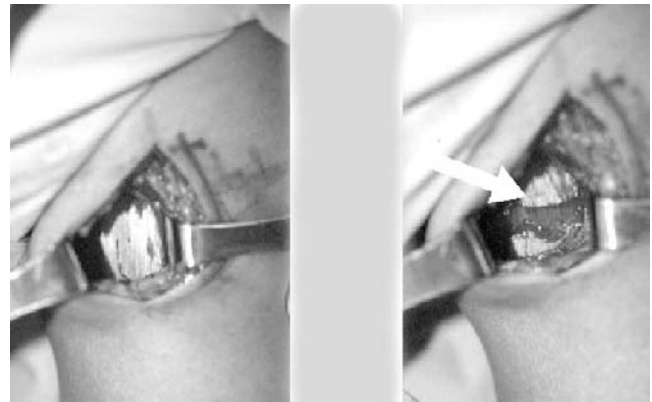

FIGURE 35-27

Lengthening of biceps at myotendonous junction. Photo on left reveals shiny biceps tendon with unseen muscle on its undersurface. Photo on right reveals dissection and separation of tendon, exposing the muscle belly underneath (which is not transected)

brachialis muscle is exposed and lengthened over its' broad muscle tendon junction. Through a separate incision on the radial aspect of the forearm, the myotendinous junction of the involved brachioradialis is identified and lengthened using similar technique.

When the muscles have been lengthened with this method, no immobilization is needed. Active range of motion exercises are started on the first day after surgery. No resistive exercises are allowed for 3 weeks to prevent over-lengthening of the muscles with resulting weakness. Functional elbow flexor lengthening has significantly enhanced the fluid control of elbow motion and improved hand placement in properly selected patients.

**Elbow Flexor Release for Passive Function** Persistent muscle overactivity of the elbow flexors causes myostatic contracture and flexion deformity of the elbow. This results in skin maceration and breakdown of the antecubital space. The position of severe elbow flexion also predisposes the ulnar nerve to an acquired compression neuropathy by increasing the vulnerability to direct pressure and decreasing the cross sectional area of the cubital tunnel. Surgical release of the biceps tendon and brachioradialis muscles and lengthening or release of brachialis is performed depending on the severity of the contracture. The joint capsule is not released. Gradual extension of the elbow with serial casting or physical therapy corrects the pre-operative deformity and decreases the ulnar nerve compression.

Approximately 50% correction of the deformity can be expected at surgery without causing excessive tension on neurovascular structures that are also contracted. Serial casting or drop out casts with electrical stimulation of triceps can be used to obtain further correction over the ensuing weeks.

*Surgical Treatment of Ulnar Nerve Compression* Prolonged elbow flexion with traction on the nerve can lead to decreased volume of the cubital tunnel resulting in nerve compression. Support of the torso by leaning on a chronically flexed elbow may result in direct compression of the nerve. The patients are often limited in their ability to complain about ulnar nerve symptoms because of limited cognitive and communicative abilities. The diagnosis is usually suspected because of intrinsic atrophy, and confirmed using nerve conduction studies. A 2.5% incidence has been shown in patients with traumatic brain injury. Treatment is ulnar nerve transposition, often at the same time as elbow flexor lengthening, or flexor releases. Subcutaneous transposition in the forearm is preferred.

### **Technique and Post-Operative Rehabilitation of the Forearm**

*Fractional Lengthening of Forearm Pronators* Muscle overactivity or contracture of one or both pronators impairs the ability of the forearm to orient objects in the hand toward the body by means of supination. The use of feeding and grooming utensils and clothes fasteners becomes problematic when supination is restricted. Dynamic EMG of pronator quadratus, pronator teres and biceps (to rule out weak supination) is informative. When pronator teres is involved, it is approached in the interval between the mobile wad and the flexor carpi radialis in the mid forearm. Myotendinous lengthening is then performed by cutting the tendinous fibers of the musculotendinous junction and allowing the tendon fibers to slide on the muscle belly, thereby lengthening the muscle tendon unit.

When pronator quadratus is involved, it is approached via an incision over the volar aspect of the forearm just proximal to the wrist crease. The finger flexor tendons are retracted radially to expose the broad myotendinous junction of the pronator quadratus. The tendon fibers are transected, leaving the underlying muscle fibers intact. The forearm is then supinated, separating the ends of the tendon fibers and lengthening the pronator quadratus. No immobilization is used and active exercises are begun immediately after surgery. No passive stretching of the wrist by a therapist is allowed for 3 weeks. Resistive exercises can be started 6 weeks after surgery.

### **Technique and Post-Operative Rehabilitation of the Wrist**

*General Comments* A flexed wrist is common after TBI but hyperextension deformity may also be seen. Patients complain of difficulty inserting their hand into shirts, jackets and other narrow openings and they frequently have pain on passive motion. They may also have symptoms

of carpal tunnel syndrome secondary to compression of the median nerve against the transverse carpal ligament by taut flexor tendons. In severe cases, wrist subluxation may be present. Ulnar (sometimes radial) deviation and a clenched fist are often present as well. When a patient has underlying voluntary control, the surgical treatment for wrist flexion is usually myotendinous lengthening of the wrist flexors. Finger flexors may also be lengthened if they are strongly overactive and contribute to wrist flexion deformity. When the goal is to improve passive function only, selective muscle releases, wrist fusion, proximal row carpectomy and superficialis to profundus tendon transfer may be considered

*Technique of Fractional Wrist Flexor Lengthening* In a limb with volitional control, fractional lengthening of the appropriate wrist flexors is performed. This is done in conjunction with lengthening of the extrinsic finger flexors when indicated. A longitudinal incision is made on the volar surface of the forearm. This incision is extended distally if a carpal tunnel release is necessary. The palmaris longus tendon is divided if tight. A myotendinous lengthening is performed by transecting the tendinous portion overlying the myotendinous junction. No immobilization is used after surgery. The patient is begun on a program of active exercise immediately after surgery. No passive stretching of the wrist by a therapist is allowed for 3 weeks. Resistive exercises can be started 6 weeks after surgery.

*Wrist Flexor Release and Wrist Fusion* When wrist flexion deformities are severe and there is little or no active function seen in the hand, release of the wrist flexors is performed. A proximal row carpectomy may be needed in some patients to correct a severe deformity. Because the median nerve is compressed against the proximal transverse carpal ligament causing painful neuropathy, a carpal tunnel release is performed as well. The wrist is then stabilized with a wrist fusion and is placed in a well-padded splint or cast for six weeks until the fusion has healed. Wrist fusion is done to eliminate the need for a wrist orthosis after surgery. Splints tend to be lost by these patients and their caregivers and, without wrist fusion, gravity alone can cause a recurrence of the flexion deformity.

### **Technique and Post-Operative Rehabilitation of the Hand**

*Fractional Lengthening of Extrinsic Finger Flexors* The clenched fist pattern may have early origins in an unmasking of the primitive grasp reflex. Muscles that contribute to the clenched fist deformity include flexor digitorum sublimis (FDS) and flexor digitorum profundus (FDP). If the proximal interphalangeal (PIP) joints flex while the distal interphalangeal (DIP) joints remain extended, the

'fingernails visible' sign, overactivity of FDS rather than FDP is suspected. When fingernails are not visible because the DIP joints are curled into the palm, overactivity of FDP is also suspected. Dynamic EMG studies have shown that FDS exhibits a marked degree of overactivity while FDP can be minimally overactive with better volitional control. Many patients can have voluntary EMG recruitment in finger extensors but extension is masked by overactive finger flexors that are simply stronger.

Surgery is performed through a longitudinal incision on the volar surface of the forearm, commonly at the same sitting with wrist flexor lengthenings. The palmaris longus tendon is divided. Lengthening of the individual tendons of FDS and FDP is performed by sharply incising the tendon fibers as they overly the muscle belly at the musculotendinous junction, allowing the tendon to slide distally (Figure 35-28). When involved in a thumb-in-palm deformity, the flexor pollicis longus tendon is lengthened in an identical manner. This technique allows the tendons to lengthen with minimal scarring. By transecting the tendon over the muscle belly, no sutures are needed. This eliminates scarring from foreign body reaction to suture material. The underlying support and vascularity of the muscle provides an optimal environment for the tendons to heal and reconstitute themselves.

Post-operatively a wrist splint is used for one week to prevent excessive stretch of the finger flexor. The patient begins a program of active and active assisted exercises on the first post-operative day. For patients with

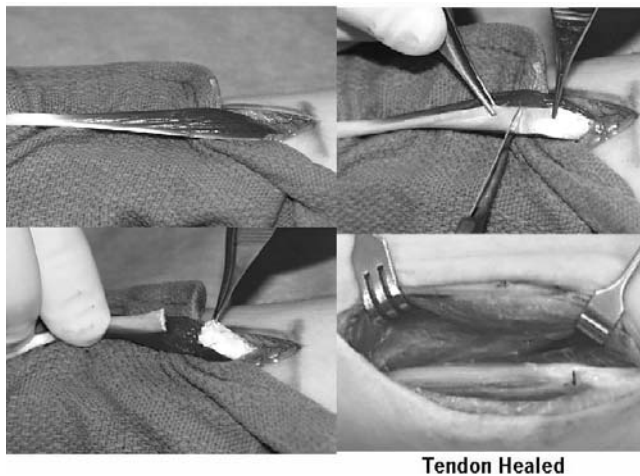

FIGURE 35-28

Technique of fractional lengthening. Muscle and tendon overlap. In the upper right figure, the tendon is exposed and sharply dissected without cutting through muscle tissue. In the lower left figure, the tendon is allowed to slide distally. The underlying support and vascularity of the muscle provides an optimal environment for the tendons to heal at a longer length and reconstitute themselves as seen months later in the lower right figure

limited motor control, it is often useful to use the splint for a longer period to position the wrist while the patient exercises the fingers. The immediate active motion allows the flexor tendons to continue to lengthen in the post-operative period as necessary. Ultimately, the amount of flexor lengthening is determined for each individual muscle by its' underlying tone and control rather than by the surgeon's estimate of tone. Using this technique we have had marked improvement in functional results when compared to our previous regimen of post-operative immobilization (Figure 35-29).

*Superficialis to Profundus Tendon Transfer* In a hand with skin maceration, malodor and pain on passive motion and in the absence of volitional control, more significant lengthening of flexor tendons is obtained with a superficialis to profundus (STP) tendon transfer. This provides a more cosmetically pleasing hand position, aids in hygiene by getting the fingers out of the palm and provides some passive restraint to otherwise unchecked extension.

The superficialis to profundus tendon transfer is performed through a longitudinal volar incision that may be extended distally to allow release of the carpal tunnel and access to Guyon's Canal. The palmaris longus tendon is identified and transected. The four superficialis tendons are sutured together distally and then transected for the en masse transfer. The profundus tendons are sutured together proximally and then cut. The fingers are

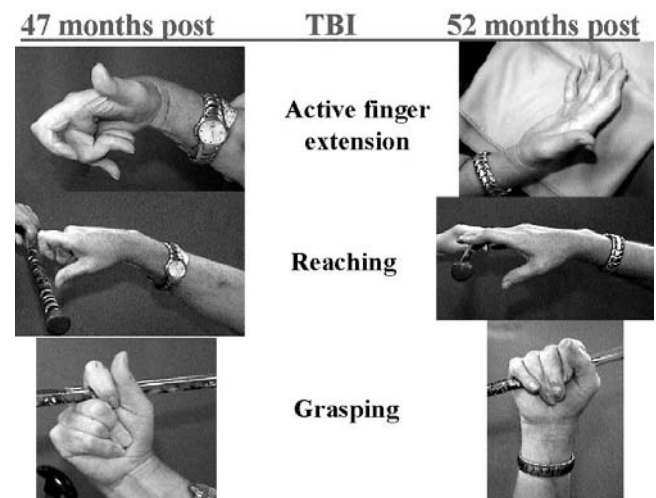

FIGURE 35-29

This patient was seen 47 months after TBI. He had UMN and had developed contracture of the superficial finger flexors. He was able to flex and extend his fingers but the arc of motion was extremely limited. Maximum finger extension is seen in the top left photo. Fractional lengthening of superficial finger flexors and joint capsuloplasties were performed in order to open up the hands. The patient did well postoperatively as seen in the upper, middle and lower right photos

extended and the distal end of the superficialis tendons is then sutured en masse to the proximal end of the profundus tendons.

Several other surgical procedures are routinely done in combination with the superficialis to profundus tendon transfer to treat the concurrent deformities. A neurectomy of the motor branch of the ulnar nerve is needed to prevent an intrinsic plus deformity from developing. If an intrinsic contracture is seen at the time of surgery following the STP lengthening, then release of the intrinsic is also performed. A carpal tunnel release is done to decompress the median nerve. To prevent a recurrent wrist flexion deformity from occurring secondary to passive wrist flexion, the wrist must be stabilized. Wrist extensor tenodesis has been attempted but often will stretch out with time. A cock-up wrist splint can be worn but patient compliance is poor. A fusion of the wrist in 15 degrees of extension provides the most reliable means of maintaining hand position and is now routinely performed. A proximal release of the thenar muscles is often needed to correct a thumb-in-palm deformity but, when needed, it is performed at a later time because STP transfer and wrist fusion are extensive procedures.

Post operatively, the wrist is immobilized for three weeks in a short arm splint which includes the fingers and thumb. The wrist is held in 15 degrees of extension and the fingers are immobilized with the metacarpophalangeal (MCP) joints in 60 degrees of flexion and the interphalangeal joints extended. Gentle range of motion of the MCP joints is started after cast removal. A volar wrist splint is used until the wrist fusion is healed.

### Technique and Post-Operative Rehabilitation of the Thumb

*Thumb-in-Palm Deformity* The thumb-in-palm deformity may result from overactivity in flexor pollicis longus, adductor pollicis (AP), and/or the thenar muscles (particularly flexor pollicis brevis (FPB)). The thumb is held within the palm, the IP joint of the thumb is commonly flexed and the thumb is unable to be positioned for key pinch or three-jaw chuck grasp (i.e. in opposition to the pads of the index and third fingers). Clinically, overactivity of flexor pollicis longus is indicated by flexion of the interphalangeal joint. Adductor pollicis and, sometimes, first dorsal interosseous can narrow the web space. Flexor pollicis brevis contributes to flexion of the metacarpophalangeal joint of the thumb.

*Thenar Muscle Slide* FPL is lengthened as previously described. Under tourniquet control, an incision is made along the thenar crease on the palm. The origins of FPB, opponens pollicis and abductor pollicis are detached from their origins while protecting the recurrent branch of the median nerve. The thumb is extended allowing the

released muscles to slide radially and reattach in an improved position, preserving function and preventing a hyperextension deformity.

The origin of the AP is released from the third metacarpal. Careful dissection to retract the digital neurovascular bundles and flexor tendons to the index and long digits is necessary. The deep palmar vascular arch and deep branch of the ulnar nerve are identified as they penetrate the AP between its oblique and transverse heads prior to adductor muscle release. The neurovascular supply of the AP is preserved. If the first dorsal interosseous muscle is contracted, a release is performed through a dorsal incision along the ulnar margin of the thumb metacarpal while protecting the radial sensory nerve. The origin of the first dorsal interosseous is released from its origin on the base of the first metacarpal. In persistent web space contractures despite appropriate muscle releases, a Z-plasty of the thumb web space is indicated. Post-operatively, the patient is immobilized in a thumb spica cast for 3 weeks. Active therapy is initiated after cast removal to optimize functional results.

### Technique and Post-Operative Rehabilitation of the Pelvis and Hip

*Heterotopic Ossification (HO) of Anterior Hip (Flexor)* After traumatic brain injury, HO typically occurs along lines of tension caused by muscle overactivity. Anterior HO is seen to follow the iliopsoas muscle. Anterior HO usually extends from the anterior superior iliac spine (ASIS) and inner aspect of the pelvis to the proximal femur in the region of the lesser trochanter. Preoperative computed tomography (CT) scans with 3 dimensional reconstruction can be extremely helpful in preparing for the morphology. When resecting anterior hip HO, a standard anterior approach to the hip is performed but the femoral triangle and its contents are also dissected. Care is taken to identify all major divisions of the femoral artery, nerve, and vein. It is prudent to place vascular loops around all major vessels proximally in order to assure easier control of bleeding should a major vessel be damaged during the procedure. A wide exposure and meticulous hemostasis are needed. Although all the neurovascular structures may be encased in HO, it is more common for the nerve to be entrapped. The femoral nerve is already dividing into its many branches within the femoral triangle. The motor branches are small in diameter and must be carefully identified. Because it is difficult to mobilize the neurovascular structures, the heterotopic bone must be removed in small segments. It is difficult to distinguish normal from abnormal bone. The morphology of the normal bone and the HO must be closely observed. A 3 dimensional reconstruction of the hip based on CT scans and intraoperative radiographs are used to guide the resection.

*HO of Medial Hip (Adductor)* Heterotopic bone seen inferomedial to the hip joint follows the adductor muscles from the pubis and extends towards the medial aspect of the femur. A medial approach to the hip is used for resection. If there is a significant hip adduction contracture, release of the hip adductors may also be needed. Often HO is seen both anterior and medial to the hip. In these cases it is necessary to make two separate incisions and work between both.

*HO of Posterior Hip (Extensor)* Posterior HO lies immediately posterior to the femoral head and neck. Although posterior bone forms in conjunction with hip extensor overactivity, it is usually associated with a flexion contracture of the hip. A posterior approach to the hip is used for resection. The sciatic nerve is identified distally and dissected proximally. It is common for the sciatic nerve to be encased within the mass of heterotopic bone. Significant scarring is also seen around the sciatic nerve secondary to the intense inflammatory reaction that occurs during the intermediate stages of bone formation. Neurolysis of the sciatic nerve may be needed. Once the sciatic nerve is identified, a more aggressive resection of the bone is begun. If a significant hip flexion contracture persists after excision of the posterior HO, an anterior soft tissue release may then be necessary.

*HO of Lateral Hip (Abductor)* When HO is seen in the abductor region, it is usually a result of trauma or surgical stimulation. A straight lateral or posterior incision can be used. It is important to separate the heterotopic bone from the abductor muscles and preserve as much muscle function as possible. The abductor muscles are usually very atrophic.

*Obturator Neurectomy for Scissoring Thighs (Hip Adduction Deformity)* Scissoring of the legs in an ambulatory patient gives the patient a narrow base of support while standing and results in poor balance. A preoperative obturator nerve block will eliminate adductor overactivity and allow assessment of adduction contracture. Alternatively, the patient can be examined at the time of surgery while under anesthesia to determine if a fixed myostatic contracture is present. If no adduction contracture is present, transection of the anterior branches of the obturator nerve will denervate the adductors and allow the patient have a broader base of support. A longitudinal incision is made directly over the adductor longus muscle. Commonly, a small contracture is present and the adductor longus muscle is released and retracted. The anterior branch of the obturator nerve is then transected over the muscle belly of the adductor brevis. Early gait training with weight bearing as tolerated is instituted in the postoperative period.

*Hip Adductor Tenotomy for Severe Contracture* Indications for surgical release of hip adduction contracture

include interference with perineal care and hygiene in a non-ambulatory patient and excessive limb scissoring during attempted transfers and ambulation in a patient with active function. Hip flexion contracture is a frequent accompaniment (see next section). With the patient in the supine position, a longitudinal incision is made over the adductor longus muscle. The incision is made distal to the groin crease in a more hygienic location. The adductor longus muscle is dissected free and transected using electrocautery. The anterior branches of the obturator nerve are identified and transected. The adductor brevis and gracilis are released close to their origin on the pubis. The wound is closed over a drain. Daily wound care is essential to prevent infection in this potentially contaminated area. The hips should be kept in abduction for 4 weeks using casts or an abduction pillow splint to prevent recurrence of the deformity during wound healing.

*Functional Hip Flexor Release* Muscle overactivity in the hip flexors can result in a crouch gait with compensatory knee flexion to maintain balance. This is a very costly deformity since it requires constant use of the quadriceps, hip extensor, and calf muscles to maintain upright posture. The energy requirement for continuous firing of these muscles is extremely high. Few patients are able to remain ambulatory with this deformity. The hip flexor muscles are needed to advance the limb during gait. Therefore, complete release of the hip flexors should be avoided in any patient with potential to ambulate. Since the iliopsoas has capsular insertions, release of the iliopsoas tendon from the lesser trochanter of the femur does not provide a complete release. Release of the tendon from the lesser trochanter permits the iliopsoas to recess proximally, diminishing its pull but retaining its function.

A medial approach to the hip is used. A longitudinal incision is made overlying the adductor longus tendon. The adductor longus is released since it contributes to hip flexion. The pectineus muscle is identified where it lies deep to the femoral vessels and medial to the adductor longus. The pectineus muscle is divided using electrocautery. The lesser trochanter of the femur can be palpated in the depth of the wound. The tendon of the iliopsoas is visualized by placing narrow reverse retractors above and below the lesser trochanter. The iliopsoas tendon is divided from the trochanter and allowed to retract proximally. The wound is closed over a drain. Postoperatively, the patient begins range of motion exercises and full weight bearing gait training as tolerated. Prone lying and electrical stimulation of the gluteus maximus muscle are helpful to correct any residual hip flexion deformity.

*Non-Functional Hip Flexor Release* In a non-ambulatory patient, indications for surgical release include hip flexion contracture or severe muscle overactivity causing poor hygiene or pressure sores that cannot be healed

because of limited positioning of the patient. When a severe adduction contracture of the hip is present, it may be necessary to perform a percutaneous release of the adductor longus tendon in the groin in order to position the patient adequately and prep for further surgery. Any flexion contracture of the knee should be corrected simultaneously to prevent the leg from positioning in flexion and causing a recurrent and more resistant contracture.

With the patient in the supine position an anterior incision is made beginning just below the anterior superior iliac spine and is carried distally following the sartorius muscle for a short distance. The lateral femoral cutaneous nerve is identified as it passes distal to the anterior superior iliac spine and protected. The sartorius muscle is detached from its origin on the anterior superior iliac spine. The rectus femoris muscle is released from its origin on the anterior inferior spine of the pelvis. The femoral nerve and vessels are gently retracted medially to expose the iliopsoas muscle on the anterior aspect of the hip. The iliopsoas and pectineus muscles are carefully divided over the pelvic brim using the electrocautery to diminish post-operative bleeding. Since the iliopsoas has capsular insertions, release of the iliopsoas tendon from the lesser trochanter of the femur does not provide a complete release. The tensor fascia lata and the anterior portion of the gluteus medius and gluteal aponeurosis may be released from the iliac crest, if necessary. The hip joint capsule is not released.

In a severely contractured patient, care must be taken to identify all structures prior to release since the anatomy is frequently distorted by the long-standing deformity. A large dead space is left after releasing the hip flexor muscles and a drain should be used. Careful wound closure and a compressive dressing are helpful in preventing post-operative infection. As with release of other contractured joints, approximately 50% of the deformity will be corrected at the time of surgery. Daily wound care will help prevent infection in this area where bacterial contamination is likely and a large dead space remains following surgery. Placing the patient in a prone position three times a day for increasing periods and gentle stretching exercises will assist in correcting any residual hip flexion deformity. When release of a knee flexion contracture has been performed simultaneously, the weight of the long leg cast will also provide a correcting force. Sitting in a wheelchair is allowed for short periods.

### **Technique and Post-Operative Rehabilitation of the Knee**

*Distal Hamstring Lengthening* A knee flexion deformity is caused by overactivity of the hamstring muscles. A lengthening procedure is done when the knee flexion deformity is less than 60 degrees and the patient has documented volitional activity in the hamstrings. This will

correct the flexion deformity while preserving function of the hamstrings. With the patient in the supine position, a longitudinal incision of approximately 8 cm. is made on the lateral aspect of the distal thigh just proximal to the knee joint. The peroneal nerve is isolated and protected and the biceps femoris tendon is divided obliquely as it overlies the muscle belly. This allows the tendon to slide distally while still maintaining continuity of the muscle. The portion of the iliotibial band that is posterior to the axis of knee flexion is also divided transversely.

A longitudinal incision is then made on the medial aspect of the distal thigh. The tendons of the gracilis and semimembranosus are isolated and fractionally lengthened at the myotendinous junction by making an oblique cut in the tendon as it overlies the muscle belly. The semitendinosus tendon has a very short myotendinous junction that does not permit fractional lengthening. This tendon is simply transected.

After surgery, the extremity is immobilized in a long leg cast. Approximately 50 percent correction of the knee flexion deformity can be expected at the time of surgery. Further correction is limited due to tethering of the neurovascular structures. The extremity is casted in the position of knee extension it assumes while being supported under the heel, without attempting forced extension. Forced knee extension can result in limb ischemia. The long leg cast is changed weekly until full knee extension has been obtained. Splints are used at night for an additional 4 weeks to maintain correction.

*Distal Hamstring Release* In a non-ambulatory patient with a marked increase in hamstring muscle tone, knee flexion contractures result. When severe hamstrings overactivity and/or a knee flexion contracture greater than 60 degrees is (are) present, attempts to correct knee position with casting or bracing may result in posterior subluxation of the tibia. With the patient supine, distal hamstring release begins with a longitudinal incision made on the lateral aspect of the distal thigh just proximal to the knee joint. The peroneal nerve is isolated and protected and the biceps femoris muscle and tendon are divided just proximal to its insertion using electrocautery. The portion of the iliotibial band that is posterior to the axis of knee flexion is also divided transversely.

A longitudinal incision is then made on the medial aspect of the knee and the tendons of the gracilis, semimembranosus and semitendinosus are isolated and divided. In severe contractures, release of the sartorius muscle is also performed. By using electrocautery the procedure is easily performed without a tourniquet, which facilitates localization and protection of the posterior tibial artery, vein and nerve. Following localization of the neurovascular bundle, any remaining restricting bands are divided as required. The posterior fascia at the knee is often thickened limiting extension and may require

release. The posterior joint capsule may need to be released in long standing contractures. The joint capsule is stripped from the distal posterior femur using a periosteal elevator. The cruciate ligaments are not divided. If more correction is required, a closing wedge osteotomy can be performed. A closing wedge will allow for some shortening of the femur and some release of tension from the neurovascular structures and posterior skin.

After surgery the extremity is immobilized in a long leg cast. Approximately 50 percent correction of the knee flexion deformity can be expected at the time of surgery. Further correction is limited due to tethering of the neurovascular structures. The extremity is casted in the position of knee extension it assumes while being supported under the heel, without attempting forced extension. (Forced knee extension can result in limb ischemia.) If a severe hip flexion deformity is not corrected at the same time as the hamstring release, recurrent knee flexion contracture, resistant to surgical correction, is likely to develop.

Postoperatively, the long leg cast is changed weekly until full knee extension has been obtained. Splints or a knee immobilizer are used at night for an additional 4 weeks to maintain correction. Distal release of the hamstring tendons does not prevent ambulation.

### KNEE EXTENSION DEFORMITY

*Rectus Femoris to Gracilis Transfer for Dynamic Stiff Knee Gait* Patients with a stiff knee gait are unable to flex their knee during swing phase. The impairment is dynamic meaning that it only occurs during walking. There is no restriction of passive knee motion and the patient does not have difficulty sitting. Toe drag, which is likely in the early swing phase, may cause the patient to trip: thus balance and stability are also affected. A gait study with dynamic EMG commonly reveals dyssynergic activity in rectus femoris and vastus intermedius. If knee flexion is improved with a block of the rectus femoris or vastus intermedius, the rationale for surgical intervention is strengthened. Any equinus deformity of the foot should be corrected prior to evaluation of a stiff knee gait since equinus causes a knee extension during stance that may carry over to swing. Since the degree of knee flexion during swing is directly related to the speed of walking, the patient should be able to ambulate with a reasonable velocity in order to benefit from surgery. Good hip flexion strength is also needed for improved knee flexion since it is the forward momentum of the leg that normally provides the inertial force to flex the knee.

The rectus to gracilis transfer begins with a longitudinal incision that is made on the anterior thigh from mid-thigh to the middle of the patella. The rectus femoris muscle is dissected free from the other vasti muscles. Dissection is carried distally to the patella where a strip

of periosteum is also removed from the patella to gain additional length. If significant overactivity was seen in the vasti muscles on the dynamic EMG study, these muscles are fractionally lengthened by transecting their tendons as they overly the muscle belly.

A second incision is made over the medial hamstrings just proximal to the knee. The gracilis tendon is identified and released proximally. This provides a distal length of tendon to attach to the transferred rectus femoris. A subcutaneous tunnel is then made between the two incisions and through the intermuscular septum. The distal end of the rectus femoris tendon is passed through the tunnel to the medial wound with the knee flexed 90 degrees and the femur externally rotated. The rectus femoris tendon is sewn to the gracilis tendon.

The patient is placed in a knee immobilizer splint for one week after surgery to prevent a knee flexion deformity from occurring secondary to the tension and discomfort of the transfer. The patient can begin gait training in the immobilizer on the first postoperative day. Because of the good fixation into the gracilis tendon, knee range of motion and ambulation without the splint is started one week later. A marching gait pattern is stressed during therapy to facilitate knee flexion during swing.

### Technique and Post-Operative Rehabilitation of the Foot and Ankle

*Achilles Tendon Lengthening for Equinus* The commonest upper motoneuron deformity causing gait difficulty is equinus. An equinus deformity may be static secondary to contracture or dynamic secondary to muscle overactivity of the gastrocnemius and soleus muscles. This deformity prevents initial heel contact, promotes knee hyperextension, hyperextension thrust and knee pain in early stance and impedes rollover and push-off in late stance. Surgical lengthening of the Achilles tendon is indicated when the patient's foot and ankle position is not adequately controlled by an orthosis or when attempting to make the patient brace free. Adequate lengthening of the Achilles tendon can be performed using the Hoke triple hemisection technique percutaneously. With the foot held in maximum dorsiflexion, three percutaneous hemi-transections of the Achilles tendon are made. If a varus deformity of the foot is present, the proximal and distal cuts are made in the medial half of the tendon and the center cut is placed laterally. The foot is then pushed into dorsiflexion allowing the tendon to lengthen. Postoperatively, the patient is placed in a short leg walking cast at surgery, holding the foot in a neutral position. Gait training can be started on the first postoperative day allowing the patient to bear full weight on the foot as tolerated. Postoperative management requires 6 weeks of rigid immobilization. After this the patient uses a molded, high resistance, ankle-foot orthosis for an additional 6 weeks.

*Split Anterior Tibialis Tendon Transfer (SPLATT) for Varus* Varus deformity of the foot promotes unstable weightbearing on the lateral border of the foot during the loading response subphase of gait. It also renders brace wear difficult or impossible. Varus deformities most commonly occur as a result of increased and inappropriate activity of the tibialis anterior (TA) muscle. When dynamic EMG has documented tibialis anterior as a source of varus, the deformity is corrected by a SPLATT. The SPLATT maintains half of the TA tendon on the medial aspect of the foot and transfers the other half of the TA tendon to the lateral side of the foot (Figure 35-30). Varus deformity is usually accompanied by equinus as

**FIGURE 35-30**

When tibialis anterior is a source of varus, the deformity is corrected by a split anterior tibialis tendon transfer (SPLATT). The SPLATT procedure maintains half of the tibialis anterior (TA) tendon on the medial aspect of the foot and transfers the other half of the TA tendon laterally into the cuboid bone

well as toe curling due to overactivity of extrinsic and intrinsic toe flexor muscles. Lengthening of the Achilles tendon should be performed first, followed by division of toe flexor tendons.

The SPLATT begins with an incision made over the distal insertion of the TA on the medial aspect of the foot. The lateral half of the tendon is sharply divided from its insertion. An absorbable suture is placed at the end of the tendon for ease of handling. A second incision is made on the anterior distal third of the leg just lateral to the crest of the tibia over the TA muscle. An opening is made in the fascia overlying the TA. We use a long twisted wire loop as a tendon passer. The wire loop is passed under the fascia and follows the TA tendon to the incision on the medial foot. The suture in the free end of the tendon is passed through the wire loop and is pulled into the proximal wound. This suture is used to pull the free end of the tendon into the proximal wound thereby splitting the TA tendon and a portion of the muscle belly.

A third incision is then made on the lateral aspect of the foot. The cuboid is exposed. A 5 mm drill is used to make a tunnel through the cuboid. The TA tendon is passed subcutaneously to the lateral foot incision. A straight needle is used to pull the suture and then the TA tendon into the bony tunnel of the cuboid. With the foot held in a corrected position, the tendon is then secured in the cuboid by placing an absorbable 7 mm interference screw in the tunnel adjacent to the tendon. The free end of the suture is trimmed at skin level. To correct curl toes, a longitudinal incision is made on the plantar surface of each toe at the level of the metatarsophalangeal joints. The flexor tendons are identified and released under direct vision. This procedure is commonly done in combination with an Achilles tendon lengthening since bringing the foot into a plantigrade position will worsen toe curling. When an Achilles tendon lengthening has been performed, the foot must be immobilized as described above.

Postoperatively the patient is placed in a short leg walking cast at surgery holding the foot in a neutral position. Gait training can be started on the first postoperative day allowing the patient to bear full weight on the foot as tolerated. The cast is kept on the foot for 2 weeks. Two weeks after surgery the cast and sutures are removed. The patient is then placed in a cam walker boot for the next 4 weeks (Figure 35-31). With reliable patients we allow the cam boot to be removed once daily for washing and skin care. The foot must be maintained in a neutral position while the boot is off and now weight bearing is allowed. Six weeks after surgery the patient begins using a non-articulated, moderately rigid ankle foot orthosis for an additional 6 weeks. The patient must sleep wearing AFO during this time to protect the foot from an inadvertent stretch. At 3 months after surgery the brace can be removed for sleeping and gait training. The

**FIGURE 35-31**

Patient in a cam walker boot. When an Achilles tendon lengthening has been performed, the foot is initially immobilized in a walking cast for 2 weeks. Two weeks after surgery, cast and sutures are removed and the patient is placed in a cam boot for the next 4 weeks. The cam boot can be removed once daily for washing and skin care. Six weeks after surgery the patient begins using a nonarticulated, moderately rigid ankle foot orthosis for an additional 6 weeks

AFO can be discontinued if and when the patient has established sufficient strength in the calf muscles to permit safe walking.

*Tibialis Posterior (TP) Lengthening* In a small percentage of patients, TP is also overactive and can contribute to varus deformity. Clinically, increased heel varus is observed in addition to forefoot varus caused by TA. When overactivity of TP is present, a myotendinous lengthening of the tendon is performed posterior and slightly proximal to the medial malleolus. Complete release of the tibialis posterior tendon is not recommended as a planovalgus deformity may occur secondarily.

**FIGURE 35-32**

Achilles tendon lengthening to correct equinus weakens the gastrocnemius-soleus muscle group. Transfer of FDL into the os calcis can be done to augment calf strength. The figure depicts the transfer beginning with an incision on the medial border of the foot, dorsal and parallel to the abductor hallucis muscle. With this transfer, more patients eventually achieve brace free ambulation (see text)

*Transfer of the Flexor Digitorum Longus (FDL) to Os Calcis* Muscle paresis (weakness) is a classic negative sign of the upper motoneuron syndrome. Lengthening the Achilles tendon to correct an equinus deformity weakens the gastrocnemius-soleus muscle group, which was already weak as a consequence of the underlying upper motor neuron syndrome. Calf weakness generally requires an ankle foot orthosis (AFO) during ambulation but transfer of FDL into the os calcis can be done in order to augment calf strength. With this transfer, more patients eventually achieve brace free ambulation. In prior studies of equinovarus foot deformity, 30 percent of patients were able to walk safely without an AFO. When gastroc-soleus strength is augmented by transfer of FDL into the os calcis, 70 percent of patients achieve brace free ambulation.

The transfer begins with an incision on the medial border of the foot dorsal and parallel to the abductor hallucis muscle (Figure 35-32). The abductor hallucis is reflected plantarward from the base of the first metatarsal and flexor hallucis longus (FHL) and FDL are isolated through the deep fascia at the master knot of Henry. At this level, FDL has not yet split into four tendons and FHL is easily dissected free. If the flexor brevis tendons are to be released simultaneously to correct toe curling, they are released prior to transecting the FDL tendon. FHL and FDL are dissected at the knot of Henry.

A second incision is then made at the medial supra-malleolar region where the muscle belly of the FDL is isolated with its tendon and delivered through the medial supramalleolar incision. A one centimeter incision is made over the medial posterior superior aspect of os calcis. A 5mm drill is used to create a tunnel through the posterior superior calcaneus that exits on the lateral side. A suture ligature is placed in FDL and the tendon is passed subcutaneously to the medial heel wound. Using a straight needle attached to the tendon suture, the tendon is then passed mediolaterally through the tunnel created in the os calcis. With the foot held in maximum dorsiflexion, the tendon is secured in the bony tunnel using an interference screw. Holding the foot in maximum dorsiflexion while tensioning the transferred tendon prevents a recurrent equinus deformity.

Postoperatively, the patient is placed in a short leg walking cast at surgery with the foot held in a neutral position. Gait training can be started on the first post-operative day and the patient is allowed to bear full weight on the foot as tolerated. The cast is kept for 2 weeks after which the cast and sutures are removed. The patient is then placed in a cam walker boot for the next 4 weeks. With reliable patients, we allow the cam boot to be removed once daily for washing and skin care. The foot must be maintained in a neutral position while the boot is off and now weight bearing is allowed. Six weeks after surgery the patient begins using a non-articulated, moderately rigid ankle foot orthosis for an additional 6 weeks. The patient must sleep wearing an AFO during this time to protect the foot from an inadvertent stretch. At 3 months after surgery, the brace can be removed for sleeping and gait training. The AFO can be discontinued if and when the patient has established sufficient strength in the calf muscles to permit safe walking.

## Gastrointestinal and Nutritional Issues

*Donald F. Kirby*

*Linda Creasey*

*Souheil G. Abou-Assi*

**D**epending on the extent of neurological injury, the spectrum of gastrointestinal and nutritional ramifications can be vast. Often the patient who has suffered a traumatic brain injury (TBI) or a spinal cord injury (SCI) is well nourished prior to the injury; however, hypermetabolism resulting from an injury can quickly deplete nutritional stores, especially protein, resulting in a nitrogen death (1).

Many other gastrointestinal (GI) and nutritional problems are common and predictable. Knowledge of their occurrence and protocols for their prevention can help limit their impact on patients. This chapter discusses the GI and nutritional problems that can befall the patient with TBI in the acute and chronic phases of injury. Patients with SCI in addition to TBI may complicate the overall care, and the care of patients with SCI will generally not be discussed in this chapter. However, older references may not have delineated between the two patient populations of TBI with and without SCI. Thus, we will attempt to highlight some of the short comings in our present knowledge of patients with TBI.

### BACKGROUND

The interrelationships of gastrointestinal and nutritional reactions to TBI were not appreciated for many years.

Although Drew et al. reported on the rapid nutritional deterioration after craniotomy in 1947, it was not until 1975 that hypermetabolism was correlated with TBI (2, 3). It was noted that many patients tolerated gastric feeding poorly and widely regarded that hyperosmolar parenteral solutions could worsen cerebral edema (4). Thus, many patients succumbed to their neurological illness or injury, not so much from the initial insult, but from the lack of subsequent feeding during the hospitalization. Furthermore, it was not until 1983 that Rapp and colleagues showed that there was a higher survival rate in patients feed early by total parenteral nutrition (TPN) rather than by attempts at intragastric feeding (5). This was an important conceptual advance since it dispelled the myth that the hyperosmolar TPN solutions would exacerbate cerebral edema, and thereby increase morbidity and mortality.

The actual molecular and cytokine reactions to TBI are beyond the scope of this chapter. However, certain GI or nutritional problems may be associated with changes in hormonal actions that are important to recognize. These will be highlighted with their physiologic consequences.

### GASTROINTESTINAL COMPLICATIONS

Gastrointestinal complications should be separated into conditions that are associated with acute injury and later

events. There will also be some differences when there is also an associated spinal cord injury.

### Gastritis/Erosions/Ulcers

Depending upon the severity of the neurological damage, there appears to be an increased incidence of acute GI erosive lesions in the stomach. A prospective study by Kamada et al. demonstrated a higher rate of gastroduodenal lesions (6). Up to 75% of patients had lesions that were mostly in the stomach (78%). Erosive gastritis was the most common lesion and was often found in the first week after the injury. The use of steroids did not seem to affect the incidence of gastritis. However, it should be noted that this study was performed prior to the commonplace usage of H<sub>2</sub>-receptor antagonist blockers or proton pump inhibitors and the advent of early enteral feeding, all of which may ameliorate this type of injury.

The risk of gastric ulceration from TBI has also been well described and may be the result of another mechanism unrelated to the high incidence of stress gastritis previously mentioned. It has been reported that there is gastric acid hypersecretion which can be the direct result of the elevated serum gastrin levels that have been seen in patients with head injury (7). While gastric ulceration is well known after traumatic injuries, those associated with brain injury have

been noted to be potentially quite severe and may progress to perforation. These have been referred to as Cushing's ulcers (8). Since gastric acid hypersecretion can be controlled with either H<sub>2</sub>-receptor antagonist blockers or proton pump inhibitors, initial care protocols for the patient with TBI should include one of these classes of medications to control intragastric pH. Table 36-1 lists commonly used protocols; note that these may not be specifically approved by the Food and Drug Administration (FDA), but rather what is commonly used in clinical practice (9–14).

### Delayed gastric emptying

Delayed gastric emptying or gastroparesis can occur either with isolated head injury, as previously mentioned, or with cervical spinal cord injuries (15,16). This has ramifications for both nutrition and general care as some patients may experience severe gastric stasis or dilatation that may require nasogastric decompression. Ileus is variably present, but appears more commonly in patients with spinal cord pathology (17). Since the enteric nervous system and smooth muscle layers are still intact, promotility agents should be useful. Unfortunately due to concerns over cardiovascular side effects, cisapride has been removed from the market for common usage. Although it is still available under strict protocol for compassionate usage

**TABLE 36-1**  
*Control of Intragastric pH in Prevention of Stress Gastritis/Erosions/Ulcers\**

ROUTE	MEDICATION	USUAL PROTOCOL
<b>Histamine-2-Receptor Antagonists (H<sub>2</sub>RA)</b>		
IV	Cimetidine** (Tagamet)	300 mg bolus, 50 mg/ hr continuous infusion; Creatinine Clearance (CrCl) < 30ml/min reduce dose by 50%
	Famotidine (Pepcid)	20 mg bolus, 40 mg every 24 hours continuous infusion (or 20 mg every 12 hours) (CrCl) < 50ml/min reduce dose by 50% or increase interval to every 36–48 hours
	Ranitidine (Zantac)	50 mg bolus, 150–200 mg every 24 hours continuous infusion (or 50 mg every 8 hours) (CrCl) < 50ml/min 50mg every 18–24 hours, give more frequently every 12 hours, as necessary
<b>Proton Pump Inhibitors (PPI)</b>		
Enteral	Lansoprazole suspension (Prevacid)	30 mg every 12 hours
Enteral	Omeprazole suspension (Prilosec)	40 mg bolus, repeat 40 mg dose in 6 hours, then 20 mg daily (or 40 mg/ day or 20 mg every 12 hours)
	Pantoprazole IV (Protonix)	40 mg every 12 hours (some centers bolus with 80 mg initially)

\*Table created from references 9–14. Trade name in parentheses.

\*\*Currently the only FDA-approved agent for stress ulcer prophylaxis, often not preferred clinically as the first line H<sub>2</sub>RA due to drug interactions

as an investigational limited access study drug which requires an Institutional Review Board protocol and approval, it is less likely to be used in the initial care of the TBI/SCI patient. With further study it may have been preferred over metoclopramide due to its lack of CNS side effects, but limited data exists in patients with TBI (18). Metoclopramide is presently the only FDA-approved promotility agent. Unfortunately, its use may be limited by its potential for CNS side effects due to its central dopaminergic blocking activity. The drug should not be used in epileptics since the severity and frequency of seizures may be increased. Also, patients that are receiving medications that can increase the risk of extrapyramidal side effects should avoid this medication. Published experience with metoclopramide in TBI is limited and consists mostly of case reports (19).

Erythromycin is a macrolide antibiotic that is structurally similar to the GI hormone motilin. It has been used very effectively as a promotility agent, but as an off-label use and not as a FDA-approved indication. There are currently no known trials of its use for this indication in patients with TBI.

Domperidone is another promotility agent that is available outside the United States. It has not been approved for sale in the U.S., but can often be obtained from pharmacies in Canada or Mexico or even as a compounded, unapproved medication from some pharmacies in America. Thus, inpatient use is unlikely, but it may be useful in carefully selected outpatients.

### Diarrhea and Constipation

Diarrhea is not a common finding in patients with TBI. Thus, patients who have diarrhea should be investigated like any other patient who presents with this symptom. Table 36-2 lists some of the key elements in investigating the cause of diarrhea. If the patient is hospitalized and/or has recently, up to six weeks, received antibiotics, then the standard workup should include stool for white blood cells, investigation for ova and parasites, and stool cultures that include testing for *Clostridia difficile*. Flexible sigmoidoscopy or colonoscopy may be required in some patients.

Other causes of diarrhea must also be considered. The administration of liquid versions of medications may contain sorbitol, which even in modest amounts can cause diarrhea. Antacids may contain magnesium and other medications, like lactulose, are commonly used. Many other drugs may have diarrhea as a side effect, and medication profiles should be reviewed carefully for potential clues.

Diarrhea is the most common complication of enteral tube feeding; however, reports have varied in the incidence from 2.3–68% (20–22). Differences in definitions by various investigators make many studies difficult

**TABLE 36-2**  
**Diarrhea**

#### QUESTIONS TO CONSIDER

How is "diarrhea" being defined?  
Is there a new fever?  
Has the patient received antibiotics in the past 6 weeks?  
Is the patient being tube fed?  
What medications are being given to the patient, especially liquid meds?  
Does the patient have diabetes mellitus?  
Are there any GI complications that could lead to diarrhea?  
Does the patient have a malabsorptive disorder?  
Is the diarrhea "secretory" or "osmotic"?  
Is there visible or occult blood in the stool?  
Is there a history of inflammatory bowel disease, radiation therapy or ischemic bowel?  
Is there a pre-existing motility disorder?

Stool for osmolality

to compare or interpret. It may be that the actual genesis of diarrhea in these patients is multifactorial. Etiologies can include concurrent use of antibiotics or diarrhea-inducing medications, formula composition, rate of infusion, altered bacterial flora, enteral formula contamination, and hypoalbuminemia (23, 24). Additionally, it appears that the more critically ill patients seem to experience a higher incidence of tube feeding-related diarrhea (22). Initiation of feedings at slower rates until tolerance is seen can help limit this problem.

Blood in the stool must also concern the clinician to look for inflammatory causes or ischemic bowel. Occult blood in the stool is a nonspecific finding, but may

require a more throughout investigation and gastrointestinal consultation. Etiologies are numerous and are beyond the scope of this review.

Constipation can be a much more serious problem in the TBI/SCI patients. Patients who have spinal cord lesions above the fifth thoracic root can experience autonomic dysreflexia which can be a life threatening event. Either bladder distention or fecal impaction can precipitate this abnormal autonomic reflex that can lead to tachycardia and severe hypertension (25). Treatment must be prompt since subarachnoid hemorrhage, stroke or seizures can occur. These patients should be managed with prevention of constipation and routine bladder catheterization to avoid this complication.

### Gallbladder Disease

Acute acalculous cholecystitis is an often unrecognized and a potentially fatal complication that may develop among patients hospitalized for trauma. The cause, although not yet clearly defined, is believed to be multifactorial, resulting from bile stasis, ischemia, bacterial infection, sepsis, narcotics (opiates) that induce sphincter of Oddi spasticity and the activation of factor XII (26). Mortality rates of 10–75% have been reported. That high mortality is attributed to the fact that the gallbladder disease (i.e., necrosis, gangrene, or perforation) is frequently advanced by time of diagnosis. The symptoms and signs are not much different from those of cholecystitis with stones, the most common being right upper quadrant pain, fever, and leukocytosis. However, in the post-traumatic neurosurgical patient, obtundation or neurological deficits can make these valuable physical findings hard to detect (26, 27). Most reports showed that symptoms usually begin between 1–4 weeks after the trauma. The most important factor in early diagnosis of this condition is the clinician's awareness of abnormal laboratory findings and any unexplained deterioration of a previously improving posttraumatic course. Suggestive laboratory findings include elevated serum bilirubin, alkaline phosphatase, liver enzymes and leukocytosis; suggestive physical findings consist of fever, vomiting, abdominal distention, ileus, and in some cases palpable right upper quadrant mass (28, 29).

Ultrasonography is the investigation of first choice and strongly recommended whenever acalculous cholecystitis is suspected. Additional radiologic studies should include plain abdominal X-ray, which is useful predominantly to exclude a perforated viscus, bowel ischemia, or renal stones. Another advantage of ultrasonography includes its ability to examine the liver, pancreas, kidneys, and bile ducts in addition to the gallbladder (30, 31). Ultrasonographic features suggestive of acalculous cholecystitis may include the following: 1) absence of gallstones or sludge; 2) thickening of the gallbladder wall (>5 mm)

with pericholecystic fluid; 3) a positive Murphy's sign induced by the ultrasound probe; 4) failure to visualize the gallbladder; 5) emphysematous cholecystitis with gas bubbles arising in the fundus of the gallbladder (champagne sign); and, 6) frank perforation of the gallbladder with associated abscess formation.

On the other hand, in a retrospective study Puc and coworkers questioned the utility of ultrasonography and found that abdominal ultrasound was sensitive only in 30% and specific in 93% of 62 trauma patients who underwent cholecystectomy for suspected acute acalculous cholecystitis (32). In stable patients in whom the diagnosis is unclear after ultrasonography, radioisotope HIDA scan may be useful. HIDA is an iminodiacetic acid derivative, which is given by intravenous injection, taken up by hepatocytes, and excreted into bile with concentration in the gallbladder. Failure to opacify the gallbladder is indicative of cystic duct obstruction or necrosis with very high sensitivity up to 100% and 90% specificity. Leakage into the pericholecystic space suggests perforation. HIDA should not be recommended in critically ill patients in whom a delay in therapy can be potentially fatal (30, 33). Treatment should be instituted promptly, intravenous broad spectrum antibiotics should be started, and emergent cholecystectomy is now believed to be the treatment of choice. Although cholecystostomy has been advocated, it should be only reserved for the sickest patients not tolerating surgery (26, 27, 34). In a series reported by DuPriest et al, a gangrenous gallbladder was found in 52% of cases (35).

### Pancreatitis

Elevations of serum amylase and lipase have been described in patients in the neurointensive care setting. Hyperamylasemia has been observed in 19–41% of patients with severe head injury and in 45–60% of patients with intracranial bleeding from head trauma with no clinical signs or symptoms of pancreatitis (36, 37). However, making the diagnosis of acute pancreatitis can be difficult in this patient population. These patients often suffer from altered mental status or require therapeutic sedation +/-or paralysis to reduce intracranial pressure, so the clinical information obtained from the physical examination may not always be accurate. In addition, it is not clear whether this enzyme elevation is due to head trauma itself, intracranial bleeding, or some nonspecific intracranial event. Proposed causes include vagal stimulation, altered modulation of the central control of pancreatic enzyme release, and release of cholecystokinin from the brain (36, 37). To investigate the role of intracranial events in patients with TBI, Justice et al. prospectively studied 38 patients admitted to their neurointensive care unit with traumatic intracranial bleeding for elevations of pancreatic enzymes (38). Twenty-five patients (66%) had

elevated lipase enzyme activity, and 17 of the 25 also had elevated amylase without any evidence of clinical pancreatitis. Most lipase elevations occurred earlier than those of amylase, and there was significant interaction between lipase elevation and decreasing Glasgow Coma Score (GCS), indicative of increasing severity of intracranial bleeding (38). Similar findings were seen in a retrospective study by Liu and coworkers of 75 patients with TBI from Cook County Hospital where none of the patients with elevated serum lipase and amylase had any clinical or radiographic evidence of pancreatitis (37). In summary, because of the lack of their diagnostic value, routine pancreatic enzyme monitoring should not be performed in this patient population unless it is clinically indicated, and physician awareness of the association between intracranial bleeding with elevation of pancreatic enzyme of no significance can save the patient needless cost and manipulation.

### Other Less Frequent GI Problems

There are several other GI problems that occur in the patients with TBI and/or SCI, but they are less common than the other problems already discussed. The first two of these can be considered extensions of the altered bowel function that can occur with constipation and less commonly with TBI unless the patient is at a low level of function. Over time, diverticulosis can occur in these patients and lead to the usual complications of this disease; diverticulitis and/or diverticular hemorrhage (17). In the chronic SCI patient, this may be particularly problematic as the abdominal presentation may be altered and even delayed, leading to an acute abdomen in cases of diverticulitis. A diverticular bleed may be minor or cause hemodynamic compromise and potentially be life threatening. This argues for the adherence of a good bowel program to try and minimize the occurrence of these potential complications.

The superior mesenteric artery (SMA) syndrome has been reported in patients with neurological diseases. The syndrome occurs when the SMA that naturally crosses over the duodenum obstructs the duodenum, usually due to a more acute angle than usual. This can lead to dilatation of the proximal duodenum and stomach (39, 40). Multiple precipitating factors can be seen in TBI/SCI patients including weight loss, prolonged bed rest, loss of tone in the abdominal wall musculature and previous abdominal surgery.

Once SMA syndrome is considered, a radiological study is usually confirmatory. The diagnosis can be made by an upper GI series, computed abdominal tomography or rarely angiography. Management can include removal or reversal of a precipitating factor, nasogastric decompression as well as intravenous hydration. Occasionally, patients are tube feed for a short period of time while patients, who are very thin, gain weight.

## COMPLICATIONS OF BRAIN INJURY WITH NUTRITIONAL SIGNIFICANCE

Several other problems can be seen in patients with TBI that can have an impact on the patient's nutritional condition. These include the following: hyperglycemia, syndrome of inappropriate antidiuretic hormone (SIADH), cerebral salt wasting, seizures and the use of barbiturates.

### Hyperglycemia

TBI is associated with an acute sympathoadrenomedullary response characterized by increased blood levels of norepinephrine, epinephrine, and dopamine. Catecholamines levels reflect the severity of head injury and appear to predict the neurological outcome in both the acute and chronic phases of TBI. This increase in circulating catecholamines seems to contribute to intracranial hypertension, hyperdynamic cardiovascular response, increase in brain oxygen requirements, and the rise in serum glucose levels (41, 42). Rosner et al. showed that hyperglycemia occurred within minutes of experimental head injury in cats (43). In this animal model, hyperglycemia was related to severity of injury and was thought to be caused by catecholamine release. Similar results were also seen in rats (44). In another study in humans, Young et al. found that at the time of hospital admission 48% of 59 brain-injured patients had a blood glucose concentration  $>200$  mg/dL (45). Patients with peak 24-hour admission glucose greater than 200 mg/dL had worse neurologic outcome at 18 days, 3 months and 1 year than those with glucose levels less than or equal to 200 mg/dL. In a larger study of 169 patients who underwent surgery because of a traumatic intracranial hematoma, Lam and colleagues reported that glucose concentration at the time of hospital admission depended on the initial GCS (46). Patients with a best day-1 score of  $<8$  had an admission serum glucose of  $192 \pm 7$  mg/dL, compared with only  $130 \pm 8$  mg/dL in patients with a score of 12 to 15. Patients who subsequently remained in a vegetative state or died had significantly higher glucose levels both on admission and postoperatively than patients with good outcome or moderate disability. Among the more severely injured patients (GCS score  $<8$ ), a serum glucose level greater than 200 mg/dL postoperatively was associated with a significantly worse outcome ( $p < 0.01$ ) (46).

In summary, hyperglycemia is a common metabolic derangement seen early after both experimental and human TBI and is a significant predictor of poor outcome. It is thought that high glucose levels enhance ischemia-mediated cell damage, probably through lactate accumulation (47). When hyperglycemia is over 150 mg/dL, it is advisable to treat it with insulin. It has been shown that maintaining blood glucose at or below 110 mg/dL

reduces morbidity and mortality in critically ill patients in a surgical intensive care unit (48). However, more studies are needed to see if this can positively affect the neurologic outcome in patients with TBI.

### **Syndrome of Inappropriate Secretion of Antidiuretic Hormone (SIADH)**

The syndrome of inappropriate antidiuretic hormone secretion (SIADH) should be suspected in any patient with TBI with hyponatremia ( $<135$  mEq/L), hypoosmolality ( $<280$  mOsm/L), a urine osmolality greater than that of plasma, a urine sodium concentration that is usually above 25 mEq/L, normal acid-base and potassium balance, and frequently a low plasma uric acid concentration. An inappropriate elevation in ADH release will produce hyponatremia by interfering with urinary dilution, thereby preventing the excretion of ingested water (49). In a review of 1808 patients with craniocerebral injuries, Doczi et al. reported that 84 patients (4.6%) developed SIADH. The prevalence varied depending on the severity of their head injury as follows: SIADH occurred in 0.6% of patients with mild head injury, 10.6% of those with moderate head injury, and 4.7% of the severe ones (II-10).

In another study of 109 patients with severe head injury with GCS  $<7$ , 33% of the patients had SIADH. The authors proposed to subdivide SIADH into two clinical forms: an early syndrome (5% of the patients) that becomes apparent towards the second day and is significantly associated with lesions at the base of the skull; and a delayed syndrome, which is more common occurring at the end of the first week where the cause could be due to different factors linked to intensive care procedures (51). Patients with this syndrome are generally responsive to fluid restriction, but this should be performed with extreme caution given the importance of maintaining normovolemia in patients with TBI (52). If serum sodium level falls below 140 mEq/L, the maintenance intravenous infusion should be changed to normal saline. For hyponatremia below 130 mEq/L, intravenous urea is safe and rapidly effective in correcting this problem. Urea is a potent osmotic diuretic and significantly increases sodium reabsorption at the kidney. The usual dose is forty grams of urea in 150 ml of normal saline, to be given over 2 hours and can be repeated every 8 hours. On average the serum sodium levels will rise 6 and 10 mEq/L after 24 and 48 hours of initiating therapy. Infusion of hypertonic saline is also effective, but generally takes longer than urea in correcting the hyponatremia and requires close monitoring of urine electrolytes (53). When tube feeding is done with patients with SIADH, formulas that are calorie dense (2 Kcal/cc) are generally used to limit the total volume delivered to the patient. Feeding tubes are then flushed with small amounts of normal saline rather than water.

### **Cerebral Salt Wasting (CSW)**

A less common syndrome than SIADH has been described in patients with brain injury (particularly subarachnoid hemorrhage) that mimics all of the findings in the SIADH, except that salt wasting is the primary defect with the ensuing volume depletion leading to a secondary rise in ADH release. The major distinction from SIADH is the volume status of the patient. In patients with CSW, the extracellular volume is contracted and the patient often appears dehydrated, whereas in SIADH a clinical picture of fluid overload is often seen. In addition to salt-wasting, affected patients also may have hypouricemia due to increased urinary uric acid excretion. The course of hypouricemia after therapy of hyponatremia may be helpful in distinguishing cerebral salt-wasting from SIADH. There is a suggestion that, after the correction of hyponatremia with fluid restriction, cerebral salt wasting is more likely to be present if hypouricemia continues in combination with an elevated fractional excretion of urate ( $>10$  percent) (49, 54).

The etiology of this putative syndrome is unclear. Preliminary studies supported the possible role of a circulating factor that impairs renal tubular function in many patients with intracranial disease. It had been proposed that a natriuretic hormone was released from the brain in response to certain types of injury; candidates included atrial natriuretic peptide, brain natriuretic peptide, and endogenous ouabain (55).

With the different pathogenesis, patients with CSW are treated differently from those with the SIADH. The objectives of the treatment are volume replacement and maintenance of a positive salt balance. Intravenous hydration with normal saline (0.9% NaCl), hypertonic saline (3% NaCl), or oral salt may be used alone or in combination, depending on the severity of hyponatremia and the ability of the patient to tolerate enteral administration. If the patient can tolerate oral intake, then 2–3 gm of NaCl are given 2–3 times daily or via a feeding tube, as appropriate. Volume status in response to treatment is best evaluated by daily weight and central venous pressure or pulmonary artery wedge pressure measurements (54, 56).

### **Seizures**

Three kinds of seizures can complicate the care of patients with severe brain injury, and these are distinguished by the time interval following trauma: 1) impact seizures, appearing within 24 hours; 2) early seizures, occurring within 1 week; and, 3) late seizures, observed from day 8 through to 2 years, but frequently later. The seizure type also varies with time period after brain injury, with a relatively high proportion of generalized seizures at an early stage and a progressively larger prevalence of partial seizures later (57, 58).

In a randomized trial of patients sustaining moderate or severe brain injuries, including patients with depressed skull fractures, Temkin and co-workers confirmed the effectiveness of prophylactic administration of phenytoin in significantly reducing the risk of seizures during the first week after injury (59). Routine administration of phenytoin for 7 days after sustaining a depressed skull fracture is supported by this study. In addition, other studies have shown that pharmacological control of early seizures with phenytoin, phenobarbital, valproic acid, and/or carbamazepine is effective. Anticonvulsants should be administered parenterally first, if possible, (phenobarbital 200 mg/day, phenytoin 500 to 750 mg/day, valproic acid 30 mg/kg/day, or carbamazepine 300 to 600 mg/day orally, since it is not available in intramuscular/intravenous formulations) and then switched to the oral route as soon as feasible. The enteral route is preferred due to cost and irritation to the veins from intravenous phenytoin. It should be noted that topiramate and valproic acid have been shown to cause diarrhea. Gastrointestinal function should be monitored, and treatment for diarrhea should be instituted to prevent skin breakdown for these patients (60, 61). Routine blood monitoring of anticonvulsant concentrations should also be performed when necessary for appropriate agents, and it is advisable to keep drug concentrations in the higher end of the therapeutic range (57, 62).

On the other hand, the efficacy of anticonvulsant therapy in reducing the incidence of late epilepsy remains unproven. Therefore, no acceptable effective prophylactic strategies are in place to inhibit late epileptogenesis following severe brain trauma. However, according to some authors, the decision to institute long-term prophylactic anticonvulsants can be justified in high-risk patients where the incidence of late seizures is over 20%. Such individuals would include those with the combination of post-traumatic amnesia of over 24 hours duration, seizures occurring during the first week after injury, and dural laceration or intracranial hematoma (63, 64).

It is important when providing nutrition for these sick patients at risk for post-traumatic seizures to look carefully at the factors that can lower their seizure threshold and try to address them promptly, and these include low anticonvulsant levels, electrolyte derangements (particularly low serum sodium, magnesium or calcium levels), hypoglycemia, hypoxemia, alcohol withdrawal and meningitis. It is important to recall that enteral feedings can decrease phenytoin availability by as much as 70%, and tube feedings should be held for 1 to 2 hours before and after phenytoin administration (65). This strategy has not always been effective, and serum levels of phenytoin are important to monitor. Increasing enteral doses of phenytoin may be required or even intravenous phenytoin to keep levels in the appropriate ranges (66, 67).

## Barbiturates

It is estimated that 10–15% of patients admitted with severe brain injury will ultimately manifest medically and surgically intractable elevated intracranial pressure (ICP) with an associated mortality of 84 to 100%. High dose barbiturates have been known since the 1930s to have ICP-lowering effects. However, their risks are well known, and complications have limited their applications to the most extreme of clinical situations (68). Barbiturates appear to exert their cerebral protective and ICP lowering effects through several distinct mechanisms: alterations in vascular tone, suppression of metabolism, and inhibition of free radical mediated lipid peroxidation. Pentobarbital is usually administered in an initial dose of 5 to 10 mg/Kg, given as a bolus dose of 50 mg initially, until the EEG shows burst suppression. Further intermittent intravenous doses can then be administered to maintain blood levels between 3.0 and 4.5 mg/dL. Pentobarbital usage is associated with a 20% decrease in the energy expenditure as measured by the Harris-Benedict equation (69).

Several studies showed that high dose barbiturate therapy was efficacious in lowering ICP and decreasing mortality in the setting of uncontrollable ICP refractory to all other conventional medical and surgical ICP-lowering treatments. When this therapy is used, consideration should be given to monitoring arteriovenous oxygen saturation as some patients may develop oligemic cerebral hypoxia (68, 70, 71). On the other hand, utilization of barbiturates for the prophylactic treatment of ICP was not shown to be effective and is not indicated. In a randomized controlled trial of 53 severely head-injured patients, Ward et al. showed no difference between the prophylactic barbiturate-induced coma group and the control, in the incidence of elevated ICP, the duration of ICP elevation, or the response of ICP elevations to treatment (72). Also, there were more complications seen in the treated group; arterial hypotension occurred in 14 patients (54%) in the treated group and only in two patients (7%) in the untreated group.

## GOALS OF NUTRITION THERAPY

The first important goal of nutrition therapy is to decrease the incidence of mortality associated with previously mentioned difficulties in feeding patients with TBI. These patients exhibit hypermetabolism, increased protein breakdown and turnover (73). Nutritional assessment is complicated by rapid volume shifts and fluid accumulation. Alterations in gut motility can also complicate the usual attempts to enterally feed patients.

Fortunately, most new patients with TBI/SCI are usually adequately nourished prior to their injury. The

complex physiologic response to injury creates difficulty in estimating calorie and protein needs, since these patients are often hypermetabolic (74). The hypermetabolic response can be prolonged and is usually inversely correlated with patient's GCS. Thus, the more severely brain-injured patients have a higher measured resting energy expenditure (MREE) (75). Caloric estimation is often calculated by the Harris-Benedict (HBE) equation; however, this formula has been shown to significantly underestimate energy expenditure in nearly 70% of critically ill patients (76). When available, indirect calorimetry is a better means of estimating the resting energy expenditure. Makk and colleagues showed that predictive formulas, like the HBE, could only correctly estimate the measured values obtained by indirect calorimetry in about 56% of traumatic brain injured patients (77).

It is commonly believed that the protein losses in patients with TBI come from immobility and the mobilization of protein to meet increased protein needs. However, data from trauma patients have shown that there is both increased protein synthesis and catabolism (78). The amount of nitrogen loss is associated with increased hormone levels that are associated with hypermetabolism, epinephrine, norepinephrine and glucagon (79). Immobility may exacerbate nitrogen losses, but steroid administration appears to have little effect (80). Trials that have attempted to correct negative nitrogen balance in the acute injury setting have had mixed results. Provision of high protein can help decrease nitrogen losses, but high nitrogen excretion is not eliminated by just simply increasing caloric intake (81). Recommendations for provision of protein in these patients will be discussed in more detail later. While patients are in critical condition in an Intensive Care Unit (ICU), it is more important to provide "some" nutrition rather than trying to meet 100% of a patient's estimated nutritional needs. Once out of the ICU setting, the nutritional focus should be to provide sufficient calories for growth and repair of body stores and proper weight attainment depending on the patient's functional capacity. The provision of protein is important to decrease the amount of cannibalization of muscles as a source of protein, since there is no distinct storage form for protein as there is for lipids, adipose tissue, or carbohydrate, glycogen in liver and muscle.

## NUTRITION ASSESSMENT AND REQUIREMENTS

Predicting the nutritional needs of a patient with TBI is not a simple task because no single test can predict nutrition status. In the recovery from a brain injury, nutrition status will not remain static, and therefore will require periodic reassessment and adjustments that are made depending on current weight and functional capability.

As most patients are either comatose or confused and unable to provide accurate information, family members or caregivers should be contacted as part of an initial subjective global assessment.

### Subjective Global Assessment

Subjective global assessment is well documented in the literature as a valid measure of nutritional status in hospitalized patients (82). It consists of 5 key areas from the medical history: 1) amount of weight loss over the previous six months; 2) usual dietary intake and if abnormal, length of time of abnormal intake; 3) gastrointestinal symptomatology (e.g, nausea, vomiting, diarrhea); 4) previous functional capacity (i.e., bedridden or independent); and, 5) metabolic demands of current disease state(s). A physical examination should also be completed to assess for muscle wasting, ascites, and edema. These factors should give an overall assessment of the patient's prior status and ability to utilize nutrients (82).

In response to brain injury, the systemic inflammatory process characterized by the previously discussed hormonal response, causes a shift from anabolism to catabolism (83). Hepatic glucose production leads to hyperglycemia in response to counterregulatory hormones. Despite exogenous insulin, resistance at the peripheral tissues makes glucose control difficult. Elevations in epinephrine and glucagon also increase lipolysis, which offers an additional fuel source. However, current data suggests that few lipids are oxidized and utilized for fuel (84). Therefore, protein is the major source of fuel following brain injury. Although the demand increases for acute-phase protein production by the liver, the liver is unable to keep up with urinary losses of nitrogen as protein is also used for gluconeogenesis. These losses contribute to further tissue breakdown and loss of muscle stores (83).

Severity of injury directly correlates with the degree of substrate mobilization. Therefore, the lower the GCS, the more significant the protein mobilization and calorie expenditure (85). Increased intracranial pressure is also associated with an increase in caloric expenditure (86).

In addition to severity of injury and intracranial pressure, motor activity, infection, fever, level of sedation, level of consciousness, and other trauma can also affect caloric expenditure. Ideally, indirect calorimetry is helpful in guiding nutritional care to assure adequate calories to allow protein synthesis and avoid overfeeding.

### Calculating Protein and Calorie Requirements

As indirect calorimetry may not always be available, several formulas have been published to estimate calorie needs. Estimated caloric requirements can vary from 140% to 200% above the normal. Studies have shown that this hypermetabolism can last from weeks up to one year post-injury (78). Current practice guidelines recommend to

provide 40–50 non-protein kcal/kg/day for patients with a GCS < 5 and 30–35 non-protein kcal/kg/day for patients with a GCS 8–12 (87, 88). As severe brain injury is correlated with significant stress, one must be prudent not to provide large amounts of carbohydrate as this may exacerbate hyperglycemia and potentially complicate ventilator weaning (89).

As many brain injuries do not occur in isolation, it is important to note if a spinal cord injury is present. As caloric expenditure decreases in correlation with the degree of muscle immobility, this will alter feeding regimens. Estimated caloric needs for spinal cord injury can be as low as 28 kcal/Kg for paraplegia and 23 kcal/kg for quadraplegia (78).

Despite adequate calories, excessive nitrogen losses have been noted in brain injury patients. Urinary nitrogen losses of up to 30 g/day have been documented in the acute course of injury. Nitrogen loss is well associated with epinephrine and glucagons levels (80). In addition, immobility can account for 25% of nitrogen losses (90).

Patients with TBI require 1.5–2 g of protein/Kg of usual body weight daily. Despite providing adequate calories and protein, positive nitrogen balance is often unachievable in the early weeks after injury and may be difficult to achieve until the patient stabilizes medically (88).

### Weight Loss Expectations

A secondary effect from hypermetabolism and hypercatabolism is weight loss. Loss of <10% of usual body weight is not considered significant. However, severe weight loss of up to 40% of usual body weight correlates with mortality. On average, patients lose  $15.6 \pm .9$  pounds during their acute hospitalization despite the provision of adequate nutrition support (75). If the patient also has a spinal cord injury, another 5–10% weight loss is expected due to muscle loss from immobility dependent on paraplegia or quadraplegia.

## ENTERAL VS. PARENTERAL NUTRITION SUPPORT

The use of enteral and parenteral nutrition has undergone significant changes over the past three decades. Initial fears about the use of hyperosmolar solutions in patients with TBI have been replaced with the aggressive use of TPN, but now attempts to use the GI tract as early as possible are commonplace.

### Gastric Feeding vs. Intestinal Feeding

The decision about what form of nutrition support to choose for a new patient with a TBI/SCI is an important one, and it should be addressed shortly after the initial injury. As previously shown, delays in providing nutrition

increase the risk of mortality or at least could prolong rehabilitation time (5). For patients with TBI, the main question will be if there is an associated abdominal injury that requires laparotomy? If so, then a surgeon may place a jejunal feeding tube at the time of surgery, thereby providing small bowel access. This concept has been popular at many trauma centers around the country, and more importantly, early enteral feeding may limit the progression to multiple organ failure (91–95). For isolated brain injury, facial fractures and spinal injury must be detected and stabilized before decisions regarding enteral nutrition can be made. These issues are important because they guide clinical decisions regarding the initial blind passage of nasoenteric tubes and the possible use of either radiologic or endoscopic enteral access options.

Although providing parenteral nutrition may be easier than obtaining adequate enteral access, enteral nutrition has a decreased incidence of complications and cost compared to parenteral nutrition with no significant differences in measured nutritional parameters (91,93). Also, provision of fuel substrates to the intestine can stimulate gut immune function and limit deterioration of the intestinal mucosa with bacterial translocation and its potential for contributing to sepsis (96, 97). It is known that attempts at bolus feeding (BF) in patients with TBI are associated with a high incidence of intolerance (98). It is believed that elevations in intracranial pressure delay gastric emptying. Also, BF can also be associated with gastric emptying delays. Recently, Rhoney and coworkers showed in a brain-injured population that continuous gastric feeding was significantly better tolerated than BF (99). Prokinetic agents were not found to be helpful, and medications such as propofol and sucralose were associated with feeding intolerance.

Klodell and colleagues showed that after early PEG placement that intragastric feeding was well tolerated in their patients with TBI. Five of the 118 patients did experience aspiration, but there was no evidence of intolerance prior to the aspiration (100).

In a related study, Neumann and DeLegge compared gastric versus small bowel feeding in an intensive care setting (101). They were also able to show that the gastric route was highly successful in feeding ICU patients without a marked increase in complications.

It is becoming clearer that attempts at enteral therapy should be made before using parenteral nutrition. Protocols for feeding should be developed for individual intensive care areas that stress the available resources for that unit. Careful attention must be made so that pulmonary aspiration is limited. Taylor et al. showed that enhanced enteral nutrition (started feeding rate at estimated needs the first day of feeding) appeared to enhance neurological recovery, as well as postinjury inflammatory responses and incidence of major complications (102).

Our group has shown that it is possible to obtain early enteral access in patients with TBI/SCI (103–106). Our

present protocol is to attempt gastric feeding, if it is deemed safe and feasible. Otherwise, endoscopic or fluoroscopic tube placement is performed as soon as it can be arranged. In this way, patients are fed as quickly as possible.

### **When to Use Parenteral Nutrition**

If the gut is nonfunctioning or safe enteral access cannot be achieved, then it is appropriate to fall back on the use of parenteral nutrition. Central venous access is necessary to infuse the hyperosmolar solutions, but the solutions are not dangerous, as previously believed. More importantly, it is crucial to be diligent over electrolyte changes and glucose levels. It is known that hyperglycemia over 220 mg/dl is associated with changes in the immune system so that attention to this detail is potentially critical in limiting infections associated with the use of parenteral nutrition (107).

Another common pitfall for the clinician is the concept that nutrition support must be "all or none." If the patient's nutritional needs cannot be met by enteral means alone, then it is acceptable to supplement this with intravenous nutrition to help approximate a patient's needs. Although overlap of enteral and parenteral nutrition is more common during the transition from parenteral to enteral therapy, there is no reason not to try to reach a patient's requirements by whatever combination yields results safely.

### **Choosing an Appropriate Formula**

Depending on calorie and protein needs, the clinician will need to utilize either a 1 kcal/cc high protein formula or a 2 kcal/cc formula. It has been our experience, that most 2 kcal/cc formulas do not meet estimated protein requirements for this population. Therefore, most patients will initially require use of a protein supplement to meet needs. A calorie dense formula may also be warranted in instances of fluid restriction for control of the syndrome of inappropriate antidiuretic hormone (SIADH).

The use of fiber must be considered in light of the medical plan of care. Fiber is avoided in cases where paralytics or pressors are being used as they may aggravate constipation from either reduced peristalsis or reduced gut perfusion. Once these medications are discontinued, fiber should be a part of the bowel regimen. This is especially important for patients with TBI that are likely to have long-term immobility or in patients with associated SCI.

### **Monitoring the Effectiveness of the Care Plan**

Daily assessment is critical in the intensive care unit to respond to changes in medical status. At a minimum, daily assessment should include an assessment of laboratory values, gastrointestinal function, tolerance to feedings, fluid balance, and medication changes. If intracranial pressure monitoring is present, it is helpful to

know how frequently it is drained as this may correlate with feeding tolerance. As feeding intolerance is noted, alternative recommendations should be noted. Weekly, a prealbumin and weight should be monitored for assessment of overall nutritional status.

Once medically stable and transferred to a non-intensive care unit, feeding tolerance should be monitored daily. Laboratory values may be checked more infrequently as long as not medically indicated, and the patient continues to tolerate feedings. Weights and prealbumins remain important indicators in this population to monitor overall status and needs. As time progresses, a patient's metabolism may slow, requiring a change in feeding regimen in order to achieve weight maintenance or loss. Prealbumin is useful in determining if calories and protein intake are adequate to prevent skin breakdown, while continuing to decrease overall calories. Feedback from physical and occupational therapists regarding mobility and skin breakdown is also helpful in estimating ongoing calorie and protein needs.

### **Micronutrient Supplementation**

Vitamins and minerals should be supplemented if feeding volumes or oral intake does not meet the recommended dietary allowances. Antioxidants are felt to play a protective role in the recovery after brain injury. No significant changes in vitamin E levels have been observed in a recent study after brain injury. Therefore, it is felt that there is no benefit for additional supplementation (108).

Ascorbic acid is also known for its antioxidant properties. Polidori and coworkers demonstrated that ascorbic acid levels decreased during the first week after brain injury likely as a result of oxidative stress. These levels were inversely related to the GCS score and the major diameter of the lesion. Further studies are needed to see if vitamin C supplementation would be beneficial (109).

Zinc deficiency has been observed on admission and through the first two weeks of hospitalization (110). Adequate zinc status is necessary to minimize neuroimmune cell death in animal models. In addition, zinc supplementation has been utilized to treat deficiency and the severe protein turnover in patients with TBI (111). Daily supplementation of 12 mg of zinc is recommended (112). Losses can be substantial if patients have diarrhea or associated traumatic injury with enterocutaneous fistulas that drain significant amounts of fluid.

## **IMMUNE ENHANCING NUTRITIONAL SUPPORT ISSUES**

### **The Role of Arginine**

Arginine is a conditionally essential amino acid. Under normal circumstances it is synthesized endogenously from

L-citrulline. However, during stressful periods such as growth, illness, or metabolic stress, endogenous synthesis is unable to meet the increasing body demands, and a dietary source is required. On administration of pharmacologic doses, arginine stimulates the pituitary growth hormone, insulin-like growth factor, prolactin, insulin and other hormones, resulting in net positive effect on wound healing and immune functions (113). It is also a precursor for growth substances like putrescine, spermine, and spermidine. Importantly, arginine is a precursor for nitrates, nitrites, and nitric oxide. Nitric oxide is particularly important as a vasodilator, but it also participates in immunologic reactions, including the ability of macrophages to kill tumor cells and bacteria. These and other functions of arginine are still being evaluated, but it is clear that supplementation of arginine can have a generally positive effect on immune system functions and wound healing in humans and animal (114,115). Numerous studies have demonstrated suppression of T-cell mediated immune function after major surgery or trauma. Daly et al. studied the effect of 30 g per day of arginine on patients undergoing elective surgeries compared to an isonitrogenous placebo (116). T-cell mediated immune function was evaluated preoperatively and 1, 4, and 7 days postoperatively. Patients who received arginine demonstrated a quicker return to normal T-cell function measured by *in vitro* mitogen proliferation assays. This study also revealed increases in the CD<sub>4</sub> phenotype, which further suggests that supplemental level of arginine helps T-cell levels to recover faster (116).

### The Role of Glutamine

Glutamine is also considered a conditionally essential amino acid. Of interest, it is the most abundant amino acid in the body. One of glutamine's major roles is as an oxidative fuel for rapidly replicating cells including gastrointestinal mucosal cells, enterocytes and colonocytes, as well as immune cells, lymphocytes and macrophages (113). Furthermore, glutamine appears to convey a protective or restorative influence on the GI tract, which may decrease translocation of enteric bacteria across the mucosal barrier. Perhaps the most compelling evidence for the immunomodulatory effects of glutamine comes from Ziegler et al. who studied 45 bone marrow transplant patients receiving either TPN supplemented with glutamine or an isonitrogenous, isocaloric control. Patients who received glutamine in their TPN demonstrated decreased incidence of infection and shorter hospital stay compared to the control group (117).

Unfortunately, the chemical structure of glutamine is relatively unstable in solution, unless the glutamine is bound to protein. Until recently, enteral formulas supplemented with glutamine were available only in powder form. Also, new technology using glutamine

hydrolysate formulas and glutamine dipeptide has led to the development of high glutamine liquid formulas that are compatible with TPN. It is important to note that there are no studies available that currently assess the direct effect of either glutamine or arginine in patients with TBI.

### Are Immune Enhancing Formulas Indicated in This Population?

There is sparse information available discussing immune enhancing diets and brain injury. The first study was published in abstract form, patients with severe closed head injury defined as GCS <8 with evidence of brain injury on imaging were randomized to an immune-modulated diet rich in glutamine, arginine, fish oil and nucleotides (11 patients), Impact (Novartis Nutrition, Minneapolis, MN) or standard diet (9 patients), both via feeding tube (118). Patients were followed prospectively up to one week. In their findings, the infection rate was significantly lower in the enhanced diet group (9.1% vs 100%,  $p < 0.0001$ ), also there was significant improvement in the total lymphocyte count and percent of CD<sub>4</sub> count in the study group (118). However, this study generated several areas of concerns as follows: the study is only available in abstract form, and also the sample size was too small to provide significant statistical analysis. The next paper addressing the use of immune enhancing formulas compared two immune diets; Crucial (Nestle Nutrition, Deerfield, IL) and Impact (119). This study involved multiple trauma patients, but 9 of 13 patients had severe closed head injury. This prospective study consisted of 13 patients randomized to receive enterally either Crucial or Impact. The randomized diet was given for seven days with study measurements obtained at study entry and day 7. The feedings goals were calculated based on protein delivery of 1.5 g/Kg body weight. Feedings were started at 30 ml per hour and advanced 20 ml per hour every 4 to 8 hours until goal was met. The exact study conclusion was very difficult to interpret. The authors concluded that patients receiving Crucial had normalization of IL-1 release from peripheral monocytes incubated with lipopolysaccharide (LPS) *in vitro*, but no alteration was noted with Impact (119). This limited study did not lead to any concrete conclusions regarding these diets in patients with TBI.

The most recent study dealing with immune enhancing diets in head injury compared early enteral feeding to late enteral feeding with Impact in a prospective, randomized fashion. The early group received enteral feeding <72 hours after admission and the late group received feeding upon resolution of the ileus from their head injury. The overall conclusion was that there was no significant difference between the two studied groups, but there was trend for higher mortality in the late group (4 of 15) (120).

Based on the available studies, very few conclusions on the use of immune modulated formulas in patients with TBI can be made. The single best conclusion is that these diets seem to be well tolerated. Further clinical investigations are needed in this area, involving larger number of patients, to be studied in a randomized, prospective blinded way, comparing the immune enhancing diets to an isonitrogenous control.

## REHABILITATION ISSUES

Once the patient stabilizes and transfers to the rehabilitation service, the team's goals are to normalize the patient's care in a safe environment and provide education for post-discharge placement. The major nutritional issues are dysphagia, maintaining a realistic body weight, and bowel regimens.

### Dysphagia

The treatment of dysphagia requires a team effort between the speech-language pathologists, physiatrist, nursing staff, and dietitian. The overall goal is to find the least restrictive diet that promotes safe swallowing and maintains nutritional status. Patients who have been found to be at the highest risk for oropharyngeal dysphagia include the following: those with an admitting GCS of 3–5, a Ranchos Los Amigos Scale of Cognitive Functioning at Level II, a CT scan which demonstrated midline shift or brain pathology requiring an emergency craniotomy, or ventilation time greater than or equal to 15 days (121). Patients who remain lethargic and have a GCS less than 12 should not be considered for oral intake without a swallowing evaluation.

Typical swallowing disorders include oral preparatory problems, oral transit disorders, delayed pharyngeal swallow and pharyngeal neuromuscular abnormalities. A modified barium swallow or flexible endoscopic evaluation of a swallow are two useful tests to identify safe consistencies for oral intake and patients at risk for silent aspiration (122).

In addition to evaluating a functional swallow, patients must be assessed for readiness to feed. Barriers to feeding include cognitive and motor planning behaviors, such as impulsivity, distractibility, inability to stay on task, poor sequencing skills, lack of initiation, and inability to motor plan self-feeding. For patients exhibiting these behaviors it is imperative to provide an environment for feeding that is free of distractions and yet can provide a safe level of supervision and assistance (123). For further review of dysphagia issues, please refer to Chapter 47 entitled "Evaluation and Treatment of Swallowing Problems After TBI."

The National Dysphagia Diet was instituted in April 2002 to standardize food consistencies and terminology throughout the health care continuum. Liquids can be

given as thin, nectar-like, honey-like, and spoon-thick. Of concern, is that the thicker the liquid is made, the less fluid is usually consumed by the patient. Many of these patients will require an additional source for hydration either by intravenous fluids or by a feeding tube (124).

Solid food consistency can be determined by the speech language pathologist. These textures may vary from a blended smooth texture (called pureed), to a ground moist consistency (called mechanically altered), to a general diet. Dry foods are generally eliminated as they are difficult to maneuver in the oral phase with decreased tongue movement and/or difficult to propel with disco-ordination in the pharyngeal phase of the swallow.

Once a patient is advanced to oral intake, nutrition support regimens should be reevaluated. A dietitian is helpful in evaluating adequacy of oral intake and assisting in making recommendations for the weaning of nutrition support. Feeding schedules should either be nocturnal or after a meal to encourage oral intake. Calorie counts are often useful in weaning a patient from tube feeding. According to the Nutrition Practice Guidelines for Dysphagia of the American Dietetic Association, tube feedings should be discontinued when patients can consume 80% or greater of their estimated nutritional needs consistently.

### Maintenance of Realistic Body Weight

The hypercatabolism of brain injury that drives weight loss generally stops and plateaus at three months post-injury. Information regarding mobility and progress in therapies and activities of daily living are useful in reassessing calorie needs. The more muscle groups utilized, the more muscle that is spared from disuse (125). Many patients have increased calorie needs during rehabilitation due to the calories spent during the work process of therapy. This increase can be 30–60% higher than control groups. Assistive devices can ease this increase (126).

Weekly weights are very useful in monitoring for weight gain or loss. As medical status normalizes, calorie demands decrease. Of utmost importance for patients and their families is to realize that if they have limited mobility or paresis, calorie needs are likely lower than normal. Indirect calorimetry was performed on non-ambulatory tube fed adults with neurologic disabilities. This study demonstrated an approximate 25% decrease in caloric needs for patients with fixed upper extremity contractures (127). Weight gain is also the result of altered food intake patterns. Some patients experience hyperphagia, which is compounded by a poor memory of when they last ate. Brain injured patients are noted to consume larger meals and more calories per day than controls. This occurs without regard to pre-meal stomach contents. Also, social factors are not an indicator of meal size (128).

These are important considerations in regards to planning a diet for weight loss or weight maintenance.

Behavior strategies should be employed that will limit access to food and get individuals into a set schedule of eating. Memory boards or diaries may be helpful in reminding individuals of the time and content of their last meal. Individuals should be discouraged from automatically eating because they think they are hungry.

Patients should be encouraged to follow a low-fat well-balanced diet. The food guide pyramid is a starting resource for diet planning. In addition, they should consult a registered dietitian or recognized weight management center (e.g. Weight Watchers) for assistance with individualized dietary meal plans. A registered dietitian can also provide the caregivers' support and assist in monitoring the effectiveness of the weight loss plan.

Obesity and decreased mobility can precipitate pressure sore development in the chronic care setting (129, 130). Therefore, all brain injury patients with limited mobility should receive periodic routine skin assessments. If skin breakdown is noted, a further nutritional assessment is warranted.

Malnutrition can delay wound healing. It is important that deficiencies of protein, vitamins and minerals be replenished to allow for tissue growth and repair. Frequently, a deficiency is not clinically noted; however, it has become practice to provide daily supplementation of vitamins (131, 132). In patients without significant liver or renal disease, a daily multivitamin and an additional 500 mg of ascorbic acid are recommended. Vitamin A and zinc should also be given if pressure sores do not heal or progress in staging (133). Clinicians should review dietary habits with patients to also ensure adequate calories and increased protein for wound healing (134).

### Bowel Regimens

For non-ambulatory patients and especially those with a spinal cord injury, bowel programs are an essential part of their medical management. The chronic patient should eat a high fiber diet of at least 30 grams per day. Good sources of fiber include whole grains, bran products, leafy greens and raw vegetables (135).

### WITHDRAWAL OF FEEDINGS

It is beyond the scope of this chapter to delve in to all of the medical, legal, religious, and emotional issues that concern the potential withdrawal of nutrition support. Many states in the U.S. as well as many countries worldwide deal with end of life issues differently. Most importantly we, as health care professionals, must be advocates for the patient who may not be able to voice an opinion, and we must seek guidance as to their possible wishes from family and/or other loved ones.

### CONCLUSIONS

Care of patients with TBI can be complex, yet rewarding. The gastrointestinal and nutritional ramifications of an individual's disease may be straightforward or require a specialist's input. Time should be taken to review the potential needs of each patient and care plans should be created and implemented. Further understanding of the underlying disease will improve the delivery of comprehensive care to these afflicted patients. The next few decades will likely see marked advances in both.

## Sexuality, Reproduction, and Neuroendocrine Disorders Following TBI

*M. Elizabeth Sandel*  
*Richard Delmonico*  
*Mary Jean Kotch*

### INTRODUCTION

Our understanding of human sexuality has evolved over the last century to a greater appreciation of the biological, cultural and psychological factors that underpin sexual behavior. Freud's groundbreaking and controversial theories on psychosexual development and sexuality were based on the understanding that sexuality is a primary component of human development and functioning. Although some of Freud's beliefs about sexual development have been questioned, his understanding of the importance of sexuality in human life has been an important contribution to medicine, science, and the social sciences.

Biologists and ethnologists have studied animal models of sexual physiology and functioning, and these models have been important in advancing our understanding of human sexual behavior. These approaches have informed us that there is a wide range of variability in the expression of sexual and reproductive behaviors across species. In addition, anatomists and physiologists have further advanced our understanding of human reproduction and human sexuality.

Social and cultural beliefs have also contributed to our evolving understanding of sexual behavior. Sociologists and anthropologists have studied broad variations in human behavior across cultures. Behaviors considered deviant in one culture might be accepted practices in another. Gender, sex roles, and sexual orientation are

prime examples of differences that may be heavily influenced by cultural and political forces. Human sexual behavior is based upon a complex interaction of biological, psychological, and cultural factors. Unfortunately, most of sexology research over the last few decades has focused on males and on heterosexual populations, although this bias is gradually being recognized and funding of research in the area has been more comprehensive in recent years. Research focused on women with traumatic brain injury is also sparse (1).

A traumatic brain injury (TBI) profoundly affects every aspect of an individual's functioning. These injuries have an impact on physical, cognitive, emotional, behavioral, and social functioning. Physical disabilities may be caused by anatomic or physiologic changes as a result of the injury. Cognitive disabilities commonly include problems with concentration, learning, memory, information processing, language, problem-solving, reasoning, planning, and organizational skills. Emotional difficulties are not only limited to psychological disorders such as depression, but also difficulties that affect behavior and personality. Behavioral problems can include impulsivity, poor initiation, perseverative behaviors, and other frontal lobe disturbances. Interpersonal skills problems may significantly influence social and occupational functioning. The complexity of all of these factors and their interrelationships creates a number of methodological challenges for research in the area of sexuality and TBI.

## SEXUAL RESPONSE MODELS AND SEXUAL DYSFUNCTION

According to the Masters and Johnson model of the 1960's, the sexual response cycle consists of four phases: excitement, plateau, orgasm, and resolution (2). A simplified model, described by Kaplan (3), included only desire, excitement, and orgasm. More recently described models take into account new perspectives and new research, suggesting that the genital focus of previous models and the linear sequence inherent to these models inaccurately reflects the cyclical nature of the interactions within the mind and between the mind and body during intimacy and sexual activity. Sexuality for women, and also for men, includes an interaction of personal factors such as self-image and desire for connection, but must also be seen within the context of family, interpersonal relationships, society and culture. Life stressors, including financial and health issues, also contribute to the sexual and intimate interactions between couples (4, 5).

An alternative sexual response cycle model described by Basson (6) takes into account other aspects of sexuality and intimacy: the desire to express affection and to share pleasure, a sense of being attracted to and attractive to another, and a sense of commitment. This model emphasizes that sexual experiences may begin with a non-sexual state of mind, and take place within a much larger context of cognition and behavior, acknowledging the importance of the aspects of intimacy that contribute to both the non-sexual and the sexual state of mind. These factors include communication, respect, trust, vulnerability, and fear of loss.

### Definitions of Sexual Dysfunction

Sexual desire disorders include sexual aversion and hypoactive sexual desire. Sexual arousal disorders result in poor lubrication in women and erectile disorders in both men (penile) and women (clitoral). Orgasmic disorders include anorgasmia in men and women and premature ejaculation in men. Sexual pain disorders include dyspareunia and vaginismus. An international consensus development conference on female sexual dysfunction resulted in an expansion of these classifications.

The existing classification system for sexual dysfunction, based on the World Health Organization (WHO) International Classification of Disease-10 (7) and the Diagnostic and Statistical Manual of Mental Disorders (8), has been challenged by an interdisciplinary consensus conference panel, consisting of 19 experts in female sexual dysfunction. The former classifications were expanded to include psychogenic and organic causes of desire, arousal, orgasm, and sexual pain disorders. A personal distress criterion has been added; this criterion specifies that a condition is considered a disorder only if

it creates distress for the woman experiencing the condition. As noted by Sipski (9), patients with traumatic brain injuries may lack awareness and appreciation of "personal distress." Definitions of sexual arousal and hypoactive sexual desire disorders were developed in this new classification system, and a category of noncoital sexual pain disorder was added (10).

Many psychological and biological factors influence the processing of sexual, sensual, or erotic stimuli. Psychological factors include past experiences (positive, affirming, negative, or traumatizing) and responses to the present sexual context. Inadequate or impaired emotional development may also influence openness to sexual experience, and result in lack of sexual arousal or even dysphoric arousal. Emotional intimacy and physical satisfaction with the sexual experience may not necessarily include orgasmic release. Biological factors that affect the processing of sexual stimuli include depression, medications that impair sexual function, fatigue, sleep disturbance, substance use, other medical conditions, and neuroendocrine factors.

Individuals may also experience anxiety about intimacy, sexual performance, or consequences of sexual activity. This anxiety may be a primary or secondary factor in the development of sexual dysfunction. Anxiety may interfere with any stage of the sexual response cycle and commonly plays a role in arousal conditions such as premature ejaculation, erectile dysfunction, and arousal dysfunction in women.

Studies suggest that sexual dysfunction is more prevalent in women than in men in the United States and a number of other countries. Prevalence data is dependent on the assessment techniques, which are variable (4). The Massachusetts Women's Health Study (11,12) documented decreased sexual desire among married women, those with psychological symptoms, cigarette smokers, and those in the perimenopausal state. However, of note, in healthy women, the prevalence of sexual dysfunction actually appears to decline with age, and frequency of sexual intercourse is not related to menopausal status. (11-13)

There may be differences in sexual desire and drive between men and women, although this is still an area of considerable controversy (14). Male sex drive may be more urgent, less distractible, more goal-oriented, and more focused on intercourse; female sex drive may be more diffuse, more distractible, more receptive, and more motivated by a desire for affection and emotional connection. Female desire may be more contextual, more aroused by words than images, more emotional than biological, more sensual than genital, more flexible and mutable. Men report more sexual fantasies and thoughts and experience more spontaneous sexual desire, report having more desire for more sexual partners, masturbate at younger ages and with greater frequency, and become aware of their sexual drive earlier than women. Men also

show a greater preference for sexual variety and novelty, have more favorable attitudes towards their genitals, and report higher and more consistent levels of desire across their lifetime (15, 16). To what extent these differences are culturally driven, or influenced by societal roles, teachings and expectations, is poorly understood (14–16).

Most studies of sexuality to date have focused on heterosexual populations. The research related to sexuality within gay, lesbian, and transgender populations suggests that even more complexity is inherent in the study of human sexuality than has been formerly appreciated. As these topics are discussed and researched more widely, our understanding of human sexuality is evolving towards a greater awareness of how societal and cultural influences shape the understanding and expression of sexuality. This may in fact lead to more openness, acceptance, diversity of expression, and greater sexual health for all.

## NEUROLOGICAL SYSTEMS AND SEXUALITY

The neurological aspects of sexuality include widespread and complex relationships among the neuroanatomic, neurochemical, neurophysiological, and neuropsychological systems that govern behavior, including what we define as emotional, physical, sensory, and cognitive components. The resulting sexual behaviors can be described more concretely as motivation, desire, arousal, genital responses, and orgasm.

Our understanding of the brain-behavior relationships that are the basis for human sexuality is primarily derived from animal studies, and therefore our conclusions must be tentative. The inter-relationships among the systems that contribute to these concrete behaviors are not completely understood. However, the peripheral nervous system, including motor, sensory and autonomic neurons, and subcortical and cortical systems, contribute to sexual interest and responsiveness through an elaborate network. Lesions at any level may influence this behavior, although the actual effects of such lesions in humans are not fully established. Central nervous system control of sexual function is similarly organized in men and women (17).

### Chemical Messengers

Neurotransmitters play a critical role in the physiological basis of sexual behaviors and sexual response. Spinal cord centers are under the control of brain regions that exert both excitatory and inhibitory influences. Sexual desire has been linked to activity of dopaminergic systems, including the mesolimbic and mesocortical systems. Serotonin may have an inhibiting effect on sexual function. Hypothalamic spinal pathways using oxytocin as a neurotransmitter have also been identified. Nitric oxide, crucial for sexual function at the genital level, may also

be an important central nervous system messenger. Receptors for gonadal hormones include neurons in the midbrain, hypothalamus, and amygdala. The supraspinal sites involved in the sexual response network have both extensive interconnections and receive genital sensory input. There does not appear to be a strict division between reflexive and psychogenic responses given this organizational structure (17).

### Spinal Systems

A coordinated system of sympathetic, parasympathetic, and somatic spinal outflow tracts are the basis for human sexual response. The spinal cord is “necessary and sufficient” to produce sexual responsiveness (17). Genital innervation is somatic as well as autonomic (i.e., parasympathetic and sympathetic). Somatic sensory afferents, synapsing in the sacral spinal cord, induce local sexual responses and project sensory information to cortical regions, resulting in sexual awareness and sexual excitation. Parasympathetic innervation originating at the sacral level, organized in the pelvic nerves, supply the neuronal inputs and outputs responsible for the initiation and maintenance of the erectile response. Erections are observed after lesions of sacral cord segments and pelvic nerves and the psychogenic erections in paraplegics with conus or cauda equina lesions may occur because of other non-cerebral proerectile pathways operating via the hypogastric nerves (18). Psychogenic mechanisms of arousal may also be transmitted in sympathetic pathways. Sympathetic neurons from the thoracic cord, contained in the hypogastric plexus, provide efferent and afferent innervations to the internal genitalia; this system provides the neurological basis for emission. Ejaculation is a result of sympathetic outflow from T11-L2 segments including the sympathetic chain, the hypogastric plexus, and pelvic and pudendal nerve systems (19).

In women, these neurological connections are also the basis for sexual responses, including arousal, lubrication, and female ejaculation. Parasympathetic activity causes clitoral erection, engorgement of the labia, and vaginal lubrication. Orgasmic sympathetic activity results in contraction of pelvic structures including uterus, fallopian tubes, paraurethral glands, and pelvic floor muscles (20).

### The Brainstem and Related Structures

Brainstem centers that contribute to human sexual responses include the reticular activating systems of the pons and midbrain. These pathways, which provide input for initiation and maintenance of arousal and alertness, connect with limbic and other frontal structures, many of which play a role in sexual and sexually related behaviors, including affective responses. Brainstem regions connect with diencephalic structures and limbic and paralimbic structures including the hippocampus, septal

complex, cingulate gyrus, amygdala, and hypothalamus. Stimulation of these structures produces erection, and in some cases pre-orgasmic sensations of pleasure. Lesions of the piriform cortex, which is inter-connected with the olfactory cortex, produce hypersexual responses in animals. The role of the basal ganglia in sexual function is not clear, although stimulation may result in species-specific sexual behaviors (21).

### Subcortical Systems

The primary areas of the hypothalamus that contribute to sexual response are the paraventricular nucleus, tuberal region, medial preoptic area, and the dorsal hypothalamic area. These hypothalamic regions are likely involved in both sexual desire and sexual response. The basal hypothalamus is influenced by tissue levels of testosterone, dihydrotestosterone, and estradiol. The preoptic area has high concentrations of androgen and estrogen receptors, and the enzyme that converts androgens to estrogens. Manipulating androgens and androgen receptors in this region affects sexual behavior. Lesions in the medial preoptic area of the hypothalamus reduce or eliminate sexual behavior. This area receives neuronal inputs from other brain regions such as the olfactory system and the cerebral cortex, including the visual cortex (17, 19, 22).

The dorsomedial nucleus of the hypothalamus, when stimulated, produces ejaculation. This nucleus may receive input from the medial preoptic area and probably from other brain and body regions. The ventromedial nucleus of the hypothalamus appears to play a role in female sexual behaviors. This nucleus is also strongly influenced by sex hormones, in particular estrogen and progesterone. The hypothalamus receives some of its information in the form of neuronal messages, but other information arrives in the form of chemical messages, including gonadal steroids. In addition, the hypothalamus synthesizes and secretes hormones of its own, many of which exert influences over sex and reproduction (22).

The pituitary hormones play a crucial role in the sexual and reproductive activity of humans. Gonadotropin-releasing hormone stimulates the release of follicle-stimulation hormone (FSH) and luteinizing hormone (LH) regulates the menstrual cycle in women and testosterone secretion in men. Males with hypothalamo-pituitary disorders have decreased or absent sexual desire, and often this is the first symptom to appear. In females with hypothalamo-pituitary disorders, two-thirds notice absence or a considerable decrease in sexual desire; lubrication and anorgasmia are also very common (23).

### Cortical Systems

The Kluver-Bucy syndrome results from injury or ablation to the anterior temporal poles, and the syndrome

includes hypersexual and exploratory behaviors, and hyperorality (24, 25). Temporal lobe seizures may be manifested by genital sensation and other sexual phenomena, with hypersexual or hyposexual behavior during both ictal and interictal periods. Endocrine disturbances, which are common in both men and women with temporal lobe epilepsy, result in decreased libido, impotence, menstrual disturbances, and reproductive disorders (26–28).

The frontal lobes are clearly involved in the regulation of sexual behaviors. Injury to the orbitofrontal regions (limbic and paralimbic lesions) may produce hypersexual responses. Socially inappropriate behaviors are displayed more often than sexual behaviors. In the case of dorsolateral frontal injury, when attention and initiation impairments are primary, libido or sexual assertiveness may be impaired (29). Injury to these areas may also lead to an inability to fantasize (30). The role of the olfactory system is unclear, but recent research indicates that anosmia may not significantly affect sexual function. The hypothalamus is a crucial structure in the elaboration of the human sexual response. The supraoptic nucleus of the hypothalamus synthesizes oxytocin, a hormone involved in lactation, birthing, and orgasm. Naloxone, an opiate antagonist, prevents the release of oxytocin, suggesting that the release at orgasm is controlled, at least in part, by the endorphin system (31, 32).

## SEXUAL DYSFUNCTION AFTER BRAIN INJURY

For the person with a disabling disease, condition, or injury, questions of sexuality are complex. Because of multiple, interrelated impairments that coexist after traumatic brain injury, questions concerning the specific etiologies of sexual dysfunction remain unanswered. How do we understand the impact of the pathophysiologic processes on the individual? What alterations in sexual desire, drive, arousal, or sexual responses are due to organic factors, and what can be attributed to secondary factors, such as cognitive, emotional, behavioral, and communication impairments or mobility deficits that result from the disease, condition, or injury?

Although much of the literature about TBI focuses on psychosocial consequences, no well-designed studies have established clear links between both the various impairments that frequently occur and the sexual dysfunction. Are impairments such as communication or cognitive deficits more important in interpersonal relationships than physical deficits? What roles do depression or other psychological conditions play? What are the effects of medication? What interpersonal and relationship issues contribute to sexual dysfunction? What are the anatomic correlates of sexual dysfunction?

The impact of TBI on relationships within the family and on mood and affective states of significant others and spouses has been explored in a large number of studies both in the United States and abroad. Thomsen's study (33) of 50 severely injured Danish patients demonstrated that family members were more disturbed by intellectual than physical deficits. The relationships were better between single adult patients and mothers than between patients and spouses. In Rosenbaum and Najenson's study (34) of brain-injured veterans in Israel, wives endorsed with high frequency the statement "dislikes physical contact with husband." The spouse's mood was associated with decreased levels of sexual activity. Lezak (35) emphasized that emotional adjustment for family members, including spouses, occurred only after detachment and acceptance of the permanence of deficits. This adjustment culminated in divorce, separation, and long-term placements for some partners. Bond (36) noted that the level of sexual activity among partners was not related to severity as measured by the duration of post-traumatic amnesia or level of cognitive or physical impairment.

Sexual function and marital adjustment were studied in a small group of married couples (37). Frequency of intercourse declined for all couples, but to a greater degree for couples in which the husband was brain-injured; orgasm in female spouses also showed a significant decline. Kreuter and associates (38) examined quality of relationships in 92 persons with TBI from 1 to 20 years post injury. They found that 58% had a stable partner relationship at the time of the study and of these 55% were established after the injury. In a larger study, sexual functioning, mood, and quality of life were examined in 322 individuals with TBI and a non-TBI sample of 264 individuals without disability (39). This study found that men with TBI were less sexually active and fewer were involved in a relationship when compared with non-disabled controls. Interestingly, there were no significant differences between women with and without TBI on these same variables.

Kreuter, Dahloff and associates (40) also examined sexual adjustment following TBI. In a group of subjects who were sexually active prior to their injury, 30% of the men experienced erectile dysfunction and fewer ejaculations. Although 59% reported no changes in orgasm, 40% experienced orgasm difficulties. "Dissatisfaction with the frequency of sexual activity" was found in 56% of the subjects. This study found that approximately one third of respondents had no intimate partner following the injury. However, they found that sexual dissatisfaction in individuals with partners was related to decreased interest, low self-esteem, partners' decreased interest (willingness to engage in sexual activity), "physical unattractiveness," and decreased sexual ability.

Kosteljanetz and associates (41) noted a correlation between intellectual impairment and sexual dysfunction in

a group of 19 mildly injured patients. Although some studies (34) indicate no relationship between locus of lesion and sexual dysfunction, medial basal-frontal injury or diencephalic injury was associated with hypersexuality and limbic injury with changes in sexual orientation in a population of 8 patients (42) Kreutzer and Zasler (43) studied a population of 21 brain-injured men and noted declines in sex drive, erectile function, and frequency of intercourse. Although one third of the married subjects reported their relationship as worse post-injury, 40% rated their relationships as good or very good when compared to their pre-injury relationship status. The authors found no correlation between affect and sexual behavior.

Although Zasler (44) found no association between affect and sexual dysfunction, a larger study (45) using measures of anxiety and depression for both partners found a significant level of psychiatric dysfunction. In addition, as time since injury increased, males with TBI became more sexually dissatisfied and sexual communication became more problematic for their partners. Age and time since injury were related to measures of psychosexual dysfunction, but severity of injury was not. TBI subjects in another study reported significant levels of anxiety and depression and found significant correlations between sexual adjustment and measures of psychosocial adjustment (38, 40).

The negative impact of pre-injury and/or post-injury substance use on physical, cognitive, and psychosocial functioning is clearly documented in the literature. The rates of pre-injury and post-injury substance abuse in individuals with TBI are substantial. Approximately 16% to 66% have chronic pre-injury problem drinking and 10% to 50% continue to experience post-injury problems with alcohol (46–48). Problems include a higher incidence of medical and psychological complications during TBI recovery, poorer cognitive recovery, poorer long-term outcome, and exacerbation of cognitive and behavioral deficits. Most substances of abuse have been shown to adversely affect sexual functioning at some stage in the sexual response cycle in non-TBI subjects, and have a substantial negative impact on sexual functioning in individuals with TBI who use substances (49).

Given that most injuries occur in individuals between the ages of 15 and 25, limitations in the person's pre-injury sexual experience can influence post-injury sexual functioning. Individuals with limited sexual experience and knowledge often have significant deficits and experience in establishing and maintaining intimate relationships. These relationship deficits can greatly reduce their ability to meet people who may become potential intimate partners. In individuals who have an intimate relationship at the time of injury, cognitive, emotional, behavioral, physical impairments, and substance abuse post-injury can clearly have a negative effect on the quality of the relationship as well as the sexual functioning

of partners. For individuals who have limited relationship skills prior to their injury, these problems are amplified.

The impact of TBI on the sexual response cycle has also been closely examined. In general, problems may occur at any stage (desire, excitement or arousal, orgasm, and resolution). Sexual difficulties are found in a number of areas including decreased frequency of intercourse, decreased desire, impaired arousal, and orgasmic dysfunction (40,41,45) Aloni and Katz (50) reviewed the existing literature on the effects of TBI and the sexual response cycle. Although significantly more individuals with TBI experience decreased desire, some report increased desire. Kreuter et al. (40) examined 65 men and 27 women with TBI and found decreased desire, erectile dysfunction, and orgasmic dysfunction in many of their subjects. However, 59% of their sample reported no change in orgasm post-injury and 50% noted no change in frequency of sexual intercourse post-injury.

A study by Sandel and associates (51) examined sexual functioning in a group of male and female outpatients with severe traumatic brain injuries (average length of post-traumatic amnesia was 54 days). Sexual function was consistently lower than in the normal population but significantly only on the (1) orgasm and (2) drive and desire subscales of the Derogatis Interview of Sexual Function (52). Location of injury was relevant; patients with frontal lesions and right hemisphere lesions reported higher sexual satisfaction and higher function. No correlations were found with cognitive measures or clinical examination. Subjects with more recent injuries and subjects with right hemisphere injuries reported greater levels of arousal.

Hibbard et al. (39) examined sexual response cycle difficulties as well as other aspects of sexual function in both male and female subjects with TBI and without TBI. Men with TBI experienced significantly more difficulties on self-ratings of sexual energy, drive, ability to initiate sexual activity, ability to experience orgasm, and the ability to maintain an erection. Women with TBI experienced significantly more difficulties than women without TBI on self-ratings of sexual energy, drive, ability to initiate sexual activity, arousal, pain during sex, ability to masturbate, ability to experience orgasm, and with vaginal lubrication. This study found significant difficulties in both men and women with TBI in sexual positioning, sensation, and body image variables. Clearly, the findings noted above are dependent on many factors that include cognitive, emotional, interpersonal, physical, and physiological functioning.

The etiologies of sexual dysfunction in TBI are certainly multiple. Sexual dysfunction following TBI may be due to one or more factors, including injury to specific brain regions, neurochemical changes related to this pathology, endocrinologic abnormalities, medications, secondary medical conditions, physical limitations, cognitive deficits, emotional difficulties, behavioral deficits, and interpersonal difficulties.

## DISABILITY AND SEXUALITY

Individuals with disabilities are a diverse group of people, representing a range of sexual expression and orientation, just as is the case in the population of individuals without disabilities. Providers often incorrectly assume that individuals with disability are sexually inactive or neglect to consider the issue of sexuality. In a recent study (53), 94% of the subjects with physical disabilities were found to be sexually active, a rate matching that of non-disabled individuals.

The paucity of information and biases that exist in the medical and scientific literature include myths that individuals with disabilities are asexual, lack sexual desire or attractiveness, are incapable of healthy sexual function, and lack the social and/or problem-solving skills necessary for sexual functioning. In addition, women with disabilities are viewed as less affected sexually than men with disabilities. These myths are not based on scientific data and have been perpetuated by a general lack of knowledge about disability and sexual functioning, although they may still guide healthcare professionals' behavior (54, 55).

The result of this general lack of awareness or bias is that individuals with disabilities may not receive adequate screening, education, or treatment for sexual dysfunction or reproductive health (55). Women with physical disabilities encounter serious barriers to receiving general, as well as reproductive health care, and have difficulty locating physicians who were knowledgeable about the disability to assist them in managing their pregnancy (53).

For individuals with disabilities, the associated features of the disabling condition may adversely influence the assessment and treatment of sexual dysfunction. Incontinence may have a serious impact in their sexual functioning (56). Intellectual or cognitive disabilities may present as an invisible disability. For this reason, healthcare professionals may not recognize the ways in which the disabling condition may affect sexuality and intimacy. Deficits in cognitive and social skills may have a serious effect on self-esteem, and contribute to difficulties establishing and maintaining relationships. An individual with a traumatic brain injury may lack insight, judgment, self-awareness, and perception of others needs or social cues. In other cases, the patient may not initiate conversation with the healthcare provider regarding issues related to sexuality. Individuals with TBI who have attention, memory, and judgment deficits may experience difficulties identifying and describing their symptoms. Conditions can be neglected or misdiagnosed.

For persons with TBI, a combination of cognitive and behavioral deficits may place them at increased risk of exposure to sexually transmitted diseases. Given the risk and potentially serious impact of sexually transmitted

diseases and sexual victimization in persons with disabilities, it is extremely important for healthcare providers to be knowledgeable about sexuality and sexual functioning and to be prepared to open the discussion in the clinical setting. Professionals should perform a careful and comprehensive history and physical that includes information about all aspects of sexuality and sexual functioning as outlined in subsequent sections of this chapter.

Cultural and religious beliefs and values can impact how open the patient will be to discussing sexuality and to accepting information. For example, in many Latino, Asian and Native American cultures, women are not permitted to talk about their sexuality (57). Cultural awareness and sensitivity are essential during any clinical encounter.

### **LESBIAN, GAY, BISEXUAL, AND TRANSGENDER AND INTERSEX INDIVIDUALS**

Lesbian, gay, bisexual, transgender, and intersex (LGBTI) issues in individuals with TBI have received little attention in the literature. Given the diversity among the lesbian, gay, bisexual, transgender and intersex members of society, combined with stigmatization, negative attitudes, and the political climate, population estimates are difficult to obtain. Prevalence estimates range from 5.5% to 20.8% depending on the definition (57).

Sexual prejudice has led to homophobic, heterosexist attitudes and heterosexual-centric attitudes in many areas of our culture including healthcare (57–59). Having a disability and being in a sexual minority places one at risk for discriminatory behavior for multiple reasons. Individuals who are LGBT with TBI may not receive an optimal level of medical care or rehabilitation. For example, lesbian and gay sexuality issues may not be appropriately addressed in sexuality education, examinations, or treatment (59). Intersex or abnormal sexual differentiation conditions and their effects are often poorly understood by medical professionals.

Sexual dysfunction may not be accurately identified due to a lack of knowledge or discomfort among healthcare professionals. Professionals lacking specific knowledge about LGBT issues or holding certain biases may make incorrect conclusions or diagnoses based on inadequate information, especially if the patient feels threatened or lacks trust in the provider. The stress of sexual orientation disclosure and a fear about including partners in the treatment program may result in inadequate or inappropriate recommendations. Concerns regarding confidentiality may limit the amount of information the LGBT individual and partner will disclose, particularly in an interdisciplinary setting, where a team of healthcare providers are providing care.

The incidence of traumatic brain injury in adolescents and early adulthood is significant. During this stage

of development there is a developing awareness of sexuality and TBI “can terminate such exploration” (60). Building a trusting and open relationship with LGBT adolescent patients and using a non-judgmental communication style will both facilitate discussion and identify if the adolescent should receive counseling to facilitate exploration of sexual orientation.

## **NEUROENDOCRINE DYSFUNCTION AFTER BRAIN INJURY**

### **Introduction**

Neuroendocrine disorders occur at a frequency that varies according to research methodologies but is not insignificant. In fact, more recent studies suggest incidence and prevalence rates that are higher than previously reported. Neuroendocrine dysfunction after TBI may include temperature lability, appetite disturbances, hypothalamic and pituitary disorders, disorders of fluid regulation, hypertension, and immunologic disorders. The neuroendocrine system mediates hormonal and neuronal responses to stress, and therefore, a disruption in this system can have widespread effects. Neuroendocrine disorders after TBI are a consequence of specific injury to centers of regulation of physiological functions, represented in many different brain regions, but most frequently the hypothalamic-pituitary axis. Alterations in antidiuretic hormone (ADH), cortisol, growth hormone (GH), thyroxine, follicle stimulating hormone (FSH), luteinizing hormone (LH), prolactin, glucagon, and somatostatin have been reported (61–63).

The most recognized pituitary hormone abnormality after TBI is a result of effects (which are not well-understood) on the posterior pituitary, resulting in disordered production of vasopressin (also termed antidiuretic hormone or ADH). ADH is released from the posterior pituitary gland in response to hyperosmolarity, hypovolemia, nausea, and other factors and then acts on the renal distal tubule and collecting duct to increase water resorption. Diabetes insipidus (DI) results in excessive urination in conjunction with hypernatremia and hyperosmolarity. The syndrome of inappropriate secretion of antidiuretic hormone (SIADH), associated with hyponatremia, may occur as well. The other major hormonal abnormalities that occur after TBI are the result of anterior pituitary dysfunction.

Until recently, anterior pituitary dysfunction following TBI was considered uncommon, although in the 1980's, Horn reported 28% of TBI patients in a rehabilitation setting had abnormal endocrinologic studies and 12% required treatment (61, 62). More recent studies have shown anterior pituitary damage to be fairly common following TBI. Dysfunction of the anterior pituitary gland may lead to a compromise in growth hormone (GH), thyroid, glucocorticoid, sex hormone (testosterone

in men/estrogen in women), and prolactin production. The clinical presentation of this syndrome varies widely, depending on the particular neuroendocrine axes that are involved, and the severity and rapidity of pituitary damage. Depending on which anterior pituitary hormones are missing, the presentation might range from subclinical disease to marked muscle dysfunction or cardiovascular collapse. Anterior pituitary dysfunction often accompanies posterior pituitary dysfunction (64). Immediate hormonal replacement is recommended for patients with panhypopituitarism, adrenal insufficiency, hypothyroidism, and diabetes insipidus. Replacement therapy includes adrenal and thyroid replacement, anti-diuretic hormone, and if necessary, gonadal and growth hormone replacement. In the case of growth hormone deficiency, retesting is recommended prior to a determination of replacement.

### **Incidence of Hypopituitarism**

What is not clear from research to date are: 1) the implications of deficiencies for each of the axes, 2) the time frames for when these deficiencies develop, 3) the permanency of the deficiencies, 4) appropriate ways of testing for GH.

Two studies (41, 65) indicate that posttraumatic hypopituitarism with permanent hypogonadotropic hypogonadism is a rare complication of TBI. More recent studies question this finding, at least for patients with severe brain injury. The prevalence of post-traumatic hypopituitarism was initially reported over 50 years ago as less than 1%. However, in a more recent study of men with severe head injury, 88% had subnormal testosterone levels at 7–10 days after TBI; 3–6 months later, 24% of a smaller sample still had low testosterone levels with loss of libido and impotence (66). A recent review also suggests the prevalence may be much higher (67). A total of 367 cases (from 1942–1998) were reviewed; the highest prevalence of disorders within the category of hypopituitarism was hypogonadism, hypothyroidism, (over 90% of the sample) and adrenal insufficiency (about 50%). Diabetes insipidus was present in about 30%, and growth hormone deficiency in about 25% of the sample.

Risk factors for hypopituitarism in TBI include moderate to severe head injury (Glasgow Coma Scale of 10 or less), diffuse brain swelling, and a hypotensive/hypoxic episode (although the latter has not been observed in every study). Some degree of hypopituitarism appears to exist in about 40% of patients with moderate to severe head injury, with growth hormone and gonadotropin deficiencies occurring at the highest frequency (68). In a study of 70 adults with traumatic brain injury, 21.7% had evidence of growth hormone deficiency, and 87% had both TSH and free T4 below the mid-normal level. Basal morning cortisol was below normal in 45.7% of subjects.

Hypogonadism and hyperprolactinemia were uncommon in this study population (69).

Recent recommendations at the Global Experts Consensus Panel in Philadelphia included guidelines for assessment of hypopituitarism after traumatic brain injury (70). Patients with moderate and severe TBI should undergo baseline hormonal evaluation at 3 months and 12 months after discharge from the ICU. Adrenal insufficiency and diabetes insipidus should be considered in patients with symptoms. The hormonal screening should include 0900 AM serum cortisol, fT3, fT4, TSH, FSH, LH, testosterone in men and E2 in women, prolactin, and IGF-I. In patients with polyuria or diuresis, urine density, sodium, and plasma osmolality should also be evaluated. Low IGF-I levels strongly predict severe growth hormone deficiency (in the absence of malnutrition). Normal IGF-I levels may be found in patients with growth hormone deficiency; therefore, provocative tests are necessary in patients with another identified pituitary hormone deficit. If IGF-I levels are below the 25th percentile of age related normal limits, provocative testing is recommended.

## **CLINICAL EVALUATION OF NEUROENDOCRINE DISORDERS**

### **Posterior Pituitary Dysfunction**

The syndrome of inappropriate antidiuretic hormone secretion (SIADH) is more common than diabetes insipidus (DI). In the case of SIADH, patients are usually symptomatic only when the sodium serum level drops below 125 mEq/L. Symptoms include nausea, fatigue, muscle cramps, and eventually psychosis, seizures, and coma can develop. The workup should include urine and serum osmolalities, and the diagnosis is made on the basis of a finding of inappropriately high urine osmolality in the face of a low serum osmolality. For SIADH, when levels fall below 125 mEq/L, fluid restriction (500–1000 mL/day) is usually sufficient to correct the abnormality, but caution should be taken in elderly patients (71). Furosemide, with replacement of sodium and potassium, is an alternative to demeclocycline, which should not be used in children or in any patient with hepatic disease (72).

DI may occur in mild, moderate and severe TBI. The usual onset post-trauma is 10 days. Facial and basilar skull fractures may be a risk factor, even in the presence of a relatively mild TBI (73). Polyuria and polydipsia are clinical symptoms that may be overlooked in the hospital setting. A high serum sodium level may not be present if the patient has access to water replacement. The best test is a water deprivation test, but an alternative is a spot check of plasma and urine osmolalities, and employ a nomogram to identify the abnormality (73, 74). Hyponatremia may occur as a consequence of cerebral salt-wasting syndrome

or inappropriate secretion of ADH. In the former, water and sodium are not conserved; in the latter, water is conserved. For cerebral salt-wasting, fludrocortisone acetate may be an effective treatment (71).

### **Anterior Pituitary Dysfunction**

Patients with hypothyroidism have cold intolerance, constipation, fatigue, and may have myxedema and bradycardia in later stages; TSH is low. In one study of TBI patients, 21.7% had abnormal T4 and TSH (69).

In the case of hypogonadism, libido is reduced, and impotence, menstrual abnormalities, infertility, breast and testicular atrophy may be present; an AM free testosterone, and estradiol in females and a prolactin level are diagnostic.

Growth hormone (GH) deficiency may present with fatigue, decreased muscle mass, exercise intolerance, and truncal obesity; a GH stimulation test may be diagnostic. Cognitive deficits, including impaired judgment, problem solving, concentration, and memory may be present. In one study of TBI patients, 15% had an abnormal glucagon stimulation test (69).

Patients with adrenal insufficiency from decreased ACTH (Addison's disease) present with weakness, fatigue, weight loss, hypoglycemia, postural hypotension, and occasionally nausea and vomiting and abdominal pain. AM cortisol levels are low, and adrenal insufficiency is based on deficient plasma cortisol response to ACTH stimulation. In TBI, the incidence of low cortisol levels may be as higher than previously recognized (67). An acute phase reaction, with the finding of low cortisol levels two hours after injury has been reported in a series of 400 patients with trauma, including severe brain injury (75). Disturbed sleep may be a manifestation of a more common phenomenon in TBI patients, i.e. dysfunctional cortisol diurnal rhythm (61, 62, 72).

### **Precocious Puberty**

Sexual/reproductive effects of brain injury in children can be identified as either hypogonadotropic hypogonadism or precocious puberty. Klachko and associates (76) reported the case of a 39-year-old man with hypopituitarism due to a severe brain injury at age 4 years. Shaul (77) reported accelerated growth of pubic hair and estrogenization of the vaginal mucosa occurring within 5 months of a brain injury. Two other cases (girls, ages 3 and 5), were described after traumatic brain injury; both exhibited breast development, pubic hair, and changes in vaginal mucosa consistent with estrogenization (78). The neuroendocrinologic mechanism is postulated to be destruction of inhibitory neuronal pathways into the hypothalamus, with premature activation of gonadotropin-releasing hormone from the arcuate nucleus

### **GENDER DIFFERENCES IN OUTCOME: PROGESTERONE AND ESTROGEN**

Studies suggest that female patients with traumatic brain injury may recover better than males. Laboratory studies in animals suggest that either progesterone or estrogen or both may be protective or even facilitate regeneration (79, 80). The effect in humans seems to depend on the presence of functioning ovaries (81).

Progesterone and estrogen have widespread effects on brain metabolism. Progesterone may be protective during the injury cascade, may correlate with reduced levels of edema, and may increase neuronal survival. The mechanisms postulated for these effects may be through interactions with cytokines, excitotoxicity, apoptosis, GABA, or other factors. Estrogen may also have a neuroprotective or neuroregenerative effect. Ovariectomized female rats with estrogen replacement have improved survival following traumatic brain injury. The mechanism may be cerebral blood flow preservation, with microvascular effects involving a combination of endothelial nitric oxide synthase induction and an antioxidant effect (80).

### **SEIZURE DISORDERS AND NEUROENDOCRINE DYSFUNCTION**

Temporal lobe seizures usually arise from limbic structures, such as the amygdala, that exert a modulatory influence on the hypothalamic regulation of the pituitary. Limbic and brainstem structures contain neurons with high concentrations of gonadal hormone receptors. Approximately 20% of patients with post-traumatic epilepsy have temporal lobe seizures (82). Up to 58% of men with temporal lobe seizure disorders are impotent or hyposexual, and up to 40% of women have menstrual irregularities or reproductive dysfunction, including polycystic ovarian syndrome, premature menopause, hypogonadotropic hypogonadism, and anovulatory cycles (26–28). Estrogens lower the seizure threshold, and frequency of seizures often increases in females at the time of menses and during pregnancy. Temporal lobe epilepsy has effects on the hypothalamic-pituitary-gonadal axis through effects on dopamine. Because dopamine is a prolactin-inhibitory hormone within this system, decreases in dopamine result in hyperprolactinemia.

Hypogonadotropic hypogonadism, accompanied by amenorrhea in patients with temporal lobe seizures, is associated with low levels of luteinizing hormone (LH). Because no hypothalamic disorder has been identified, this abnormality may be due to limbic discharges that result in altered secretion of gonadotropin-releasing hormone (26). Premature menopause also occurs. In polycystic ovarian syndrome, which also is associated with temporal lobe seizures, LH and prolactin are elevated,

whereas follicle-stimulating hormone (FSH) is depressed (28). Men with temporal lobe epilepsy and hypogonadism, unlike those with isolated hypogonadism, may have no improvement in libido or potency when parenteral testosterone is given; however, initial treatment of the epilepsy, followed by neuroendocrine treatment (bromocriptine or pergolide for hyperprolactinemia and testosterone for hypogonadism), is sometimes effective (27).

## COMPREHENSIVE EVALUATION

### Medical History

Evaluation of the patient begins with a careful history including past illnesses, surgeries, and sexual activity and function (18). Many diseases and chronic conditions can influence sexual function (83). Whenever possible and with consent, information should be obtained from the current partner. Cultural aspects should be considered and sensitivity to cultural differences is essential. Questions should focus on the following areas: (1) a review of neurologic, cardiovascular, endocrine, and urologic medical and surgical history; (2) preinjury and postinjury sexual functioning; (3) sexual orientation (4) history of victimization, including sexual assault, domestic violence; (5) substance use and abuse history; (6) current medication; (7) safe sex practices; and (8) reproductive history and contraceptive practices.

The history should define the patient's expectations in regard to sexual activity and functioning, and through the course of the evaluation, information gaps and misconceptions will become apparent. Dependency patterns, lack of self-esteem, and perceptions of unattractiveness should be identified. Education can be provided during the course of the history-taking session and written materials should be provided (84–86). The examiner must be comfortable discussing all aspects of sexuality, including alternative forms of sexual expression and alternative lifestyles (60). A nonjudgmental style is essential; staff training that focuses on attitudinal issues as well as education is recommended for physicians (87).

In regard to sexual functioning, the following areas should be further explored: 1) sexual desire; 2) sensory experience, as related to sexual arousal, and including a history of painful experiences during sexual activity; 3) sexual response including patterns of erections (penile or clitoral) and vaginal lubrication, 4) ejaculation (including forceful ejaculation of fluids from the urethra during orgasm in women); and 5) orgasmic sensations and experiences.

### Psychological Evaluation

A comprehensive evaluation of sexual functioning includes a psychological evaluation. Establishing rapport

with the client or with the couple is essential when discussing sexual issues. A widely used approach in the field of sexuality is the PLISSIT model (88). This approach emphasizes the importance of giving the client permission to discuss uncomfortable sexual issues. It also highlights the importance of helping the client feel comfortable discussing sexuality and intimacy, and other related issues. It is important for clinicians to remember that sexuality and relationship issues are often very difficult for clients and their partners to discuss. The more comfortable they feel during the interview, the more specific and useful the assessment will be. Establishing the etiology of the sexual difficulty provides the basis for the development of an appropriate treatment plan. It is often more comfortable for clients if the interview begins with a review of the medical history, demographic information, marital/relationship and family history and then gradually begins to focus on emotional, relationship, intimacy, sexuality, and sexual dysfunction issues (89).

Although there are many different formats for organizing and conceptualizing information, the Multiaxial Problem-Oriented System for Sexual Dysfunctions (90) is a useful guide. This approach assists the clinician in classifying sexual problems across a number of domains: desire, arousal, orgasm, coital pain, and frequency dissatisfaction. Another category labeled "Qualifying Information" includes sexual practices such as fetishism, exhibitionism, as well as other problems that may interfere with sexual functioning such as substance abuse and severe psychopathology. In addition, problems are classified as lifelong vs. not lifelong to more clearly identify individuals who have a history of relatively normal functioning followed by a period of sexual dysfunction. The circumstances under which the problems occur (global or all situations vs. specific situations) are also documented. This model provides the clinician with a framework in which to conceptualize the individual's sexual dysfunction as the basis for a problem-focused treatment plan. The DSM-IV utilizes a similar model; subtypes of conditions are used to more clearly define the onset of sexual dysfunction (life-long vs. acquired), context (generalized vs. situational) and presumed etiology (psychological vs. combined factors) (8).

The sexual assessment and history should focus on identifying the sexual difficulties and how they function within the individual or the couple's relationship. LoPiccolo and Heiman (91) provide an outline for the interview and suggest using open-ended questions and including information about the client and the primary partner (if one exists) in all domains. It should include information about the client/couple's life situation, adolescent and sexual development, attitudes, and values and beliefs toward sex (both past and current). Information about current behavior, including relationship issues, communication, displays of affection, intimacy, and sexual

orientation, should also be obtained. The clinician must determine specific information about the nature of the sexual difficulty including onset, frequency, circumstances, treatment attempted, and both the client and partner's responses to the problem.

The history must include information about previous psychological problems and treatment, as well as history of physical, emotional, and/or sexual abuse. Current psychological symptoms must be examined, including anxiety, depressive or mood, adjustment, psychotic behavior, personality disorders, and use and abuse of substances. In addition, it is important to obtain information about coping strategies, interpersonal communication skills, sexuality-specific anxieties (e.g. performance anxiety) and social support. Although most of this information can be obtained through an interview, some psychological assessment instruments such as the Beck Depression Inventory-2 (92), the Minnesota Multiphasic Personality Inventory-2 (93) the Millon Clinical Multiaxial Inventory-3 (94) may be helpful. When psychological disorders are identified, they must be treated because they are often significant contributing factors to sexual and relationship difficulties.

The cognitive difficulties experienced by survivors of TBI are well documented in the literature. Problems with attention, speed of processing, learning, memory, and problem-solving/reasoning skills are common and can clearly impact the sexual problem(s) and relationship. If the cognitive issues have not recently been assessed, a neuropsychological evaluation may be helpful. The neuropsychological evaluation may clarify the nature of the deficits as well as compensatory strategies to lessen their impact on the person's functioning. The impact of these deficits can then be incorporated into the treatment plan for the sexual dysfunction.

### Questionnaires

A number of questionnaires have been developed to assess sexuality in more detail than the usual history-taking session. The Derogatis Interview of Sexual Functioning (52) collects information by self-report in the five domains of fantasy, arousal, experience, orgasm, and drive and desire. A general sexual satisfaction score is obtained as well as a total score.

The Golombok-Rust Inventory of Sexual Satisfaction (GRISS) (95) is a 28 item self-report scale, provides male and female scores (two versions) in the categories of vaginismus, anorgasmia, impotence, premature ejaculation, non-sensuality, avoidance, dissatisfaction, infrequency, and non-communication, as well as a total score. This scale examines sexual functioning within the context of a relationship.

Kreutzer and Zasler (43) developed an 11-item Psychosexual Assessment Questionnaire. The items are grouped into 3 domains: sexual behavior; affect and

self-esteem; and relationship issues with a focus on changes in functioning following a TBI.

Another scale originally developed for use in spinal cord injury, but modified and used in TBI, is the Sexual Interest and Satisfaction Scale (SIS) (96). This scale examines sexual desire, satisfaction with sex before and after injury, and ability to satisfy a partner.

For the woman with a history of sexual dysfunction, a number of instruments have recently been developed. These include the Female Sexual Function Index (FSFI) (97), the Female Sexual Distress Scale (FSDS) (98), and the Sexual Function Questionnaire (SFQ) (99).

### Physical Examination

A neurological and general physical examination should be completed, with a focused assessment to identify impairments that may influence communication, positioning, movement, oral ability, and sensory awareness. Aphasias, dysarthrias, aprosodias, and deficits in attention and concentration or memory should be noted. Facial scars, oral and facial movement and visual and hearing impairments should be identified. Range of motion, especially in the proximal lower extremities, must be evaluated, along with movement of the limbs and trunk. Sensation is a crucial aspect of the examination. The genitalia, rectum, and the breasts should be examined. The bulbocavernosus muscles can be palpated in the male, and tested for voluntary and reflex contraction. Anal sphincter tone should be assessed. The cremasteric reflex (L1) and the bulbocavernosus and anal reflex (S2-5) should also be evaluated. In women, a Papanicolaou smear and pelvic examination are essential (44).

### Medication Review

A thorough review of all medications is necessary. The most common cause of impotence in the general patient population is medication. Drug-related effects on sexual function are usually reversible after discontinuation of the drug. Frequently implicated are (1) antihypertensive agents, (2) antipsychotic drugs, (3) antidepressants, (4) anxiolytics, (5) sedatives; and (6) hormonal agents (including contraceptives and tamoxifen).

The most frequent adverse reactions with selective serotonic reuptake inhibitors (SSRIs) are decreased desire, anorgasmia, and ejaculatory delay (100). Impotence is less frequently reported with SSRIs than non-selective monoamine reuptake inhibitors. Trazadone has the highest number of reports of priapism of the antidepressants, and has also been implicated in persistent sexual arousal syndrome in women. High-dose sildenafil may be effective in reducing ejaculatory latency (101).

Antihypertensive drugs may affect sexual function (libido and sexual response) through vascular or neurologic

effects. Alpha- and beta-adrenoreceptor blocking agents can cause ejaculatory failure. Antipsychotic agents may cause priapism, ejaculatory failure, and painful retrograde or spontaneous ejaculations (102).

In addition to the above medications, large number of other agents have been implicated: baclofen, cimetidine, clofibrate, cyproterone, digoxin, estrogen, indomethacin, lithium, metoclopramide, naproxen, phenoxybenzamine, prazosin, and progesterone, to name a few (103).

### Laboratory Tests

Screening tests for sexual dysfunction include sedimentation rate, blood cell count, fasting blood sugar, serum lipids, urinalysis, hepatic function, kidney and thyroid function studies, prolactin and testosterone levels (in both men and women).

Hypopituitarism may be manifested by low levels of growth hormone, thyroxine or cortisol or by hypogonadism. In men, low sperm count, low serum levels of testosterone, and low levels of LH and FSH characterize hypogonadism. Because protein-bound testosterone may be increased by thyroid hormone therapy or cirrhosis and decreased by hypothyroidism or obesity, free testosterone levels or sex steroid-binding globulin may give a more accurate picture. In women, low serum levels of estradiol and low serum levels of LH and FSH characterize hypogonadism. Hypogonadism may be caused by primary gonadal failure, as well as secondary failure at a central level. Klinefelter syndrome, for example, which has an incidence of 1 in 500 men, may be an unrelated cause of low testosterone in a patient with brain injury. The gonadotropin-releasing hormone test is useful in distinguishing hypothalamic from pituitary causes of hypogonadism, although it is not infallible. The clomiphene citrate-provocative test is also used to evaluate the gonadal axis. Single determinations of any of the above levels may not be accurate reflections of function (104).

### Neurophysiologic and Vascular Evaluation

Spontaneous nocturnal penile tumescence and rigidity can be measured in the sleep laboratory using strain gauges, visual inspection, and other measures and is the most accurate technique for measuring erectile function. Rigidometers for evaluation at home have also been utilized (105–107). If no major vascular problem is present, intracorporeal injection (papaverine, papaverine/phentolamine, or prostaglandin E1) can be used as a diagnostic tool (108). If intracorporeal injection testing of penile tumescence is suggestive of a vascular etiology of sexual dysfunction, penile blood pressure using a Doppler method can help to further evaluate (109).

Neurophysiological and vascular studies may further elucidate the pathophysiological underpinnings of

the disorder. Somatic sensory, somatic motor, autonomic, and visceral sensory testing are available in some centers to further evaluate sexual dysfunction. These tests include dorsal penile nerve conduction studies, pudendal somatosensory evoked potential tests, pudendal motor latency, bulbocavernosus and anal reflex latency measurements, and electromyography (corpus cavernosum and somatic), cystometry, and anorectal manometry.

For women, magnetic resonance imaging (MRI) technology and vaginal photo-plethysmograph devices are used for objective measurement of sexual response. Vaginal photoplethysmograph devices measure blood flow or engorgement following response to visual sexual stimulation (4, 110, 111).

### PHARMACOTHERAPY

The following review of the literature focuses on medications that may have potential benefit, as there are no well-controlled studies in patients with brain injury. Clearly much more research is needed to understand the types of sexual disorders that occur in women, both disabled and non-disabled, and effective treatments for these disorders.

Women's sexuality has not been adequately addressed in research to date, but progress is being made. Recently the Diagnostic and Statistical Manual of Mental Disorders-IV (DSM-IV) classifications of female sexual dysfunction have been expanded to include psychogenic and organic causes of desire, arousal, orgasm, and sexual pain disorders that cause personal distress (8). The United States Food and Drug Administration Guidance paper<sup>10</sup> details the recommendations for the clinical development of pharmacologic interventions for female sexual dysfunction. Major pharmaceutical companies are now developing agents for female sexual disorders and or post-menopausal symptoms. These include dopaminergic agonists and related substances, melanocortin-stimulating hormones, adrenoceptor antagonists, nitric oxide delivery systems, prostaglandins, and androgens (4).

### Phosphodiesterase Inhibitors

For men, major progress has been achieved in the development of medications for erectile dysfunction by the introduction of phosphodiesterase 5 inhibitors, and these agents have been utilized in a variety of populations with success (112–116). Phosphodiesterase enzymes are ubiquitous throughout the body and participate in a variety of functions. PDE5 is the predominant enzyme in the corpus cavernosum, and plays a significant role in penile erection. Sildenafil, tadalafil, and vardenafil are all potent inhibitors of PDE5. This class of medications is the most effective oral agents for the treatment of erectile dysfunction (117). These medications have led to a significant decrease

in the use of other methods of treatment for erectile dysfunction. Side effects include flushing, headache, dyspepsia, and visual disturbances (112). These medications interact with nitrates, and should not be given to patients on nitrates (118). Improved sexual function and sexual satisfaction appears to be well maintained over years following the initiation of treatment (119).

Antidepressant-associated (SSRI) or antipsychotic-associated sexual dysfunction may be effectively treated with sildenafil or other agents of this class (120, 121).

### Prostaglandin E1

These agents are utilized topically for men with erectile dysfunction to maximize genital smooth muscle relaxation (122). Topical alprostadil (prostaglandin E1) has been recommended for men with erectile dysfunction, and appears to be well tolerated, with the most common adverse side effect being urogenital pain (123). Sildenafil combined with alprostadil administered via the intraurethral or intracavernous route was effective in some men with erectile dysfunction who failed other monotherapy. (Steers, 2003) Topical administration of alprostadil has been utilized in the study of women with sexual arousal and orgasmic disorders and ultrasound studies document clitoral cavernosal arterial changes that may be helpful in diagnosis of underlying pathology, but is not recommended as an intervention at this time (124).

### Dopaminergic Agents

Dopaminergic agents may be efficacious in the treatment of erectile dysfunction, and may be an alternative to treatment with phosphodiesterase inhibitors. Because dopaminergic systems may be particularly vulnerable to traumatic brain injury (especially mesocortical and mesolimbic systems), sexual dysfunction may be associated with decreases in dopaminergic activity. L-dopa was investigated following the observation that patients with Parkinson's disease who were treated with the drug reported increased sexual activity (125).

Apomorphine (a D2 greater than D1 dopamine receptor nonselective short-acting agonist) decreases secretion of prolactin, stimulates production of growth hormone, and induces erections. Apomorphine may act on neurons located within the paraventricular nucleus and the medial preoptic area of the hypothalamus (126). A MRI study (placebo-controlled) demonstrated frontal limbic area activity after administration of apomorphine (127). A PET study has demonstrated cerebral activity in the right prefrontal cortex (128). Used in research to establish potential efficacy of longer-acting agents (129,130) the drug is now licensed in some countries, for the treatment of erectile dysfunction, in a sublingual

formulation. Side effects are nausea, dizziness, diaphoresis, syncope, and hypotension. The drug interacts with nitrates, increasing the risk of hypotension. Apomorphine combined with phentolamine was effective in one study and this combination may prove to be an alternative to phosphodiesterase inhibitors (131).

### Hormonal Agents

O'Carroll and associates reviewed the results of investigations of hypoactive sexual desire disorder in women and described it as "the major female psychosexual dysfunction (132)." However, little evidence suggests that the disorder can be traced to hormonal inadequacies in women. Hypogonadal women (with androgen deficiency due to pathophysiologic problems that affect androgen production in the ovaries and/or adrenal glands) do demonstrate an increase in sexual interest after androgen replacement (133).

Androgen substitution should be administered as an adjuvant treatment to counseling in women with low libido only when low androgen levels are due to inadequate ovarian and/or adrenal function in the presence of normal estrogen levels. Administration of androgens to women without low androgen levels who complain of decreased sexual interest or desire is not recommended (134). The "normal" ranges for androgens and estrogens, especially as related to female sexual dysfunction, remain a subject of controversy (135). The possible adverse effects from testosterone therapy in women include breast cancer, fluid retention, masculinization (hirsutism, acne, temporal balding, voice deepening, clitoromegaly), and hepatocellular damage (with high doses).

For women, intramuscular or subcutaneous injections, transdermal patches, or topical agents are available. But, again, the only clinical indications for testosterone replacement in women are symptomatic testosterone deficiency following natural menopause, or due to surgical menopause, chemotherapy or irradiation, premature ovarian failure, or pre-menopausal loss of libido with diminished serum free testosterone. Aging is associated with a decline in testosterone in normal premenopausal women (136).

Increasing age may result in a gradual hypogonadal state in men, referred to as andropause. The age of presentation for erectile dysfunction and andropause, or "partial androgen deficiency in aging men," typically occurs in the fifties and beyond, and these health issues may be harbingers for other related diseases such as cardiovascular disease and depression (137). Treatment with hormone replacement is controversial, and a recent statement from Committee on Assessing the Need for Clinical Trials of Testosterone Replacement Therapy of The Institute of Medicine argues for caution. Testosterone can cause gynecomastia, testicular atrophy, congestive heart

failure, and stroke, and can accelerate the growth of prostate cancer (138).

For men, testosterone delivery systems include depot-testosterone, scrotal patches (scrotal or nonscrotal), or a drying gel. Oral administration is associated with hepatic injury. Intramuscular injections, favored by bodybuilders and competitive athletes, produce a fast rise and fall in levels. Testosterone injections biweekly for 6 weeks increased the frequency of sexual thoughts in a group of eugonadal men with low libido compared with placebo. However, no effect was observed in men with inhibited erectile dysfunction (139). Apparently testosterone increases sexual interest in men with pretreatment levels in the normal range. This study also suggests that men with hyposexual sexual desire disorder may benefit from testosterone injections even if serum levels are within the normal range. Additional research is needed, however, because the study included only 20 men.

Human chorionic gonadotropin was used as a treatment in 45 men with erectile failure and 6 men with lack of sexual desire (140). The treatment period was 1 month with twice weekly injections of 5,000 IU or placebo in a double-blind design. The investigators reported that 47% of treated patients had a "good result" compared with 12% of the placebo group; however, they did not separate the cases of erectile failure from the cases of low sexual interest or fully define "good result."

### Antidepressants

Although many antidepressants (tricyclic antidepressants and monoamine oxidase inhibitors) have been noted to cause a variety of sexual side effects, others have been noted to improve sexual functioning in patients without brain injuries, including both serotonin agents and bupropion, which inhibits reuptake of dopamine. Fluoxetine has been associated with orgasm dysfunction (141). Researchers postulate an excitatory mechanism for adrenergic systems and an inhibitory role for serotonergic systems but in view of reports of both increased and decreased sexual functioning, the neurochemical effects are unclear. Trazodone and fenfluramine have been associated with improvement in libido in a number of case reports (142–144), although both also have been reported to cause sexual dysfunction. Bupropion has also been shown to improve libido in individuals with hypoactive sexual desire disorders. In a study of 60 female and male outpatients with psychosexual dysfunction (sexual aversion, inhibited sexual desire, inhibited sexual excitement, and/or inhibited orgasm), 12 weeks of double blind treatment with bupropion resulted in significantly greater improvements in sexual functioning among treated patients than in the placebo group. Only 3% of placebo-treated patients reported improvement compared with 63% of the medicated group (145).

### Opiate Antagonists

Opioids have also been implicated in sexual function. (159) In a small study involving 7 men, 25–50 mg/day led to full return of erectile function as well as nocturnal penile tumescence in 6 patients (32). In a study of 30 men (age 25–50 years) with idiopathic impotence, naltrexone, an opiate antagonist, increased "sexual performance" (defined as intercourse) in 11 of 15 treated patients (31).

### Natural Compounds

A number of compounds from nature have been identified as treatments for erectile dysfunction. These include yohimbine, Citrulline, pyrano-isoflavones, berberine, forskolin, and Korean red ginseng (146, 147). Yohimbine, an alpha-adrenoceptor blocker, has been investigated in multiple studies of sexual dysfunction (148–153). Identifying the cause of impotence (arterial insufficiency) may also identify potential responders to yohimbine (153). Tobacco may negatively influence its effectiveness (149). Yohimbine administered with L-arginine glutamate (a nitric oxide-precursor) resulted in substantially increased physiologic (vaginal pulse amplitude) responses in a group of women with female sexual arousal disorder (154). Similarly, this combination treatment was effective in improving erectile function in male patients with mild to moderate erectile dysfunction (155).

### Other Treatments for Erectile Dysfunction

Intracavernosal injection (papaverine, phentolamine, prostaglandin E1, vasoactive intestinal peptide), transurethral vasoactive agents (prostaglandin E1), vacuum erection devices, vascular surgery and penile prostheses are other therapeutic strategies for erectile dysfunction (156).

Self-injection of papaverine (a smooth muscle relaxant) or papaverine with phentolamine (an alpha-adrenergic blocker) is a treatment modality for impotence due to neurological or vasculogenic causes. Nearly all patients with neurogenic impotence and 60–70% of patients with vasculogenic impotence respond to intracavernous injections (157). Priapism, fibrosis of erectile tissues, hematomas, vasovagal reflex, and chemical hepatitis have been reported (158). Intracavernous injection of prostaglandin E1 is another approach, although painful erection occurs in up to 20% of patients, perhaps related to concentration and/or neuropathy (159, 160). Papaverine (with or without phentolamine) and prostaglandin E1 acts by increasing arterial inflow through vasodilatation and decreasing venous outflow by occluding draining venules, probably through relaxation of smooth muscle in the corpus cavernosum. Unilateral injection results in bilateral effects through cross-circulation.

Prosthetic surgery is less frequently chosen because other alternatives are available for men with erectile disorders. The two major categories of penile prostheses are the semi-rigid and the inflatable prosthesis. Complications include mechanical failure, infection, pain, and perforation, but the rate of complications is now lower because of technologic advances. Other alternatives include vacuum constriction devices, vascular reconstruction, and arterial and venous surgery. Nerve grafts, nerve growth factors, neuroprotection and nerve regeneration, explored at a basic science level, and may offer promise for the management of erectile dysfunction (161).

### Other Alternatives for Women

Lubrication can be effective to promote sexual arousal in women with inadequate secretion and to treat dyspareunia and vaginismus. Some components of the sexual response continuum, including engorgement, elevation, and elongation of the vagina and clitoral erection, are not influenced by lubricants alone. Oral-genital stimulation and the use of vibrators may be helpful for some women.

Zestra for Women is a botanical feminine massage oil (containing borage seed oil, evening primrose oil, special extracts of angelica, coleus forskolin, antioxidants, and vitamin E) formulated to enhance female sexual pleasure and arousal. The formulation has been shown to improve level of arousal, level of desire, satisfaction with arousal, genital sensation, ability to have orgasms, and sexual pleasure in a group of women with and without sexual arousal disorder in a randomized, placebo-controlled, double blind, crossover design trial (162).

## INTERVENTIONS FOR SEXUAL BEHAVIOR DISORDERS

As pointed out by Simpson (163) the literature on sexually aberrant behavior is fraught because of a lack of consensus in defining and delineating the boundaries of such behavior among researchers and clinicians. Documentation of sexual behavior disorders after traumatic brain injury is recorded in surveys and case reports (42, 164–167). Research documents such types of behaviors in animals.

Sexual offending disorders are defined as sexual acts against another person that cause affront or distress (163). These behaviors include touching (frotteurism, toucherism), exhibitionism, voyeurism, and sexual aggression. In one study of 445 patients with TBI, 6.5% were identified as individuals who had committed some form of sexual offense. Alcohol was a factor in only three. The most common offenses were inappropriate touching, followed by exhibitionism and overt sexual aggression (162).

The individual with brain injury may have reduced social skills and this can be demonstrated in disinhibited interpersonal behaviors. These behaviors may cause responses from care providers based on individual sexual attitudes. Unwanted sexual advances may occur and require redirection. Sexual acting out is a result of disinhibition, which creates a variety of inappropriate behaviors and social interactions with sexual implications (84).

The term disinhibition, associated with orbitofrontal injury, presents the underlying force leading to hypersexual, or inappropriate behaviors. Such behaviors are usually described in the context of interpersonal contact but also may manifest as perseverative self-directed behaviors, such as excessive masturbation. Such behaviors may represent response to injury, loss of self-esteem, or need to act out psychological conflict. Changes in sexual preference may represent release of inhibitions from frontal damage (42). Behavior modification may also be helpful in reducing the frequency of some of these behaviors (168).

Sexual offenders have been treated with hormonal therapy such as medroxyprogesterone and other antiandrogens (e.g., cyproterone) that are progesterone derivatives and these agents have been used successfully in treatment of aggressive hypersexual behavior in patients with brain injury to decrease levels of serum testosterone (168, 169). Such interventions have not been thoroughly studied in brain-injured patients, and violent sexual behaviors are rare in this population. Brain-injured persons are more likely to be victims of sexual abuse by others than perpetrators of violent crimes (170).

## SEX THERAPY

Sex therapy focuses on various strategies to improve sexual functioning in both individuals and couples in which one or both partners may have some type of sexual dysfunction. Although sex therapy is more commonly conducted within the context of relationships, individuals without current partners may benefit from some of the techniques used. As previously mentioned, a thorough assessment of the problem(s) is essential to the development of a problem-oriented treatment plan. In this way, sex therapy focuses on the specific area of dysfunction. In addition, sex therapy often involves collaboration between the sex therapist and physicians (171). Therefore, treatment may include medication or change of medications and behavioral and cognitive psychotherapeutic techniques.

LoPiccolo (172) presented the concept of direct treatment of sexual dysfunction which included some basic therapeutic principles such as viewing sexual dysfunction within the context of the relationship, provision of basic sexual education and information, examination about sexual attitudes, addressing performance anxiety, improving sexual communication, improving the partners' ability to

use sexual techniques, prioritizing sexual activity, and providing specific techniques to change behavior. Therefore, in addition to common couples therapy, techniques such as exploration of feelings and direct communication strategies, cognitive therapy techniques such as reframing and coping skills development are also utilized (173).

Behavioral strategies may include increasing affectionate behaviors, relaxation, behavioral rehearsal and/or more sex specific strategies such as desensitization, non-demand pleasuring, directed masturbation, Kegel exercises, non-demand stimulation, start-stop techniques, the squeeze technique, and the quiet vagina exercise (18, 174). Such techniques vary in effectiveness and require intervention by therapists with specific training in both sex therapy and experience in treating individuals with TBI. In this way, standard approaches to sex therapy can be appropriately modified to accommodate any physical, emotional, behavioral, or cognitive impairments that may be present. These techniques of sex therapy may be useful for persons with brain injury and their partners as they explore new ways of relating intimately and sexually to each other.

Treatment of premature ejaculation (PE) is an example of the usefulness of sex therapy techniques. PE is defined as, "Persistent or recurrent ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it . . . the disturbance causes marked distress or interpersonal difficulty(8)." Estimates of incidence vary from 30% to 75% in men and suggest that it is a common problem (175). Given the demographics, cognitive, and behavioral characteristics of males with TBI, PE may be a common but unidentified problem. Treatment of PE can involve several components including an exploration of early sexual or masturbatory experiences in adolescence or young adulthood that may have reinforced rapid arousal and ejaculation as well as interactions within a sexual relationship that may be reinforcing or influencing decreased ejaculatory control. Specific information about the frequency of PE, sexual expectations and their negative effects, and the usefulness of improving communication during sex are also helpful. Treatment may also include masturbation exercises coupled with techniques such as the squeeze technique, visualization or relaxation exercises, the start-stop technique, and graduated steps to increased stimulation. Using these approaches within the broader context of sex therapy can lead to good outcomes for these individuals and their partners (175).

### PROFESSIONAL AND PATIENT EDUCATION

For many individuals and couples, the essential aspects of programs addressing sexuality are education and counseling. In both disabled and non-disabled populations,

lack of education may result in problems establishing and maintaining healthy intimate, sexual relationships. Loss of sexual capacity may be related to failure of the rehabilitation program to address sexuality needs of clients (40). The goal of rehabilitation is to look holistically at the person with a disability and this perspective includes sexuality (176). Quality of life is a goal of rehabilitation and a commitment to including sexuality education as a component of information provided is essential. Education is an integral component of inpatient, outpatient, and residential programs.

Educational program development and implementation requires that healthcare professionals are knowledgeable and comfortable discussing the topic, and value the importance of addressing sexuality. The healthcare professional must have an awareness of the perceptions and feelings that may influence communication of information to patients, partners and families. Barriers identified that result in sexual education not being addressed in healthcare settings include inadequate knowledge, a perceived lack of time, an assumption that someone else is providing the education, and poor patient/family readiness to learn (177).

Staff education can be a method of exploring staff attitudes, awareness, and values. Key goals of education are to increase both the staff's comfort level and knowledge and to gain skills in communicating about sexuality with their peers, patients and families. Discussions can explore the normal development of sexuality throughout the life cycle, human sexual response, cultural differences, and the impact of traumatic brain injury on sexual function (178, 179). In a recent study, results indicated that persons with traumatic brain injury had more negative feelings about their sexuality and relationships than did participants without brain injury. Education in sexuality and ego adaptability for persons working with them is identified as a need (180).

Determining the best time for presenting information and education related to sexuality for the person with brain injury and partners and families is subject to debate, but is probably best provided in the early phase after injury. Sexual dysfunction can develop later in recovery, and follow up with patients regarding sexual function, and integration of prevention programs is essential program components (181). Lack of awareness of deficit can be prolonged, and education is helpful before and after return to the community (182). Nevertheless, learning readiness needs to be determined on an individual basis. The timing, topic areas, amount and method of education should be individualized.

In some settings, sexuality is not addressed until socially inappropriate behavior occurs. Common behaviors seen in persons emerging from coma may be touching genitalia, and self-stimulation, including masturbation. As the individual regains speech, verbal expression that

includes sexual references may occur. Patients may be disinhibited and express sexual feelings to staff or family members. Privacy, safety for patients, and education and support are critical. It is important for partners and families to be prepared for such behaviors. Staff are the most common targets for inappropriate social behaviors. Education is important for all members of the treatment team in inpatient and outpatient settings (163, 183, 184).

Health promotion and prevention is essential. Key topics to include in education of patients and family are potential changes after TBI that may impact sexuality. Of crucial importance is the provision of information about sexually transmitted diseases, including gonorrhea, chlamydial infections, herpes simplex viral infections, syphilis, parasitic infections, hepatitis, genital warts, urethritis, prostatitis, and acquired immunodeficiency syndrome. Safer sex practices include a careful selection of partners, mutual screening as necessary, and use of condoms and spermicides. Information on contraception should be provided, as well as strategies to address memory and compliance challenges due to cognitive impairments (84). Individuals with brain injury are at increased vulnerability to sexual abuse (170).

Education to prepare the person with brain injury for optimal independent living, making informed choices, and socially appropriate behavior will facilitate a successful sexual adjustment (178). Addressing issues of self-esteem directly may be helpful (184). Social and communication skills, integral to initiating and sustaining relationships, should be included in education. Clinical practice guidelines for interventions may be helpful. Three psychosocial components of the guidelines are one-to-one verbal interpersonal skills, one-to-one nonverbal interpersonal skills and strategies to deal with rejection. The guidelines provide specific interventions to foster the development of necessary social skills in long-term traumatic brain injury clients (185).

Education on psychosocial and sexual issues can be accomplished through group education meetings, social skills groups, family/patient meetings, community skills training, and individual or group counseling (182). Role-playing and more concrete and structured, repetitive styles are better choices for presenting education (38). The group setting for patient education also provides experience with improving social skills. Treatment is adapted to the level of awareness of the individual (182). Identifying the person's preferred learning style is important, as well as combining various teaching methods to improve retention of the information. Providing written materials, at an appropriate reading level and font size, are particularly important when there are cognitive impairments.

An interdisciplinary team approach, with all professional staff prepared to discuss sexuality issues in an atmosphere of permission is ideal. Leadership that fosters a team approach with the expectation that sexuality edu-

cation is consistently delivered as part of the program will result in the best outcomes (178).

The PLISSIT model is a structure to guide interventions for sexual counseling and education. Permission (P) can be achieved by simply asking patients an open-ended question to identify concerns. This can be accomplished during the initial assessment and validates for the patient that you are open to discussing sexuality and lead to further questions and dialogue. Limited Information (LI) may include factual information related to concerns such as how the disability can affect sexual functioning. Specific Suggestion (SS) may include information on problem solving or when to seek medical attention/intervention. Intensive Therapy (IT) is individualized treatment provided by sex therapists and counselors. This model recognizes that there may be individual comfort levels and abilities among staff members (88, 176, 177).

A sexuality education program should include both professional and patient/family educational components and be integrated into the interdisciplinary rehabilitation programs in both inpatient and outpatient settings. A comprehensive sexuality education program, implemented in the Statewide Head Injury Program in Massachusetts, outlines both staff and patient education programs, implemented in residential and day treatment programs for adults with traumatic brain injury. Components of the program include patient and staff needs assessments and evaluation measures, and policies and procedures. Sexuality education for staff occurs at the orientation level with advanced level workshops and professional readings programs. Patient education classes are presented in a style adapted to enhance learning, with various strategies in written, question and answer format with prompt feedback and reinforcement, role-playing, and pre-post testing (186).

## REPRODUCTIVE ISSUES FOR WOMEN WITH BRAIN INJURY

A full discussion of reproductive issues for women with brain injury is beyond the scope of this chapter. However, a number of articles and books, written by women with disabilities, are useful for persons with brain injury as well as the professionals who care for and advise them. Although the specific effects of the brain injury on pregnancy, labor, and delivery have not been investigated, other sources offer practical recommendations (86, 187, 188).

Several issues with particular relevance to women with traumatic brain injury are addressed below, including (1) amenorrhea, (2) seizure disorders and anticonvulsant medications, (3) other drugs with teratogenic potential, (4) management of pregnant women in coma or vegetative state, (5) contraception, and (6) infertility.

### **Amenorrhea**

Although female reproductive dysfunction after brain injury is largely unstudied, amenorrhea is frequently observed. Hypopituitarism after head trauma results in amenorrhea, among other clinical signs, but many cases of amenorrhea after brain injury are not associated with hypopituitarism. A pregnancy test should be performed initially when indicated. A low or normal serum prolactin level indicates anovulation, and medroxyprogesterone for 5–10 days will produce withdrawal bleeding, indicating stress and trauma as a likely cause. If there is no response, then a serum LH and FSH level should be obtained. A low or normal level may indicate hypopituitarism or hypothalamic disorder. Consultation with an endocrinologist or gynecologist is recommended.

### **Seizures and Pregnancy**

The risk of malformations associated with use of anticonvulsant drugs during pregnancy in women with epilepsy is clear (189). The absolute risk of major malformations in neonates exposed to anti-epileptic drugs in utero is 7–10%, which is 3–5% higher than for the general population. Barbiturates and phenytoin are associated with congenital heart malformations and craniofacial anomalies. The fetal hydantoin syndrome is further characterized by prenatal and postnatal growth deficiencies, mental retardation, and limb defects; less often microcephaly, ocular defects, hypospadias, and hernias may be caused by other epileptic agents (190). Valproate and carbamazepine are associated with spinal bifida and hypospadias (191). High daily dosage, high serum concentration, low folate levels, and poly-therapy are additional risk factors (189). Infants of epileptic mothers may develop hemorrhagic disorders, apparently due to a deficiency of vitamin K-dependent factors (192). Despite such risks, 90% of women with seizure disorders deliver normal infants.

Because teratogenicity of anticonvulsant medications is associated with elevated levels of oxidative metabolites, an enzymatic marker may be useful in determination of risk. Low enzymatic activity was found in 4 of 19 fetuses, and the predicted high risk for fetal hydantoin syndrome was confirmed postnatally (190).

The risk of seizures during pregnancy, labor, and delivery is increased in 40% of women with epilepsy, although 50% have no change and 10% have a decrease in seizures (193).

In one study, however, 68% of pregnancies in which seizure frequency increased were associated with non-compliance with treatment recommendations (194). Pregnancy can affect anticonvulsant levels, which decline over time, because of emesis, decreased absorption, and due to increases in plasma volume, liver metabolism, and renal clearance. In addition, hormone changes may lead to increased seizures, and protein binding may be altered.

The International League Against Epilepsy (ILAE) published guidelines for the care of women with epilepsy who may become pregnant (195). The recommendations include: counseling about the risk of seizures, bleeding, and toxemia in pregnant women; counseling about malformations, prematurity, seizures, and developmental disorders in fetus and infant; ultrasound evaluation for neural tube defects, heart malformations, and craniofacial anomalies, and amniotic fluid analysis of alpha-fetoprotein for neural tube defects; counseling about options for termination of pregnancy; careful choice of anticonvulsant and monitoring of anticonvulsant levels, both during pregnancy (when they may decrease) and after delivery (when they may increase); adequate amounts of folate (192, 196).

Anticonvulsant drugs have different rates of transmission in breast milk: 5–10% for valproate, 30% for phenytoin, 40% for phenobarbital, 45% for carbamazepine, 60% for primidone, and 90% for ethosuximide (195). Other medications, including antidepressants, antipsychotic agents, and antimigraine medications, prescribed to persons with traumatic brain injury with relative frequency, may have adverse effects on the fetus. These include antidepressants, antipsychotic agents, and antimigraine medications (197).

### **Coma and Vegetative State**

Pregnant women with moderate to severe brain injury who are hospitalized in trauma centers may be in coma, vegetative state, or be classified as in a state of “maternal brain death” during pregnancy. Some may emerge from coma during pregnancy, but a small percentage, evolve into and remain in a vegetative state. Both maternal survival and emergence from the vegetative state are possible. Medical as well as ethical and legal questions are raised.

Dillon and associates (198) recommend maternal life-support measures at 24–27 weeks of gestation, followed by cesarean section at 28 weeks, but no extraordinary measures at less than 4 weeks for mother or fetus. Others (199) recommend continued maternal support until 32–34 weeks to increase survival rates. Obviously, for the fetus that does not survive the trauma suffered by the mother, the pregnancy must be terminated to save the mother's life. Experimental evidence suggests that the fetus may be less vulnerable to acute asphyxia than the mother. Redistribution of blood flow to vital organs, anaerobic metabolism, and decreased oxygen consumption may be the essential mechanisms (200).

### **Contraception**

Options for contraception are not usually limited by medical considerations in patients with brain injury. Poor patient compliance because of memory difficulties may

dictate choice; oral contraception may be ill advised for this reason. Long-acting injectable techniques may be preferable; permanent solutions, if desired, include vasectomy and tubal ligation. Subdermal delivery of the synthetic progestin levonorgestrel has a failure rate of 4 or 5/1,000 users/year compared with 20–50/1,000 users for oral contraceptives; for persons taking phenytoin or carbamazepine, pregnancy rates are higher (201). Oral hormonal contraception may increase the risk of venous thrombosis, and this must be considered in women historically or potentially at risk (84, 86).

### Infertility

In patients with traumatic brain injury, initial evaluations should include hormonal assays, including LH, FSH, prolactin, thyroid function studies, and total testosterone. Low concentrations of LH, FSH, and testosterone suggest hypopituitary or hypothalamic injury, and a releasing hormone stimulation test should be conducted. Hypothalamic ovulatory dysfunction may be treated with clomiphene citrate, menotropins (human menopausal gonadotropins or LH and FSH), or gonadotropin-releasing hormone. In men, hypothalamic-pituitary failure may be treated with menotropins, human chorionic gonadotropin, or gonadotropin-releasing hormone. Testosterone promotes virilization and may enhance sexual function but has no effect on spermatogenesis.

### CONCLUSION

This chapter has focused on the pathophysiology of sexual dysfunction and the contributions of medical, psychological, social and cultural factors that influence sexual functioning in disabled populations. Whenever possible, we have attempted to focus on the specific needs of the TBI population. Updates for the evaluation and treatment of sexual dysfunction, depending on etiology, are provided to practitioners in the field of rehabilitation. Other areas of focus have included neuroendocrine disorders and women's health care in regard to both sexuality and reproduction in this population. Further research is needed to further clarify the incidence and prevalence of these disorders, and effective treatment approaches for optimal outcomes for this population of men and women with disabling injury. In addition, additional attention to the needs of sexual minorities, including gay, lesbian, and transgendered individuals is required to further advance our understanding of sexuality across the entire disabled and non-disabled population. Despite gaps in our basic science and clinical knowledge base, major advances over the last decade have been made in the evaluation and treatment of sexual, reproductive, and neuroendocrine dysfunction that will be of benefit to our

patients with traumatic brain injury. Rapid development in these areas of research will no doubt lead to many new interventions in the not too distant future.

## Post-Traumatic Pain Disorders: Medical Assessment and Management

*Nathan D. Zasler*  
*Lawrence J. Horn*  
*Michael F. Martelli*  
*Keith Nicholson*

### INTRODUCTION

The medical management of pain in persons with traumatic brain injury (TBI) is fraught with challenges that are multidimensional in nature. The co-occurrence of pain with TBI has been found to be a common phenomena (1, 2). Clinicians evaluating patients with TBI with comorbid pain complaints need to be aware of the types of neurological, both peripheral and central, as well as orthopedic injuries that may result in post-traumatic pain syndromes in this patient population. Adequate assessment and optimal treatment will typically require a multidisciplinary neuromedical and an interdisciplinary rehabilitation approach.

### NEUROANATOMY AND NEUROBIOLOGY OF PAIN

The neuroanatomic systems involved in pain perception are complex and dynamic (i.e. plastic) and differ in many ways for acute versus chronic pain states (3). The nociceptive system is now recognized as a sensory system in its own right. There are multiple redundancies and feedback loops for both ascending and descending inhibition or facilitation. Important structures include the peripheral afferents, the dorsal horn (replete with its complex interneuronal pool), ascending spinal tracts, descending

spinal tracts, brain stem structures (including the periaqueductal gray, pontine and mesencephalic reticular centers), thalamus, primary sensorimotor cortex, paralimbic and limbic structures (4). Much of the cerebral cortex is involved with processing different aspects of pain.

### Ascending Systems

Pain receptors are located throughout the peripheral somatic and visceral systems. They are sensitive to almost any mechanical, toxic, metabolic and thermal injury. Peripheral afferents are unmyelinated C and myelinated A  $\delta$  neurons with cell bodies in the dorsal root ganglia. These enter the spinal cord at the dorsal horn (DH). Pain receptors and the primary afferent neurons are also affected by peripheral inflammatory processes and mediators released during tissue injury. These mediators may lower the threshold for firing of the primary afferent neurons, perpetuating or augmenting peripheral pain input to the central nervous system. This process is called peripheral sensitization. The nociceptors themselves may release bradykinin, serotonin, substance P and histamine that, in turn, increase the sensitivity of the receptor. In addition, inflammatory mediators such as leukotrienes, cytokines, prostaglandins and potassium from injured cells or via the inflammatory cascade contribute to increased sensitization of the nociceptors and peripheral afferents (5).

Traditionally, the ascending systems of the central nervous system begin in the dorsal horn of the spinal cord (DH). The direct pathway, also referred to as the lateral pathway or neospinothalamic tract, begins in the nucleus proprius (lamina III and IV) of the DH where the second order neuron crosses over in the anterior white commissure to the lateral funiculus of the opposite side, forming or joining the spinothalamic tract. This cross over occurs over 1–3 levels above the afferent spinal level. The second order neuron ascends to the ventropostero-lateral (VPL) nucleus of the thalamus where a third order neuron projects to the primary sensorimotor cortex of the parietal lobe. It is believed that fine discrimination of the type of nociceptive input and location is largely the function of this tract.

However, there are also other, much more polysynaptic ascending pain systems referred to as indirect pathways and which comprise a medial pain system. These principally mediate the autonomic, endocrine, arousal and emotional aspects of pain perception. Unlike the lateral system, these ascend bilaterally, have poor somatotopic organization, and synapse over multiple levels of the neuroaxis. The paleospinothalamic tract leaves the DH and ascends bilaterally in the ventrolateral spinal cord to synapse in the reticular formation, the midline and intralaminar nuclei of the thalamus (including the dorsal medial nucleus) and then project diffusely to limbic structures including the anterior cingulate gyrus. Associated tracts include the spino-reticular tract that ascends in the anterior white matter of the spinal cord to synapse in the medullary and pontine reticular nuclei, which then project to the midline and intralaminar nuclei of the thalamus and then project on to the cortex and limbic structures. The other major paleospinothalamic tract is the spinomesencephalic which projects from the DH to the periaqueductal gray (PAG) of the mesencephalon, then to the midline and intralaminar nuclei, and on to the cortex and limbic system. Both the periaqueductal gray and the reticular nuclei generate important descending modulatory tracts to the DH and its interneuronal pool.

The dorsal horn (DH) is the origin of second order neurons ascending to multiple levels of the central nervous system and which synapse locally with a variety of interneurons as well as the primary peripheral afferent. The synapse between the first and second order nociceptive neurons is subject to both facilitatory and inhibitory inputs from these interneurons, as well as, descending influences from the brain. Ascending neurons largely consist of nociceptive specific neurons and “wide dynamic range” neurons that receive input from both nociceptive and non-nociceptive afferents (6). There is substantial local (peri-segmental) interconnectivity via interneurons, accounting for spinal motor reflexes whereby a noxious input causes withdrawal via anterior horn (motor) neurons.

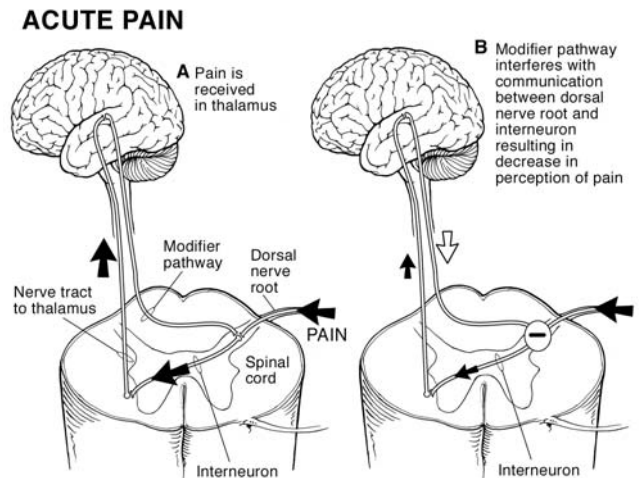

FIGURE 38-1

Proposed pathways for acute pain transmission

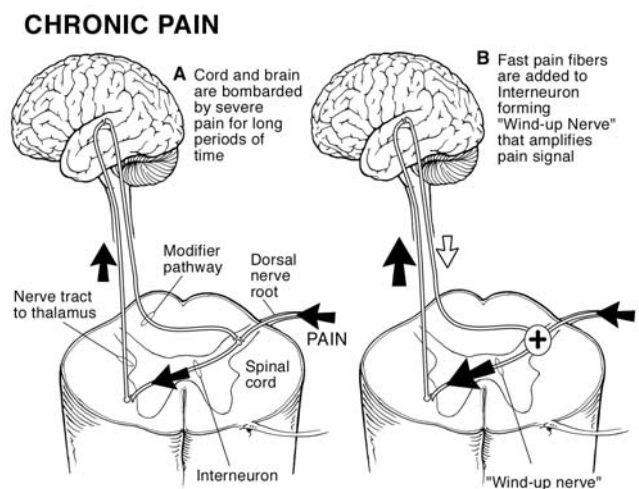

FIGURE 38-2

Proposed pathways for chronic pain transmission

As discussed above, the primary peripheral nociceptive neuron may become sensitized by local tissue injury. It may also begin to develop spontaneous ectopic discharges that may also appear in a region near the dorsal root ganglia (7). Wind-up refers to a progressive increase in magnitude of C-fiber evoked responses in the dorsal horn neurons produced by repetitive firing of the C-fibers and the dorsal root ganglia. This process does not persist after a stimulus ceases, and seems to be related to activation of NMDA receptors and is akin to kindling in some forms of complex partial epilepsy. Wind-up is theorized to occur when successive synaptic depolarizations of the voltage dependent NMDA receptor lead to magnesium depletion; thereby, allowing an influx of intracellular calcium which in turn activates protein kinases and

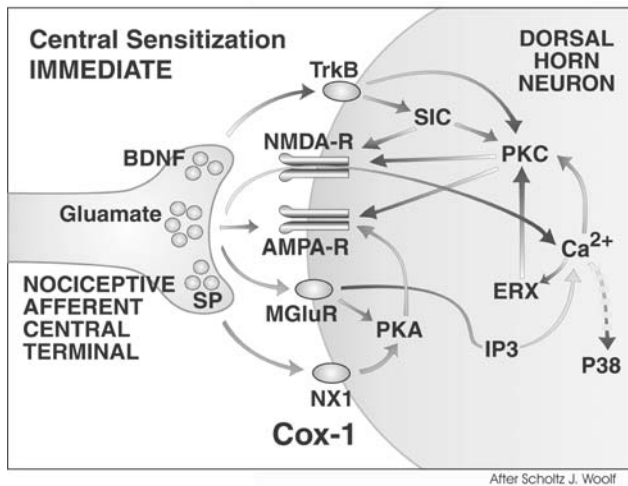

FIGURE 38-3

Theorized mechanisms of central sensitization, immediate

FIGURE 38-4

Theorized mechanisms of central sensitization, late

ultimately causes further amplification of nociceptive responses to stimuli (see Figures 38-1 and 38-2). Ectopic impulse generation after nerve injury is associated with increased expression of messenger RNA for certain voltage-gated sodium channels leading to increased accumulation of sodium channels at sites of ectopic impulse generation, decreasing the neuron’s threshold for firing (7).

Central sensitization is a related phenomenon which, at the spinal level, refers to increased excitability of dorsal horn neurons associated with increased spontaneous activity and decreased firing thresholds in response to primary afferent inputs. The receptive field for the involved dorsal horn neuron also expands. Sensitization of dorsal horn neurons may persist after a stimulus stops, often occurs after tissue injury, and contributes

to secondary hyperalgesia whereby there is increased excitability of nociceptive spinal cord neurons to stimuli outside of the injured area (8). Different mechanisms have been theorized to be responsible for immediate/early central sensitization versus late central sensitization (see Figures 38-3 and 38-4).

Both wind-up and central sensitization contribute to allodynia — the perception of pain from otherwise neutral stimuli — particularly when the wide dynamic range neurons are affected. Furthermore, both peripheral and central sensitization may contribute to sympathetically mediated complex regional pain syndromes. The clinical implications for windup and central sensitization are that they can be minimized by early and thorough pain management (9, 5). As an example, in treating chronic migraine patients, it is imperative that attacks be aborted early. Triptans may not be effective once cranial allodynia has occurred (10).

The neurochemical milieu of the dorsal horn is no less complex than the anatomy. Of the neurotransmitters that we can manipulate with present-day medications, opioids, serotonin, GABA, and norepinephrine all have receptor sites throughout the pain neuro-axis. Although some are primarily pro or anti-nociceptive, some have mixed effects depending on the site of action and the subtype of receptor present. Furthermore, it does not appear that the traditional concept of “one neuron, one neurotransmitter” is valid. Several neurotransmitters may be released from a single neuron, or neuronal system.

At the synapse between the peripheral afferent fiber and the nociceptive or wide dynamic range neuron in the dorsal horn, the pre-synaptic primary afferent may co-release glutamate, substance P, neurokinin A, and calcitonin gene-related peptide (CGRP). These neurotransmitters are all stimulatory to the dorsal horn neuron and are largely considered pro-nociceptive. The presynaptic afferent terminal also has opiate ( $\mu$ ) and  $\alpha 2$  noradrenergic receptors that are inhibitory to the release of the aforementioned neurotransmitters and are considered anti-nociceptive. In addition, the presynaptic terminal has 5-HT<sub>3</sub> serotonin receptors that facilitate the release of Substance P.

The dorsal horn neurons themselves are influenced by neurotransmitters released by cells other than the peripheral afferent fibers (PAF). GABA interneurons (A and B) inhibit the firing of the Dorsal Horn cells. 5-HT<sub>3</sub> also facilitates the GABA interneurons. Stimulation of  $\alpha 2$ ,  $\mu$  opiate, and 5-HT<sub>1a</sub> receptors on the DH cell also inhibit its firing. Some of these chemicals originate from descending inhibitory pathways in the dorsal lateral pontine catecholamine cell groups (DLP) or the rostral ventromedial medulla (RVM). Therefore, within the DH,  $\alpha 2$ ,  $\mu$  opiates, 5-HT<sub>1a</sub> and GABA are all anti-nociceptive; 5-HT<sub>3</sub> has mixed effects, facilitating release of pro-nociceptive transmitter release from the peripheral afferent neuron, but also facilitating release of GABA. Glutamate, substance P,

neurokinin A, and CGRP are all pro-nociceptive (Rao, 2002). Therefore, from the perspective of clinical pharmacologic interventions, those agents that result in net stimulation of opiate,  $\alpha_2$ , GABA, or 5HT<sub>1A</sub> receptors, or that block Substance P, Glutamate or neurokinin receptors should all have analgesic properties.

The second order neurons that ascend via the lateral spinothalamic primarily carry pain and temperature sensation from the contralateral body. Visceral pain is largely transmitted via the medial pain system discussed below. A lesion of the spinal cord involving the spinothalamic tract, therefore, will produce a loss of pain and temperature over the surface of the body contralateral to the lesion, beginning 1 or 2 segments below the injury level. Incomplete lesions of the neospinothalamic tract may produce spinal generated central pain syndromes. Similarly, lesions of the thalamus may produce "thalamic pain" over the contralateral body and face, due to abnormal firing in the VPL nucleus.

The paleospinothalamic system carries nociceptive information from the body viscera and is bilaterally represented in the spinal cord and above. Second order neurons synapse rostrally in the periaqueductal gray of the mesencephalon and the parabrachial nucleus of the pons; these pathways then project to thalamic and limbic structures and appear to be involved in the motivational and affective elements of pain, and associated dysphoria. They also have extensive interconnectivity with hypothalamic, limbic, and brain stem structures related to autonomic control. They are closely linked, regionally and functionally, to the nucleus solitarius and afferent nuclei of the trigeminal nerve, which is implicated in vascular headache (see below) (11, 12).

Projections from the periaqueductal gray and parabrachial region ascend rostrally to thalamic nuclei and then to cortex, anterior cingulate gyrus, insular cortex, and/or directly to the amygdala. The PAG appears to be the center of the most powerful antinociceptive neuromodulator system in the brain (13). There is also extensive interconnectivity between the PAG and orbito-frontal cortex; this system may be key to behavioral responses to threat and stress, switching attention away from pain when essential to survival. NMDA receptors in the anterior cingulate and insular cortices enhance persistent chronic behavioral responses to tissue injury and inflammation, without affecting acute nociception in the spinal cord (11). The anterior cingulate gyrus appears to occupy a key position in the affective responses to pain. Interestingly, there is some evidence to support overlap of emotional pain (social rejection) with somatic pain in this region on fMRI (14). The non-dominant ventral prefrontal cortex appears to dampen emotional distress caused by pain through its limbic and anterior cingulate connections. PET and fMRI studies have demonstrated that regional cerebral blood flow (rCBF) increases to

noxious stimuli are almost constantly seen in the secondary somatic (SII) and insular regions and in the anterior cingulate cortex, with slightly less consistency in the contralateral thalamus and primary somatic area (SI). Activation of the lateral thalamus, SI and SII and insula are thought to be related to the sensory-discriminative aspects of pain processing. Bilateral thalamic responses may be related to the generalized arousal from pain. The anterior cingulate does not appear to be involved in coding intensity or location, but rather in the affective, attentional, and response selection behavioral aspects of pain. Allodynia is associated with amplification of thalamic, insular and SII responses with a paradoxical decrease in rCBF in the cingulate. The anterior cingulate may both respond to pain and participate in endogenous pain control circuitry (15). Interestingly, PET studies of 6 healthy volunteers given intravenous fentanyl showed increased rCBF in the cingulate and orbitofrontal and medial prefrontal cortices; these are areas responsive to nociceptive stimuli and are involved in avoidance learning, reward, addiction, visceromotor control, maintenance of attention and pain-related affective behavior. Fentanyl effects appear to be highly localized and specifically affect these areas (16).

Given the susceptibility of these structures to damage in traumatic brain injury, it would seem likely that higher order pain perception and its emotional resonance would be disturbed. Lesions of the primary and secondary tactile sensory cortex, which receives input from traditional lateral spinothalamic projections as well as the medial system, may produce a cortical loss of tactile sensation not confined to pain and temperature, or disturbances in tactile/pain localization.

As indicated above, there are reciprocal connections between cortical, thalamic and limbic structures and the brain stem regions intimately involved in pain transmission. The periaqueductal gray appears to occupy a pivotal function in this regard, influencing other brain stem structures that in turn modulate dorsal horn nociceptive transmission. Stimulation of the PAG leads to inhibition of dorsal horn neurons, an effect mediated by PAG connections to structures in the rostral ventromedial medulla (nucleus magnus raphe, reticular formation) that provide the primary source of spinal 5HT (and inhibitory influences on nociception). The rostral ventromedial medulla (RVM) has a somewhat complex internal relationship between "on" cells and "off" cells. However, the net descending effect is anti-nociceptive via 5HT. Glutamate from the PAG facilitates this outflow, as do intrinsic opioids receptors. Finally, the RVM serotonergic outflow is also facilitated by norepinephrine from the dorsolateral pontine (DLP) catecholamine cell groups.

The DLP is also facilitated by the PAG. Its primary outflow is alpha-2 adrenergic and is anti-nociceptive not only at the RVM, but also through direct NE influences

on the dorsal horn through its descending pathways. The major descending noradrenergic axons originate in the locus ceruleus, subceruleus, and the Kölliker-Fuse nucleus. These nuclei are also the source of much of the adrenergic innervation to the cortex, cerebellum, and limbic system. Whereas approximately 50% of patients with intractable pain can be helped with chronic electrical stimulation of the PAG and thalamic relay nuclei, additional patients may be helped by stimulation of the Kölliker-Fuse nucleus (17).

In addition to classical neurotransmitters, prostaglandins also increase sensitivity of peripheral nociceptors and are also present in the dorsal horn and central nervous system. Cyclooxygenases are enzymes that become active/are produced during any inflammatory process. They convert arachidonic acid to prostaglandins. Peripheral inflammation increases COX-2 activity in the CNS. In the dorsal horn, prostaglandins produced by COX-2 cause increased release of pro-nociceptive neurotransmitters by primary nociceptive afferents and directly depolarize dorsal horn neurons. They also inhibit glycine release, which is typically anti-nociceptive.

A special consideration in traumatic brain injury is the anatomical and functional associations related to post-traumatic head pain (cephalalgia) and neck pain (cervicalgia). Primary nociceptive afferents for the front of the scalp and face comprise the trigeminal sensory system. Afferents from the meninges travel with the “ophthalmic” division of the Vth cranial nerve. The brain itself does not appear to have any nociceptive afferent fibers. The area around the ear and the external auditory canal gives rise to sensory afferents to the IX and X cranial nerves. Finally, the posterior scalp and upper neck are innervated by the upper 3 cervical dorsal roots; the greater occipital nerve C<sub>2</sub> and the lesser occipital nerve C<sub>3</sub>. Nociceptive afferents from the Trigeminal nerve, IX and X travel to second order neurons in the spinal tract and nucleus of the trigeminal nerve, which extends from the medulla to at least C<sub>2</sub>, at times to C<sub>4</sub>. Interestingly, the V1, or ophthalmic division, is most caudal. The upper cervical dorsal horn and the spinal tract of the trigeminal nerve are contiguous and overlap (18). It appears that there is also overlap between the second order neurons in this region as well, so that central sensitization and expansion of receptive fields by second order neurons may lead to perception of pain in the occiput or neck when the primary nociceptive generator is trigeminal, and vice versa. Therefore, a primary nociceptive generator in the cervical musculature of occipital nerves could also activate the trigeminovascular system through central sensitization (19, 20). Central afferent convergence and sensitization of afferent second order neurons may underlie the spread of pain and referral from supratentorial dura to areas innervated by cervical afferents (muscles and joints of the head and neck). This would be the basis for

one theory of referred pain: the “convergence-projection theory” whereby pain originating from an affected tissue (primary nociceptive generator) is perceived as originating from a distant receptive field (21).

In migraine, sensitization of trigeminal meningeal neurons leads to central sensitization and often results in hemicranial allodynia (10). Also, stimulation of the occipital nerve clearly activates spinal nucleus caudalis of V in the same distribution as when the meninges or V innervated structures are stimulated (in the cat)(19). Migraine appears to cause unique activation of the brain stem PAG, as well as, the dorsal raphe nuclei, which provide diffuse serotonin projections to cortex and blood vessels (22).

As with somatic nociceptive inputs, the PAG seems central to pain mediated by the trigeminal system (as in migraine) (23). PET studies demonstrate activation of the PAG, dorsal raphe nucleus and locus ceruleus on the contralateral side headache (24). Capsaicin trigeminal stimulation in rats results in neuronal activation of the trigeminal nucleus, area postrema, solitary tract, reticular nucleus, locus ceruleus, parabrachial nucleus, raphe nucleus, PAG, intralaminar thalamic nucleus and various hypothalamic nuclei as well as the amygdala (25).

The nociceptive systems in the peripheral and central nervous systems are both complex and dynamic and the interplay of PNS and CNS in pain mechanisms is complex (see Figure 38-5). Modulatory effects on pain transmission occur in the spinal cord, brain stem, and thalamus, and occur via interconnections with limbic and frontal structures, especially those with relevance to the affective or attentional aspects of nociceptive processing. Many of the aforementioned sites are also uniquely susceptible to the pathology of traumatic brain injury. The neurochemistry, and hence neuropharmacology, of pain

FIGURE 38-5

Interactions between PNS and CNS sensitization pain processes

transmission and perception in the CNS often overlaps that of other disorders related to TBI such as depression, spasticity, and cognitive deficits, making any effort to treat these problems in isolation, without duly diligent awareness of the impact on the neurochemistry of associated conditions, ill advised. The plasticity of nociceptive transmission accounts for central sensitization and may also explain the neurological basis for referred pain. While on the one hand, the pain practitioner may wish to eliminate or control central sensitization, it is possible that the chemical and cytological architecture underlying central pain may also provide the structure for other important "plastic" processes in the CNS, such as motor recovery, learning, and memory. It is not clear whether effective treatment of central pain (when available) will benefit or impede these other neuro-plastic processes.

The neuroanatomical pathways associated with pain perception are clearly complex and not completely understood. Readers are referred to more in-depth sources for further detail (26–28). Cortical pain centers include the somatosensory cortex which receives input from the thalamus which receives its input from the mid-brain nociceptive centers which in turn receives input from brain stem nociceptive neuraxes. Input to the brain stem occurs through the spinothalamic tract which derives its input through both wide dynamic range neurons and nociceptive specific neurons which both compromise second order afferents (4).

The lateral and medial pain systems should also be further considered given the importance of these tracts in mediation of pain processing (27). Vogt and colleagues considerably extended the concept of the medial pain system by demonstrating projections of the medial thalamic nuclei to area 24 of the anterior cingulate cortex. The anterior cingulate cortex is an extensive area of the limbic cortex overlying the corpus callosum and is involved in the integration of cognition, affect, and response selection. The descending connections of the anterior cingulate cortex to the medial thalamic nuclei and to the periaqueductal gray in the brain stem suggest that this system may also be involved in the modulation of reflex responses to noxious stimuli. Partly because of the differences in latency of responses and their respective connections, researchers have suggested that the lateral and medial pain systems are predominantly responsible for processing acute and chronic pain, respectively (29). However, it is evident that these systems are highly interconnected and parallel. Only at the level of the cortex do they become less obviously interdependent. The intensity of sensation and pain perception is directly related to the energy level at the pain location. Primary efferents are composed of A-delta fibers and C-fibers. A-delta fibers are small, thin, myelinated neurons, 1–5 micrometers in diameter with conduction velocities in the range of 5–30 meters per second. Pain mediated by A-delta

fibers tends to be fast, sharp, localized and well defined. These fibers have small receptive fields and tend to be modality specific. They are divided into thermoresponsive and mechanoresponsive sub-groups.

C-fibers are small unmyelinated afferent fibers with diameters of 0.25 to 1.5 micrometers and conduction velocities from 0.5 to 2.0 meters per second. Pain mediated by C-fibers tends to be slow, diffuse, poorly localized and of a burning, throbbing or gnawing nature. These polymodal fibers subserve noxious nociceptive input from thermal, mechanical, and chemical stimuli, as well as, non-noxious, low intensity stimulation. Input to the primary afferents is provided through nociceptors which ultimately are the first step in the sensory pathway of transduction of a painful stimuli to a relevant neural signal. Nociceptors occur in cutaneous, muscular and visceral structures.

Pain may be triggered by sensory inputs, especially when acute, but may also be generated independently, especially when chronic. Sensitization effects represent hyper-responsiveness in either the peripheral or central components of the nervous system. Supraspinal sensitization effects associated with the medial pain system (27) and related limbic structures (30, 31) seem to mediate the pain response. Thus, pain could be produced by the output of a widely distributed neural network in the brain, rather than directly by nociceptive stimuli. Importantly, the central pain control processes seem to encompass the cognitive-evaluative, motivational-affective, and sensory-discriminative systems (32) that characterize the pain response. Finally, it should be noted that "the pain system" is intimately related to other systems in the brain (e.g., motor, mnemonic, social).

## PAIN ASSESSMENT

Pain is a subjective experience and therefore a patient's self-report of pain is in actuality the cornerstone of pain assessment. There are several important aspects of the experience of pain that should be assessed. Pain character, onset, location, duration, and factors that exacerbate or relieve the pain should be explored. The clinician should also query about pain frequency and intensity and interference with everyday activities. Two useful methods of assessing pain intensity in adults are the Visual Analogue Scale (VAS) (33) and the Verbal Analogue Scale. The Visual scale is a 10 cm line with anchors of "no pain" and "the most pain imaginable", while the Verbal Analogue Scale solicits rating of pain on a 0 to 10 scale with the same anchors. The scale appears to be sensitive to treatment changes and is widely used in clinical settings.

Pain is a complex perceptual process comprised of behavioral, affective, cognitive, and sensory components, thereby requiring evaluation of not only the patient's

medical findings, but also physiological, behavioral, and cognitive-affective functioning, including vulnerabilities and strengths. Martelli, Nicholson and Zasler, in chapter 39 of this text, provide a thorough review of the most useful pain assessment instruments, along with a model and method of pain assessment.

Importantly, a comprehensive, multimodal, biopsychosocial assessment becomes critical when pain is chronic, and should address beliefs about the individual's pain condition, pain coping strategies, psychological adjustment, activity level and quality of life (34, 35). The impact of various cognitive processes on the subjective perception of the patient's pain must be considered in the context of a comprehensive pain assessment. Turk has emphasized the importance of understanding and addressing the important role of patient pain appraisals, beliefs and expectancies (36). Furthermore, Dr. Turk has noted that patients who have chronic pain resulting from traumatic events tend to view any physical sensation as harmful and noxious, thereby increasing anxiety, as well as, subjective pain perceptions ultimately leading to further avoidance of activities and greater functional limitations which only serves to facilitate further deconditioning perpetuating this cycle.

Components of emotion that are relevant to the pain experience include: the subjective experience of how the pain feels, autonomic arousal associated with bodily reactions to pain, cognitive appraisal(s) of the painful experience as related to the personal meaning of the pain or the learned responses to pain and injury, non-verbal behaviors including facial expressions and body language associated with pain, and lastly, affective reactions to pain including anxiety (more typical acutely) and depression (more typical chronically) (37). People who have chronic pain have a much higher predilection and incidence of depression, anxiety, as well as, anger. Diathesis-stress models have been proposed to explain the higher rate of depression in this patient population, however, the implications are likely applicable to other psychoemotional responses to chronic pain as well.

Finally, psychological assessment is now a required element of pain treatment programs accredited by the Commission on Accreditation of Rehabilitation Facilities (38) as well as several managed care companies. Again, readers are referred to Chapter 39 in this text for a more thorough review of pain assessment methodology. This chapter includes a survey of general classes and useful pain assessment instruments including a model of assessment based on previous work (39).

## PAIN MANAGEMENT STRATEGIES

The management of pain represents a significant public health issue in the United States. It is both costly to our

health care system and devastating to the patient's quality of life. The need to improve pain outcomes is reflected by the congressional declaration of the present decade as the "Decade of Pain Control and Research," and the acknowledgment in January 2001 of pain as the "fifth vital sign" by the Joint Commission of Healthcare Organizations.

The goal of pain management is to modulate and ideally negate the associated physical and psychological symptoms of pain, prevent chronicity and reduce functional disability. Realistic endpoints of pain relief consistent with the clinical situation should be established. Pain management methods include both non-pharmacologic and/or pharmacologic methods and are optimized when provided in a coordinated interdisciplinary and multidisciplinary fashion (see Chapter 39). Clinicians should strive to identify pain generators and treat them as directly as possible versus simply treating the symptom of pain. The simplest, least invasive, lowest risk and most cost effective management approaches that allow for optimization of patient compliance and maximal functional restoration should be used whenever possible. When pharmacologic agents are used, analgesia should be delivered with minimal adverse effects and inconvenience to the patient, with clearly defined treatment expectancies, all of which will optimize compliance.

### Medical Management: General Considerations

In the acute care setting, already compromised neurological status may limit the array of pharmacotherapeutic agents that might be appropriate to use in a patient where the neurosurgical and neurological status is either stabilized and/or static. Medications that potentially alter any aspect of the neurological assessment should be used with caution in the acute care setting if there is a more significant brain injury and/or neurologic instability. Additionally, consideration should be given to medications with reversible effects (e.g. opiate reversal with naltrexone) whenever there is question of medication effect versus ongoing deterioration of neurological status.

During the acute care phase, the primary pain generators in trauma patients will be fractures, intra-abdominal injuries, soft tissue injuries and pain associated with invasive procedures. Pain treatment should be tailored to the degree of pain assessed and reported via metric (e.g. Visual Analog Scale) or qualitative (e.g. mild, moderate, severe and excruciating) descriptors. For neurologically compromised patients with response limitations, prophylactic pain management should be practiced based upon injuries sustained and clinical presentation. Pharmacologic prophylaxis of pain should be considered in low level patients with TBI (e.g. vegetative and/or minimally conscious) given: a) difficulty in assessment of pain in this patient sub-group, as well as, controversies

regarding pain appreciation and suffering in patient's whose awareness of pain may be difficult if not impossible to confirm and b) the negative impact of pain (even in patients in a vegetative state) related to sub-cortical physiologic responses to nociceptive stimuli including increased tone/posturing, tachycardia, tachypnea, diaphoresis in addition to other adverse effects.

In the sub-acute setting, many of the same issues present in the acute care setting will continue to serve as pain generators. As patients are weaned from pain medication, pain severity can increase and acute pain generators can evolve into sub-acute pain generators. Ongoing attention to pain management must be continued as patients are moved to neurosurgical step-down units and/or inpatient rehabilitation units. Changes in patient status in the sub-acute setting may reflect underlying neural changes that are adaptive or maladaptive. Maladaptive changes can result in additional pain generators (e.g., progression and/or increase of tonal abnormalities resulting in hyper-tonicity and rigidity) as well as central pain phenomena. Pain often affects functional assessment in lower level neurologic patients and must be adequately assessed and treated. This includes pain associated with spasticity, posturing, fractures, pressure sores, peripheral nerve changes, complex regional pain syndrome (CRPS) and post-surgical incisional pain.

Chronic pain has many elements of acute and sub-acute pain but is generally promulgated by additional factors including psychological ones. Current evidence strongly supports mechanisms of central sensitization in chronic pain phenomena which are not present in the acute and sub-acute periods. The patient suffering from chronic pain should be treated just as aggressively as a patient with acute or sub-acute pain, but because peripheral pain triggers are frequently less obvious, with different modalities. With chronic pain, biopsychosocial models for assessment and management are indicated and inclusion and integration of behavioral and psychological interventions usually optimizes treatment outcome.

It is critical in the context of assessment to take an adequate pain history in order for the clinician to provide an adequate foundation for identifying possible or probable pain generators. Clinicians are cautioned against assumptions that commonly reported pain symptoms are due to the brain injury itself (e.g. post-traumatic headache) when pain is more commonly produced by extra-cerebral injury. Evaluating clinicians should be familiar with both the broad array of pain symptoms that may be reported by post trauma patients, as well as assessment methodologies for the various types of pain seen in this population. Clinicians are referred to various other sources for a more detailed description of patient assessment methodologies for persons with pain disorders including dual diagnoses of TBI and pain for more in-depth discussions of this topic (40, 41).

## Pharmacological Management

Mild pain medicines that should be considered typically include aspirin, acetaminophen and non-steroidal anti-inflammatory drugs. For moderate pain the following may be considered: high dose aspirin or acetaminophen, oral NSAIDs, newer generation NSAIDs such as Cox II inhibitors (now limited to the single agent, celecoxib), injectable NSAIDs, mixed narcotic analgesics with aspirin or acetaminophen (with or without caffeine) and tramadol. For severe pain, medications to consider would include: parenteral narcotics (Morphine Sulfate = standard), mixed agonists/antagonists (pentazocine, nalbuphine), partial agonist narcotics (buprenorphine), antidepressants, anticonvulsants, and/or atypical agents. Stimulants such as methylphenidate are used with opioid analgesics as an adjuvant analgesic and to help manage opioid-induced sedation and cognitive impairment. Common medications used in pain management are included in Table 38-1.

Nerve damage with both peripheral and central pain generators is not uncommon in post-trauma patients. Some post-trauma patients may present with both opioid sensitive and opioid insensitive pain at different sites and due to different etiologies. Medications that have been used for opioid insensitive pain include non-steroidal anti-inflammatory drugs (42), tricyclic anti-depressants, newer generation antidepressant agents such as venlafaxine or duloxetine, tizanidine, anti-epileptic medications, and various topical medications (some of which may need to be produced through compounding pharmacies), among other pharmacotherapeutic options.

Adjuvant analgesics are drugs that are analgesic in specific circumstances but have primary indications other than for pain management. Adjuvant analgesics are usually combined with analgesics. Corticosteroids, such as prednisone, are commonly used as short-term therapy to decrease pain and nausea and improve mood, appetite, and general sense of well being. Adverse effects of short-term corticosteroid use include edema, dyspepsia, and neuropsychiatric changes. Diabetic patients should be counseled about careful blood glucose monitoring while taking corticosteroids due to their hyperglycemic effect.

Antidepressants and anticonvulsants are used to manage a variety of neuropathic pain states that have not been responsive to opioid analgesics (see Table 38-4). Tricyclic antidepressants (TCAs), particularly amitriptyline, have shown efficacy in the management of diabetic neuropathy, and are used for other neuropathic states. TCAs can also manage underlying depression in pain states. Other TCAs such as nortriptyline, imipramine, and desipramine are also used. Agents that are SNRIs such as venlafaxine (Effexor) and duloxetine (Cymbalta) have also been found effective in certain pain conditions due to apparent antinociceptive properties. TCA adverse

Meperidine	300 mg q 2–3 h	100 mg q 3 h			
Fentanyl	IM or IV		Fentanyl	Transdermal: 25 g patch 45–135 mg Morphine p.o. over 24 h	

Opioid-naïve adults and children ≥50 kg body weight

*Note:* The above mentioned drugs are only a partial listing of available opioids.

effects include anti-cholinergic effects (dry mouth, sedation); weight gain; orthostatic hypotension; and cardiac arrhythmias. Secondary amines such as nortriptyline and desipramine have fewer adverse effects and should be used in patients, such as the elderly, when there is concern for anticholinergic effects, sedation, and orthostatic

hypotension. Antidepressants generally should be initiated at a low dosage and titrated up slowly based on pain relief and patient tolerance.

Anticonvulsants, such as carbamazepine and gabapentin, can be effective for the management of neuropathic pain, particularly lancinating or paroxysmal

pain. Because carbamazepine can decrease platelets, neutrophils, and red blood cells, patients on carbamazepine should have complete blood counts performed routinely. Gabapentin has shown efficacy in diabetic neuropathy and post-herpetic neuralgia, and generally has a milder adverse effect profile consisting of sedation, ataxia, and does not require routine lab work. A recent Cochrane review examining the role of AEDs (anti-epileptic drugs) for acute and chronic pain noted that although they are widely used in chronic pain surprisingly few trials show analgesic effectiveness. They noted that there was no evidence for anticonvulsant effectiveness in acute pain, however, in chronic pain syndromes it was suggested that aside from treatment of trigeminal neuralgia, that AEDs be relegated to basically third line treatment. Lastly, it was noted that there was no evidence to support the contention that gabapentin was superior to other AEDs in neuropathic pain management (43). As with the antidepressants, one should institute treatment at a low dosage and titrate the dose up slowly to improve tolerance and optimize compliance. Valproate, oxcarbazepine, lamotrigine, topamax, levetiracetam, phenytoin and clonazepam are other anticonvulsants that also have been used for neuropathic pain. Newer AEDs, such as pregabalin, an alpha2-delta ligand, recently approved for certain types of neuropathic pain may also prove useful in the management of post-traumatic pain conditions (44, 45).

Newer agents such ziconotide (Prialt), a synthetic neuronal N-type calcium channel blocker, which has received recent FDA approval, may also offer promise for treatment of intractable severe chronic pain in patients intolerant of or refractory to other forms of treatment (46). This agent, like other intraspinal (intrathecal or epidural) analgesics should only be tried when other standard treatments have failed and must be administered via a programmable implanted microinfusion device for long term users. Morphine is the only other agent that is FDA approved for intrathecal use for chronic pain, although other agents including ketamine, midazolam, clonidine and various local anesthetics (i.e. lidocaine and bupivacaine) have been used, alone or in combination, in this application on an off-label basis (47).

Other agents that have more recently been recognized as adjuncts in the pharmacologic management of pain include tizanidine (Zanaflex) and sodium amobarbital (Amytal). Tizanidine has been shown to be effective in a variety of pain conditions including fibromyalgia, as well as, tension type headache, possibly on the basis of modulation of substance P and/or owing to its alpha-adrenergic effects (48). Mailis and Nicholson (49) have provided an excellent review of the use of sodium amytal infusion in the assessment and treatment of chronic pain (and functional disorders).

Capsaicin can be used topically to help decrease pain associated with peripheral neuropathies. Capsaicin

depletes peptides such as substance P that mediate nociceptive transmission. Application of capsaicin is associated usually with a burning sensation, which may be severe enough to require pre-medication with either an oral analgesic or a topical lidocaine cream or ointment. Patients should be counseled not to touch mucous membranes after applying capsaicin.

Compounded agents, typically formulated through "compounding pharmacies" may also play a role in pain management of the patient after TBI. Agents that have been used in topical formulations for pain include: local anesthetics, antidepressants, alpha-2 agonists, opioids, glutamate antagonists such as Gabapentin, calcium channel blockers, skeletal muscle relaxants, capsaicin, Ketamine, menthol, and NSAIDs. Standard topical formulas such as "speed gel", which contains amitriptyline, lidocaine, guaifenesin and ketoprofen, can work quite well for neuropathic/neuralgic scalp pain, scar pain, and post-traumatic myalgias. Similar compounded topicals with varying ingredients such as gabapentin, ketamine and clonidine may be more helpful as adjuvants for CRPS related pain (50).

Surgery produces pain by releasing pain and inflammatory mediators via damaged tissue. This pain is acute pain and will improve as the wound heals and the patient convalesces. The goal of postoperative pain management is to provide continuous and effective analgesia with minimal adverse effects. NSAIDs such as parenteral ketorolac are used both intra-operatively and post-operatively to decrease the production of inflammatory prostaglandins released at the site of injury. The ketorolac dose is dependent on route, patient age, and weight, and should only be continued at the appropriate dosage for five days due to the development of renal dysfunction and GI toxicity. Opioid analgesics are the most commonly used medications for acute and sub-acute post-operative pain, usually administered intramuscularly or intravenously on an as needed basis. This approach can lead to delays in the patient receiving adequate analgesia due to medication administration delays and intramuscular route absorption.

Patients should be switched to oral opioid analgesics when oral administration is tolerated. Patient-controlled analgesia (PCA) is a process where the patient is allowed to self-administer low doses of intravenous opioid analgesics to maintain analgesia. To use PCA, a patient should be sufficiently cognizant to understand the goals of PCA and understand the use of the equipment. Patients who are confused or cognitively impaired are not good candidates for PCA. The number of injections and attempted injections can be monitored for efficacy and adverse effects, in addition to the patient's report of pain. Opioid analgesics can also be administered into the epidural or intrathecal space, combined with local anesthetics such as bupivacaine or ropivacaine for postoperative pain

management. Patient-controlled epidural analgesia may be considered in specific circumstances.

Opioid analgesics stimulate the opioid receptors ( $\mu$ ,  $\kappa$ , and  $\delta$  subtypes) that are widely distributed throughout the brain, spinal cord and peripheral nervous system. The opiate receptors appear to function at pre-synaptic potassium channels and indirectly affect voltage gated sodium channels to reduce the release of excitatory amino acids and substance P. Analgesia occurs primarily via action at the  $\mu$  receptors, and less so at the  $\kappa$  and  $\delta$  receptors.  $\mu$  receptor stimulation is also responsible for some other opiate effects such as miosis, depressed gastric motility, and respiratory depression.  $\kappa$  stimulation does influence spinal analgesia, and also causes miosis and respiratory depression. Stimulation of  $\delta$  receptors seems to account for hallucinations, confusion and stimulation of respiratory and vasomotor centers (51).

Desirable clinical effects of opioid analgesics include analgesia and reduced anxiety. Undesirable effects include sedation, urinary retention, respiratory depression, tolerance and dependence. Circumstantial side effects include euphoria, depressed bowel motility, and depressed cough. Tolerance to side effects develops fairly rapidly as compared to analgesic effects. Tolerance is simply a shift in the dose-response curve to achieve a desired therapeutic effect – one needs to either increase the dose or shorten the dosing interval. This phenomenon is not unique to opiates and occurs with a variety of medications. Physical dependence refers to the phenomena of the body becoming accustomed to the presence of the medication and that an abstinence syndrome may be precipitated by abrupt withdrawal of the medication, again a phenomenon not unique to narcotics (e.g. also seen with SSRI's). In the case of narcotics, abstinence syndrome symptoms may include lacrimation, diaphoresis, nausea and vomiting and typically does not persist for more than 72 hours; however, associated sleep disturbances and depression can last several weeks. Tolerance and physical dependence are simply physiologic responses to opioid exposure and do not imply aberrant drug use. Addiction is a complex set of maladaptive behaviors resulting in physical, psychological or social harm. There is an alteration in central nervous system function which the affected individual finds desirable resulting in a craving for the drug in question, often associated with tolerance for the non-analgesic, desired effect, resulting in unsanctioned dose escalation and preoccupation with acquisition of the drug and resultant adverse psychosocial consequences. The term pseudo-addiction refers to behaviors similar to those in addiction, but more specific to desired analgesic affects. The behaviors cease when appropriate analgesic management leads to adequate pain control (in other words, the physician has failed to provide sufficient medication or alter dosing in response to expected physiologic tolerance) (51, 52).

“Cognitive” and affective side-effects do occur with opiate medications. Euphoria, or dysphoria, sedation, hypnagogic or hypnopompic hallucinations appear typically within 3–7 days of dose initiation or escalation, but abate within the same time frame (52). Any worsening of cognitive performance occurs within the first few days of use, or first few hours after a dose, but tolerance develops to this phenomenon. There are relatively few differences found in cognitive performance in patients taking opioids compared to their performance before opioids or with the performance of a comparable pain population not taking opioids (53). Overall, there is no evidence that there are any long term cognitive side effects from narcotics, and adequate pain control may enhance cognitive performance (54, 51). In a study of 144 patients with low back pain, Jamison administered Digit Symbol and Trail-Making Test B prior to taking opiates and then at 90 and 180 day intervals. Test scores significantly improved while patients were taking opioids for pain (55). Finally, a TBI clinician must consider the fact that the opiate system is intimately involved in learning and reward. In the rodent model, genetic absence of the  $\mu$  receptor, but not the  $\kappa$  receptor, results in severe impairments in spatial learning (56). Therefore, the possibility exists that narcotic use in TBI may not simply be humane (analgesic properties) and without any significant long term negative cognitive consequences, but may also promote certain cognitive or affective improvements. However, practitioners must be aware that there may be adverse cognitive effects in those persons taking undue/excessive amounts of opioid medications, either due to inappropriate physician prescribing practices or patient non-compliance. Other potential reasons for occurrence of opioid related cognitive impairment include drug sensitivity, concurrently use of other substances (e.g. alcohol), or temporary impairment associated with increasing of opioid dose.

There are a variety of derived and synthetic narcotics available, each with different potencies and properties. Meperidine, and to a lesser extent, propoxyphene have mixed opioid agonist and antagonist properties and may cause severe cognitive problems in the elderly, including hallucinations. Neither drug, nor should most narcotics, be used with MAO inhibitors secondary to a risk of hypertensive crisis or autonomic dysregulation. Moderate potency narcotics (hydrocodone and oxycodone) are metabolized by liver P450 enzymes into morphine and if given with other drugs that inhibit metabolism via this enzyme (SSRI's for example) a given dose of these narcotics may produce less than optimal pain relief. Similarly, the low potency synthetic narcotic tramadol should be used with caution with SSRI's and other anti-depressants secondary to increased seizure risk (more likely a function of its agonistic properties on NE and 5HT receptors, that may also be desirable in dampening central sensitization)(57).

The use of narcotics in chronic non-malignant pain management remains controversial. Poppy derivatives and opioid medications have demonstrated proven pain relieving properties for hundreds of years. It has only been in the last century that a significant social stigma has been attached to the use or prescription of narcotics for chronic pain treatment. Now, the pressures from agencies like JCAHO to provide appropriate and thorough pain management appear to be at odds with legislative and legal considerations imposed by State Boards of Medicine. Physicians and patients are concerned about addiction, tolerance, and side effects from narcotics, all of which may generally be more hyperbole than fact although such concerns may sometimes be very real such as in the case where a patient becomes addicted to medication due to inappropriate prescribing or monitoring practices of their treating physician.

Furlan et al. (submitted) (58) have recently completed a systematic review of opioids for CNCP (chronic non-cancer pain) that will serve as the CPSO's (College of Physicians and Surgeons of Ontario) updated guidelines to be released this year (2005). This systematic review of 38 Randomized Controlled Trials (RCTs) concluded that: (1) Opioids are effective in the treatment of CNCP by reducing pain and improving functional outcomes when compared to placebo (2). Opioids are equally effective for both nociceptive and neuropathic pain syndromes when compared to placebo (3). Opioids are effective in fibromyalgia by reducing pain, but did not improve functional outcomes when compared to placebo (4). Opioids were superior to other drugs (e.g., NSAIDs, tricyclic antidepressants), in reducing pain, but failed to improve functional outcomes (5). Constipation and nausea were noticeable side effects more commonly associated with opioids (6). While recent studies indicate development of significant endocrinological abnormalities and erectile dysfunction on chronic opioids, the majority of the studies did not inquire about sexual dysfunction. The only two studies that provided a sexual activity score showed that patients on opioids actually reported they were better in terms of sexual behaviour compared to controls. Improvement of mood or adjustment secondary to better pain control may account for this result (7). However, addiction/abuse in patients with chronic pain can not be assumed not to exist (despite popular statements), because the existing literature a) excluded high risk populations (therefore it is not representative of chronic pain patients seen particularly in pain clinics); b) is methodologically not designed to look for "addiction", and c) the duration of the trials is too short to allow for development of the disorder (even if appropriate definitions and screening tools for addiction had been used).

Most patients taking long acting opioids should be supplied with a fast acting rescue opioid to treat breakthrough pain. Oral rescue medicine may be needed every

2–4 hours. The usual dose is the analgesic equivalent of 5–15% of the 24 hour baseline dose of the scheduled long acting opioid analgesic. As with any pain medication and/or intervention, the prescribed agent should be titrated to achieve optimal pain relief with minimal side-effects. Clinicians should discuss treatment expectancies prior to issuing prescriptions for any pain medication.

Clinicians treating patients with TBI may be especially concerned about cognitive side effects and slowing of cognitive recovery; again, a concern that may be overemphasized. Indeed, for non-brain injured patients with multiple fractures or other injuries, physicians would have no qualms about administering narcotics, especially in the acute care setting. Yet in the acute and sub-acute phases of brain injury, when the patient may be unable to communicate or have severely altered consciousness, physicians are reticent to provide adequate analgesia with narcotics. From a practical perspective, it would be appropriate to use narcotics for analgesia if the physician can reasonably assume that a patient with brain injury has opiate responsive sources of pain, even if they have limited ability to communicate. In fact, a common contributor to "agitation" in the acute care or rehabilitation setting may be inadequate analgesia. On the other hand, there is evidence that patients in a vegetative state do not have conscious awareness of nociceptive stimuli; specifically, there is activation of brainstem, thalamic and primary somatosensory cortices, but not of secondary association cortex (59). The implication is that patients who are truly in a vegetative state (i.e. arousal without awareness) and not MCS may in fact be incapable of "suffering" (in line with historical neurologic community dogma that persons in VS do not feel pain). Opioid analgesic treatment could, however, be considered even in patients in VS if they were experiencing dysautonomic type symptoms from a suspected nociceptive stimulus and/or were manifesting significant physiologic reactivity associated with noxious stimuli including tachycardia, tachypnea, diaphoresis and rigidity. Good clinical care would dictate that every attempt to modulate and/or minimize nociceptive stimuli should be made before using opiate analgesics.

Clinicians should be familiar with important documents concerning the use of controlled substances such as opiate medications. In 2004, the Federation of State Medical Boards of the United States published a *Model Policy for the Use of Controlled Substances for the Treatment of Pain* which was developed in collaboration with pain experts around the country to provide guidance to state medical boards in developing state pain policies and regulations. Written in the form of a model policy document, the guidelines provide model language that may be used to by states to clarify their positions regarding the use of controlled substances to treat pain, alleviate physician uncertainty about such practice and encourage better

pain management. In 2004, the Federation's House of Delegates adopted recommendations and revised the pain policy to reflect new medical insights in pain treatment, particularly with regard to the undertreatment of pain (60). As prescribers, professionals should also be aware of the myriad issues that may confront both the clinician and the patient when opiate medications are utilized for chronic pain management (61). One must also remain aware of the current evidence based medicine regarding the utility of chronic opioid therapies in specific types of pain conditions, such as chronic, non-malignant, neuropathic pain (62, 63).

Current consensus among pain specialists dictates that concerns regarding addiction are generally not a contraindication to opioid treatment for otherwise intractable pain although the possible problems associated with inappropriate opioid treatment should be kept in mind. In particular, the need and efficacy of opioids with chronic pain patients having prior drug abuse histories or addiction prone personalities should be carefully assessed and monitored when being considered for or treated with opiates. The effectiveness of opioids with respect to both reduction in pain severity ratings as well as effect on functional capacity should be considered. Clinicians should always use a "controlled substance agreement" when using such agents for pain management to protect not only the patient's safety but also their own given the litigious nature of our society (64). Ultimately, clinicians must have insight into the fact that chronic pain should be managed in a rational manner via integration of pharmacological approaches with behavioral and traditional rehabilitation interventions (65).

### **General Guidelines for Pain Pharmacotherapy**

The physician should aim for drug prescriptions that optimize compliance and minimize potential side-effects. Particularly in cognitively impaired patients, physicians should aim for once to twice a day drug dosing. Patients should be counseled on the goals of treatment and what to expect regarding adverse effects, especially constipation with opioid analgesics or GI side-effects with NSAIDs. As possible, significant others should also be informed of treatment regimen and possible complications.

Depending on the severity of the pain and the patient's pain tolerance, consider a trial of acetaminophen as an initial management strategy. If prescribing a non-selective NSAID for more than 10–14 days then consider co-administration of a mucoprotectant agent such as a proton pump inhibitor and/or misoprostol. For elderly patients, a gastroprotectant should be used regardless of the duration of NSAID therapy. Only proceed to opiate-like and/or opiate medications when the pain level and functional disability associated with the pain are moderate to severe (42).

When using opioid analgesics, fears regarding dependence should be openly discussed as should any sexual function side-effects. Ideally, the clinician should aim for decreasing polypharmacy, however, when appropriate, combination drug regimens should be considered. It is critical to ascertain whether patients are taking their medicine correctly (e.g. taking scheduled medicine on a prn basis) and/or supplanting their prescribed medications with over the counter (OTC) products.

### **Non-pharmacologic Medical Management**

A wide variety of medical rehabilitative interventions focusing on physical modalities (e.g., physiotherapy, exercise, chiropractic, massage, etc.), as well as, other non-pharmacological medical interventions for chronic pain may be helpful in ameliorating pain complaints and suffering following TBI (66, 67). However, more recent evidence suggests that many such treatments may be of questionable value relative to placebo or no treatment. Depending upon the etiology of the pain generator in question, numerous non-pharmacologic medical and psychological approaches may be considered in the management of pain conditions including use of physical agents and modalities, injection therapies, exercise, biofeedback, adaptive equipment and/or psychological interventions. These treatment modalities should all be given adequate consideration in conjunction with possible pharmacologic alternatives if physicians are to develop adequate functionally oriented treatment regimens for addressing chronic pain issues in persons with TBI. Readers are referred to chapter 39 for details regarding the behavioral and psychological management of pain following TBI.

### **Physical Modalities**

Physical agents utilized to modulate pain may include superficial heat and cold. The most common modalities used are hot/cold packs, heat lamps (incandescent or infrared), paraffin baths and cryotherapy. Hydrotherapy interventions for pain management may involve prescription of whirlpool or contrast baths. Various diathermy techniques may also be utilized to facilitate pain control including ultrasound, phonophoresis, as well as, short-wave and microwave diathermy. There are also a number of electrical stimulation techniques utilized in pain management such as transcutaneous electrical stimulation (TENS) and iontophoresis that are commonly employed as adjuvants for pain control. Although historically used for chronic pain modulation, a recent Cochrane (68) review examining the efficacy of TENS in the aforementioned application found inconclusive results with published trials not providing information on the stimulation parameters most likely to provide optimum

pain relief, nor the effectiveness of long term treatment. A more recent study (69) found that evidence was lacking, limited or conflicting for efficacy in mechanical neck disorder management for electrotherapy interventions including PEMF (pulsed electromagnetic field) therapy, galvanic current, iontophoresis, TENS, diadynamic current, and electrical muscle stimulation. Cranial Electrical Stimulation (CES) is a treatment for pain reduction that, unlike TENS, targets central nervous system function. The technique involves attachment of electrodes carrying microcurrent across the scalp and induces an approximate 15Hz cortical rhythm. Many controlled studies support that it is a safe and useful treatment for pain, especially chronic pain and its associated symptomatology of anxiety, depression and insomnia (70).

Physical modalities tend to play a more predominant role in the treatment of pain complaints of musculoskeletal origin and may include traction, manual medicine techniques (e.g. joint manipulation, myofascial release techniques and strain counter-strain), as well as, massage (71). Body-work techniques and bioenergetics, although not well studied aside from acupuncture, are two additional classes of intervention that may also be used as adjuncts in chronic pain management (e.g. Reiki, Alexander, Trager and meridian, acupuncture, polarity, respectively). Injection techniques including intra-articular, peri-articular, peritendinous, ligamentous/fibrous tissue (i.e. prolotherapy) and trigger point can all be used in various types of musculoskeletal pain disorders (72). Axial injections such as epidurals, zygapophyseal joint, and sympathetic blocks may all be relevant considerations for pain treatment in this population, depending on the presumptive pain generators.

Exercise, is an underappreciated and therefore under-prescribed treatment intervention in persons post-TBI or for that matter many other patients with pain complaints. Exercise can play a significant role in controlling pain both on a central and peripheral basis improving deconditioning that may be resulting in nociception and concurrently improving weight control, affect, and general state of health and well-being (73, 74). Exercise has also been shown to elevate beta endorphin levels as much as five times that of resting levels (75). Additionally, recent information strongly supports the argument that exercise results in up-regulation of brain-derived neurotrophic factor (BDNF) and therefore may play a role in promoting neural repair and enhance learning and memory by increasing neurotrophic support (76). Of course, the benefits of exercise are dependent upon the patient taking an active involvement in rehabilitation.

Adaptive equipment such as reachers, sock aides, long handled scrubbers and/or brushes, as well as, ergonomically modified task analyses for ADLs, mobility and work environments are a few of the many different interventions that may also facilitate greater pain modulation and

tolerance. Appropriate education regarding pacing and energy conservation techniques may also add to further improvement in functional status depending upon the type of chronic pain condition being treated.

## **SPECIAL TOPICS IN PAIN MANAGEMENT IN PERSONS WITH TBI**

### **Post-Traumatic Headache**

#### *Background Information*

Headache (e.g. cephalalgia) is the most common physical complaint reported after mild brain injury/concussion and cranial (i.e. head) trauma. Headache is also very frequently associated with cervical injuries and post-traumatic cervicalgia. Historically, head pain or headache was believed to be reported far less commonly in more severe injuries (77). More recent research suggests that even persons status post moderate to severe traumatic brain injury suffer from acute headache symptoms, most often on a daily basis and in a frontal location and tended to improve with time with recovery generally leveling off by 6 months post-injury (78). The general experience, however, continues to indicate a trend towards greater levels of subjective complaints of headache among those individuals with milder brain injuries as opposed to more severe ones. Zasler (79) has speculated that the primary cause for such headaches is in fact related to cervical injury and that early treatment rendered to persons with more severe TBI, such as chemical paralysis and protracted bedrest, may actually be therapeutically, albeit inadvertently, prophylaxing against the development of PTHA.

Post-traumatic headache and in particular post-concussive headaches seldom connote serious underlying neurological problems. Clinicians should be aware, however, of various significant clinical conditions that may be responsible for PTHA and therefore should always appropriately consider the differential diagnosis of this condition including late intracranial, extra-axial hematomas, tension pneumocephalus due to dural leaks, communicating hydrocephalus, ventriculoperitoneal shunt malfunction resulting in low or high pressure headaches, post-traumatic epilepsy (whether convulsive or non-convulsive) and carotid-cavernous fistulas (80).

There continue to be significant disparities in classification and nomenclature regarding post-traumatic headache (PTH), often because these are arbitrary and not predicated on physiology or established time courses for symptom manifestation (79). The etiology, course, pathophysiology and treatment remain poorly understood (81). The International Headache Society published their revised classification system in 2004 (82). As per the revised classification, there are two broad categories of

headache including acute PTHA and chronic PTHA. Acute PTHA is further divided into headache associated with moderate to severe (5.1.1) and that associated with mild head injury (5.1.2). Chronic PTHA is divided into the following sub-classifications: chronic headache due to moderate to severe head injury (5.2.1) and chronic headache due to mild head injury (5.2.2). There are many consternations regarding this classification and more importantly the specifics of the criteria including onset time, duration of headache, misuse of the modifier “chronic” (which typically is used to modify pain when pain duration is six months or greater), causation criteria, use of “head injury” as opposed to “brain injury”, among other problems. It should be noted that there are further classifications for: acute, as well as, chronic headache attributed to whiplash injury, headache due to traumatic intracranial hematoma, headache associated with other head and/or neck injury, as well as, post-craniotomy headache. Interestingly, there are no specific headache classifications for post-trauma migraine, tension headache or neuritic/neuralgic headache (82).

Potential sources of head pain that may be relevant in the assessment of a patient presenting with post-traumatic headache include the dura, venous sinuses, cranial cavities including sinuses, eye socket, ear, nasal and oral pharynx. The skin, nerves, muscles and periosteum of the cranium are all pain sensitive. Cervical/cranial joint capsules (including the temporomandibular joint), cervical facets/zygapophyseal joints and the cervical sympathetic plexus may all be primary nociceptive pain generators that produce local or referred head pain (83, 84). One of the most common, yet often overlooked, sources of head pain is referred cervical myofascial pain emanating from any of the four layers of posterior cervical musculature secondary to cervical acceleration deceleration injuries generally associated with the traumatic events that caused the brain injury in the first place (85, 86) (see Figures 38-6-9).

**Clinical Evaluation of Post-traumatic headache**

The distinction between various types of post-traumatic headache has become somewhat blurred in the majority of the scientific literature. Defining variables used in various studies may actually overlap headache subtypes. Furthermore, as discussed above, the presence of primary and

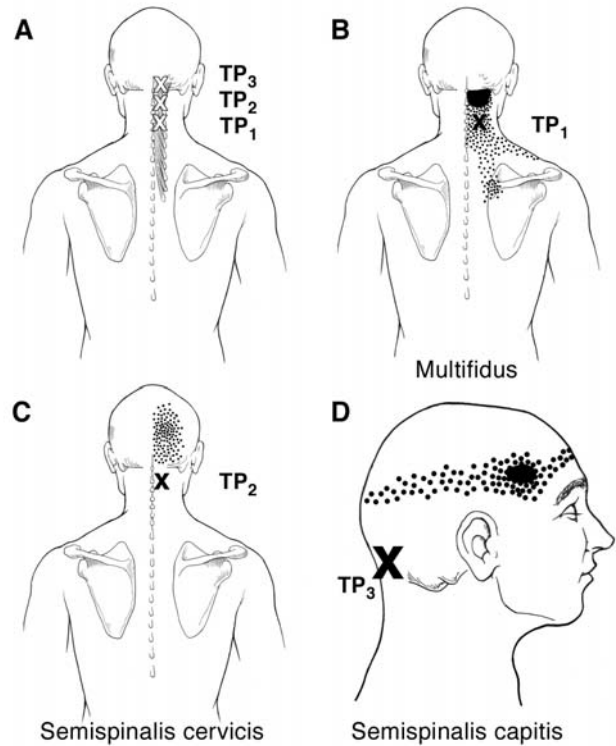

FIGURE 38-7

Posterior cervical muscles prone to development of trigger points producing referred pain perceived as cervicalgia and/or cephalgia

FIGURE 38-6

Sub-occipital muscle trigger points

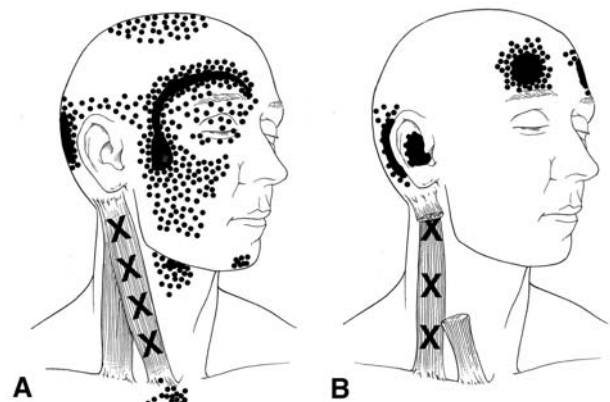

FIGURE 38-8

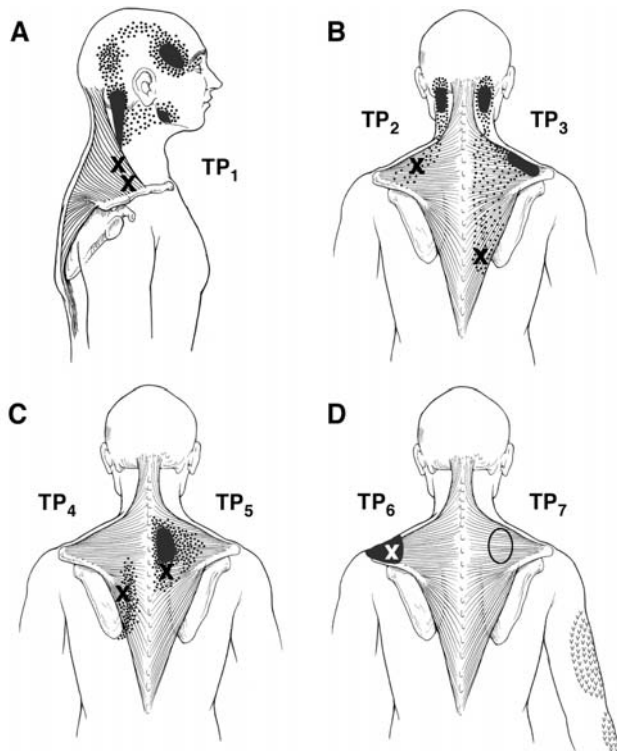

FIGURE 38-9

Trapezius muscle trigger point referral patterns

secondary peripheral sensitization, along with windup and central sensitization, along with the concepts of resulting expanded receptive fields and “convergence-projection” may make the identification of the original nociceptive generator quite difficult. This may indeed be moot, since it may be beneficial to treat both the primary pain generator and the secondary/concurrent pain generators in order to reduce the disabling consequences of post-traumatic headache. It remains important, however, to identify likely sources of pain (primary and secondary) in order to treat them. Readers interested in PTHA should consult more comprehensive treatises for a more complete overview (79, 81).

Historical information regarding mechanism of injury can help distinguish types of headache. The physical forces involved in post-traumatic headache include impact and/or acceleration/deceleration (inertial) loading; the latter typically involves “whiplash” type injury to the neck. In more generalized post-traumatic headache, surgical intervention provides yet another “external physical force” that may produce head pain.

On review of systems, it is useful to use the acronym “COLDER”; Character: dull, throbbing, lancinating, sharp, etc.; Onset: any precipitants, relationship to menses, time of day, temporal relationship to injury; Location: Unilateral, bilateral, occipital, radiating, frontal, bitemporal, etc.; Duration: length of headache

episodes; Exacerbation: stooping, valsalva, bending, touch, stress, poor sleep, menses, weather changes, etc.; Relief: Medications that work, modalities that help, sleep, etc. Other questions that should be asked include the severity of the headache (where 0 is none and 10 is the worst imaginable), frequency of the headache, associated symptoms (nausea, vomiting, photophobia, and/or phonophobia), presence of an aura, as well as the degree of functional disability associated with headache episodes including their vocational impact (e.g. how many days of work missed per month) (84, 80).

The physical examination should include observation (for traumatic changes, asymmetries and general posture), neurological examination, cervical ROM, palpation of cervical and cranial musculature, palpation of GON and LON egress points, provocative movements, ocular examination and auscultation for carotid, mastoid, temporal and ocular bruits. Although an in-depth discussion of myofascial pain is beyond the scope of this chapter, the reader is referred to other more extensive resources (84, 85, 87). Myofascial pain is very common in the sternocleidomastoids and trapezius after whiplash or inertial injury. It is interesting to note that the zone of referred pain for the sternocleidomastoid extends to retro-orbital and periorbital areas; associated “autonomic” symptoms include vertigo, tinnitus, and a sense of fullness in the ear, as well as, ear pain (commonly confused for otitis externa). These symptoms may be explained by convergence projection theory in that there is overlap in the sensory dermatomes for the SCM and the trigeminal tract as discussed above. The cervical musculature is also a major source of afferents to the vestibular systems integrating eye, head and neck movement, thereby making dizziness a common complaint in this patient population (so called cervical vertigo). The zone of referred pain to the ear overlaps the sensory area for the vagus; theoretically, peripheral sensitization in the SCM could lead to central sensitization within the vestibular and possibly vagal systems (80) (See Figures 38-6–9).

### Common Clinical Subtypes and Features of Post-Traumatic Headache

#### *Musculoskeletal Headache*

Musculoskeletal headache is classically characterized as a cap-like discomfort, but varies with the offending musculature. The sternocleidomastoid is notorious for referring pain retro or peri-orbitally. The pain may be constant or intermittent, relieved by application of heat, cold, massage and many over the counter medications including NSAIDs. There may be autonomic components to specific muscles. TMJ or craniomandibular syndrome may be considered a variant of musculoskeletal or tension headache and is almost always seen in conjunction with

direct trauma to the craniomandibular complex when traumatic in origin. This type of headache is also frequently overlooked as a primary or contributory cause for PTH (88). In TMJ, clicking, popping or malocclusion of the jaw may be noticed (89). Other etiologies of TMJD must be assessed for that may have little to nothing to do with the traumatic injury in question, whether in relation to stress or tension, dental malocclusion, and/or prior psychosexual abuse.

Many of the patients with musculoskeletal headache have as a primary or secondary component, myofascial pain. The therapeutic targets are pain relief, stretch to normal length (establish normal range of motion), and then strengthening of the involved musculature. Efforts to correct postural or skeletal problems, as well as, disordered sleep cycles, should be undertaken as well. Pharmacological interventions for myofascial pain include NSAIDs, TCAs and possibly muscle relaxants. TCA's, particularly amitriptyline, may help with disordered sleep. "Muscle relaxants" have no proven efficacy, although some resemble TCA's in their chemical structure and clinical effect. Anti-spasticity drugs are seldom used, although tizanidine may have some theoretical benefit over other traditional anti-spasticity agents due both to selectivity and anti-nociceptive properties. The hallmark of treatment of myofascial pain has been the treatment of trigger points, as well as, promulgating factors (90). These may be approached with acupressure or dry needling, but most practitioners use injections of local anaesthetic, followed by stretch of the involved muscle group and/or physical interventions directed at "myofascial release" techniques (91). Recently, the use of botulinum toxin (off label) has been advocated for modulation of chronic myofascial pain (92). Theoretically, this should allow for increased ability to stretch the muscle, but may impede later phases of treatment related to strengthening. Non-pharmacologic treatment of myofascial pain involves the use of modalities and therapy. Various heating modalities are well tolerated by most patients, and allow for muscle relaxation for therapeutic stretch. Some patients respond well to cooling with fluorimethane spray for the same purposes. Patients should be taught a home program of stretching, and then a gradual strengthening program. Current literature does not strongly support the use of physical treatments per se in the management of headache disorders (93).

Within the broad category of musculoskeletal headache, other etiologies beyond the almost omnipresent myofascial pain include cranio-mandibular syndrome, cervical zygapophyseal joint disorders (see section below on cervicogenic headache), and "cranial and somatic dysfunction." In craniomandibular disorder, there may be internal derangement of the temporomandibular joint and almost always a myofascial component related to muscles of mastication (temporalis, pterygoids, or masseter). These

muscular problems should be treated as described above. Often intervention is supplemented by the use of intra-oral appliances such as occlusal splints (bite blocks), dietary changes relative to softer food consistency and jaw exercises. Non-surgical treatment is effective in managing more than 80% of patients with craniomandibular disorders (94). In the case of joint pathology, which may be identified with MRI, arthroscopic intervention is indicated. Open arthrotomy or arthroplasty is rarely needed, and often associated with suboptimal outcomes.

### *Cervicogenic Headache*

Cervicogenic headaches may be related to dysfunction of the facet joints. Others have hypothesized that chronic pain following cervical acceleration-deceleration type injuries may be due to central sensitization (95).

Preliminary diagnostic criteria were developed in 1987 and were consolidated into a formal statement in 1990. Obligatory for the diagnosis were unilateral head pain without side-shift and symptoms or signs of cervical involvement, the latter which could include provocation of pain by neck movement or by external pressure to the upper posterior neck, concurrent cervicgia or reduced cervical range of motion. Subsequent, Sjaastad et al. (96) further amended the criteria by moving the cervical involvement to the first major criteria and relaxing the criterion for unilaterality to the point of even accepting bilateral occurrence. Emphasis to date has been on the nosologic validity of the criteria and no studies have established that patients who meet the diagnostic criteria actually have a cervical source for their pain (97). The IHS criteria of 2004 further refined the diagnostic criteria for cervicogenic headache and included a parameter noting that pain would resolve within three months after successful treatment of the causative disorder or lesion. Most patients present with unilateral (albeit sometimes bilateral) sub-occipital pain as well as secondary oculo-frontotemporal discomfort/pain.

Dysfunction of the cervical zygapophyseal joints, particularly at C2 and C3 may refer pain to the head (see Figure 38-10). Treatment considerations include injection of local anaesthetic intra-articularly, or block of the medial branches of the dorsal rami supplying the joint. At a more subtle level is the concept, which remains somewhat controversial from an allopathic perspective, of cranial and cervical somatic dysfunction. These disorders are typically treated with osteopathic techniques designed to re-align dysfunctional units. Cervical mobilization and manipulation may be effective in the treatment of chronic headaches (98). Various techniques may be used, but caution should be exercised with high velocity procedures due to risk of cervical fracture and/or vertebral artery damage, the latter which is generally avoided by avoiding mobilization in extension.

**FIGURE 38-10**

Cervical sensory dermatomes for sensory roots C2-6

Cervicogenic headache is quite common following trauma (99). Some have argued that it is likely the most common etiology of post-traumatic headache (100, 101). Numerous treatments have been assessed, most with sub-optimal study methodologies (102). The studies suggest that in appropriate cases manual therapy (103), exercise and blocks (diagnostic as well as therapeutic) may play important roles in modulating cervicogenic headache pain (97).

#### *Neuritic and Neuralgic Head Pain*

Neuritic scalp pain may occur from local blunt trauma, surgical scalp incision or penetrating scalp injuries. Occasionally, neuromatous lesions may form after scalp nerve injury and serve as a pain nidus. Pain complaints may vary from only report dysesthetic “numbness” discomfort on touching to lacinating type pain that spontaneously occurs without provocative measures. Neuralgic pain may occur secondary to occipital neuralgia (greater and/or lesser), supra-orbital and/or infra-orbital as the most common clinical post-traumatic cephalic and/or facial neuralgias seen in clinical practice although certainly other post-traumatic neuralgias/neuropathies may be observed (104).

Occipital neuralgia (ON) may occur following cervical acceleration deceleration type injuries, as well as, direct trauma to the craniocervical junction. ON may be perpetuated by contraction or myodystonia of the splenius muscle, which it penetrates. Pain is typically felt at the craniocervical junction and the sensory distribution of the nerve (e.g. C2). The affected nerve is tender to palpation and palpation generally replicates the pain associated with the headache (e.g. stabbing quality). There is frequently referral of pain into the ipsilateral frontotemporal scalp

**FIGURE 38-11**

Anatomy of upper posterior cervical region with specific reference to C2 terminal branches of the lesser and greater occipital nerves

and less frequently retro-orbitally (also ipsilaterally) secondary to ephaptic transmission between the proximal part of the C2 origin of the nerve and the ophthalmic branch of the fifth cranial nerve (86).

Whether the etiology is local neuroma formation in scar tissue in the scalp, or greater or lesser occipital neuralgia, the systemic pharmacological interventions are essentially the same and include NSAID's, TCA, and anti-convulsants, particularly, gabapentin. Injection of local anaesthetic with or without steroid may also be indicated for both diagnostic and therapeutic purposes for neuritic and neuralgic pain disorders. For greater and lesser occipital neuralgia, in particular, clinicians should be familiar with the anatomy of the region given risks of aberrantly placed injections (see Figure 38-11). In either situation, myofascial pain may be a secondary or perpetuating pain generator and must be treated as well on a concurrent basis. Rarely, surgical decompression or nerve lysis (surgical, cryotherapy) is necessary for these types of neuropathic cephalalgias.

#### *Post-Traumatic Migraine*

Post-traumatic migraine (PTM) or neurovascular headache is more common than originally thought although its true incidence is poorly defined in the available scientific literature. Patients with PTM may have a genetic predisposition to development of migraine following trauma to either the head/brain and/or neck (105).

There is inadequate information to stipulate how acute PTM may differ mechanistically and otherwise from chronic PTM.

PTM is most likely to be described as throbbing. Vascular headache is usually unilateral and is exacerbated by coughing, bending over; cold may help, but heat usually makes the pain worse. There may be associated nausea, vomiting, or anorexia. Hemicranial allodynia may occur after central sensitization takes place.

The aim of treatment of migraine or neurovascular headache is to prevent or reduce the frequency of the onset of headache (prophylactic treatment) and/or to abort a headache rapidly should it occur (as well as sustain the headache relief once aborted). The precise trigger for migraine or vascular headache remains obscure and controversial; this is especially true in relation to post-traumatic vascular headache. What is clear is that the trigeminal afferent system becomes sensitized by a sterile inflammatory “soup” that includes excitatory neurotransmitters, nitric oxide, histamine, prostaglandin E<sub>2</sub>; this sensitization then produces vasodilatation of extracerebral vessels, including those in the meninges, and accentuates the inflammatory response. The pounding headache of migraine appears to originate from dilatation of large cranial vessels innervated by the trigemino-vascular system and the associated release of CGRP, substance P and neurokinin A from trigeminal neurons; sensitized trigeminal afferents may provide nociceptive input from simple mechanical stimulation of the dilated vessels, akin to a vascular allodynia. Triptans block the release of CGRP at 5HT<sub>1B</sub> and D receptors. However, stimulation of 5HT<sub>2B</sub> receptors promote migraine; TCA’s may block these receptors (106). Second order neurons in the brainstem are sensitized; the periaqueductal gray seems particularly vulnerable in migraine (13).

Prophylactic migraine medications include some NSAIDs, beta-blockers, calcium channel blockers, TCA’s and depakote as more traditional treatments. Naturopathic agents such as butterbar and feverfew can also be considered as can nutritional therapies such as B complex vitamins and magnesium supplementation. Abortive medications may include ergot derivatives, dihydroergotamine derivatives, triptans, parenteral atypical antipsychotics (107) and/or narcotics, among other drugs. However, triptans, as a class, may be ineffective if their use is delayed and allodynia develops (10). Many of the drugs were used for their vasoconstrictive properties (ergot derivatives) even though extra-cerebral vasodilation is a secondary phenomenon in migraine; they have significant systemic or cardiac side effects; If patients experience chronic daily headache and use abortive analgesics, they are at risk for developing rebound or medication overuse headache. Stimulation of various analgesic receptors in the brainstem affects 5HT. Short term use (including acetaminophen) increases 5HT release from raphe spinal

FIGURE 38-12

Schematic representation of interconnectivity between the spinal nucleus and tract of cranial nerve V, upper three cervical roots and the ophthalmic branch of the fifth cranial nerve through the gasserian ganglion

pathways, and has a therapeutic effect. However, long term use may lead to 5HT depletion and up-regulation of 5HT<sub>2A</sub> receptors particularly. Whereas stimulation of 5HT<sub>1b</sub> and 1D receptors aborts acute migraine (e.g. triptans), 5HT<sub>2A</sub> stimulation increases neuronal excitability and potentiates nociceptive transmission. The increased density of 5HT<sub>2A</sub> receptors could lead to an “excitable brain,” a hyperalgesic state, with increased headache frequency and severity. It also undercuts the antagonism of 5HT<sub>2</sub> which is a common mechanism underlying preventative medications in migraine management (22). Caffeine over-use may also contribute to patients becoming refractory to abortive medications containing this substance.

Again, due to central overlap of primary nociceptive afferents involved in true vascular headache and those related to cervical sensory nerves, the patient may present with a combination of vascular, neuralgic, and/or musculoskeletal headache, all of which may require treatment. Cervical nociceptive input may also promulgate migraine through the trigeminocervical complex (108) and therefore must be addressed as part and parcel of comprehensive migraine assessment and treatment (23) (see Figure 38-12).

Botulinum toxin has also been used (off label) to treat migraine headache (109). Botulinum toxin may

exert this effect not only through muscle relaxation but through inhibiting release of sensitizing neurotransmitters such as glutamate and substance P. Current research with botulinum toxin seems to be focusing on specific headache sub-types, specifically, chronic daily headache (110) and not trigeminovascular type headache disorders.

### *Post-Traumatic Tension Headache*

Tension-type headache (TTHA) is one of the most common primary headache disorders and like many other headache conditions can be considered a spectrum disorder. Per ICDH-2 criteria 2.1 to 2.4 diagnostic categories for TTHA include: infrequent episodic TTHA, frequent episodic TTHA, chronic TTHA and probable TTHA (111).

Advances in basic pain and clinical research have improved the understanding of the pathophysiologic mechanisms of tension-type headache. Increased excitability of the central nervous system generated by repetitive and sustained pericranial myofascial input may be responsible for the transformation of episodic tension-type headache into the chronic form. Studies of nitric oxide (NO) mechanisms suggest that NO may play a key role in the pathophysiology of tension-type headache and that the anti-nociceptive effect of nitric oxide synthase inhibitors may become a novel principle in the future treatment of chronic headache (112). It should be noted, however, that other neurochemicals including calcitonin gene-related peptide (CGRP), serotonin, substance P, neuropeptide Y and vasoactive intestinal peptide (VIP) have all been in either episodic and/or chronic TTHA (111).

The mechanisms by which trauma, either to the neck, cranium or cranial adnexal structures or the brain itself may trigger tension type headaches are poorly understood. TTHA may result from an interaction between changes in the descending control of second order trigeminal brain stem nociceptors and interrelated peripheral changes, such as myofascial mediated pain and/or pericranial muscles nociceptive afferent input. Clearly, stress and negative emotional states (mediated through limbic circuitry) may trigger such headaches through central mechanisms; what role TBI itself has in potentially triggering such headaches in susceptible individuals is less clear. With more frequent episodes of headache, central changes have been theorized to become increasingly more important. With greater duration, long term sensitization of nociceptive neurons and decreased activity in the anti-nociceptive system gradually leads to chronic TTHA. Current consensus is that peripheral mechanisms are most likely involved in episodic TTHA and central mechanisms play a more important role in chronic TTHA. There is still debate as to whether the pain in TTHA originates from peripheral (e.g. myofascial) versus central origins.

Treatment of TTHA should include pharmacotherapy, both acute and prophylactic, as well as, non-pharmacologic approaches (111). The mainstay of acute pharmacotherapy are NSAIDs sometimes in conjunction with caffeine, sedatives and/or tranquilizers. Adequate doses of NSAIDs must be utilized prior to labeling a trial as a failure. There is no scientific evidence to support the use of traditional muscle relaxants in TTHA. Prophylactic pharmacotherapy for TTHA is much more diversified with various drug classes being utilized including tricyclic antidepressants, tizanidine, botulinum toxin and certain SNRIs such as venlafaxine (113). Nitric oxide synthase inhibitors may also hold therapeutic promise (114). Non-pharmacological treatments may include relaxation therapy as well as EMG biofeedback, cognitive behavioral therapies including stress management, limited contact treatment, physical therapy when apropos, and lastly, oromandibular treatment in selected patients.

### *Rare Post-Traumatic Headache Subtypes: Dysautonomic Headache, Cluster and Paroxysmal Hemicrania*

Various dysautonomic headaches have been reported and although rare should be considered in the differential diagnostic work-up of a patient with PTHA. Clues to a dysautonomic source of headache pain include a unilateral episodic throbbing pain and hyperactive sympathetics involving the ipsilateral face during the attack (miosis, sweating) but between attacks, a mild Horner's syndrome (115). Trigeminal autonomic headaches have also been reported (116). Post-traumatic cluster headache and paroxysmal hemicrania are relatively rare types of post-traumatic headache (117, 118). It should be noted, however, that with less common headache variants there is always a question about the causal relationship of the injury to the headache onset and promulgation. The literature is scant in proving a causal link between trauma and these headache sub-types.

### *Analgesic Rebound Headache*

Analgesic rebound headache may be seen from overuse of a variety of analgesic and/or abortive headache agents including ergotamines, opiates, caffeine, triptans and/or barbiturates (119). Overuse of these medications may lead to development of chronic daily headache (CDH). Patients may become dependent on these symptomatic headache medications. Drug withdrawal normally results in worsening of headache this is particularly noted when medication is stopped suddenly as opposed to being slowly weaned with concurrent alternative headache management options prescribed. Headache medication overuse may also make headaches refractory to prophylactic headache medication (120).

### *Post-Traumatic Sinus Headache*

Sinus headaches, which may be post-traumatic or unrelated (or both), may be steady or have a throbbing quality. They may be seasonal or associated with allergic symptoms. A history of sinus or facial fractures is relevant. The daily pattern of sinus headaches relates to drainage angles: frontal and ethmoid are often worse with recumbency at night and better during the day when upright, whereas, maxillary and sphenoid sinus headache improves with recumbency at night.

### **Neuropathic Pain**

Neuropathic pain is defined as a chronic pain condition that occurs or persists after a primary lesion or dysfunction of the peripheral or central nervous system. Traumatic injury of peripheral nerves also increases the excitability of nociceptors in and around nerve trunks and involves components released from nerve terminals (neurogenic inflammation) and immunological and vascular components from cells resident within or recruited into the affected area. Action potentials generated in nociceptors and injured nerve fibers release excitatory neurotransmitters at their synaptic terminals such as L-glutamate and substance P and trigger cellular events in the central nervous system that extend over different time frames.

Neuropathic pain has been shown to be mediated by both peripheral and central nervous system phenomena. In the peripheral nervous system mechanisms that have been posited to be involved with neuropathic pain include, but are not necessarily limited to, spontaneous ectopic discharges, neuroimmune factors such as inflammatory cytokines and sympathetic sensory coupling. Central nervous system mechanisms that are theorized to be involved with neuropathic pain include central sensitization, disinhibition, as well as, astrocyte and microglia activation (121).

Short-term alterations of neuronal excitability, reflected for example in rapid changes of neuronal discharge activity, are sensitive to conventional analgesics, and do not commonly involve alterations in activity-dependent gene expression. Novel compounds and new regimens for drug treatment to influence activity-dependent long-term changes in pain transducing and suppressive systems (pain matrix) are emerging. At present, therapeutic options are largely limited to drugs approved for other conditions, including anticonvulsants (carbamazepine, gabapentin, pregabalin), antidepressants (TCAs, venlafaxine, duloxetine), antiarrhythmics (e.g. mexiletine), tramadol and opioid analgesics. However, treatment based on the underlying disease state may be less than optimal, in that two patients with the same neuropathic pain syndrome may have different symptomologies and thus respond differently to the same treatment. Increases

in our understanding of the function of the neurologic system over the last few years have led to new insights into the mechanisms underlying pain symptoms, especially chronic neuropathic pain.

Neurosurgical options may need to be considered when enteral pharmacotherapeutic options fail or produce sub-optimal pain control. Surgical options include modulative techniques, such as neurostimulation or implanted drug delivery systems, and ablative procedures such as DREZotomies (122).

### **Central Pain Syndromes**

Central pain is defined as “pain associated with lesions of the central nervous system.” People with TBI may experience central pain akin to that recognized as post-stroke pain, but may also have associated spinal cord injury with spinal pain. Sixty to seventy percent of patients with SCI have pain that is often chronic in nature (123). Diffuse pain below the level of the lesion may be due to involvement of the posterior spinal tracts, there may be a band-like pain at the transitional zone, or in pain developing late after injury, the source may be a syrinx (124).

Evident from the discussion of the anatomy and neurochemistry of nociceptive transmission, multiple systems contribute to the development of central pain. It is prudent to be cautious in medication and other treatment choices, given the overlap in plasticity mechanisms subserving central sensitization and more positive dynamic neurological functions such as learning, memory and motor recovery. However, it would also be clinically appropriate to consider combinations of medications with different mechanisms of action (whether in the same or different “class” of drug) in an effort to effectively treat the pain syndromes after TBI.

Brain-related central pain develops in about 8% of stroke patients, although its incidence and prevalence following TBI are unclear. It is classically seen with lesions of the thalamus, particularly the ventrocaudal nuclei. Changes in thalamocortical processing may include loss of inhibition or sensitization. Allodynia and dysesthesias, sometimes involving the entire hemispheres are hallmarks of brain-related pain. Central pain syndromes have often been very challenging for both the treating physician and the suffering patient.

Intravenous morphine and intravenous lidocaine may be effective for treatment. Enteral opioid pain medications may be effective but are sometimes poorly tolerated on a chronic treatment basis. Similarly, oral mexiletine does not seem to be as effective as its IV counterpart, lidocaine (125, 126). Tricyclic antidepressants have been used for decades, but caution must be observed in those over 65 because of anticholinergic side effects (127). Anticonvulsants have also been used; there appears to be some effectiveness with lamotrigine in doses of

200–400 mg/day for both brain and spinal cord pain (128). Gabapentin may also be effective (129), but topiramate does not seem to have clinical benefit (130).

Non-pharmacological interventions have also demonstrated benefit in some patients who are refractory to pharmacologic management. Such interventions have included transection of spinal nerves or cordotomy (although 60–80% of patients may have recurrence of pain after 2 years), spinal cord or deep brain stimulation, which appears to enhance GABA transmission (124).

### Complex Regional Pain Syndrome (CRPS)

CRPS remains a much debated clinical condition with perhaps as much misinformation as information (131). The latest research developments suggest that this condition is multidimensional with neuropathic, nociceptive and inflammatory components with associated sympathetic system dysfunction. Current consensus opinion also indicates that CRPS is likely associated with central sensitization phenomena as well as motor abnormalities. Treatments that have been shown to be efficacious include a gamut of physical interventions, pharmacotherapeutic measures, and interventional treatments. Research has suggested that interdisciplinary programs emphasizing functional restoration may offer the optimal treatment paradigm. As noted by Harden (132), “Functional restoration should provide different interventional and non-interventional modalities in a timely manner to facilitate reanimation and normalization of use and movement of the affected limb”. Pharmacotherapeutic interventions for pain can be considered as either “maintenance” or “rescue/abortive” and include such diverse drug classes as tricyclic antidepressants, opioids, anticonvulsants, NSAIDs, clonidine, nifedipine, alpha-adrenergic antagonists (e.g. phenoxybenzamine and phentolamine), bisphosphonates, calcitonin, among the most well studied (132). Interventional treatments that have shown benefit include both sympathetic and epidural blocks.

### Conclusion

Pain clearly is a complex clinical phenomena (133, 134). Treatment of post-traumatic pain conditions is even more multidimensional, whether in the acute or chronic phase post-injury. Judicious use of medical interventions must rely not only on sound medical knowledge that remains up to date with current accepted practice but also on keen observational, interview and examination skills. A sound familiarity with the post-traumatic pain literature, as well as, the myriad conditions that can be seen following multi-trauma and/or traumatic brain injury (135) is paramount to recognizing these clinical conditions when they present themselves. As was once said by Goethe, “We see what we look for, we look for what we know”.

## Psychological Approaches to Comprehensive Pain Assessment and Management Following TBI

*Michael F. Martelli*  
*Keith Nicholson*  
*Nathan D. Zasler*

### INTRODUCTION

The purpose of this chapter is to help illustrate the important components and increase awareness and understanding of psychological approaches to assessment and management of pain in persons with TBI. This illustration is intended to assist with the making of appropriate referrals, and promoting effective carryover and integration of pain management principles into care of persons with concomitant TBI. It is not intended as a substitute for the necessary training and experience that is prerequisite to providing effective assessment and treatment of pain in persons with TBI.

#### **A Brief Overview of Pain: An Informed Conceptualization**

Pain is defined by the International Association for the Study of Pain (1) as a “psychological state” characterized by “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.” An important distinction, with associated differences in definition, pathophysiology, phenomenological experience, plus assessment and treatment focus, relates to chronicity. Acute pain, usually occurring in response to identifiable tissue damage or a noxious event, has more clearly identifiable triggers and neuroanatomical pathways, and

communicates useful information that provokes adaptive responses. It has a time-limited course during which treatment is aimed at providing relief as well as promoting resolution or correction of underlying pathophysiological processes.

As time passes without resolution of an acute pain problem, subjective components may become more pronounced, identifiable triggers and neuroanatomic pathways can become obscure, and behavioral responses can become more disproportionate to underlying pathophysiology and even obstructive to resolution and adaptation. Chronic pain, simply defined as pain persisting beyond six months, may or may not be associated with any obvious tissue damage or pathological process, but can disrupt virtually all life areas and produce marked emotional and behavioral changes. Frequent concomitants of chronic pain include: maladaptive protective responses or pain behaviors; protracted courses of medication use and minimally effective or even iatrogenic medical services; and marked behavioral or emotional changes, including restrictions in daily activities. Pain related avoidance behaviors and reduced activity are likely to result in a cyclic disability-enhancing pattern. The longer pain persists, the more recalcitrant it becomes and the more treatment goals focus on improved coping with pain and its concomitants (2, 3). Finally, there is acceptance that persistent pain is often associated with peripheral or central sensitization effects in which hyper-responsiveness or

spontaneous discharge of components of the pain system develops (4, 5). Numerous functional imaging studies have begun to document the interaction of psychological and neurobiologic processes in chronic pain patients (6–13).

Pain is best conceptualized as a multidimensional subjective experience mediated by emotion, attitudes and other perceptual influences. Variability in pain responses is the rule rather than the exception and appears to reflect complex biopsychosocial interactions between genetic, developmental, cultural, environmental, and psychological and injury/illness related factors (14, 15). Important distinctions between pain and suffering (16), sensory and affective experience, and impairment and disability (17) (WHO) reflect the variability in response to pain problems. While some pain patients appear to present with unusual and possibly exaggerated suffering or disability, others present with a kind of “la belle indifférence” in which extremely high reported pain severity may be associated with no apparent affective distress, pain behavior or interference in many life activities. In some cases, the onset, maintenance, severity or exacerbation of pain is primarily associated with psychological factors and may warrant a DSM-IV (18) diagnosis of Pain Disorder Associated with Psychological Factors. In this regard, it has been noted that there is an association between post-traumatic stress reactions and development of chronic pain (19–22), with uncontrollable pain following physical injury potentially representing the core-trauma resulting in post-traumatic symptomatology (23). However, it is cautioned that one should avoid the pitfalls of mind-body dualism and always consider both psychological and organic factors in the presentation of any chronic pain patient (24).

It should be emphasized that pain may arise from a combination of numerous physical and psychological factors. Complexities in pain presentation warrant referral to pain management specialists and/or specialty interdisciplinary pain programs (25). This is particularly true in cases of “intractable” and functionally disabling pain. It is always best to intervene when “pre-chronic”, where competent, specialized, early intervention offers the greatest hope of facilitating adaptation.

The importance of assessing and managing pain has been incorporated into the prevailing standards of health-care practice in the United States. The Joint Commission on Accreditation of Healthcare Organizations (JCAHO), in its recent accreditation manuals, acknowledges that while pain coexists with a number of diseases and injuries, it requires explicit attention (JCAHO, 2000). Overall, the standards require organizations to: 1) recognize individual’s rights to appropriate pain assessment and management; 2) identify persons with pain in initial and ongoing assessments; and 3) educate patients, residents, clients and families about pain management.

### **Traumatic Brain Injury and Pain**

There is a very high comorbidity of chronic pain problems with cranial trauma whether or not there is traumatic brain injury (TBI). Indeed, headache is the primary complaint in virtually all surveys of the post-concussive syndrome (26). The frequency of post traumatic headache (PTH) in the immediate post-accident period has been estimated to be as high as 90%, with problems continuing beyond six months in as many as 44% (3), although there is generally poor understanding of the incidence, etiology or many other aspects of PTH (27).

In addition to headache, many other pain problems may follow trauma, including neck and back pain, complex regional pain syndrome, and fibromyalgia, among others. Curiously, most studies report that pain problems are much more common in less severe as compared with more severe TBI (3, 26, 28) although pain problems may also be common in the latter (29). Importantly, more severe brain injuries may result in reduced sensitivity to pain due to lesions of the CNS structures involved in processing pain, as observed in some dementias (4, 30). Those with more severe TBI may also enjoy optimal post traumatic healing due to reduced activity and extended rest periods (31). In contrast, it has also been suggested that there is increased likelihood for developing a central sensitization or neurosensitization effect (20, 26) after milder injuries, where there is not only no damage to CNS pain processing structures, but less time for healing and rest before return to usual activities with greater opportunity for psychophysiological arousal.

### **Traumatic Brain Injury, Pain, and Neuropsychological Function**

There is increasing awareness of the role that pain may play in symptom presentation following traumatic brain injury, especially with regard to cognitive complaints. Several recent reviews (3, 24, 26, 31–36) have examined literature objectively assessing these complaints. The available evidence strongly supports the conclusion that chronic pain, especially head pain and neck pain, and pain related symptomatology, independent of TBI or neurologic disorder, can and often do produce impairment of cognitive functioning. Multiple lines of evidence, including studies of acute and chronic pain, animal and human studies, experimental and clinical studies and neurophysiologic studies support this conclusion. A brief summary of the converging evidence that supports this conclusion, based on a review by (37) Dr. Martelli, is presented in Table 39-1. Notably, attentional capacity, processing speed, memory, and executive functions, as assessed on neuropsychological tests, are the cognitive domains most likely to be affected.

**TABLE 39-1**  
*Evidence of Negative Effects of Pain on Cognition in Animals and Humans*

1. Experimental animal and human information processing / attentional capacity literature indicates that distracters less aversive than pain disrupt attention, as does pain;
2. Experimental rodent and other mammalian studies showing pain related disrupted maze and other learning for both appetitive (e.g, food reward) and avoidant (eg, shock) stimuli;
3. Experimental rodent studies showing improved performance with cessation of pain;
4. Experimental rodent and other mammalian studies showing improved performance after administration of pain relieving medications known to disrupt cognition;
5. Experimental human studies showing improved cognitive performance after discontinuation of pain stimulus and/ or administration of psychoactive opioid pain relievers;
6. Animal studies showing that stress (including chronic pain) is associated with damage to the hippocampus, inhibition of neurogenesis, and deficits in hippocampal-based memory function;
7. PTSD findings of deficits in hippocampal-based declarative verbal memory associated with smaller hippocampal volume;
8. Recent preclinical evidence showing that selective serotonin reuptake inhibitor (SSRI) antidepressants promote neurogenesis, reverse effects of stress on hippocampal atrophy, improve cognitive deficits observed in OCD, depression, etc;
9. A majority of studies indicating pain cognitive interference effects, at least attention dysregulation, in chronic and acute pain patients. Study designs including experimental pain, neuropathic pain, neurophysiologic measures, combination neuropsychologic and neurophysiologic measures, and reward designs helped to bolster conclusions about interference effects despite failure of most studies to utilize explicit response bias detection measures for pain and cognition.
10. Consistent neurophysiologic studies showing very specific neurophysiologic (e.g. anterior cingulate cortex (ACC)) effects associated with chronic pain and attentional disruption, often co-existing with other patterns, consistent with other disorders also having reasonable evidence of cognitive impairments and neurophysiologic expressions (e.g., hypofrontality and depression);
11. Neural plasticity / cerebral reorganization associated with chronic pain showing functional cerebral changes (e.g. studies showing expansion of sensory cortex (e.g., Flor (11)));
12. Neuroendocrine and HPA perturbation in chronic pain and evidence that pain and chronic stress (and depression) are linked via chronic stress-induced HPA dysfunction (along with evidence of combined muscle energy depletion and serotonin deficiency (peripherally, but also centrally), along with depressed levels of somatomedin C, caused by deficit of stage 4 sleep dependent release of GH, and elevated NE response levels in fibromyalgia;
13. Amassing neurophysiologic evidence of central sensitization (38) and disrupted pain inhibitory mechanisms associated with dysfunctional ACC functioning of both anterior / ventral and posterior/ dorsal quadrants (associated with cognitive and affective regulation, respectively), plus evidence that less severe and less disruptive chronic pain is associated with a greater habituation response to painful stimuli (vs. sensitization) and not associated with cognitive disruption. The newest integration of these findings link a biopsychosocial model where genetics, learning history and psychological variables interact, with a clear role played by anxiety and avoidance conditioning to produce a pattern of pain arousal that mimics OCD, chronic or severe depression, PTSD or high trait anxiety, with hypoaroused inhibition (ACG hypofunction) of pain, obsessional thoughts, anxiety, somatic concerns, intrusive associations/ memories) and disrupted allocation of attentional resources;
14. Evidence that the concomitants of chronic pain alone may account for cognitive disruption; sleep disturbance / deprivation (e.g., metaanalytic studies showing impaired attention and psychomotor function, including greater impairment compared to alcohol intoxication; studies indicating significant trait-like interindividual variability in sleep deprivation effects that are stable within individuals); pain medications; depression and anxiety; and suggestion that combinations are additive;
15. Consistent findings showing both normalization of neuropathophysiology and cognitive function (for performance and self reported improvements in cognition) after effective pain reduction interventions.
16. Indications that chronic pain, as well as depression, are associated with structural cerebral changes. For example, chronic pain has been associated with decreased prefrontal and thalamic gray matter density compared with matched controls, suggesting that the pathophysiology of chronic pain includes thalamocortical processes.

Adapted from Martelli (37).

These reviews indicate that the concomitants of chronic pain may be as important or more important than pain itself in producing cognitive impairment. Specifically, cognitive impairment in chronic pain patients has been associated with mood change/emotional distress, somatic preoccupation and pain catastrophization, sleep disturbance, fatigue, and perceived interference with daily activities that are potential sources of chronic stress. For example, major depression is frequently found following mild TBI, is associated with higher postconcussion symptom endorsement, poor functional outcome, high distress levels, disability and cognitive impairment which typically remit after effective treatment for depression (39). In a metaanalytic review, (40) Pilcher and Huffcutt found that partial sleep deprivation impairs cognitive and motor performance. More interestingly, in a review of experimental human and animal studies, (41) Kundermann, Krieg, Schreiber and Lautenbacher found that sleep deprivation produces hyperalgesic changes and can counteract analgesic medication effects via disruption of both serotonergic and opioidergic processes.

Mahmood et al. (30) examined the previously observed association between sleep disturbance, cognitive and pain complaints and TBI (e.g., Beetar, Guilmette, Sparadeo, (42)). They noted that, while severe TBI is more likely to produce subcortical damage and reduce pain experience, mild TBI is associated with increased pain and sleep disturbance, and that sleep disturbance is associated with frontal hypoactivation that, especially when associated with depression, may render post TBI individual especially vulnerable to cognitive dysfunction. They observed that measures sensitive to executive functioning and information processing speed were associated with sleep quality scores. Consistent with these findings, Mooney et al.'s (39) review of poor recovery following mild TBI found that most of the variance in recovery of mild TBI compensation seekers seems to be explained by depression, pain and response bias versus brain injury variables.

Importantly, these associated factors have consistently been found to be more strongly associated with both cognitive complaints and impairments than is pain severity, although problems with the assessment of pain severity (e.g., response biases to report pain and the restricted range of measurements) may account for the relatively weak predictive power of pain severity ratings. Further, metaanalytic studies and increasing recent evidence have associated these individual factors with decrements in cognitive functioning, independent of chronic pain or combination effects (24, 26, 32–34, 36).

Hart, Wade & Martelli (34) reviewed studies of cognitive functioning in patients with chronic pain with an emphasis on the role of emotional distress and the mechanisms of stress-related effects. The association between psychological distress and cognitive impairment was found to be especially significant for pain-related

negative emotions and variables that mediate suffering, such as interference with activities and increased somatic vigilance. This relationship was independent of the effects of pain intensity. It was noted that the anterior cingulate cortex (ACC) plays an important role in pain processing, attention and affective-motivational experience, and that the ACC appears to mediate the impact of pain-related emotional distress on cognitive functioning through allocation of attentional resources. Further, maladaptive physiologic stress responses and dysregulation of the hypothalamic-pituitary-adrenocortical (HPA) axis can produce negative effects on hippocampal function and memory. The underlying mechanism for cognitive impairment that Hart et al. (34) postulated is the anticipation of unpredictable pain symptoms, especially in individuals high in trait neuroticism. This presents a significant stressor that repeatedly activates both the HPA axis and ACC areas and results in disruption of cognitive efficiency. Hart et al. (34) did not address what remains a potentially important research area, i.e., how these putative mechanisms might interact in cases of persons with brain injury where neurologic impairments and additional sources of stress are operative.

Clearly, chronic pain and associated problems can complicate the symptom picture in TBI. Especially in cases of persistent sequelae following mild TBI, increasing evidence suggests that chronic head and other pain and associated problems can present a differential diagnostic challenge, and contribute to or maintain symptoms. This evidence provides strong support for the argument that resolution of the post concussive syndrome and successful adaptation to residual sequelae frequently relies on successful coping with post traumatic pain and/or other pain and associated symptomatology. In addition, careful consideration of pain in the differential diagnosis of brain injury is required. Some recommended procedures for conducting neuropsychological assessment of persons when pain is a significant complaint have been included in Table 39-2.

## PAIN ASSESSMENT

Pain is a complex and subjective perceptual process comprised of behavioral, affective, cognitive, and sensory components. Especially when chronic, it often has no clear cut objective pathophysiological correlates. The complexity of this subjective and multidimensional experience is highlighted by independent replicated functional imaging studies showing that anticipation of pain produces similar activation of cortical networks as does pain itself (7, 12, 43). Dualistic (i.e., organic/biologic versus functional/psychologic) models that explain disease and health primarily in terms of measurable biomedical variables have generally not proven useful for measuring or

**TABLE 39-2**  
***Recommendations for Assessing and Minimizing the Confounding Effects of Pain During Neurocognitive Examination***

1. Always assess pain when present, when post traumatic adaptation seems compromised by pain and related symptomatology, or limitations in daily functioning, and decrements in test performance seem atypical. Clarify the frequency, intensity and character of pain during the examination and more generally, the characteristics of the chronic pain experience and related problems.
2. Assess problems that are commonly associated with chronic pain (e.g., sleep disturbance, fatigue, somatic preoccupation, anxiety, depression) as these all have the potential to markedly disrupt aspects of cognitive functioning.
3. Repeat administration of measures sensitive to the effects of fatigue (e.g., sustained, attention-demanding, timed tests) during examinations to help identify or corroborate fatigue-related deficits.
4. Always assess effort, motivation and response bias during examination, especially with regard to symptom complaints.
5. Consider postponing cognitive assessment in cases where pain and related symptomatology have not been appropriately or aggressively treated.
6. Use accommodating? procedures during examinations where possible (e.g., optimizing comfort, providing frequent breaks, allowing frequent position changes and use of personal orthotics [cushions, heating or ice pads, etc.], modifying lighting and sound, etc.).

treating pain. Biopsychosocial models better explain variability in health care outcomes and direct more effective interventions for challenging chronic health care situations, including chronic pain rehabilitation (44).

A biopsychosocial stress and coping formulation conceptualizes adaptation to injury as a series of stressful demands which require interactions between existing coping resources and injury related stresses and demands. Hence, identification of coping liabilities is an integral prerequisite to bolstering coping resources and improving long term adaptation. A biopsychosocial assessment perspective affords the optimal understanding of the patient with pain and the myriad of factors that might contribute to this subjective experience and complicate, or otherwise affect symptom presentation (45). Such factors include not only the patient's medical findings, but also physiological, behavioral, and cognitive-affective functioning, including vulnerabilities and strengths.

A comprehensive, biopsychosocial assessment should be considered the standard of care when pain is chronic (46, 47). Initial assessment should address self report, via interview of patient and relevant others, and use of appropriate assessment instruments, in the following areas:

1. Pain intensity
2. Affective response
3. Quality / characteristics, and
4. Location.

History from the patient regarding the presentation of the pain problem is as important as examination results, and should include inquiry about such questions as: onset and course (e.g., when, where, how; sudden or progressive, fluctuating or steady, etc.), intensity level,

duration, activities preceding an exacerbation, stress related effects, variability across the day and night, effect of movement and posture change, irritating and relieving factors, medications employed and effects, current activities and pain related activity changes, specific effect of pain on mood, activity, cognition, affect, sleep, appetite, and more general effects of pain in the persons life. Importantly, special assessment procedures are indicated in cases of persons with response limitations or significant cognitive impairments. These include special versions of instruments and reliance on observation and structured interview of relevant others and observers, and integration of this information with physical examination procedures (see Hadjistavropoulos, von Baeyer, and Craig (48), for an extensive review of self-report, observational and physiological measures used in pain assessment of adults with impaired communication abilities).

A comprehensive assessment should also address the following areas:

5. Pain behaviors and environmental effects / responses
6. Beliefs about the pain condition
7. Coping strategies and effectiveness
8. Psychosocial context and social responses to pain,
9. Personality and psychoemotional status and adjustment, including how this affects or is affected by pain, and
10. Activity, level of function / disability and quality of life.

A brief survey of general classes and useful instruments for inclusion in a comprehensive pain assessment, updated from previous work (49) is included in Table 39-3. Also included in this table are special instruments designed for persons with significant response limitations and/or cognitive impairment, including the very young and elderly.

**TABLE 39-3**  
**General Classes and Instruments Commonly Included in an Assessment of Pain and Psychological Variables Relevant to Adjustment and Coping**

**Specific Pain Domain Instruments: Self Reported Pain Intensity and Location**

- *Visual Analogue Pain Scale* (VAS (1)): is a brief graphical, nonpsychometric measure of subjective pain intensity represented by a straight line with typical endpoints of no pain and worst possible pain. It is widely used to quickly assess pain report, track changes during treatment, and assess outcome (50).
- *Verbal Rating Scale* (VRS) is a similar measure where pain intensity is indicated on a linear scale with verbal anchors ranging from no pain to worst possible pain and including mild, moderate, severe and very severe (50, 51).
- *Numeric Rating Scale* (NRS) is another similar measure where pain intensity is indicated verbally or by pointing at a number from 0 or 1 to 10 (50, 52).
- *Pain Drawing* ((53, 54)) is a measure of the location aspect of pain. It is the most common instrument used for this type of self-report (50).
- *McGill Pain Questionnaire*, short form (SF-MPQ: (55)) was designed to measure descriptive aspects of pain via selection of adjectival pain descriptors. It provides three classes of pain descriptors: Sensory (burning, sharp, sore), Affective (e.g., exhausting, punishing), and Intensity (e.g., intense, excruciating). Different combination of descriptors may be associated with different nociceptive or psychological factors.
- *Pain Diaries* are temporal measures of frequency, duration and intensity of pain episodes (56, 57). They typically ask subjects to self-report, in a journal for several days or weeks, when and in what situations pain increases or decreases. More complete versions typically assess such areas as: location, intensity, onset (e.g., sudden or progressive; fluctuating or steady, etc.), characteristics (e.g., throbbing, dull aching), duration, preceding activities, stress, effects of pain on activities, cognition, affect, sleep, appetite, and factors affecting pain mitigation or exacerbation (e.g., weather, activity, stress, medications, distraction).

**Instruments Designed for Children and Adults with Significant Cognitive Impairment**

- *FACES Scale* (51) was designed for young children and consists of six cartoon faces ranging from a smiling face for “no pain” to a tearful face for “worst pain”. Versions have been adapted for cognitively impaired adults.
- *Oucher Scale* (58) consists of sequenced pictures of a child’s face, ranging from “no hurt” to “the biggest hurt you could ever have”, which are shown and explained to a child who selects which exemplifies current pain level. It is designed for children and can be used with adults with significant cognitive problems (59). Versions are available for most ethnicities.
- *FLACC* (FACE, LEGS, ACTIVITY, CRY, CONSOLABILITY) Scale is a standardized rating composite measure of observed physical indicators of pain in infants and preverbal children who are unable to provide verbal report. It can also be used in children and adults with severe cognitive impairments (see McGrath and Gillespie (60)).
- *Observational Pain Scale* (61) is a standardized rating measure for estimating pain level in cognitively impaired patients who can’t respond to VAS, Numeric or Oucher Scales. It produces a composite pain score based on observation of: facial expressions, verbalizations/ vocalizations and body movements; changes in interpersonal interactions; changes in activity patterns or routines; changes in mental status; and/or physiologic changes.

**Pain Specific Measures of Functioning: Pain Quality, Affect and Behavioral, Cognitive/ Attitudinal and Emotional Coping**

- *Multidimensional Pain Inventory* (62) employs a biopsychosocial conceptualization to assess relevant psychosocial, cognitive, and behavioral aspects of responses to pain. This well researched instrument has 61 items, includes 13 scales and measures pain severity, patient-perceived pain interference, affective distress, life control, social support, response from others, and disability. It includes specific norms for different statistically derived chronic pain subtypes (63): interpersonally distressed with inadequate social support; globally dysfunctional coping; and adaptive coping. An inexpensive software scoring program is available (64). This multiaxial classification system is a psychometrically sound and objective method of evaluating chronic pain patients, may be integrated with useful psychological information from multiple other sources, and offers benefit for matching patients to types of pain management interventions. In a recent study (65) the MPI successfully classified chronic whiplash associated disorders into homogenous subgroups
- *Pain Affect Visual Analogue Scale* (VAS) can also be used to quickly assess affective pain distress (52) versus sensory intensity, and similarly offers utility for assessing treatment changes and outcome.
- *Pain Patient Profile* (P3) (66) is a screening measure for depression, anxiety, & excessive somatization in pain patients. It is a double normed (both healthy controls and chronic pain patients) screening test developed to measure psychological factors related to chronic pain conditions in order to help identify those who would likely benefit from mental health treatment as part of their treatment plan.
- *Battery for Health Improvement* (BHI) assessment (68) is a dual normed (community samples and pain patients) instrument designed for multidimensional assessment and computerized progress tracking to identify affective,

TABLE 39-3 (continued)

characterological, psychophysiological and social factors that affect pain, recovery and rehabilitation progress, vocational training or job placement readiness, and impairment and disability. It can contribute useful information regarding psychosocial factors underlying pain reports, perceived disability, somatic preoccupation, design for interventions and outcome. A recent revision, the BHI-2, offers expanded national norms and multiple reference groups, along with expanded and updated scales.

- *Profile of Chronic Pain: Screen* (PCP:S:) (68) is a brief 15-item measure designed to identify individuals who merit more detailed psychosocial evaluation. It assesses the psychological impact of chronic pain in terms of: pain severity, functional interference, and pain-related emotional burden. Random national sample data were employed to demonstrate good validity and minimal social desirability response. National norms are available by gender for three age groups.
- *Profile of Chronic Pain: Extended Assessment Battery* (PCP:EA) (69) is a very new, 86-item instrument with: (a) 33 items assessing pain location and severity, pain characteristics (e.g. worst daily pain), medication use, health care status, the identity of the most important person in the patient's life, and functional limitations in 10 areas of daily living; (b) 13 multi-item subscales addressing aspects of coping (guarding, ignoring, task persistence, and positive self-talk), catastrophizing, pain attitudes and beliefs (including disability beliefs, belief in a medical cure for pain, belief in pain control, and pain-induced fear), and positive (tangible and emotional) and negative (insensitivity and impatience) social responses. National stratified samples across three age groups, two survey studies providing strong evidence for the hypothesized factor structure, internal consistency, independence from response bias, and validity, and the presence of normative data suggest good diagnostic and prescriptive utility.
- *Pain Stages of Change Questionnaire* (PSOCQ) (70, 71) has good demonstrated reliability and validity in predicting patient readiness to adopt new beliefs and coping responses to pain. More recent research (72, 73) suggests some utility in identifying patient cluster types that differentially respond to specific multidisciplinary or cognitive-behavioral pain treatments consistent with a self-management approach to chronic pain problems.
- *Survey of Pain Attitudes* (SOPA-R-35:(74)) is a well-researched instrument that assesses patient feelings about pain control, solicitude (solicitous responses from others in response to one's pain), medication (as appropriate treatment for pain), pain-related disability, pain and emotions (the interaction between emotions and pain), medical cures for pain, and pain-related harm (pain as an indicator of physical damage or harm)
- *Pain Catastrophizing Scale* (PCS;(75)) is a brief, well-researched measure of the negative mental set in the presence, or anticipation of pain marked by magnification, rumination and helplessness. Pain catastrophizing is a robust predictor of analgesic use, distress, psychosocial dysfunction, & disability, and superior in comparisons to disease severity, pain levels, age, sex, depression, or anxiety. It also demonstrates benefit as a therapeutic measure of cognitive restructuring as a therapeutic tool (76). A child version is also available (77).
- *Pain Anxiety Symptoms Scale* (PASS) (78) is a measure of fear of pain across cognitive, overt behavioral and physiological domains. It has good correlations with related measures of anxiety and disability and has been found to predict disability and interference due to pain when controlling for emotional distress and pain.
- *Kinesiophobia Scale* (K-Scale:(79)) is a quick screening measure of unreasonable or irrational fear of pain and painful reinjury upon physical movement. It assesses pain-phobias or avoidance conditioned pain related disability (i.e., unhealthy pain maintaining habits that are a major contributor to pain related disability) and correlates highly with similar measures. High scores, once malingering factors are ruled out, signal the need for combination therapies with emphasis on reeducation, countering maladaptive phobic responses and promoting adaptive attitudes and treatment participation/ cooperation (e.g., graduated exposure, cognitive reinterpretation and systematic desensitization). Recently, a version has been adapted for use in the general population (80).
- *Cogniphobia Scale* (C-Scale) (81), adapted from the K-Scale, quickly screens unreasonable or irrational fear of headache or painful reinjury upon cognitive effort / exertion. The C-Scale is designed to assess anxiety based avoidant behavior with regard to cognitive exertion. Like the Kinesiophobia scale, this instrument measures anxiety based avoidant behavior and offers information about need for combination therapies that include such anxiety reduction procedures.
- *Chronic Pain Coping Inventory* (CPCI:(82)) is a 65-item measure of strategies used by patients to cope with chronic pain across 11 pain coping dimensions. In cross validation studies, four scales (Guarding, Resting, Asking for Assistance, and Task Persistence) reliably predicted patient- and significant other-reported patient adjustment. Eight scales (Guarding, Opioid Medication Use, NSAID Use, Sedative-Hypnotic Medication Use, Resting, Asking for Assistance, and Exercise/ Stretch) demonstrated moderate-to-strong consistency between patient and significant-other versions.
- *Chronic Pain Acceptance Questionnaire* (CPAQ) (83) and a revised version (84) is a measure of acceptance of pain. The 20-item revised form has 2 empirically derived subscales: Activity Engagement (i.e., degree to which respondents are living a normal life despite pain) and Pain Willingness (i.e., degree to which respondents have pain experiences without avoidance or control efforts). In a very recent large sample (85) the CPAQ scales were reliably stronger predictors of distress and disability compared with coping variables, suggesting that a pain management efforts can benefit from shaping a more accommodating view of pain experience for certain individuals or circumstances.

TABLE 39-3 (continued)

- *Psychosocial Pain Inventory* (PPI:) (86) is a 25-item, eight-page structured interview designed to assess the influence of psychosocial factors in chronic pain syndromes in 10 areas: 1) pain behavior (e.g., up time, time in bed), 2) social reinforcement, 3) life changes, 4) litigation, 5) financial status, 6) use of alcohol, 7) medication use, 8) coping strategies, 9) social environment, and 10) environmental stress. It also includes questions concerning personal and family histories, past and current medical histories, and reactions and adjustments to the pain and medical treatments.
- *Hendler Chronic Pain Screening Test* (87) assesses contribution of physical versus psychological variables to pain behavior. Higher scores reflect strong psychologically influenced or motivated pain behavior, and suggest recommendations for conservative treatments with multimodality treatment programs. Very high scores typically require further psychological or psychiatric intervention.
- *Headache Disability Rating* procedure of Packard and Ham (88) is a scale that estimates impairment from headache rated on frequency, severity and duration of attacks and how activities impact on functional skills and activities of daily living. Importantly, it includes a modifier variable for rating motivation (i.e., treatment motivation, exaggeration/over concern, and legal interest) that are used to adjust the total impairment rating.
- *Pain Assessment Battery – Research Edition* (PAB) (89): four measures that provide information regarding patient stress, pain reports with qualitative pain analysis and pain coping strategies, including nonorganic pain complaints. Format allows serial computerized administrations and tracking.
- *Oswestry Low Back Pain Disability Questionnaire* (90) assesses the amount of restriction pain imposes on functional levels. Assessment areas include intensity, personal care, lifting, walking, sitting, standing, sleeping, sex life, social life, and traveling. The percentage of endorsed items gives an indication of the amount of disability. It has been proposed that up to 20% indicates minimal disability, 20 to 40% indicated moderate disability, 40 to 60% indicates severe disability, and greater than 60% indicates severe disability.
- *Vanderbilt Pain Management Inventory* (91) measures chronic pain coping strategies (e.g., active, passive) and provides useful information for treatment planning and recommendations
- *Cognitive Coping Strategies Inventory* (92) assesses the degree to which patients engage in adaptive and maladaptive cognitive coping strategies.
- *Coping Strategies Questionnaire* (64) is a 48-item scale that rates the frequency of engagement in 8 different behavioral and cognitive coping strategies in response to pain or physical symptom experience.

#### **Measures of General Health Functioning and Behavior**

- *Millon Behavioral Health Inventory* (MBHI) and its recent upgrade, the *Millon Behavioral Medicine Diagnostic test* (MBMD) (93) is one of the most frequently used health inventories for medical populations in the US. The MBHI provides information across four broad categories: basic coping styles, psychogenic attitudes, specific disease syndromes, and prognostic indices. It has good psychometric properties, a large normative database of representative medical patients, with specific disease scales developed for specific patient groups. The MBMD has updated and expanded the research base and clinical scales (165-items, 38 scales, 3 validity scales). The MBMD assists with: identification of significant psychiatric problems, making specific recommendations; pinpointing personal and social assets to facilitate adjustment; identifying medical regimen compliance problems; structuring post-treatment plans and self-care responsibilities in the patient's social network. Computerized scoring and an interpretive report facilitate use.
- *The SF-36 Health Survey* (SF-36) (94) surveys general health status in terms of physical and mental health and functional status. Widely used in research, and as an outcome measure (95), it assesses 8 areas, including limitations in physical functioning and social functioning and roles and activities, pain, mental health, vitality and health perceptions.
- *The Neurobehavioral Functioning Inventory* (NFI) (96). The NFI is a multipurpose inventory designed to measure current cognitive, physical, and emotional functioning in persons with traumatic brain injury or other neurobehavioral disorders. It is comprised of six independent scales reflecting problems frequently experienced by persons with neurobehavioral disorders: depression, somatic, memory/attention, communication, aggression and motor functioning. This well researched instrument includes separate forms for patient and family, demonstrates concurrent validity with neuropsychological test data and objective personality inventory profiles, can assist with treatment planning and allows measurement of change over time.
- *The Sickness Impact Profile* (SIP) (97) is a behaviorally based measure of health status designed to assess both psychosocial and physical dysfunction. It has sound psychometric properties, is used widely with chronic pain patients and can provide relevant information regarding degree of functional limitation in daily activity.
- *The Illness Behavior Questionnaire* (IBQ:(98, 99)) provides useful information about attitudes, perceived reactions of others and psychosocial variables. It delineates 7 factors that include general hypochondriasis, disease conviction, psychological vs. somatic focusing, affective disturbance, affective inhibition, denial, and irritability. In addition, it has value in identifying patients who rely on illness behaviors as a coping style for need procurement.

TABLE 39-3 (continued)

**General Psychological Measures: Mood, Anger and Anxiety**

- *The Beck Depression Inventory – 2 (BDI-2)* (100) is a common self-report measure that assesses depressive symptomatology. It has been reported to differentiate chronic pain patients with and without major depression utilizing an optimal cutoff score of 21 (101) and has well documented predictive validity.
- *The Zung Self-rating Depression Scale (SDS)* (102), seems especially well suited for medical settings, and has several advantages over other measures. It is shorter, simpler to administer and score, requires a lower reading level, fits well with medical and injury situations and can be easily administered in an interview format (62). Items are self ratings on a scale ranging from 1 to 4 (“Not at all” to “Most or all of the time”) and are scored in the direction of increased depressive symptomatology, with a raw score cutoff for mild depression of approximately 40 points.
- *The State-Trait Anger Expression Inventory-2 (STAXI-2)* (103) and its recent update is a reliable, well-normed instrument for assessing the experience, expression and control of both current state and trait anger. Anger Expression and Anger Control scales assess four relatively independent anger-related traits: (a) expression of anger outward; (b) holding anger in; (c) controlling outward expression; and (d) controlling internal angry feelings. This instrument provides information regarding how experience, expression and control of anger may contribute to psychophysiologic arousal and symptoms and increase risk for developing somatic symptoms and medical problems. Indirectly, it offers suggestions for the direction of appropriate interventions. Importantly, anger is a frequent concomitant of chronic pain that has been unfortunately underappreciated (57).
- *The Beck Anxiety Inventory (BAI)* (104) is a screening measure of severity of patient anxiety. Specifically designed to reduce overlap with symptoms of depression, it assesses both physiological and cognitive components of anxiety in 21 items describing subjective, somatic, or panic-related symptoms. The BAI differentiates well between anxious and non-anxious groups in a variety of clinical settings.
- *The Perceived Stress Scale (PSS)* (105) is a widely used instrument for measuring the degree to which situations in one’s life are appraised as stressful. Items measure how unpredictable, uncontrollable, and overloaded respondents find their lives and directly queries current levels of experienced stress. Higher PSS scores have been associated with greater vulnerability physical and psychological symptoms following stressful life events.

**Comprehensive Personality Assessment Instruments**

- *The Minnesota Multiphasic Personality Inventory (MMPI)*:(106) *MMPI-2* (107) ) is the most widely used psychological assessment instrument in the US. The MMPI is a 567 item (true/false) objective measure of personality function and emotional status with 10 clinical and 3 (7 in revised version) validity scales that were derived through empirical discrimination). Its predictive abilities are based on more than fifty years of actuarial data collection and analysis. It is a very sensitive measure of psychological states, traits and styles (e.g., excessive anxiety, tension, depression, hostility and problematic anger, somatization tendencies, sociopathy, substance abuse, deviant thinking and experience, social withdrawal, etc.). Through configural interpretation of the relative scale elevations, tentative hypothesis regarding personality and coping style and relative degree of particular types of psychological disturbance can be gleaned. Importantly, although the MMPI can and is frequently misused and misinterpreted (e.g., application of psychiatric norms to medical patients tends to beg psychiatric interpretations), it represents one of the most useful adjuncts to personality assessment and treatment planning. A cursory summary of potential utility of MMPI profile interpretation for assessing psychological reactions and contributions to physical conditions was offered by Fordyce (101), and roughly includes configural guidelines for interpreting: 1) Willingness to display physical symptom behaviors; 2) Distress/discomfort about illness (“How comfortably sick?”); 3) Poor general coping skills; 4) Depression complicating physical symptoms; 5) Tension (and sympathetic arousal) contributing to physical symptoms (High back, head, neck, shoulder, etc.); 6) Treatment outcome issues. A number of subtypes of chronic have been identified by other researchers although, as with other measures, it remains unclear to what extent results may inform the degree to which complaints are associated with organic (especially peripheral pathology) versus psychologic contributions to patient presentation (108, 109).
- *The Personality Assessment Inventory (PAI)* (110) a good measure of general psychopathology that can help with identification of a wide variety of risk factors that could adversely affect adjustment. It has good psychometric properties and contains 340 items, with 22 scales, including 4 validity scales. As with most other general psychological assessment measures, it has no norms for chronic pain and tends to overpathologize this group.
- *Millon Clinical Multiaxial Inventory, 3rd edition (MCMI-III)*: (111): includes scales assessing DSM-IV based psychiatric disorders, including affective, personality and psychotic disorders, somatization and others. It is useful for the differential diagnosis of personality disorders and psychological vulnerabilities for adaptation to pain. Like other psychiatric measures, it has limited pain group norms and may be prone to overpathologizing patients.

TABLE 39-3 (continued)

**Pain Assessment Measures with Built In Response Bias Indicators**

Pain Assessment Battery (PAB) (89): – Research Edition:  
Proposed clinical hypothesis procedure evaluating:

- Symptom Magnification Frequency (SMF) > 40%
- Extreme Beliefs Frequency (EBF) > 35%
- Four other “validity” indicators (i.e., alienation, rating percent of max, % extreme ratings (2 scales)

Millon Behavioral Health Inventory (MBHI) (93)

Elevation on three built-in validity scales

Hendler Chronic Pain Screening Test (87)

- Scores of 21–31 (Exaggerating)
- Scores >31 (Primary psychological influence)

**Factors Suggestive of Significant Exaggeration, Illness Behavior or Malingering**

Main & Spanswick Indicators (112)

- Failure to comply with reasonable treatment
- Report of severe pain with no associated psychological effects
- Marked inconsistencies in effects of pain on general activities
- Poor work record and history of persistent appeals against awards
- Previous litigation

These instruments are intended to be integrated with a thorough history taking, interview of patient and relevant others as available, and examination of relevant medical and allied health records.

The understanding derived from a comprehensive biopsychosocial pain assessment provides the framework for designing individually tailored treatment interventions and recommendations. Examining the impact of various cognitive processes on the subjective perception of the patient's pain is a critical component of this comprehensive assessment. Turk (113) has emphasized the importance of understanding and addressing the important role of patient pain appraisals, beliefs and expectancies. He, and others (e.g., Asmundson, Nicholas & Carleton (114)), note that patients with chronic pain resulting from traumatic events are predisposed to experiencing physical sensations as harmful and noxious which increases both anxiety and subjective pain perceptions. This, in turn, leads to further activity avoidance and functional limitations that block recovery and facilitate increased deconditioning, creating increased risk for developing chronic and disabling pain.

Important psychoemotional components relevant to the assessment of chronic pain (115) include: the subjective experience of pain; autonomic arousal associated with bodily reactions to pain; cognitive appraisal(s) of the painful experience as related to the personal meaning of the pain or the historically learned responses to pain and injury; non-verbal behaviors including facial expressions and body language associated with pain; and affective reactions to pain, including anxiety and depression. Persons with chronic pain have a much higher predilection and incidence of depression and anxiety as well as anger. A diathesis-stress model has been proposed to explain the higher rate of depression in this patient population, and likely applies to other psychoemotional responses to chronic pain (116).

Finally, pain assessment and treatment strategies are best conceptualized in terms of suitability to a multidimensional process that evolves significantly as it persists over time. The stages of pain processing model (117–119) is an illustrative model that distinguishes the sensory, affective, cognitive-evaluative, and behavioral dimensions of pain as it changes with increasing chronicity. The first two stages involve sensory discrimination and associated affective responses. The former is commonly assessed by ratings of pain intensity and location, while the latter is assessed by ratings of pain unpleasantness. The third stage involves the meaning and implications of pain for the patient and associated emotional suffering, and is commonly assessed by measuring pain-related emotional states (e.g., depression, anxiety, frustration) and beliefs (e.g., perceived ability to control or endure pain). The fourth stage refers to illness behavior (e.g., lifestyle and role disruption, avoidance) and can be assessed through self and collaborated ratings and observation (e.g., pain behaviors manifested at home, work, clinical interview). As pain persists, there is a transition of the focus of assessment from the first two stages to the latter two.

**Response Bias Assessment**

Diagnosis and treatment is the usual reason for assessment of chronic pain, along with impairment and disability evaluation in compensation situations. Importantly, assessments can involve contexts with strong financial, personal, social and/or other incentives. Hence, chronic pain patients may present with response bias, or the tendency to report or present pain or related disability in a less than fully truthful, accurate or valid fashion. For example, many assessments occur in such forensic contexts as health care insurance policy coverage, disability insurance policy

application, social security disability application, personal injury litigation, worker's compensation claims, functional capacity evaluations and determination of capacity for work. These contexts often present strong financial (120) and numerous other and often more powerful vocational, social, personal and other incentives (see Martelli, Nicholson et al., Chapter 64, in this text).

Response bias in pain presentation can range from symptom minimization to symptom exaggeration and malingering. Hence, assessment of examinee veracity in report and attribution of symptoms, and motivation during presentation and assessment, becomes critical with regard to increasing diagnostic accuracy. This is prerequisite to provision of appropriate and timely treatment, prevention of iatrogenic impairment and disability reinforcement, and appropriate legal compensation decisions (Martelli, Nicholson, Zasler & Bender, Chapter 64 in this text).

A thorough analysis of response bias in chronic pain is beyond the scope of this chapter. Chapters that more fully explore the topic of response bias assessment in chronic pain can be found in Martelli, Zasler, Nicholson et al. (121) and Nicholson and Martelli (36). Chapter 64 in this text is specifically devoted to the general assessment of response bias and provides background, relevant measures and a general model for assessment. Measures specific to response bias regarding pain report are included, and readers are referred to that chapter for a detailed review. Additional pain response bias measures with potential utility are included in Table 39-3.

Importantly, because Chapter 64 emphasizes assessment of neurocognitive response bias, additional clarification of the unique nature of pain and the challenges in pain assessment is indicated. Pain, unlike cognitive impairment from brain injury, is a subjective complaint that is more viscerally, directly and universally noxious. It is much more difficult to assess than neurocognitive impairment due to limitations of existing measures and is, in fact, extremely difficult to verify or refute. (122–128). Assessment of pain presents a significant diagnostic challenge for all but the most conspicuous cases of severe, functionally disabling physical pathology. The advances that are being made in assessment, treatment and outcomes in chronic pain owe to new biopsychosocial models and psychophysiological advancements. These are based on discarding simple dichotomous models in favor of evidence of central processing factors and psychophysiologic etiologies, as a preponderance of data are accumulating to indicate that chronic pain is often represented in dysfunctional cerebral processing and not only the same peripheral mechanisms as acute pain on which medical assessments are more usually conducted (24, 35).

Unfortunately, there remains predominant overrepresentation of simplistic and uninformed dichotomous pain conceptualizations. These persist despite failed

attempts to make dichotomous discriminations between “organic” and “nonorganic” pain using either medical or psychological measures. For example, in Fishbain et al's (126, 127) metaanalytic review, it was concluded that the Waddell signs, the most relied upon measure of “non-organicity” in medicine and physical therapy, are invalid. That is, even when properly used, they do not discriminate organic from nonorganic problems, are associated with higher pain levels, may represent an organic phenomenon and are neither correlated with psychological distress or secondary gain. It shouldn't be surprising that many psychological measures have proven inadequate, given that they were derived from prediction of physical measures of nonorganicity that were invalid.

The lack of any reliable or valid measures of presence or degree of pain and pain exaggeration or malingering necessarily weakens the utility of psychological measures designed to make such predictions. Nonetheless, attempts to develop methods and guidelines for the detection of response bias and malingered pain are continuing. Malingering, or the act of willful, deliberate, and fraudulent feigning, or significant exaggeration of pain is only one variant of response bias, and an extreme one. The presence of response bias, which may not be an uncommon response to aversive stimuli, is much more easily documented than malingering. However, the two are often confounded and used synonymously in professional neuropsychological publications and practice, where response bias measures are frequently referred to, explicitly or implicitly, as “malingering tests”. Inferences about malingering, especially in a restrictive health care environment with strong gate keeping pressures, are inherently problematic. In the absence of dependent measures or clinical methods with demonstrated validity for assessment of possible malingering of pain, inferences about pain malingering using current measures and procedures necessarily produce fallible judgments with unknown false positive rates.

Despite the absence of reliable or valid measures and methodologies for detecting degree of pain exaggeration or malingering (35, 124, 128–130), estimates, unreliable as they must be, have been proffered. Fishbain (124) in his systematic review of available samples and methodologies estimated that malingering may occur in 1.25 – 10.4% of chronic pain patients, while Mendelson and Mendelson (129) concluded that notable exaggeration or malingering of chronic pain across settings is less than 20%.

However, it must be emphasized that, in the case of chronic pain, malingering and exaggeration are usually distinct entities that are not simply differentiated by degree. Exaggeration, which appears much more commonly, can be distinguished from malingering in several important ways. While deliberate exaggeration and malingering are typically driven by external monetary or other incentives, chronic pain mechanisms frequently

involve dysregulation of central pain processing mechanisms and derive from exaggerated neurophysiologic pain responses (see Zasler, et al., Chapter 41 in this text), including allodynia (pain from stimuli that are not usually painful), hyperalgesia (increased response to painful stimuli) and hyperesthesia (abnormal acuteness of sensitivity to sensory stimuli). In addition, suboptimal psychological adaptation to chronic pain frequently involves catastrophization and related processes rather than exaggeration for purposes of monetary or other secondary gain. Finally, pain is, by nature, highly aversive and associated with physiologic and behavioral avoidance reflexes that are genetically programmed and present at birth, and accompanied by anxieties and aversive emotions that are both highly conditionable and strongly and inherently disruptive of adaptive behavior. This not only makes differentiating exaggerated from non-exaggerated pain responses difficult and necessarily reliant on value judgments, but represents a clearly distinct phenomenon in contrast with exaggeration for the purposes of secondary gain.

The task of making determinations regarding genuine pain severity and impact and related functional impairment and disability is complicated by numerous factors. These factors are not necessarily fully appreciated except by the most informed chronic pain management specialists, and usually misunderstood by nonspecialists. These factors should be considered as reasons for considerable caution in making inferences about response bias and malingering during chronic pain assessments. In brief summary, they include:

- The subjective and complex nature of pain, as previously noted;
  - The lack of valid measures of presence, severity, exaggeration or malingering of pain;
  - The lack of formal, scientifically validated conceptual models and “rating systems” of pain associated impairment and disability;
  - Numerous methodological problems with response bias assessment measures generally, including those designed for domains that are much easier to assess than chronic pain (e.g., problems with reliability, validity; sensitivity, specificity, misclassification, generalizability, lack of mutual exclusion, etc.; see Chapter 64 in this text for a review of generally problems with available response bias measures)
  - The challenge of disentangling not only the multiple contributors to subjective pain experience, but also to associated functional disability;
  - The context of assessment, where referral may be for treatment or compensation (e.g., where the latter is typically associated with higher rates of response bias and malingering; see Chapter 64 in this text) and numerous factors may be exerting motivational influence
- The nature of aversive events and anxiety, which are known to produce strong classical and operant conditioning, especially relating to avoidance behavior, and to decompensate efficient behavior and adaptation in animals and humans. That is, pain, by its aversive nature, predisposes organisms to avoidance as a typically adaptive, biological survival mechanism. However, the presence of anxiety, distress and avoidance behavior is often misinterpreted as a sign of “nonorganicity”, exaggeration and/or malingering in physical examinations, or as a psychogenic etiologic factor, when evidence indicates it is most often a reaction to pain or an indicator of severity (14, 59, 126, 127). The failure of the highly relied upon Waddell signs as a purported indicator of nonorganicity, and the evidence that they are in fact not associated with secondary gain and appear more associated with organic phenomenon and severity of pain, is a good illustration of how this misconception has contributed to misdiagnosis and associated misunderstanding and mistreatment of persons with chronic pain.
  - Western cultural tendencies to interpret distress responses and avoidance to aversive pain experience as inherently pathological. Evidence of this comes from the misrepresentation and misinterpretation of the “fight-flight” response. The overwhelming majority of ethological and human evidence indicates that flight attempts almost invariably precede fight attempts in coping with aversive events, in the following sequence: freeze, flee, fight, fright (131). In fact, adaptation to chronic pain requires learning to overcome the avoidance responses that are innate to all organisms.
  - The distinct nature of exaggeration versus malingering of pain. Mechanisms underlying development of central and peripheral sensitization that lead to allodynia and hyperesthesia are becoming better understood. These, by definition and appearance, represent an exaggerated response. However, they are neurophysiologically based and not driven by external incentives like secondary gain. Similarly, pain catastrophization and related processes represents an exaggerated pain response, but are explained by suboptimal psychological coping and must be differentiated from deliberate exaggeration for purposes of secondary gain.
  - The critically important distinction between acute and chronic pain. Chronic pain is distinct from acute pain not only with regard to the absence of clearly identifiable peripheral tissue damage or neuroanatomical pathways, but, as recent neuroscience evidence shows, also in terms of how it is processed in the central nervous system. In addition to previously noted differences, recent reviews of functional

neuroimaging studies clearly demonstrate that chronic pain is processed differently than acute pain both in terms of the lateral versus medial pain systems and the activation of affective-evaluative mechanisms (see Zasler, et al, chapter 39 in this text, or Apakarian (6) for a review). When these distinctions are blurred, and chronic pain is assessed in terms of standards for acute pain, as is generally practiced in medicine and psychology, the absence of clearly identifiable pain triggers and greater emotional activation leads to conclusions that erroneously infer deliberate exaggeration and malingering. Given strong external incentives in a restrictive health care environment (Martelli et al, in Chapter 64 of this text) with increasing preponderance of insurance and adversarial medicolegal referrals, an inflation of false positive diagnoses of malingering might be expected.

The unique nature of chronic pain and limitations with regard to its assessment require caution with regard to over-interpretation of response bias procedures and emphasize the importance of integrating multiple data sources and making thoughtful inferences only after integration of thorough historical information, interview, assessment, behavioral observations, collaborative interview and data sources, and so on. Importantly, Martelli (132) and Nicholson (133) have argued that assessments conducted by persons without specialty chronic pain training and experience likely violate professional ethical standards.

## PAIN MANAGEMENT

Early after the emergence of pain, and when pain is in the acute stage, treatment interventions invariably address amelioration of distress, correction of underlying pathophysiology and promotion of healing. Inherent in all pain management interventions is the prevention of chronicity, which is undoubtedly the most important purpose and most effective accomplishment in pain management. Zasler et al. (Chapter 39 in this text) address the medical approaches involving assessment and treatment of acute pain. They emphasize the importance of effective assessment and treatment by using the compliment of medical and pharmacologic agents and other strategies designed to minimize distress while correcting underlying pathophysiology and restoring function. Although acute pain management interventions are primarily medical in nature, behavioral and psychological pain management interventions still play an important role in cases where associated psychological distress is significant, medical interventions do not produce expected pain relief, and/or where correction of pathology is complicated or where

traditional analgesic medications or other medical interventions cannot be employed.

Unfortunately, acute pain is not always resolved. As it persists, it becomes chronic and more intractable. The goal of preventing chronicity gradually transforms to include reducing the severity and persistence of pain related distress, associated psychological and physical symptoms, functional disability and life interference, and improving adaptation and coping with pain. Although the goals of comprehensive chronic pain management interventions can vary with individuals and settings, they can generally be summarized as addressing the following areas:

- Modulation and reduction of intensity, frequency and duration of sensory, as well as cognitive-evaluative and affective distress responses related to pain experience
- Modulation and reduction of associated physical and psychological symptoms and concomitants of pain, especially as they relate to mood and emotions, cognition, energy, sleep, eating, physiological arousal and general physical and emotional health
- Reduction of functional disability, maladaptive avoidance and illness behavior, and interference with regular and preferred activities, including regular daily activities and preferred family, social, avocational, vocational and recreational function and activities
- Increasing self management to actively utilize available strategies to minimize pain related distress, functional disability and life interference

Because persistent pain may be associated with a combination of physical and psychological factors, combination treatments and a multidisciplinary approach to chronic pain management, consisting of pain specialists in medicine, psychology, physical therapy, occupational and/or vocational and/or other allied health professions, are indicated. This approach is widely accepted as the most clinically successful and cost effective process in treating chronic pain (25, 134–137). This is best conducted, and can usually only be effectively accomplished, within the context of a specialty pain clinic. Specialty pain clinics are the treatment of choice for chronic pain conditions, with clinical efficacy supported by several recent reviews (134, 138–141). Referral to pain management specialists and specialty pain clinics should be considered the standard of care for the treatment of persons with chronic pain.

When the person with pain has also sustained a TBI, additional recommendations are warranted. In persons with TBI and pain, there is evidence that pain is harder to manage (29), that it takes longer to complete a pain management program (142), and that special attention is required because of cognitive difficulties (26).

Hence, referral to pain specialty pain programs with experience in treating persons with TBI, and/or consultation with such providers to allow expectation of extended treatment periods and incorporation of cognitive compensatory strategies, is indicated

### **Model for Conceptualizing Chronic Pain Treatments**

There is considerable evidence and growing acceptance that many or most forms of chronic pain involve central and/or peripheral sensitization (143). Evidence for a neuromuscular conceptualization of many chronic pain problems has grown very fast and represents a convergence of findings across multiple specialties (38). Most forms of chronic pain are now considered (4, 5, 26, 38, 144) to possibly include a hyper-responsiveness of the pain system involving “wind up” or sensitization in the CNS / brain. Conceptually, the thrust of current efforts in chronic pain management seem to be toward “desensitization” of the CNS through combination treatments. In addition, multidisciplinary and multicomponent or combination treatment packages represent the most effective treatments in chronic pain, especially when comorbid with brain injury (3, 20, 31).

The authors have proposed a preliminary classification model for planning and conceptualizing chronic pain management interventions (143, 31). This model, summarized in Table 39-4, can include combination of any of the included treatments. It facilitates the classification of currently available and potentially useful chronic pain treatment approaches according to specific area and manner of desensitization targeted, which can include any of the treatments included. This model offers

a potentially useful classification system for conceptually organizing the wide variety of available treatment interventions and in planning combination treatments.

It should be noted that Tyrer and Lievesley (145), among others, recommend the development of pain management facilities specifically designed for persons with brain injuries. The emotional disturbances associated with pain are also frequently comorbid with TBI, highlighting the importance of a biopsychosocial perspective. Such a perspective allows for a holistic conceptualization of the patient, incorporating multimethod, multimodal assessments that facilitate individualized treatment planning. Treatment goals include not only the reduction/relief from pain, but also increased self-control, increased adaptation to life changes secondary to pain and brain injury, and improved functioning and quality of life.

### **Behavioral–Psychological Management**

Behavioral and psychological services are an important component of comprehensive pain management services. A review by McCracken and Turk (146) identified more than 200 studies confirming that behavioral medicine interventions such as cognitive-behavioral therapy, biofeedback, and relaxation, are effective in reducing pain and pain related distress. Table 39-5 includes a summary of some of the most frequently used and empirically supported strategies. This table borrows from the review by Martelli et al. (3), but readers are referred to additional reading for more comprehensive summaries in the work of McQuay and Moore (147), reviews of evidence-based recommendations for management of chronic non-malignant pain (e.g., College of Physicians and Surgeons (148)), or the

**TABLE 39-4**

*A Desensitization Model for Chronic Pain Treatment Interventions*

**Desensitizing Peripheral CNS Procedures**

- EMG and Temperature Biofeedback; Various Relaxation and Imagery Procedures; Transcutaneous Electrical Nerve Stimulation (TENS)

**Desensitizing CNS Medications**

- Anti-epileptic drugs, tizanidine HCL, Amytal, neuroimmunomodulators, SSRI's etc.

**Desensitizing Behavioral Activity Procedures**

- Operant behavioral activity programs; graduated exposure / graduated activity programs; relaxation, imagery, refocusing; cognitive behavioral reinterpretive strategies

**Desensitizing Psychotherapeutic Procedures**

- Emotional desensitization of catastrophic reaction to injury and pain and other fears and trauma; splinting of emotional reactions and calming of catastrophic reactions and hypervigilance to pain; specific formal pain and fear desensitization procedures; pain exposure / desensitization procedures; cognitive behavioral reinterpretive strategies

**Desensitizing Neurophysiologic Procedures**

- Cranioelectrotherapy Stimulation (CES). Consider EEG Biofeedback or other potentially helpful adjunctive relaxation procedures such as sound and light (AudioVisualStimulation, AVS) and Transcranial Magnetic Stimulation and Brain Electrical Stimulation.

**TABLE 39-5**  
**Summary of Useful Behavioral Treatments for Chronic Pain**

*Patient Education:* The most conspicuous and malleable factor that contributes to psychophysiological arousal and stress responding is patient expectancy and knowledge about symptom management. For example, Ham and Packard (154) found that headache patients that desired an explanation of their headache at least as much as pain relief. In the case of mild TBI, education about expected symptoms and course has been shown to reduce the anxiety and selective attention and misattribution that can unnecessarily prolong symptoms (155). The best education treatment packages generally contain elements targeting numerous factors. Accurate information and expectancies help with this and also assist with coping with pain more adaptively. Stress management information and strategies can assist with reducing sympathetic arousal / discharge that exacerbates pain, while specific postural training and sleep hygiene can assist with postural rehabilitation and normalizing sleep patterns.

*Cognitive-Behavioral Treatments:* Cognitive approaches incorporate the physical, psychological and behavioral aspects of the pain experience in promoting patient self management of pain. They typically emphasize learning of self regulation and self control skills and taking greater personal responsibility for lifestyle habit change, especially with regard to identifying and replacing maladaptive beliefs about pain. Specific training is provided in cognitive strategies and skills to replace such inappropriate negative expectations and beliefs as catastrophization and associated magnification, rumination and helplessness that maintain physiologic arousal and maladaptive avoidance and illness behaviors that complicate symptom resolution (113). A comprehensive multimodal approach should include education, skills acquisition, cognitive and behavioral rehearsal, homework and generalization and maintenance (156).

*Relaxation Training:* Progressive muscle relaxation (PMR) is the most studied relaxation procedure (157). PMR involves the systematic tensing and relaxing of various muscle groups to elicit a deepening relaxation response, usually with combination of muscle groups and addition of diaphragmatic breathing to shorten the protocol. Meta-analytic reviews generally conclude that relaxation training and biofeedback training are equally effective. Relaxation training presumably serves to (1) reduce proprioceptive input to the hypothalamus, thereby decreasing sympathetic nervous system activity (150) and (2) directly reduce muscle tension or pre-headache vasoconstriction (158).

*Operant Treatment:* Operant based treatment strategies require altering environmental contingencies to eliminate reinforcement of pain and illness behaviors (e.g., verbal complaints, inactivity, avoidance) while rewarding "well" behaviors (e.g., incrementally increased exercise, activity level, involvement and participation).

*Biofeedback:* Extensive research supports the utility of EMG or thermal biofeedback for headache pain, and chronic musculoskeletal pain disorders more generally. The forehead, trapezii, frontal-posterior neck, and neck areas are frequent EMG feedback sites. Patterns of pathophysiologic neuromuscular activity that underlie pain complaint and functional limitations, which can be remediated through feeding back physiologic information to allow self-correction, include: a) Stress-related hyperarousal in musculoskeletal or other physiologic systems; b) Postural dysfunction; c) Hyper- or hypotonicity induced by reflex systems activated by inflammation, active trigger points and cumulative strain or recurrent trauma; d) Learned guarding or bracing to mitigate anticipated pain or injury; e) Learned inhibition or avoidance of muscle activation / activity; f) Chronic compensation for joint hypermobility/hypomobility (e.g., muscles taking over the role of damaged joint tissue); f) Faulty motor schema and muscle imbalance reflecting development of one or more of the preceding syndromes, and resulting in the lack of coordination and stability between typically coordinated muscle groups. Recently, data are emerging which indicates that EEG biofeedback, and associated EEG driven stimulation offers efficacy in treatment of some persistent pain and persistent post-concussive symptoms (159, 160). Finally, evidence has been reported that individuals can gain specific voluntary control over rostral anterior cingulate activation to directly control pain perception in severe, chronic clinical pain (161).

*Social and Assertiveness Skills Training:* Skills training may help some patients with more effective communication of needs. Increased need fulfillment decreases distressful emotions which reduces physiological arousal that contributes to pain experience (162).

*Imagery and Hypnosis:* Using some combination of autohypnosis, suggestions of relaxation and visual imagery, patients are generally instructed to visualize the pain (i.e., give it form) and focus on altering the image to reduce the pain. Imagery based treatment is most effective following establishment of a good therapeutic alliance in order to facilitate compliance (163).

*Habit Reversal:* These treatment packages teach pain patients to detect, interrupt, and reverse maladaptive habits (e.g., maladaptive head/jaw posture, jaw tension, negative cognitions). Specific skills are taught to both reverse poor functional habits and stressful thoughts as well as feelings that precipitate/perpetuate them (164).

many systematic reviews prepared for the Cochrane Collaboration (149). Although there is a paucity of studies examining pain management in persons with TBI, the interventions used are the same, qualified by understanding that treatment may take somewhat longer and require cognitive compensatory strategies, commensurate with cognitive impairments, to assist with learning.

When persons with TBI initially present to psychologists for pain management services, the initial assessment process is always benefited by establishment of a therapeutic rapport. This includes countering any patient resistances or misconceptions (e.g., that pain must be in “their head” because they are seeing a psychologist) and engendering accurately informed and hopeful expectancies. Psychological management of persons with pain and TBI begins with an assessment that identifies all variables relevant for treatment. In addition to areas such as personality and emotional status, coping style and strategies, social support, and pain specific factors (see Table 39-3 and preceding pain assessment section), evaluation must also include specific sequelae associated with brain injury. An integration of this information is necessary to ensure that the full constellation of residual sequelae and strengths are considered to optimize an individually designed treatment plan that anticipates and implements compensatory strategies for all potential obstacles to benefit from behavioral interventions. For example, deficits in memory, attention, or executive functioning might be addressed through task-analytic instruction and compensatory memory notebooks with provision of external reminders for completion of at-home assignments. The patients specifically tailored treatment plan should provide a framework and outline for treatment, define goals and patient / therapist expectations and sequences, and provide psychoeducational information about the particular type of chronic pain and rationale for treatment.

Despite the previously noted dearth of outcome studies examining the behavioral treatment of pain after traumatic brain injury, the available literature suggests general similarities in clinical presentations, pathophysiologies and treatment responses, with somewhat greater similarities for traumatic versus not traumatic chronic pain, and some evidence suggesting greater treatment resistance for the latter type (150).

In cases of post traumatic pain, the severity and frequency of pain attacks or exacerbations and chronic pain-related sequelae such as coping abilities, depression, and anxiety are significantly improved by combined psychological treatment protocols (64, 151–153). Supportive counseling that begins early after trauma and is continuous results in better patient response (64).

Table 39-5 includes a summary of some of the most frequently used and empirically supported strategies (3), but readers are again referred to additional reading for more comprehensive summaries (McQuay & Moore (147);

College of Physicians and Surgeons (148); The Cochrane Library (149)).

## Conclusion

Chronic pain is a frequent concomitant of TBI. However, the assessment and treatment of persons with pain is a complicated and challenging process. Pain, by itself, can have a more disabling effect across a wider range of functions than brain or many other types of injuries. In addition to the absence of clear and objective measures for assessment and monitoring of pain, pervasive misconceptions dominate modern medical and psychological practice. Fortunately, recent advances in chronic pain assessment and treatment can be attributed to adoption of a biopsychosocial perspective. The most promising current treatment interventions are combination treatments that are holistic in nature and target the patient’s reaction to pain within his/her daily life and ability to exercise self-control. Multicomponent treatment packages are currently the preferred treatment choice for chronic pain (3, 20, 162), especially when it accompanies TBI. The current chapter is intended to promote familiarity with many important issues and current knowledge required to increase awareness and understanding of psychological approaches to assessment and management of pain in persons with TBI. This will hopefully assist with the making of appropriate referrals, and promoting effective carryover and integration of pain management principles into care of persons with concomitant TBI.

## Neurorehabilitation Nursing of Persons with TBI: From Injury to Recovery

*Terri Antoinette*

### INTRODUCTION

It is critical for nurses who will provide neurorehabilitation nursing care to persons who have sustained a traumatic brain injury (TBI) to possess highly specialized knowledge and acute clinical assessment skills. This must be based on an understanding of the pathophysiologic effects of the TBI, the potential medical complications which can affect all body systems, and the physical, cognitive, neurobehavioral, psychosocial, and functional impact of the TBI on the person and the significant others in his/her life.

The delivery of rehabilitation nursing care extends far beyond the delivery of care at the bedside. The licensed, registered, professional nurse: (1) collaboratively practices with the physician and the interdisciplinary team to implement rehabilitation interventions based on evidenced-based practice, (2) provides ongoing support and supervision to licensed practical nurses and direct care givers (i.e. certified nursing assistants) in the delivery of quality care, and (3) conducts patient/family teaching to promote the achievement of individualized quality outcomes.

This chapter presents an overview of neurorehabilitation nursing care issues throughout the continuum of care from prehospital management through acute/ sub-acute, neurobehavioral, and post-acute rehabilitation.

### PRIMARY AND SECONDARY BRAIN INJURY

Primary brain injuries occur at the time of impact and result from an immediate biomechanical disruption of brain tissue and vasculature. Primary injuries may include: (1) concussions, contusions, lacerations, and skull fractures, (2) epidural, subdural and intracerebral hematomas, (3) penetrating injuries, (4) subarachnoid and intraventricular, hemorrhages, and (5) diffuse axonal injuries (DAI) (1, 2).

Secondary brain injuries may begin within minutes after the initial injury and throughout the early post-traumatic hours, days, and weeks. The pathophysiology of secondary injury has numerous etiologies. This include neurochemical changes and physiological events which precipitate a metabolic cascade effect followed by cerebral edema, increased intracranial pressure (ICP) and increased metabolic demand with resultant hypoxia, cerebral ischemia, impaired cerebral autoregulation, altered ion homeostasis, additional neuronal destruction, and cell death (2-7).

In a study by Jones et al. (8), involving 124 severely injured patients, 91% were found to have secondary injuries and mortality was associated with the duration of hypotension, hypoxia, and hyperthermia (9). The role of the nurse is paramount in the assessment, intervention and ultimate prevention and minimization of these injuries.

## PREHOSPITAL NURSING CARE

The Guidelines for the Management of Severe Head Injury (10–12) provide evidence-based recommendations for practice which guide the delivery of critical care nursing interventions and clinical pathways from pre-hospital resuscitation through intensive care treatment to adults who have sustained a severe TBI with Glasgow Coma Scores (GCS) of 3 to 8 (13–18).

Critical care nurses may be involved in the care of the patient both at the scene as well as in route to the emergency department. Prompt intervention at the scene has been associated with improved outcome. An advanced trauma life support (ATLS) evaluation is conducted and the person's airway, breathing and circulation assessed. Fluid resuscitation is initiated with isotonic solutions, a patent airway established, ventilation and rapid physiologic resuscitation performed and emergency intervention for multisystem injuries instituted (10–12, 16–18).

Although the incidence of concomitant cervical spinal cord injuries has been cited as 2%–6% (19–21), iatrogenic post-traumatic spinal cord injuries after arrival to the hospital have been estimated to range from 10% to 25% (22). Emergency nursing and paramedic personnel should implement spinal cord injury precautions specific to modification of resuscitative techniques, airway stabilization, neck immobilization and spinal stabilization (16, 19).

During the brief pre-hospital assessment phase, the nurse should continuously assess vital signs (pulse, respiration, blood pressure and pain), perform the Glasgow Coma Scale, and observe pupillary responses for size, shape, symmetry and reactivity to light, eye position, and extraocular movement. Observation should also occur for fluid/bleeding from the ears or nares and a determination made as to whether or not the fluid is cerebral spinal fluid (CSF). Additional assessments to be performed include muscle strength grading and observation for weakness, asymmetry of facial movements, paralysis, pain, decerebrate and decorticate posturing (4, 5, 17, 18, 23).

The skill of the nurse in astutely assessing the patient is of paramount importance. These assessment findings serve as a baseline of comparison for subsequent serial neurological exams, for interventional decision making, and for evaluating treatment effectiveness to minimize secondary brain injury (6, 15).

Valuable information to obtain from the patient, or if not possible, from witnesses at the scene include: (1) mechanism of injury (e.g. blow to the head, fall, ejection from the vehicle), (2) time of injury and extrication time, (3) presence of protective devices (e.g. seat belt, airbags, helmet), (4) loss of consciousness or change in cognitive status, (5) progressively worsening headache, repeated vomiting, (6) periods of apnea or cyanosis, (7) the presence of hypotension (8), amount of blood loss, (9) signs

of substance abuse, (10) the position in which the person was found (i.e. lying face down) and (11) medication history (5, 16, 19, 23).

If the person is conscious and able to converse, a history should be taken and an assessment of level of consciousness (LOC) should include orientation to person, time, place, and situation, assessment of confusion, attention, level of arousal and the ability to follow commands (5, 16, 23).

Key determinants of survival are the adequacy of resuscitation efforts (restoration of circulating blood volume, blood pressure, oxygenation and ventilation), the identification of injury severity and the expeditious transfer to a facility with neurosurgical capabilities (10–12, 15).

## CRITICAL CARE NURSING MANAGEMENT

This section will focus on the rationale and the general principles which guide the nursing care of the TBI patient in the ICU. The reader is referred to other chapters in this text for more detailed, clinically specific information regarding acute management.

The priority of nursing care in the ICU is protecting the brain from secondary injury and includes: (1) maintaining the ICP and cerebral perfusion pressure (CPP) within normal limits, (2) avoiding systemic hypotension, hypoxia, and hypercapnia, (3) controlling cerebral metabolic rate (e.g. seizure control, normothermia, sedation) (4) assuring adequate fluid volume status, (5) maintaining serum glucose level at 80–120mg/dL, and (6) providing nutritional support. The use of mannitol, barbiturates and hyperventilation will vary depending on the course and severity of neurological deterioration (3, 6, 10–12, 18).

Because of the extreme sensitivity of the traumatized brain, the nurse must conscientiously interpret the benefits and risks of each potential intervention. Implementing clinically appropriate treatment is paramount because even a brief delay can result in further neurological insult (3).

### Hypoxia

Immediate correction is imperative for episodes of hypoxia (partial pressure of arterial oxygen (PaO<sub>2</sub>) less than 60mmHg or arterial oxygen saturation (SaO<sub>2</sub>) less than 90% if pulse oximetry is used). Studies from the Traumatic Coma Data bank reported a mortality rate of 50% for patients with hypoxia versus 27% for those without (8, 18, 24).

Acute respiratory failure has been reported in 20% of patients with neurological trauma (6, 25). Ongoing assessment of respirations includes airway clearance, rate,

pattern and characteristics of breath sounds, and monitoring of arterial blood gas (ABG), and oxygen saturation levels. In ventilated patients, the nurse must detect airway obstruction complications by monitoring the position of tubes, cuff pressures and problems with mucous plugs. An ambu bag and mask must be available for emergency use (26).

Early detection of respiratory complications is paramount. A study from the Traumatic Coma Data Bank revealed that 41% of patients in the study developed pneumonia and pulmonary insufficiency was reported in 28% (8, 27). Other complications include adult respiratory distress syndrome, pulmonary contusion, neurogenic pulmonary edema, pulmonary empyema, atelectasis, pulmonary embolus, hemothorax or pneumothorax (6, 18).

### **Hypotension**

The nurse must immediately intervene to correct hypotension (systolic blood pressure less than 90 mm Hg). Hypotension that is tolerated in healthy individuals is not well tolerated in the injured brain and can lead to disruption of cerebrovascular autoregulation, a drop in CPP, elevated ICP and ischemic injury (3, 8).

Chestnut et al. (24) reported that a single episode of hypotension from the time of injury through resuscitation increased mortality 150% and also increased morbidity. Fearnside, (28) in a prospective study, reported that hypotension occurring anytime during a patient's pre-hospital and in-hospital course independently predicted increased mortality and morbidity.

### **Increased ICP**

Increased ICP significantly influences morbidity and mortality. Saul et al. (29) reported a mortality rate of 15% for patients whose ICP remained below 25 mm Hg as opposed to 69% for those persons with ICP values in excess of 25 mm Hg. ICP values greater than 40 mm Hg is considered to be intracranial hypertension that is life threatening (8, 29, 30).

Cushing's triad (hypertension/widening pulse pressure, bradycardia and irregular respiratory pattern) is an ominous sign associated with rising ICP, pressure on the medullary center of the brainstem and irreversible damage (6, 16).

### **Suctioning**

Since ICP can increase with endotracheal suctioning, it is important that the nurse adhere to patient specific protocols regarding the timing and appropriateness of the procedure, administration of medication prior to the procedure, hyperoxygenation of the lungs before suctioning, and instructions specific to the number and time limits for

each of the suctioning attempts. Suctioning of the nasal passage should not occur until the possibility of basal skull fracture and dural tear have been ruled out (6, 14, 26).

### **Positioning**

One of the most frequently performed activities that ICU nurses perform is that of therapeutically positioning the patient. Prior to any positioning it is imperative that spinal cord injury is ruled out. It is important to maintain neutral alignment of the head and neck and avoid disruption of cerebral venous outflow due to tight cervical collars or taped endotracheal tubes. Rotation of the head and flexion of the neck can increase ICP, decrease jugular venous outflow, and affect changes in cerebral blood flow (3, 14, 31–34).

Positioning recommendations based on neurological criteria, while at times conflicting, generally cite that elevating the head of the bed up to 30 degrees may decrease ICP, enhance venous return and decrease cerebral vasoconstriction. Caution must be taken, however, because cardiovascular, pulmonary and other body system responses to positioning may influence hemodynamic stability, cerebral perfusion pressure and systemic oxygenation. For example, in patients who are hypovolemic, hypotension may worsen if the head of the bed is elevated (3, 14, 31–35).

Turning and repositioning for contracture and spasticity management and to prevent skin breakdown must also be considered. Hip flexion of greater than 90 degrees may also elevate ICP. It is important for the nurse to obtain individualized patient specific instructions from the physician regarding positioning (3, 14, 18, 31–34, 36).

### **Nutrition**

The body's initial response to severe TBI is that of a hypermetabolic/ hypercatabolic state. The Guidelines for the Management of Severe Head Injury recommend enteral or parenteral nutrition (particularly jejunal feeding) to replace 140% of resting metabolism expenditure in nonparalyzed patients and 100% in paralyzed patients (10–12, 16).

Options for feeding include parenteral, enteral-gastric and enteral-jejunal. Advantages of jejunal feeding include: (1) improved absorption of nutrients and gastric tolerance, (2) improved nitrogen retention (3) greater increases in serum prealbumin, (4) increased caloric intake, and (5) lower rate of pneumonia. When compared with parenteral feeding, the advantage of jejunal feeding includes: (1) lower theoretical risk of infection and sepsis, (2) decreased risk of hyperglycemia, and (3) lower cost. Once gastric tolerance is attained, enteral gastric feedings have practical advantages specific to the resumption of the normal digestive process and the capability for the delivery of bolus feedings (10–12, 18, 37–39).

### **Neurological Complications**

In order to recognize subtle neurological improvement or deterioration, nurses must perform a systematic, organized neurological assessment which includes the Glasgow Coma Scale, level of consciousness (arousal, awareness, higher cognitive functioning, speech and language), pupillary reflexes, cranial nerve function, sensory and motor function, and deep tendon reflexes. A Mini-Mental Status Examination should be done when clinically appropriate (4, 40).

The nurse should be able to accurately describe and recognize all classifications of seizures. Familiarity with the patient's history in regard to the time and onset of seizures, side effects of anticonvulsants, and familiarity with the recommendations for anticonvulsants from the Severe Head Injury Guidelines is paramount (10–12). Detailed information regarding neurological complications will be discussed elsewhere in this text.

### **Pain**

Pain can adversely effect ICP and CPP and interfere with the accuracy of some parameters of vital signs and neurological assessment (e.g. pupillary response, sedation). If the patient is unable to consciously respond to questions regarding pain intensity, it is important for the nurse to observe for facial grimacing, body movement, crying, restlessness, elevated blood pressure and heart rate and agitation (6).

### **Multisystem Complications**

Stabilization of systemic injuries is paramount to minimize blood loss and to prevent complications. The patient is also at risk for the development of multisystem complications such as coagulation disorders, deep venous thrombosis (DVT), cardiac arrhythmias, syndrome of inappropriate anti-diuretic hormone, electrolyte abnormalities, and glucose fluctuations. Nosocomial infections (i.e. pulmonary, urinary tract, vascular catheter, and wound) can be life threatening and require prompt assessment and appropriate treatment. Serious gastric complications include the development of stress ulcers, gastrointestinal bleeding, malabsorption syndromes and increased potential of aspiration. Hyperthermia must be closely monitored and rapidly treated (antipyretics, cooling blankets and antibiotics when indicated) since it increases cerebral metabolic demands (4, 5, 18, 41).

### **Noxious Stimuli**

Environmental noise, lights, loud conversations and nursing activities have been reported to increase ICP in some patients, particularly those with minimal reserves of

intracranial compliance. It is important that the nurse monitor if ICP and CPP increases during nursing care activities and be prepared to stop and place the patient in a neutral position if the ICP increases above a level predetermined by the physician (26).

The nurse must monitor the environment to protect the patient from excessive stimulation and plan and organize patient care to assure that nursing procedures (i.e. turning positioning, bathing, oral care, suctioning) are done in a manner that minimizes noxious stimulation to the degree possible. It is also important for the nurse to educate the family regarding the effects of noxious stimuli (6, 14, 26).

### **Clinical Pathways**

Protocols and clinical pathways are valuable clinical tools which describe observable and measurable outcomes with specified time frames and provide an organized, systematic model for analysis of trends which require intervention by various members of the interdisciplinary team (6, 13, 26). Mcilvoy (41), in a study of the effect of implementing a TBI clinical pathway at a level one trauma center, noted decreases in hospital length of stay and reduction in costs.

### **Family Dynamics/Supportive Interventions in the ICU**

The concept of family focused nursing in the ICU is based on the premise that the family is the primary unit of health care and the patient is best understood within the context of the family system rather than in isolation. It is essential that communication occur with the family/significant others as early as possible. Loved ones can provide pertinent information about the patient's preinjury medical history and, if present, details surrounding the events preceding the TBI. Also, the patient emerging from coma may demonstrate less confusion/agitation in the presence of a loved one (42–44).

The need for medical information was identified as a priority in several studies which investigated the needs of family members whose loved ones sustained a brain injury (44–46). Ideally, the nurse should be present when the physician discusses the patient's medical condition and prognosis with the family (44, 47). The nurse can then reinforce this information in a caring manner with kind, clear, realistic explanations of the patient's medical condition.

Because of the severe nature of TBI, the family of the injured person often demonstrates symptoms of shock, disbelief, denial, anxiety, and anger. This anger can be displaced onto the nursing staff, since it is the nursing staff who provide care around the clock and have more contact with the families than other health care professionals (45).

Hainesworth (48), in a study of acute care nurses caring for neurologically devastated patients, reported that nurses expressed feelings of severe stress and anxiety when they had to endure verbal and occasional physical outbursts from family members. Villaneuva (49) and Bell (50) reported that the experience level of the nurse and the responsiveness of the patient accounted for many of the variations of how nurses interact with patients and families. For some nurses, particularly novice ones, the technical care in of itself can be overwhelming and the nurse, if not provided with support, may have a tendency to focus more on the technological aspects of care and less on the patient as a person.

Educational instruction specific to family dynamics, the recovery process, and strategies for intervention should be an integral part of the training that nurses receive. Villanueva (49) stressed the importance of experienced nurses serving as role models in the sharing and teaching of the knowledge they have acquired to help ease the transition of the new nurse. The nurse's inclusion as part of the interdisciplinary team also serves to allay a sense of isolation and provides a consistent, consensual approach to dealing with family members who are demonstrating challenging interpersonal interactions.

### **Rehabilitation Services in the ICU**

The initiation of interdisciplinary rehabilitative services in the ICU should begin once it is determined that sufficient medical stabilization has occurred (51, 52). A 1992 study by MacKay et al. (53) assessed the occupational and long-term benefits of a formal early intervention program which provided physical, occupational and speech-language therapy services to a group of patients two days after admission compared with a nonformalized group who received rehabilitation services after an average of twenty three days into their hospital stay. The study demonstrated a dramatic reduction in inpatient (acute care and rehabilitation facility) length of stay in the formalized intervention group from 10 months to 5 months. Ninety-four percent of the patients from the formalized group were able to be discharged home as compared with fifty seven percent from the nonformalized group.

### **ACUTE/SUBACUTE REHABILITATION**

Due to increasingly shortened lengths of stay in the acute care hospital, patients are being discharged sooner to acute/sub-acute settings with multiple medical complications and neuropsychological sequela. The intent of this section is to provide a concise multi-system overview that briefly outlines the nursing care issues most commonly encountered. The reader is referred to the other chapters in this text for in-depth discussions.

### **Care of Persons in Low-Level Neurologic States**

The goals of nursing management for patients functioning at the Rancho Los Amigos Levels I, II and III who are admitted to an acute/subacute rehab facility are the same as in the acute care hospital. The Rancho Los Amigos Levels of Cognitive Function scale, while less valid and reliable than the Disability Rating Scale and other outcome measurement tools, is useful as a descriptive tool to categorize behavioral criteria that describe the patient's level of awareness and capacity to appropriately interact with the environment (54, 55).

Nursing staff are in an ideal position to observe spontaneous eye opening, purposeful versus nonpurposeful movement, the person's cognitive/behavioral level of responsiveness to stimulation and commands and the return of sleep-wake cycles. It is important that nurses understand the definitions and diagnostic criteria for the various disorders of consciousness (e.g. coma, vegetative state, minimally conscious state) (56).

After a diagnosis has been established, and consideration given to the etiology and location of injury, length of time since injury, comorbidity of medical complications, age, and knowledge of the patient's wishes, the physician may choose to discuss treatment alternatives (i.e. do not resuscitate (DNR) orders, mechanical ventilation, dialysis, administration of blood/ blood products, the administration of antibiotics and other medications, artificial hydration/nutrition) with the family/decision maker (57-59).

The nurse will be directly involved in supporting the family/decision maker throughout this process. It is, therefore, helpful to have the nurse present whenever the physician discusses these treatment alternatives. In addition to the medical rationale underlying treatment alternatives, the nurse must be cognizant of the legal and ethical policies of the health care facility and the need for compliance with state laws (statutory or court recognized) regarding advance directives (60).

Factors to consider include the emotional readiness of the family, the prognosis for functional recovery (56, 57, 59), (See other chapters for detailed prognostic information) and, most importantly, respect for the patient's wishes. Religious and cultural beliefs and the family's feeling of needing to deal with "unfinished business" all impact on this process.

### **Sensory/Environmental Stimulation of Persons in Low-Level Neurological States**

Persons may present to the rehab setting from the ICU with orders for multiple medications (e.g., anticonvulsants, benzodiazepines, narcotics, antihistamines, neuroleptics, antispasticity agents, gastrointestinal agents, anticholinergics, antiemetics, hypnotics) that may potentially impair recovery. As medications that can potentially

impair arousal are discontinued and cognitive enhancing medications initiated, the nurse must objectively observe the patient's level of neurobehavioral responsiveness, recognize potential side effects and promptly report objective assessment findings to the physician and the interdisciplinary team (59).

While caring for the patient, the nurse should be respectful of the possibility that the patient may be able to hear and possibly understand what is being said. The nurse should always address the patient by name, provide simple reality orientation to person, time and place and always talk calmly in a clear and concise manner to prepare the patient for what procedure or treatment is going to next occur (6, 61, 62).

The nurse can encourage the family to interact with their loved one through therapeutic touch, hand-holding and passive range of motion exercises, if clinically appropriate. Bringing in familiar objects from home and playing music and television programs that the patient enjoyed may provide meaningful visual and auditory stimulation. If the person begins to follow even one step verbal or written commands, a simple communication system can be established with head nods, eye blinks, up and down eye movements, or finger raising yes-no signals (6, 61, 62).

The nurse should educate the family regarding the importance of preventing over stimulation and alert the family that possible causes of restlessness may include pain, irritation from tubes/positioning devices, full bladder/bowel, constipation and other noxious stimuli (6, 61).

### *Respiratory Abnormalities*

Clinical conditions which can increase the propensity toward respiratory complications include chest trauma, weakened or absent gag reflex, dysfunction of the lower esophageal sphincter, dysphagia, ineffective airway clearance, aspiration, recurrent regurgitation, and decreased mobility (61, 63–65). Bontke et al. (63) in a study of rehabilitation patients in the TBI Model System Programs identified respiratory failure (defined as requiring artificial ventilation for more than one week) in 39% of cases followed by pneumonitis (26%) as the most common extracerebral complications seen after brain injury.

Monitoring for a patent airway, rate, depth and pattern of respirations, auscultation for breath sounds, assessment of cough reflex, turning and positioning every one to two hours to mobilize secretions, humidification and suctioning are critical nursing interventions. Secretions should be observed for viscosity, color and odor (6, 61). Decannulation protocols may be initiated when deemed clinically appropriate, but in the low level patient, an individual risk versus benefit decision must be made regarding the suppressed ability to cough and clear secretions versus complications from long-term tracheostomies (59, 63, 64).

Aspiration is a major cause of pneumonia. Unless clinically contraindicated, the head of the bed should be maintained at 30–45 degrees. To prevent aspiration associated with enteral feedings, an initial swallowing study should be performed with high-risk patients, correct placement of feeding tubes monitored, gastric residuals routinely checked, stomach contents aspirated to determine gastric pH, and ongoing assessment performed of the benefit/risk of continuous versus intermittent feedings (65).

### *Cardiovascular Abnormalities*

Life-threatening arrhythmias, changes in cardiac rate and conduction, and alterations in blood pressure may be neurogenic in origin and can occur during the acute/subacute rehab stay. The nurse should ongoingly perform a comprehensive cardiovascular assessment which includes the monitoring of vital signs and the rate, rhythm and quality of apical pulses. An admission ECG can serve as baseline to determine changes in cardiac status (6, 16, 68, 69).

Post traumatic hypertension can resolve spontaneously. Labi and Horn (68) reported that only 45% of persons who had been receiving antihypertensive medications during their rehabilitation stay, required them at the time of discharge. It is important that the nurse keep the physician apprised of blood pressure readings so that a determination can be made by the physician regarding the appropriateness of weaning and/or discontinuing these medications, particularly those with sedating and central nervous system side effects, which could impair recovery (69).

After major brain trauma, the incidence of deep venous thrombosis (DVT) has been reported to be as high as 54% (69, 70). The nurse should monitor vital signs, assess peripheral pulses and Homans'sign, perform bilateral circumferential leg measurements, and examine extremities for redness, pain, tenderness, edema, and dilated superficial veins. DVT and pulmonary embolism may occur, however, without warning thereby making prophylaxis essential (71).

Compression stockings are mechanical methods of prophylaxis and should be fitted in accordance with the manufacturer's sizing chart. Stockings which are too large will not provide adequate support to the extremities and stockings too small may cause circulatory impairment. The patient's legs should be elevated prior to application, wrinkles in the stockings avoided and the patient observed for allergic reactions, skin irritation and thrombophlebitis (72).

Pneumatic compression boots are also used as a mechanical prophylaxis to DVT; however, the boots must be applied in accordance with manufacturer's instructions. Camerota et al. (73) reported that only 48% of patients in an acute care facility and 33% in a nursing home had the boots correctly applied.

Several studies (66, 74, 75) have reported a greater reduction in the incidence of thromboembolic events when pneumatic compression boots were used in combination with anticoagulant therapy. The use of anticoagulant therapy; however, requires a case specific risk versus benefit determination by the physician (66, 69).

### *Genitourinary Abnormalities*

Urinary elimination patterns are frequently altered after brain injury. Patients typically present with uninhibited detrusor hyperreflexia (e.g. spastic bladder), and demonstrate symptoms of urge incontinence which include urgency, frequency, decreased bladder capacity, normal bladder sensation and normal to low post void residuals (61, 76).

Other types of incontinence (i.e. stress, reflex, functional, overflow, mixed) may also occur secondary to urinary retention, pudendal nerve damage, trauma to the urinary tract, benign prostatic hypertrophy, spinal cord injury, or cognitive impairment (62, 69, 76–78).

Transient causes of incontinence which need to be ruled out may include delirium, UTI's, atrophic urethritis or vaginitis, impaction, restricted mobility and even depression. Excess urine output can also be related to endocrine problems, hyperglycemia, hypercalcemia, congestive heart failure and peripheral edema (77, 79). Cognitive and behavioral disturbances, lack of initiation, decreased awareness, agitation, confusion, disorientation, communication and mobility issues also may contribute to incontinence (78, 79).

Medications such as benzodiazepines may cause confusion and secondary incontinence. Diuretics may lead to incontinence due to polyuria, frequency and urgency. Anticholinergic agents (including antihistamines, antidepressants, antipsychotics, opiates, antispasmodics, anti-parkinsonian agents), alpha-adrenergic agonists (such as those found in over the counter decongestants and diet pills), beta-adrenergic agonists and calcium-channel blockers may also cause urinary retention and overflow incontinence (77).

Persons often enter the acute/subacute rehab setting with indwelling urethral catheters. A study by Yost (80) reported the development of urinary tract infections (UTI's) within 72 hours of first use in 70% of the patients studied. Additional complications from indwelling catheters may include hematuria, obstruction, pain, bladder spasms, urethral erosion, stones, epididymitis, periurethral abscess, fistula formation, chronic renal inflammation, bacteremia and pyelonephritis (77–79).

In June of 2005, the Centers for Medicare and Medicaid Services (CMS) released a revision to the State Operations Manual (SOM) specific to Surveyor Guidance for Incontinence and Catheters. This memorandum specifies that an assessment for the appropriateness of an

indwelling catheter should be performed on admission and ongoingly and catheter use restricted to: (1) urinary retention that cannot be treated or medically/surgically corrected (i.e. post void residual volumes over 200 milliliters, unsuccessful management of retention/incontinence with intermittent catheterization and persistent overflow incontinence, symptomatic infections and/or renal dysfunction), (2) the need to prevent further contamination of Stage III or Stage IV pressure ulcers or (3) use as a comfort measure in terminally ill patients where changing is painful and disruptive (78).

The first step in assuring that the patient with bladder incontinence receives appropriate treatment to prevent UTI's and restore bladder function, is the performance of a thorough assessment. Discussion with the patient/family should occur prior to starting a bladder management program and information obtained specific to previous elimination patterns and pre-morbid urinary tract complications. A pelvic and rectal examination should be done to rule out factors which may affect incontinence (i.e. prolapsed uterus or bladder, prostate enlargement, fecal impaction). Several post-void residuals, preferably thru ultrasonographic assessment, should also be obtained to ensure adequate emptying and a cough stress test performed to determine if urine leakage is provoked (77, 78).

The two essential components of a bladder program are a schedule of fluid management and a pre-established voiding schedule. Unless clinically contraindicated, overhydrating in the morning and early afternoon serves to cue the patient to a sensation of a full bladder. To promote rest, fluids are restricted after 7p.m. (especially caffeinated drinks). The fluid needs for an average person is 2500cc per 24 hour period but may vary depending on clinical variables (77–79).

Programs range from care-giver dependent (scheduled check and change) to those requiring active patient involvement. "Habit training/scheduled voiding," a behavioral technique whereby toileting is scheduled to coincide with a predetermined analysis of the patient's voiding patterns and times of fluid intake, can begin when the person is cognitively functioning at Rancho Level V (77–79).

"Prompted voiding" may be appropriate with patients who can recognize some degree of bladder fullness, ask for assistance or are able to respond to the staff when prompted to toilet. The patient receives positive feedback if they void successfully when prompted or remain dry after declining toileting. As the program progresses, the patient may learn to recognize the need to void, to ask for help or respond when prompted (77, 78).

In a study involving nursing home residents, a 40% reduction in incontinent episodes occurred in response to prompted voiding techniques regardless of the type of urinary incontinence or cognitive deficit (residents were able to say their name or reliably point to one of two objects) (81).

“Bladder rehabilitation/bladder retraining” is appropriate for cognitively intact patients and requires the capability to delay voiding and to urinate according to a timetable. Based on the baseline assessment of voiding times, the person is encouraged to lengthen the time between voids by consciously suppressing the urge. Bladder training can also be combined with pelvic muscle (Kegel) exercises and pelvic floor electrical stimulation therapy (77, 78). A cystometrogram EMG is sometimes done to determine the patient’s degree of sensation and voluntary control (54).

Most importantly, the success of bladder programs requires the commitment and compliance of the direct care staff to implement the program and the support of administrative staff to provide adequate numbers of staff.

Anticholinergic medications are sometimes used to relax smooth muscle in the urinary tract, increase bladder capacity and increase the threshold volume for overactive bladder contractions. Caution is advised, however, due to side effects such as urinary retention, sedation and memory impairment (54, 66). Anticholinergics are contraindicated in patients with narrow-angle glaucoma (77).

Male external collection devices (i.e. condom catheters) are available, but also are associated with increased risk of UTI’s (82). Patients must be carefully evaluated prior to use for symptomatic UTI, urinary retention and upper tract damage. These devices should not be used in patients with chronic obstruction. Proper application is critical and the patient must be routinely monitored for contact dermatitis, maceration and irritation of the penis, ischemia, penile obstruction and UTI (61, 77, 78).

External collection devices for females are not widely used. Reported adverse reactions include periurethral erythema, perineal itching, skin abrasions, and adherence problems (77, 78, 83). Incontinence briefs are typically used in females. After each episode of incontinence, the skin should be checked for breakdown, a moisture barrier applied and the skin kept clean and dry.

### *Gastrointestinal Abnormalities*

After TBI, the patient is at risk for the development of gastritis, duodenitis, gastroparesis, lower esophageal sphincter dysfunction, gastric atony, and stress ulcers (74). Gastrointestinal bleeding is a serious complication which has been reported in up to 80% of patients who have sustained TBI’s (84). Medications such as steroids, nonsteroidal anti-inflammatory agents, aspirin and anti-coagulants may also exacerbate the problem due to their propensity to increase GI bleeding (66).

Antacids, H<sub>2</sub> blockers, or sucralfate may be used prophylactically in the acute phase after TBI; (74, 85) however, the patient must be closely monitored due to the increased risk of pneumonia which has been reported with the use of antacids or H<sub>2</sub> blockers (86, 87).

Metoclopramide, a central dopamine receptor antagonist, has been historically used to treat gastroparesis and gastroesophageal reflux but observation must occur for deleterious effects such as sedation and extrapyramidal symptoms (54, 87, 88).

A gastrointestinal assessment should include auscultation of the abdomen in all four quadrants for bowel sounds, palpation for signs of pain or distention, testing of stool for occult blood and monitoring vital signs and serial Hgb and Hct for changes indicative of hemorrhage. Checking stool for frequency, color and consistency is important due to the predisposition for constipation secondary to immobility, opiates and fluid restrictions. Conversely, diarrhea may occur due to intolerance to tube feeding or antibiotics (61). Other serious bowel complications include, impaction, intestinal obstruction, paralytic ileus and clostridium difficile colitis (16, 26, 76).

After brain injury, bowel incontinence typically occurs secondary to upper motor neuron damage which results in uninhibited neurogenic bowel; however, co-existing spinal cord and traumatic injuries and preexisting gastrointestinal diseases can also effect bowel continence. Prior to implementation of a bowel program, it is important to determine the type/s of neurogenic bowel dysfunction. A rectal exam should be performed to assess the condition of external and internal hemorrhoids and a physical assessment done to determine if saddle sensation, the bulbocavernosus and anal reflexes are intact (76, 89).

Discussion should occur with the family to determine preexisting elimination patterns and a baseline assessment conducted to determine the time of day and frequency of stools. Based on identified patterns, a toileting schedule can be developed preferably 15–30 minutes after meals, to facilitate the effect of the gastrocolic reflex. Unless clinically contraindicated, left side-lying or sitting will also facilitate evacuation. Adequate fluid intake and close monitoring of tube feeding to assure adequate amounts of fiber, roughage and fluid is also important (61, 76, 89).

Stool softeners and bulk formers should be utilized and dosages and times of administration adjusted as needed. Digital stimulation is not appropriate in bowel programs to manage uninhibited neurogenic bowel, but suppositories or products such as Theravac SB™, a 4cm<sup>3</sup> mini-enema/stool softener laxative may be used to trigger the defecation reflex. A daily bowel movement is not necessary but a patient should not go for more than 3 days without a bowel movement. Continuity of the program is maintained even if the patient has a bowel movement between training times (61, 76, 89, 90).

### *Nutrition and Feeding*

In a study of patients admitted to a rehabilitation unit, Brooke and Barbour (91) reported an average weight loss of 29 pounds. The need for increased nutritional support

can persist indefinitely in the rehabilitation setting and is exacerbated by medical problems such as fever, pressure sores, infection, spasticity, dehydration and loss of fluid due to wound drainage, excessive sweating and diarrhea (91, 92).

An accurate weight should be taken the day of admission and afterward, at the frequency specified by the physician or dietician. Due to problems with scale calibrations, accuracy, and inconsistencies in obtaining timely weights, it is helpful if a small number of designated staff members obtain weights using the same scale and at the same time of day. A system should be in place to assure prompt notification and follow-up by the physician and dietician. Nutritional deficiencies should also be discussed at the interdisciplinary team meeting.

Percutaneous endoscopic gastrostomy (PEG) tubes are commonly utilized in the rehab setting, particularly when long-term nutritional support is anticipated. Prior to administering feedings/medications an abdominal assessment and auscultation of bowel sounds should be performed and tube placement confirmed by checking gastric residuals and the pH of gastric contents per facility policy (72). Feeding tubes should be clamped for at least 30 minutes (or longer per pharmacist recommendations) after phenytoin administration to facilitate absorption, as noted in a study by Faraji et al. (93) who reported a decrease in available phenytoin blood levels when given with tube feeding.

To minimize the risk of aspiration, the head of the bed should be elevated 30–45 degrees. Observation of skin integrity at the stoma site is important since irritation and excoriation can occur due to leakage of gastric secretions (72). The decision to discontinue enteral feeding is dependent upon many factors including the functional integrity of reflexive and voluntary components of oral motor function, the person's level of arousal, the successful management of dysphagia, the degree of facial trauma, and the stability of the patient's nutritional status (37, 54) (Please note: see the chapter on gastrointestinal and nutritional issues and neurogenic swallowing disorders for more detailed information).

### *Spasticity and Musculoskeletal Complications*

Upon admission to the acute/subacute unit it is important to get a detailed history of the trauma that the person sustained. Fractures occur in approximately 30% of persons who have sustained a TBI, (94) 11%, of which are undiagnosed at the time of admission to a rehab setting (95). Peripheral nerve injuries occur in 34% of severely injured TBI patients with 11% also undiagnosed at the time of admission (95). The nurse should routinely assess for unexplained swelling, discoloration, deformity, pain, limitation of range of motion, and, particularly for, signs and symptoms of spinal fractures. Early fracture

fixation is typically performed which facilitates a shorter period of immobilization, earlier range of motion, and fewer problems with pain, contractures, pulmonary complications, severe spasticity and ankylosing heterotopic ossification (69).

The greatest risk for the development of heterotopic ossification (HO) is in the first 3–4 months after injury (69). Unfortunately, the process begins before clinical symptoms are observable. The nurse must be vigilant in observing for decreased range of motion in the affected joint, swelling, warmth, erythema, pain, fever and contracture formation. Range of motion exercises, physical therapy, medications and orthotic devices may be implemented both prophylactically and as a component of treatment at the physician's discretion (66, 96). Surgery may be an option 12–18 months post-injury if significant functional limitation due to deformity is present (54, 66).

Muscle tone abnormalities, flaccidity, rigidity, spasticity, dystonia, paresis, paralysis, contractures, decorticate and decerebrate posturing may be seen after a person has sustained a TBI (66, 69, 97). Nurses should be knowledgeable in performing a basic assessment of tone. The Ashworth and/or Modified Ashworth Scale which grades the degree of hypertonicity in muscle, can be easily learned and facilitates the nurse's reporting of objective input regarding the presence of spasticity (92, 97, 98).

Interdisciplinary collaboration between the physiatrist, PT, OT and nursing staff is critical. Nursing is directly involved in carry over with many treatment modalities. Specific feedback and hands-on instruction should be received from the physical or occupational therapist in regard to specific range of motion exercises, wheelchair and bed positioning programs and splinting interventions (61, 99). When orthotic or splinting devices are used, it is imperative that the nurse assure that adherence to off/on wearing schedules is maintained, neurological and vascular status monitored, and skin observed for breakdown (61).

Nurses need to provide a calm environment for patients with muscle tone abnormalities. Noxious stimuli which can trigger an increase in spasticity include: pain, fear, anxiety, irritation from tubes/positioning devices, DVT, full bladder/bowel, constipation, urinary tract infection, HO, skin breakdown, tight clothing or even the need for repositioning (98, 100).

Systemic pharmacological agents such as diazepam, baclofen, dantrolene sodium, clonidine, and tizanidine hydrochloride are sometimes prescribed but the literature regarding the benefits in treating spasticity of cerebral origin is limited (99). Nurses need to be astute in monitoring any appreciable improvement in tone versus the potentially negative effects on cognition from the use of these medications.

It is also important that protocols be established so that nurses can systematically assess the side effects and

potential complications that can arise after botulinum toxin injections, chemoneurolytic nerve blocks and intrathecal baclofen therapy (100, 101) (Please note: see the chapter on spasticity and musculoskeletal complications for more specific information).

### *Skin Care*

Although not widely discussed in the TBI literature, the failure to maintain the integrity of the patient's skin presents significant morbidity and mortality risks. The new pressure ulcer guidelines released on November 12, 2004 by the Centers for Medicare and Medicaid Services (CMS) provide a comprehensive and instructive guideline which reflect current best practices specific to the prevention and treatment of pressure ulcers (102).

A pressure ulcer is defined by the National Pressure Ulcer Advisory Panel (NPUAP) as "any lesion caused by unrelieved pressure resulting in damage of underlying tissue" (102–104). Pressure ulcers occur when soft tissue is

compressed between a bony prominence and an external surface and can develop within 2–6 hours of the onset of pressure (105). The most common sites and distribution frequency include the sacrum (36–49%), heels (19–36%), ischium (6–16%), trochanter (6–11%), and malleolus (7–8%) (106). Pressure ulcers may lead to pain, increased risk of complications, increased length of stay, staggering costs and interference with rehabilitation interventions and ultimate recovery (107, 108).

Pressure ulcers, as defined by the NPUAP, are staged to classify the degree of tissue damage and range from Stage I, "an observable pressure-related alteration of intact skin" (i.e. change in skin temperature, tissue consistency, sensation or persistent redness or change in coloration) which persists 30–45 minutes after pressure is removed to Stage IV which is defined as full thickness skin loss with extensive destruction, tissue necrosis or damage to muscle, bone or supporting structures (102–104) (See Figure 40-1) Although the nurse is primarily responsible for assessment and treatment of pressure ulcers,

## ***The NPUAP Pressure Ulcer Staging System\****

### ***Stage I***

Nonblanchable erythema of intact skin, the heralding lesion of skin ulceration. In individuals with darker skin, discoloration of the skin, warmth, edema, induration or hardness may also be indicators.

Stage I.

### ***Stage II***

Partial-thickness skin loss involving epidermis, dermis, or both. The ulcer is superficial and presents clinically as an abrasion, blister or shallow crater.

Stage II.

### ***Stage III***

Full thickness skin loss involving damage to or necrosis of subcutaneous tissue that may extend down to, but not through, underlying fascia. The ulcer presents clinically as a deep crater with or without undermining of adjacent tissue.

Stage III.

### ***Stage IV***

Full thickness skin loss with extensive destruction, tissue necrosis, or damage to muscle, bone or supporting structures (e.g., tendon, joint capsule). Undermining and sinus tracts also may be associated with Stage IV ulcers.

Stage IV.

- Stage I ulcers may not always be diagnosed reliably in patients with darkly pigmented skin.
- When eschar is present, a pressure ulcer cannot be staged accurately until the eschar is removed.
- Be alert to pressure-induced pain in patients with casts or support stockings.

**FIGURE 40-1**

the maintenance of skin integrity is accomplished thru a team approach and all members of the interdisciplinary team need to clearly understand risk assessment, wound staging, and preventive protocols.

Identification of risk factors is the first step toward prevention of pressure ulcers. After TBI, patients have a multitude of factors which place them at significant risk for the development of pressure ulcers including: (1) immobility, (2) orthopedic, neurological and vascular trauma, (3) infection, (4) altered sensorium, (5) malnutrition (dehydration, hypoproteinemia, anemia, vitamin deficiency), (6) musculoskeletal alterations (spasticity, contractures, loss of subcutaneous tissue, muscle atrophy, flaccidity), (7) bowel and bladder incontinence, (8) pain, (9) orthopedic procedures of the hip and femur, (10) medications (narcotics, sedative, analgesics, steroids), (11) decreased sensory impairment, (12) diaphoresis, (13) metabolic disturbances, and (14) external mechanical forces (i.e. pressure, friction and shear, casts, splints, orthoses, braces, fixation and positioning devices) (61, 102–104, 108).

Preventive interventions begin with an initial and ongoing completion of a validated risk assessment tool such as the Braden Scale to identify specific factors which place the patient at risk (i.e. sensory perception, moisture, activity, mobility, nutrition, friction and sheer) for the development of pressure ulcers (103, 104).

A comprehensive interdisciplinary care plan is then developed which includes: (1) a protocol for systematic total skin inspection once per day, paying particular attention to bony prominences, (2) proper bed and wheelchair positioning, (3) appropriate transferring to minimize skin injury due to friction and shear, (4) nutritional interventions to assure adequate food and fluid intake to prevent weight loss and malnutrition, (5) incontinence care followed by antibacterial, moisture barrier ointment, (6) pressure reducing seating cushions, (7) written, patient specific, turning and positioning schedules (8) pillows/devices which relieve pressure on the heels and (9) pain management (102–104, 108).

A patient specific assessment (i.e. ability to maintain position, multiple pressure ulcers, limited turning surfaces) must also be conducted to determine the most clinically appropriate support surface (i.e. pressure reduction versus pressure relief, dynamic versus static air or fluid support) and the type of device used (i.e. overlay, replacement mattress or specialty bed) (102, 104, 108).

Wound cleansing should occur with normal saline with enough irrigation pressure to enhance cleansing without causing wound bed trauma. Skin cleansers or antiseptic agents (e.g. povidone iodine, iodophor, Dakin's, hydrogen peroxide and acetic acid) are cytotoxic to normal tissue and should not be used (103, 104).

Treatment of a pressure ulcer begins with an accurate assessment of the ulcer itself specific to size, depth, edges, undermining/tunneling, location, stage, necrotic tissue,

type, color, odor and amount of exudate, skin condition surrounding the wound, granulation tissue, infection and pain (102–104).

If it is determined that debridement (sharp, mechanical, enzymatic and/or autolytic) is necessary, a decision must be made regarding the most appropriate debridement modality. It is important to note that heel ulcers with dry eschar that is clean, dry, nontender, nonfluctuant, nonerythematous and nonsuppurative need not be debrided (102, 103, 108).

Dressings are required to maintain the physiologic integrity of the pressure ulcer. The wound must be protected, the ulcer bed kept continuously moist and the surrounding intact (periulcer) skin kept dry. Moist wound dressings prevent dessication. Drying out a wound destroys healthy tissue and can lead to eschar, infection, and impaired healing. Moist wound dressings promote wound healing through an autolytic process which prevents damage to new cells while debriding the wound, but balance is needed to assure that healing is not impeded due to excessive wound exudate (102–104, 108). Wet to dry dressings should be used only in limited circumstances due to the risk of damaging healthy granulation tissue and causing excessive bleeding and pain (102).

The decision as to which wound care products (i.e. transparent films, hydrogels, hydrocolloids, alginates, foams, composite dressings,) to use should be made based on the previously noted treatment assessment factors. Other factors to consider include cost, and the time involved for the staff to perform the dressing change. Ongoing assessment and interventions for pain is paramount (102–104, 108).

If the pressure ulcer does not demonstrate healing progress within 2–4 weeks, the treatment plan/protocol and the patient's overall condition should be reassessed (102, 104). Pressure ulcer related complications include cellulitis, osteomyelitis, septic arthritis, abscess, bacteremia, septicemia and chronic infection (102–104).

Adjunctive therapies that may enhance pressure ulcer healing include electrical stimulation, vacuum assisted closure (VAC), and surgical intervention (flap) (108).

Ongoing training and education should be conducted by a nurse with recognized training and education in pressure ulcer management and directed toward all members of the interdisciplinary team and the family.

### *Family Dynamics/Supportive Interventions*

Rosen (109) studied the reactions of families whose loved ones remained in a vegetative state and described a five component model which included: (1) grief and anxiety, (2) guilt, (3) denial, (4) accommodation, and (5) disengagement and rejection. The reactions of family members have been described as dynamic, intense and disorganized with family members experiencing several reactions at the

same time and not moving through the stages in any predetermined fashion (43, 110).

Families may report feeling that they are in a state of “limbo”. Spontaneous and reflexive movements may be perceived by the family that the person recognizes them and is trying to awaken. The person is physically present yet what is gone, perhaps forever, is the person who they actually were. The uncertainty as to the likelihood of any further improvement, the guilt of “abandoning hope”, the strain of being pulled in different directions by other family members and work commitments, and the financial burdens all give rise to the family’s experiencing severe stress reactions (43, 61, 110, 111).

The family may displace feelings of anger, frustration and rage onto the nursing staff in the form of excessive criticism, blame, unrealistic demands, inappropriate emphasis on minor aspects of care, and extended vigils at the bedside (43, 61, 110–112). Families have even been observed to display hostility and open aggression directed toward the staff, a reaction described by Stern (113) as relatively unique to families with loved ones in prolonged low level neurological states exceeding four months.

It is imperative that nurses be active participants in the interdisciplinary team’s establishment of a family plan of care which acknowledges the dynamics behind the family’s responses to their loved one’s injury. Only then can specific therapeutic interventions be developed which assist the family to positively participate in the rehabilitation process (43).

### POST-ACUTE COGNITIVE NEUROBEHAVIORAL REHABILITATION

This chapter has thus far focused primarily on the physical impairments sustained after TBI. It is, however, the cognitive, psychosocial and neurobehavioral problems following TBI that can most profoundly affect the person’s response to rehabilitative intervention, their interpersonal relationships and their successful reintegration into the community (114, 115). It is the treatment of these sequelae that often poses the greatest challenge to the nursing staff caring for persons who have sustained TBI’s.

In a rehabilitation setting, a nurse is often the senior clinician with twenty-four hour responsibility for assuring that care plan approaches for intervening with a person’s maladaptive and sometimes dangerous behaviors are consistently implemented and that the patients, staff, family members and visitors are kept safe. Nurses, however, receive only limited training in their nursing education to prepare them to effectively manage behavioral sequelae or to effectively supervise licensed and paraprofessional staff members in the implementation of therapeutic interventions. This can be particularly problematic during off-shifts and weekends when staffing is likely to

be the most minimal and support persons are not immediately available (116).

The primary focus of this section will be the pragmatic aspects of the nurse’s role in maintaining a therapeutic milieu for the treatment of patients demonstrating behavioral issues after TBI. Neuropsychological assessment and psychopharmacological intervention will be addressed elsewhere in this text.

### Assessment

It is important that the nurse interview the family member/significant others. This comprehensive assessment must include a review of the patient’s premorbid level of cognitive abilities, strengths and weaknesses. Factors which can influence cognitive and behavioral manifestations of behavior include injury severity, age, early developmental factors, time post injury, diffuse versus focal or combined injuries, length of coma, and length of amnesia. Premorbid patient variables such as education, occupation, psychiatric conditions, substance abuse problems and previous brain injury can also impact prognosis (117).

Although an extensive cognitive and neurobehavioral assessment will most likely be performed by the neuropsychologist, nurses may be involved in administering simple tests such as the Folstein Mini-Mental Status Examination which provides specific, detailed and useful information regarding the patient’s orientation, insight, recall, attention, visual-spatial skills, affect and speech (118).

### Defining Behavior

It is important for the nurse to understand the need for objective, quantifiable, measurable definitions of behavior. Although less statistically valid and reliable than other scales, a cognitive recovery scale still widely used to describe a person’s level of awareness is the Rancho Los Amigos Scale. A person functioning at Rancho Level IV is “confused, agitated-inappropriate” (54, 119).

Descriptive characteristics of Rancho Level IV include: “severely impaired information processing; responding to internal confusion; attention span very limited; behavior often bizarre; short-term memory impaired; dependent in all aspects of care; safety of major concern”. This state of “agitation” may last days, weeks or throughout a person’s life time and can be internally driven or exacerbated by environmental stressors (54, 119).

Simply labeling a person as “agitated” or a “Level IV”, however, does not provide specific, measurable criteria from which treatment decisions can be made. Although studies have cited the prevalence of “post-traumatic agitation” as ranging between 11–50%, (120, 121) the meaning of the term “agitation” is vague, nonspecific and not

consistently defined. Complicating matters further, is the difficulty in evaluating the efficacy of interventions when comparing studies due to this lack of a universal definition (62).

In 1996, the following definition of the term agitation was proposed: “a subtype of delirium occurring during the period of posttraumatic amnesia characterized by excessive behaviors, including some combination of aggression, akathisia (motor restlessness), disinhibition, and emotional lability” (121–123).

It is the precise defining of these “behaviors”, however, that is necessary to assure objective assessment and therapeutic intervention. An individualized analysis of the individual’s behavior should be conducted and specific descriptors identified based on an operational definition developed by the interdisciplinary team. The Agitated Behavior Scale or the Overt Aggression Scale provide particularly useful behavioral descriptors to assist in targeting specific behaviors (124, 125).

### A–B–C Data

Once a target behavior is defined, a baseline must be established. Data collection should be instituted which includes antecedents, behaviors, and consequences (ABC). Documentation of the antecedent, the stimulus or event which precedes a behavior, allows identification of potential triggers that precipitate behavioral responses. This information may include time of day, a specific activity, hunger, thirst or sleep deprivation, environmental issues, specific caregiver/family member, or change in routine (126, 127).

Specific behaviors, as previously discussed, must be objectively quantified specific to frequency, duration, latency and intensity of the behavior. Finally, it is important to identify the consequences that follow behavior. A consequence may function as a positive or negative reinforcer which increases the likelihood of behavior or as a punishment which decreases the frequency of behavior (54, 62, 126, 127).

### Interdisciplinary Team

The need for a consistent, cohesive, interdisciplinary team led by the physician is paramount when treating persons with behavioral disorders. The interdisciplinary team determines specific interventions based on analysis of the ABC data with feedback from all members of the interdisciplinary team. Interventions should be formalized into an individualized plan of care with specific long term goals, short term objectives and specific approaches. Both the person with the brain injury and their family should be active participants in this process (116, 127).

Time *must* be allotted to include a nurse and nursing assistant as part of this meeting. Unfortunately, it is the

nurse and nursing assistant who are sometimes “pulled” from attending this meeting due to the need for “coverage on the unit”. If staff members have input into the development of the plan of care, they will be better prepared to implement consistent, structured, therapeutic interventions when they are faced with behavior that may be unpredictable and dangerous (116).

### Behavioral Interventions

Staff members need to understand how fatigue and short term memory deficits affect the person’s behavior. Staff must be taught to distinguish between a behavioral deficit in which the person does not know how to perform a particular behavior versus noncompliance in which a person can perform the behavior but is noncompliant. The team must develop a consistent approach for all staff members to follow which is specific to the patient’s learning style and cognitive awareness (116, 126–129).

Behavioral outbursts can be terrifying since they can present as sudden, unprovoked and violent. If the direct care/nursing staff are not provided with training in appropriate limit setting and deescalation techniques and ongoing support and supervision, they may demonstrate feelings of fear, frustration and helplessness, thus compromising the treatment of the patient and the safety of other patients, staff and visitors (62, 116, 128–130).

Staff must be taught to remain calm yet firm, use direct, simple statements and avoid criticizing or arguing. Redirection, consistency and reinforcement of appropriate behavior is critical. Potentially volatile situations must be defused when they begin rather than waiting until the person becomes violent and out of control. If assaultive behavior is imminent, quick, coordinated action is a team effort. A staff member should not try to deal with a potentially explosive situation alone (62, 127–130).

Contingency management systems, positive reinforcement, stimulus control, social skills training, behavior shaping, self-control techniques, cognitive remediation, redirection, distraction, differential reinforcement and modeling of appropriate behavior are examples of strategies that might be utilized to assist the person in regaining self control (54, 127, 130).

### Environmental Interventions

The control of environmental stimulation is necessary in order to decrease the person’s anxiety, restlessness and irritability and to reestablish sleep/wake cycles. Over stimulation can be caused by aggravating factors in the environment such as noise, clutter, crowding, overhead paging, lighting, room temperature variations, ringing phones, loud televisions/radios, inconsistent scheduling of therapy, too many visitors, or nursing care treatments which provoke tactile defensiveness (62, 128, 131).

The environmental milieu may not be conducive for the management of disruptive behavior. The person may be intermingled on a unit with other patients with a variety of diagnoses who are at varying stages of their own recovery. This is particularly problematic when persons who are severely medically compromised and require intensive medical interventions (i.e. vents, tube-feedings, oxygen, IV's, etc.) are intermingled with patients who are either ambulatory or independently mobile in their wheelchairs.

Environmental stimulation should be reduced to enable the staff and family to better individualize interventions which have a calming effect on the person. If stimuli can not be eliminated, the person may benefit from the use of a protective, monitored room in which the floor and walls are covered with protective padding that would enable the patient to be safely mobile (62, 116).

### Falls

Falls are a potentially catastrophic event, particularly in person's who have already sustained a brain injury. Although much of the research done in the area of fall prevention is in the geriatric and stroke literature, (132–137) persons who have suffered brain injuries, demonstrate a multitude of similar characteristics that could put them at risk for falls including: (1) cardiovascular, neurological (weakness, gait and balance disorders, dizziness) and musculoskeletal sequelae, (2) history of falls, (3) incontinence, (4) visual-perceptual disturbances, (5) pain, (6) cognitive impairments (i.e. confusion, impaired arousal, judgement and memory, motor restlessness, impulsivity) and (7) the use of psychotropic, cardiovascular, anti-hypertensive, and diuretic medications. Environmental/situational hazards (i.e. lighting, slippery floors, clutter) also increase the risk of falls.

Fall prevention interventions should be interdisciplinary and based on an individualized assessment of the person's internal and external risk factors and functional impairment. The environment must also be assessed for potential hazards. Interventions might include chair/bed alarms, low beds, strengthening and balance programs, hip protectors, call bells within reach, increased supervision/appropriate staffing, bowel and bladder programs, patient and family safety education, video monitoring systems, medication monitoring, and environmental modifications (6, 62, 132–136, 138).

The Joint Commission on the Accreditation of Healthcare Organizations (JCAHO) Sentinel Event Alert "Fatal Falls:Lessons for the Future", stresses the need for post-fall investigations to identify and analyze the root causes of falls and suggests risk reduction strategies such as fall prevention education of staff, patients and visitors, low beds, bed alarms, bed alarm checks and tests, and the revision of staffing procedures. Formal fall prevention

protocols provide a consistent, organized approach to managing fall risk in persons who have sustained TBI's.

### Restraints

Physical restraints as defined by the Health Care Financing Administration (139) in 1995, include "any manual method or physical or mechanical device, material, or equipment attached or adjacent to the resident's body that the individual cannot remove easily which restricts freedom of movement or normal access to one's body."

CARF similarly defined physical restraints as "restrictive procedures," including devices that "(1) restrict an individual's movement; (2) restrict an individual's ability to obtain positive reinforcement; and (3) restrict an individual's ability to participate in programs" (140).

Following a TBI, patients may demonstrate severe motor restlessness, lack of safety awareness, impulsivity, the need to exit their bed, and a lack of skills to safely ambulate (141, 142). Historically, the use of physical restraints was an intervention utilized to prevent falls, to ensure that medically necessary tubes remained intact, and to keep patients who were "agitated" or "wandering" under control and "safe". The use of restraints was also justified as a necessary prevention intervention to "prevent being sued" (143–146).

Schleenbaker, (147) for example in 1994, reported that 32.2% of rehabilitation patients were mechanically restrained for an average duration of 17 days during their rehab stay and that TBI was a strong predictor of medical immobilization.

Clinical studies over the past decade, however, have demonstrated that the use of physical restraints does not prevent injury or reduce the risk of falls when alternative interventions are implemented. Ironically, there are numerous adverse physical and psychological effects attributed to the use of restraints including: increased incidence of falls, head trauma due to falls, deconditioning, gait and balance problems, incontinence, contractures, pressure sores, loss of muscle tone and independent mobility, chronic constipation, neurovascular compromise, infections, cognitive decline, psychiatric morbidity and serious injuries. Restraints can also actually worsen agitation and restlessness and the person's desire to free themselves from being "tied down", increasing the risk of serious injurious falls and deaths (138, 139, 143, 148–154).

Restraint-related deaths by asphyxiation have occurred whereby the person is suspended by a restraint (i.e. vest, waist restraint) from the bed or a chair and several deaths have been reported in which persons died trying to escape restraints by setting fire to their restraints (155–158).

As of April 1992, prompted by reports of numerous injuries and deaths involving restraints, health care facilities are required to report restraint related injuries to the manufacturers and restraint-related deaths to the FDA (159).

### Siderails

Bilateral full-length siderails were historically placed in the “up” position to “prevent the patient from falling out of bed.” A siderail, however, may be considered to be a restraint depending on how it is being used for a particular individual. If a side rail impedes desired movement, such as keeping the person from getting out of bed it is considered to be a restraint (143, 160, 161).

Side rail usage has not been shown to significantly reduce the likelihood of falling or of serious injuries. Siderails are not a benign intervention (148). If a person is attempting to get out of bed, the siderail can increase the height of a fall by two feet, thus precipitating a fall from a higher distance with an increased risk of injury (139, 162, 163).

Entrapment hazards are particularly dangerous. Parker and Miles (164) studied 74 deaths caused by bedrails between 1993 and 1996 and determined that 70% occurred when the person was entrapped between the mattress and a rail with their face against the mattress. An additional 18% died when the person’s neck was compressed within the rails and 12% died when trapped by the rails after partially sliding off the bed with subsequent neck flexion or chest compression.

The 1995 FDA Safety Alert: “Entrapment Hazards with Hospital Bed Siderails” (165) and the JCAHO Sentinel Event Alert, “Bed rail-related entrapment deaths” (September 6, 2002) describe interventions such as staff education, assessment of residents for entrapment risk, re-evaluations of beds and mattresses for gaps and openings, and modifications which reduce the risk of entrapment such as retrofit kits, bedrail netting, clear padding and Velcro or anti-skid mats to prevent the mattress from shifting.

### Restraint and Siderail Alternatives

Restraint/siderail alternatives may include bed/chair alarms, bed bumpers, perimeter mattresses, low beds, Vail(beds, mattresses on the floor, wheelchair seating adaptations, anti-tipper bars, trapeze, and transfer pole/bars (62, 116, 143, 160, 166).

Restraint alternatives that may be utilized when a patient attempts to dislodge a gastrostomy tube might include an abdominal binder. Elbow splints or mitts may be an alternative to wrist restraints and sleeve covers for peripheral IV’s may be far less agitating than the use of physical restraints (62, 116, 128).

### Wandering

For persons who are at risk for wandering, the environment must provide a safe, protective setting where the person can safely walk or pace if they need to without the risk of elopement. Some units are specified as locked

units; however, in most settings, a safety beeper may be applied to the person’s ankle or wheelchair that will alert the staff whenever an attempted elopement occurs. If the ankle bracelets are used it is imperative that a system be developed whereby the ankle bracelets are monitored to assure placement and proper functioning (62, 116, 141).

### Staffing

Ongoing training for staff at all levels is imperative. The Training Manual for Certified Brain Injury Specialists (CBIS) from the American Academy for the Certification of Brain Injury Specialists (AACBIS) is a specialized training and certification program which can be used to educate and acknowledge caregivers at multiple levels of involvement (130). Staff working with potentially violent patients should also receive crisis intervention management training.

Adequate numbers of staff who are trained to behaviorally manage noncompliant and maladaptive behavior is imperative. An acuity based staffing system should be used which addresses the needs of this unique population and is sensitive to the need for ongoing readjustment. It is important to have the same primary caregiver to the degree possible. The use of agency staff in the treatment of these individuals can create a break in consistency with potentially damaging outcomes. All disciplines including ancillary personnel such as housekeeping and dietary staff must be knowledgeable of the person’s individualized plan of care.

Administrative support is particularly critical when the team decides that 1:1 observation is necessary. Staff members who serve as “sitters” must be thoroughly oriented to the specific individualized care plan for the person they are observing and be able to effectively communicate both in speaking and in writing since they are with the person constantly and can report the least perceptible changes (141, 167).

Prior to placing a person on one to one observation, goals and specific interventions must be established which include criteria for weaning the person from this intensive level of supervision. Supervision must be provided to keep the patient safe but it is also important to be cognizant of the cost associated with this intervention. A 1999 study by Eastwood and Schechtman (167) reported costs associated with 1 to1 monitoring of \$78,000 per year for each patient monitored.

### Pharmacological Interventions

The decision to use pharmacological intervention is predicated upon a risk versus benefit analysis of the intended therapeutic effect versus an adverse effect that can impede recovery. It is important to differentiate “learned” responses of maladaptive behavior that have been inappropriately reinforced from those that are secondary to

the effects of the injury and biochemical disturbances (115, 127).

Prior to beginning psychopharmacologic interventions, it is important that the physician meet with the nurses and other members of the interdisciplinary team to identify and, when possible, treat underlying conditions (e.g. sleep dysfunction, noxious stimuli, seizure disorders, pain, environmental exposures, infections, metabolic or electrolyte abnormalities, liver or renal dysfunction, nutritional deficiencies, constipation, urinary retention, bowel and bladder incontinence, substance abuse) and superimposed central nervous system changes (i.e. stroke, ischemia, focal vascular deficits) which can dramatically affect a person's behavioral presentation. The person's current medications should also be reviewed to assess for drug related withdrawal effects and all unnecessary medications discontinued or appropriate substitutions made (114, 168, 169).

The presence of premorbid behavioral disorders and psychiatric diagnoses (e.g. post-traumatic stress disorder, major depressive disorder, conversion disorder, adjustment disorder, panic disorder, generalized anxiety disorder, mood disorders, organic brain syndrome) must also be considered prior to deciding to utilize psychoactive medications (169).

Once a decision is made to use psychopharmacologic medications, the nursing staff must be vigilant in observing for both intended effects and possible adverse reactions. Concise, objective information, based on observation of clearly definable behavioral responses combined with knowledge of the patient's comorbid conditions, laboratory data, medication regime and a thorough multi-system assessment, must be reported to the physician so that a clinically sound, judicious decision is made in regard to medication use as opposed to the use of medication for convenience (169).

## CONCLUSION

The rehabilitation nursing management of persons who have sustained TBI's is complex, dynamic and uniquely challenging throughout the continuum of care. Brain injury rehabilitation presents the nurse with a unique opportunity to make a profound difference in the survival, the restoration and the maintenance of optimal health, maximal independence and quality of life in persons who have sustained traumatic brain injuries.

## Cognitive Rehabilitation

*Keith D. Cicerone*

**C**ognitive impairments are often the most persistent and prominent sequelae of brain injury in patients with moderate or good neurologic recovery. Interventions designed to promote the recovery of cognitive functioning and reduce cognitive disability are an integral aspect of brain injury rehabilitation programs after traumatic brain injury (TBI) (1). Despite this, as many as 80% of persons who have sustained a TBI believe that their need to improve their cognition had not been met at one year post-injury (2). The growth in clinical services directed at the rehabilitation of cognitive impairments has recently been matched by efforts to establish the empirical basis for cognitive rehabilitation (3). This chapter is intended to integrate some of the clinical issues involved in the remediation of cognitive impairments after TBI, with a discussion of the empirical literature. The discussion of the literature relies primarily on studies that provide evidence for the “best available practices” in cognitive rehabilitation, but includes some discussion of clinically important or innovative therapies.

### RECOVERY OF NEUROCOGNITIVE FUNCTIONS

In a seminal text on the *Restoration of Function after Brain Injury*, Luria (4) described a number of different

mechanisms to support the re-organization of higher cortical functions after brain injuries. This description rests on the distinction between the two meanings of “function.” The concept of function may be used to refer to the specific activity performed by a tissue or organ; however, in relation to the physiology of higher nervous activity and the psychology of higher cognitive processes, “function” refers to a complex adaptive activity consisting of a group of multistage representations, which are organized in a dynamic relationship, and directed toward performance of a particular task. This conceptualization of function might be better described as a “functional system,” similar to the current concept of distributed cortical networks (5). A fundamental characteristic of a functional system is that different processes may be utilized to carry out a given task under different conditions, a property which increases the adaptability of higher cognitive functions. The mechanisms for recovery of function follow a similar evolution from simple to complex. In cases of damage to the primary cerebral areas serving sensory and motor functioning, re-organization after injury may take place through (a) the ability of intra-systemic processes to take over role of damaged tissue, and (b) the intact influence of higher cortical centers on lower levels of function. At the highest levels of cerebral functional systems, recovery takes place through a process of inter-systemic re-organization, which may include completely different components that formerly served widely different functions.

Luria (4) was eloquent in relating these principles of recovery to specific methods of rehabilitation. He also identified several factors considered to moderate recovery, such as the extent of neurologic damage and the developmental level and premorbid integrity of the disturbed function. One of the principle factors determining the success of restoration of higher cognitive functioning is the patient's level of motivation (or "capacity for mental tension") since recovery at this level requires active, effortful, and conscious compensation.

The neurological mechanisms underlying recovery have continued to receive attention, with several attempts to apply these principles to neurorehabilitation (6, 7). However, few interventions for cognitive impairment after TBI have been derived explicitly from such principles. Current approaches to cognitive rehabilitation do at least implicitly incorporate some of the proposed principles of recovery. Therapies may focus on modification of inherent cognitive processes and abilities, or on the external environmental conditions that affect performance. Therapies may also emphasize retraining of multiple, basic neurocognitive components or the retraining of more integrative abilities and functional skills. Finally, the therapeutic approach can be "bottom-up," based on the sequential building from elementary to complex skills, or "top-down" via the application of superordinate controls over subordinate processes.

### Process-Specific Remediation

Skill-specific or process-specific models of cognitive remediation assume that specific interventions can impact differentially on component neurocognitive deficits. Sohlberg and Mateer (8) developed an influential, process-specific approach to cognitive rehabilitation in which treatments are directed, in highly targeted manner, at specific cognitive areas. The process-specific approach is based on the assumption that direct retraining of specific cognitive processes, through multiple repeated trials of stimulation and activation of the targeted cognitive process, can lead to the reorganization of higher level neurologic and cognitive processes. Treatments are provided in accordance with a hierarchical model of cognitive functioning from lower to higher components of cognitive functioning, in order to provide continuous stimulation and activation of the cognitive process. It is assumed that improvements in functioning at the process-specific level will generalize to tasks that contain similar cognitive requirements, and eventually to improvements in everyday functioning. Gordon and colleagues (9) also combined specific, well-controlled training procedures in basic scanning, somatosensory stimulation and size estimation, and visual-spatial organization into a comprehensive perceptual remediation program. The training program was effective in promoting improvement on psychometric

measures closely related to the training areas. Limited generalization of improvements to measures not specifically related to the training tasks occurred, although the investigators noted more time spent in recreational reading after treatment

### Functional Skills Training

Functional skills training concentrates on the patient's ability in domain-specific, context-specific areas of functioning and the retraining of "competencies of daily life" (10) rather than the putative underlying deficits. Mayer et al. (10) suggested several approaches to training, such as (1) repetition of a whole skill in a natural context (e.g., drinking from a cup during breakfast), (2) training of component parts (e.g., looking for the cup, reaching, grasping, etc) followed by whole-skill training, and (3) various attempts to substitute new procedures to perform the desired activity. Although conceptualizing behavior and presumable interventions according to a hierarchy of pre-skills, individual skills, and routine and activity patterns, this approach did not consider the cognitive task attributes distinct from the functional skills being trained. Following Tsvetkova's (11) notion of retraining within the context of a broader function, they suggest that the remediation of cognitive impairments should not address specific components through training exercises in memory, attention, reasoning, and so on, but to address these impairments only in so far as they are embedded within functional activities. Though the work of Glisky and Schacter (12) is derived from neurocognitive-oriented work on spared memory abilities after brain injury, their training approach is very functionally oriented in its emphasis on the acquisition of domain-specific knowledge by memory-impaired patients. They utilized a method of "vanishing cues" to teach four brain-injured amnesic patients computer-related vocabulary words. Consistent with a functional approach, the training was intended to provide the patients with specific knowledge in an area important to the patient's everyday lives (computer terms) rather than produce general improvements in memory function. Glisky and Schacter (12) suggested that the same procedure might be applied toward the acquisition of complex forms of knowledge by brain-injured patients, as well as the possibility of training patients to become expert in specific, defined content areas. In each of these functional approaches the patient is trained on the same task that he or she is expected to perform in the context of daily activities, and training is specific to that situation. Generalization to other related situations is not expected as a consequence of the initial training. Thus the necessity of training a wide range and number of specialized, context-specific skills and routines is characteristic of the functional model.

## Metacognitive Remediation

Metacognition refers to the subjective knowledge and experience of one's own cognitive processes, which can be used to guide cognitive activity (13). Metacognitive training therefore places its major emphasis on increasing awareness of deficits, self-monitoring of errors, and self-regulation in order to improve the ability to independently recognize or anticipate the need for compensatory strategies and utilize those strategies in the appropriate situations. Shallice's (14) neuropsychological model distinguishes between the cognitive levels of *processing structures* and two levels of *cognitive control*. Processing structures consist of special-purpose cognitive subsystems such as object recognition, semantic comprehension, spatial orientation, and so on, that can be analyzed by fractionation of the subsystems into the involved components. These cognitive sub-systems can also be organized into relatively invariant functional routines, or schema, such as eating breakfast or driving home from work. *Routine* control of activity is accomplished through relatively automatic and rapid selection of habitual schemata and the inhibition of weaker competing schemata. However, an additional level of voluntary, strategic, and *nonroutine* control is required when planning is required, when the correction of unexpected errors is required, when the required response is novel or not well learned, or when habitual responses need to be inhibited.

Reliance on the underlying assumption that patients will be able to develop sufficient awareness and insight to apply strategies in a variety of situations is a distinctive aspect of the metacognitive approach. Crosson et al. (15) has distinguished between intellectual, emergent, and anticipatory levels of awareness after brain injury. Different degrees of compensation may be available to patients, depending on their degree of awareness deficit. For example, patients with marked deficits of intellectual awareness may require external, task-specific compensation whereas patients with minimal awareness deficits may compensate by recognition or anticipation of problems while moving from one environment to another several times in the course of their daily functioning.

## REMEDICATION OF ATTENTION DEFICITS

### Remediation of Attention Deficits

Various components of attention have been identified and related to different cerebral networks. Posner and Rothbart (16) identified three different attention networks. The posterior attention network involves the parietal cortex, pulvinar and reticular thalamic nuclei and superior colliculus and is involved in orienting to and locating sensory stimuli in space. The anterior attention network involves the anterior cingulate gyrus and supplementary motor

area and appears active in the detection and selection of target stimuli and inhibition of responses to irrelevant stimuli. Although selectivity may occur on an automatic or unconscious level, situations which are novel or complex will require conscious and strategic control over attention. The vigilance network involves the locus coeruleus and brainstem reticular connections with cerebral cortex, especially lateral frontal cortex. This system may be responsible for maintaining alertness and vigilance. Whyte (17) also reviewed evidence suggesting that attention was not a single cognitive process controlled by a focal brain region and indicated that the neural control of attention was mediated by various structures including the brain stem, subcortical structures, and cerebral cortex, which interact in a richly interconnected network. Whyte (17) suggested that the distribution of attention across this dense neural network had two important clinical implications. First, he suggested that different brain lesions could produce qualitatively different attention deficits due to disruption of distinct aspects of the attentional network. Second, lesions to different brain regions could produce similar attentional impairments due to the distributed and integrative nature of the attentional system. The effectiveness of remedial interventions would, in principle, depend upon providing treatment directed at the precise nature of the attentional deficit.

Impairments of attention are common after TBI, and include reductions of processing speed, difficulty sustaining the focus of attention (e.g., maintaining concentration or a train of thought), and limitations in the ability to regulate the allocation of attention in complex situations (e.g., shifting attention to multiple speakers, or between several ongoing tasks). Therefore it is not surprising that some of the earliest formal attempts at cognitive remediation after TBI were directed at deficits of attention. In an early study of attention process training (APT), Sohlberg and Mateer (18) provided the training to four patients and compared it with training for visual perceptual abilities, using a multiple baseline across subjects design. The patients were all at least one year, and up to 6 years, after injury, so it is likely that their deficits were stable. All four subjects demonstrated gains on a single attentional-outcome measure following APT, but not after the visual-perceptual treatment. The measure used to assess improvements in attention was similar in several respects to the training tasks, so it is likely that the improvements reflected some degree of familiarity and practice with the task demands and near transfer to the outcome measure.

A more recent study of APT (19) used a randomized crossover design to compare APT with a "placebo" condition that consisted of education and support. The 14 patients with acquired brain injury were again all at least one year post-injury, ranging as far as 22 years post-injury. Most of the patients had sustained severe TBI,

including positive neuroimaging, and they all exhibited impairments of attention on neuropsychological evaluation and subjective report by the participant and/or a significant other. The APT tasks were again administered in accordance with a hierarchical approach, although the training exercises were selected for each of the patients based on their specific profiles of attention deficits. Treatment effects in this study were evaluated on a range of outcome measures, including neuropsychological measures intended to reflect specific components of attention, standardized questionnaires, and structured interviews. Significant benefits of APT, compared with therapeutic support, were most apparent in patients' self-reported changes in attention and memory functioning. Improvements in cognitive functioning on neuropsychological measures intended to assess the anterior attentional network for the regulation of attention (but not measures of spatial orienting or vigilance) were also greater following APT, and paralleled the patients' self-reports of improved functioning. The specificity of improvements on an aspect of attention related to the regulation of attention, and relationship of these improvements to patients' subjective improvements in their daily functioning, argues against the interpretation that the benefits of treatment were due either to generalized stimulation or task-specific practice effects. These findings also suggest that the benefits of training are due to patients' improved ability to control their attention, rather than restoration of more basic attentional processes.

Several additional prospective, randomized, controlled studies are consistent with the view that treatment for attention deficits are effective during the postacute phase of recovery from TBI, and related primarily to patients' ability to understand the nature of their deficits and use appropriate compensations in functional situations. One study (20) treated 26 people who had sustained a TBI between one and six years earlier and were living in the community. The attention treatment consisted of computer-based tasks directed at improving participants' ability to focus their attention or allocate their attention between tasks; in addition to practice on the computer-based tasks a significant portion of each treatment session was devoted to providing participants with feedback about their performance and implementing strategies to compensate for their attention difficulties. The group receiving the attention treatment improved significantly over the course of treatment, although these effects were relatively weak and did not transfer to additional measures. In another study (21) attention remediation was compared with a "placebo" condition of recreational computing. The patients varied widely in their time post injury and severity of deficits, and included etiologies of both TBI and stroke, although neither of the latter two factors was related to the effects of treatment. Training was intended to address attention control processes such as manipulating information in

working memory or dividing attention between two tasks, and was compared with the effects of recreational computing. Some benefit of the attention treatment were apparent immediately after treatment, but were more evident six months after treatment, at which time the patients who received the attention treatment showed continued improvement while the patients who used recreational computing did not improve, and in some cases their performance deteriorated. The treatment group's pattern of modest initial improvement followed by increased benefits over time may have represented their increased proficiency in the use of strategies in their daily functioning. This pattern of prolonged benefits of treatment being related to the active use of strategies, and lack of benefits when strategies are no longer used, is evident in a number of studies and consistent with the view that improvements in functioning are related to patients' ability to learn and implement compensatory strategies in their everyday functioning.

This approach also served as the basis for an intervention that was intended specifically to teach patients with TBI to compensate for the experience of "information overload" due to their slowed information processing during the performance of daily tasks (22). Twenty-two patients with TBI, most of whom were more than six months post-injury, received either "Time Pressure Management" training or generic instructions to improve their concentration. The Time Pressure Management (TPM) was intended to increase patients' awareness of errors and use of strategies to manage demands under distracting conditions that were likely to be encountered in their everyday lives. Participants receiving TPM showed significantly greater use of self-management strategies during task performance, particularly on more complex tasks that allowed them to adjust their approach to the task, but not on basic reaction time tasks in which such a strategy could not be applied.

Patients with mild TBI often complain of difficulties with the more complex aspects of attention, and are likely to exhibit selective impairments of attention functioning in the context of generally intact cognitive functioning. One small, observational study (23) has evaluated the effectiveness of an intervention intended to improve "working attention" in four patients with mild TBI, compared with four patients who did not receive treatment. The intervention emphasized the use of strategies to allocate attention resources and manage the rate of information during task performance. The patients receiving attention treatment demonstrated "clinically significant gains" on objective measures of attention and significant reductions of self-reported attentional difficulties in their daily functioning.

Overall, these studies suggest that significant benefits can be obtained by patients with attentional difficulties during the postacute period of recovery from TBI.

Gains on objective measures of attention are related to subjective improvements in patients' everyday functioning. Finally, these benefits appear to be related to patients' abilities to apply compensatory strategies in their daily functioning, even for relatively basic deficits such as reduced processing speed, rather than by restoration of the underlying attention processes. The evidence for generalized, functional improvements in attention functioning after treatment in the above cited studies rests primarily on patients' subjective report. However, one single-subject study has reported beneficial effects of an intervention intended to facilitate control over attention during functional activities, such as decreasing the frequency of lapses in attention while the patient was reading novels and texts (24).

The benefits of remediation for attention deficits during the acute period of rehabilitation for TBI are not readily apparent, and it does not appear possible to distinguish the effects of specific attentional training (such as APT) from the more general effects of acute brain injury rehabilitation (25) or spontaneous recovery (26).

### REMEDICATION OF MEMORY DEFICITS

Memory complaints are ubiquitous after brain injury. However, the memory difficulties seen after TBI typically do not reflect a classic amnesic disorder. Instead, memory difficulties are likely to be due to a number of different factors, and are unlikely to represent a unitary deficit. For example, attention deficits such as distractibility or slowed processing are commonly believed to cause impairments in the acquisition of information, and executive impairments may cause memory failures due to the failure to adequately organize material or initiate efficient memory retrieval processes (27).

One of the first descriptions of remediation for memory deficits after brain injury (28) presented two case studies on the use of semantic elaboration and visual imagery techniques to improve the encoding of information. After the effectiveness of these techniques was demonstrated in the laboratory, they were applied to the patient's presenting problem of reduced academic performance. The success of treatment was assessed by the patient's improved subjective ratings of her memory functioning and reduction of negative self-statements, and her ability to remain in her academic classes with less subjective difficulty. Review of her academic performance suggested that she was able to apply the procedure in her everyday life, although the effects were not as great as were seen in the laboratory situation.

Ryan and Ruff (29) examined the general effectiveness of compensatory memory remediation by combining a number of strategies for improving verbal and non-verbal memory capacities in a comprehensive remediation

program. Treatment was provided to ten patients with TBI who exhibited persistent mild to moderate memory deficits. Interventions included instruction and practice in the use of rehearsal, elaborative semantic encoding and associative strategies, imagery construction, "personalized emotional techniques", external memory strategies, and group education and practice with the various memory compensations. Individualized cuing procedures were developed for each patient and practiced on a daily basis. Control patients participated in recreational activities and psychosocial support. At the completion of the treatment both groups demonstrated significant improvement on memory measures, without any apparent specific benefits from the specialized memory remediation program. Subsequent analysis did suggest that the patients with relatively milder cognitive deficits showed greater benefit from the memory remediation strategies, while those with moderate residual impairments did not benefit from treatment. This study is important for several reasons. First, the treatment more closely resembled a multidimensional, clinical protocol than in many experimental studies. Second, the study evaluated the differential effectiveness of treatment in relation to the severity of cognitive impairment. Finally, the study provided an explicit comparison between active, specialized memory remediation and a nonspecific intervention.

Kaschel and colleagues (30) conducted a prospective, controlled study of a visual imagery technique for the rehabilitation of participants with mild memory impairment after acquired brain injury. The intervention consisted of a standardized imagery-acquisition procedure to promote imagery-generation, overlearning and automatization, and included an individually-tailored training period directed at the transfer of the strategy to everyday relevant materials. Visual imagery was compared with "pragmatic memory training" that included practical guidelines to improve memory and the use of notebooks and calendars. Twenty-four patients with TBI had initially been referred for memory rehabilitation, and memory problems were considered to be of primary importance, although patients with severe memory impairment were excluded. Significant improvement was apparent only for the imagery condition on the recall of verbal material, consistent with the expected effects of treatment. The improvements associated with visual imagery training were paralleled by positive changes in relatives' ratings of patients' memory functioning and were maintained at three month follow-up.

Another randomized controlled trial (31) has specifically compared "repetitive drill and practice" on memory tasks with training in cognitive strategies to improve memory functioning after TBI. Cognitive strategies to improve memory functioning were explained, demonstrated, and practiced three times a week for six weeks, and patients received daily homework stressing the

importance of application of memory strategies in everyday life. Intervention was highly individualized, with the specific memory problems selected for training based on the subjects' report of difficulties experienced in their daily functioning. Patients in both the strategy training and "drill and practice" groups reported subjective improvements in memory functioning, but significant effects on objective memory performance could only be demonstrated in the strategy training group, and this difference was maintained at 4 month follow-up.

In a follow-up study four years after the initial training (32), subjective memory and objective memory performance were the same for both patient groups and equivalent to a no-treatment brain injury control group (and still well below the level of normal control subjects). Of note, several subjects in the strategy training group showed a decline in their performance, while the "pseudotreatment" group showed continued, significant improvements despite the fact that patients were between five and 25 years post injury at the time of follow-up. In contrast with this study, Wilson (33) evaluated 26 patients with traumatic head injury who had been referred for memory therapy five to 10 years earlier. On standardized memory testing, most patients remained stable and 8 patients showed improved performance. It was noted that many subjects were using more memory aids and strategies at the time of follow-up assessment than they were at the completion of their initial memory rehabilitation, which may have accounted for the positive findings (34).

*Prospective Memory* The ability to remember to do something at some future time, referred to as prospective memory, appears to be one of the most common memory problems for patients with acquired brain injury (35). Prospective memory interventions may be based on modifications of other memory interventions, such as space-retrieval and distributed practice techniques or use of elaborative encoding strategies. A series of case studies (36, 37) described a specific prospective memory training procedure in five patients with severe traumatic brain injury. Training consisted of giving the patients simple, repetitive, one-step prospective memory tasks to be carried out at increasingly longer time intervals following instructions, ranging from two to ten minutes. The patients all improved with practice on the prospective memory tasks, with some evidence of improvement on neuropsychological measures and observations of daily memory functioning. However, the limited time between the assignment of tasks and their execution, lack of intervening or complex tasks, and degree of therapist control all limit the relevance of the training to real life demands.

*External Memory Compensations* Patients with memory impairments after TBI are commonly taught to use a

memory notebook or diary to compensate for their difficulties in spontaneous, or unassisted, recall of information. One randomized controlled trial (38) has compared notebook training with supportive therapy for eight patients with TBI, all more than two years post injury. The treatment consisted of teaching a specific protocol for use of a memory notebook, and individualized modifications to address the subjects' personal needs and application to novel settings. Patients who received the notebook training reported fewer observed, everyday memory failures than the supportive therapy subjects. Three of the subjects who received the memory remediation were still actively using the memory notebook to assist with their daily activities at six month follow-up.

In this study, and in the studies described above using some form of strategy training, the patients who benefited from treatment all exhibited relatively mild memory difficulties. In contrast, patients with severe memory deficits after TBI appear more likely to require training in the use of specific compensations that can be applied to specific tasks, rather than attempts to remediate their underlying memory deficits through the use of strategies. For example, the use of a memory notebook has been shown to be superior to verbal rehearsal strategies when patients are required to remember specific information, particularly for patients with more severe memory impairments (39). While external memory compensations such as memory notebooks are commonly employed in cognitive rehabilitation, patients with severe memory difficulties are likely to require an extended period of training to ensure the practical application of a memory notebook (40, 41).

*External Cuing and Environmental Compensations* In the last several years there has been increased development of external cuing and assistive technologies as a compensation for memory impairments after TBI. For example, three studies have described the use and effectiveness of a portable voice organizer to help patients to recall their therapy goals (42) or to prospectively remember to perform relevant everyday tasks (43, 44). The use of existing technologies to assist people with memory deficits will typically require additional training, and consideration of multiple factors that influence the selection of an external cuing system (e.g., the patient's cognitive strengths and weaknesses, knowledge and familiarity with specific technologies, and the necessary resources and "user friendliness" to support programming and maintenance of the assistive device (45, 46).

Several assistive devices have been developed specifically with the intent of improving the cognitive functioning of people with acquired neurocognitive impairments, such as the Essential Steps cognitive orthotic system (47), the ISAAC cognitive prosthetic system (48) and the NeuroPage paging service (49–51). Initial evidence for the

effectiveness of these systems is limited to descriptive case studies (47–49). More recently, Wilson and her colleagues (50) have evaluated the effectiveness of the NeuroPage portable paging system to reduce everyday memory failures during the performance of functional activities, such as remembering to take one's medication or shut off appliances. A randomized controlled trial of the paging system was conducted for patients with persisting memory difficulties, many of whom had been referred only after previous interventions had failed. For each patient, the use of the pager was adapted to address specific problems in their typical daily functioning (e.g., keeping appointments) identified by the patient or a relative. Significant improvements in the ability of participants to carry out everyday tasks with the use of the pager were apparent, compared with no-treatment and baseline conditions. The paging system was noted to be most useful for those people who needed to carry out certain tasks on a regular basis and had some insight into their memory deficits. Based on this research, a commercial service offering NeuroPage was subsequently established through the National Health Service in the United Kingdom (51). Among the first 40 patients, with diverse etiologies of memory dysfunction, who were recruited into this study, 31 were reportedly able to use the pager successfully. The most frequent types of reminders were related to taking medication, daily orientation (e.g., getting up in the morning) and daily household activities (e.g., making lunch, taking a shower, doing the laundry) and these accounted for about 75% of messages provided by the pager. Among the patients who used the paging system consistently for some time, the authors noted several patterns of use. One group of patients continued to use the pager on a consistent basis for many months with no appreciable change in the messages required each week. Another group of patients continued to use the pager, but adjusted the number of messages they required. Some clients found that they were able to discontinue use of the pager after some time, suggesting that the pager served to establish their routine and they could then manage alone or use a different type of self-directed reminder. It is unclear whether these different patterns of use correspond to different patient characteristics (e.g., severity of memory impairment, presence of neurocognitive co-morbidities, level of motivation) although this might provide important clinical information in the future. It is clear that different forms of memory compensations are best selected only after careful consideration of these, and other, patient characteristics.

### REMEDIATION FOR DEFICITS IN EXECUTIVE FUNCTIONING

Disturbances in executive functioning are prevalent after acquired brain injury, and represent significant obstacles

to social functioning, work and rehabilitation. Disorders of executive functioning may affect the ability to anticipate the effects of our actions, appreciate alternative perspectives, and to recognize other people's reactions to our behavior and modify our actions accordingly. Disturbances of executive functioning may be apparent after various types of cortical or subcortical damage, but are often associated with damage to the frontal lobes. The dorsolateral frontal cortex has extensive connections with polysensory posterior association areas (52) and appears to be related to deficits in complex discrimination and association (53). The medial prefrontal cortex has been implicated in the processes of motor initiation and motor regulation and also appears to play a role in tasks requiring complex attention and planning (52). The orbitofrontal cortex is part of paralimbic cortex (5) has been related to disturbances of complex social and emotional behavior in humans (54, 55).

Patients with frontal-lobe damage may exhibit dissociation between the relative preservation of verbal knowledge, and the failure of this knowledge to guide behavior in pursuit of the appropriate goals and actions. This tendency to disregard the requirements of a given task, even when these are verbally appreciated, represented a fundamental aspect of executive dysfunction, referred to as *goal neglect* (56). Levine and his colleagues (57) developed a formalized intervention for executive dysfunction, referred to as goal management training (GMT), based on the theory of goal neglect. The process of GMT involves five discrete stages of what is essentially a general purpose, problem-solving algorithm starting with an evaluation of the relevant goals in a situation, through the selection of sub-goals, and then monitoring the results of one's attempts at a solution; in the event of a mismatch the entire process is repeated. Thirty patients with mild to severe TBI were randomly assigned to receive either GMT or an alternative treatment of motor skills training. GMT consisted of a single session in which participants were instructed to apply the problem solving algorithm to two functional tasks. Patients in the motor skills training condition practiced reading and tracing mirror-reversed text and designs. Treatment effectiveness was assessed on several paper and pencil tasks which resembled the training tasks, and were intended to simulate the kind of unstructured everyday situations which might elicit goal management deficits. Participants who received GMT demonstrated significant reduction in errors and prolonged time to task completion (presumably reflecting increased care and attention to the tasks) on two of the three outcome measures following the intervention. The entire treatment in this study consisted of one hour of intervention, which may be adequate to suggest the potential efficacy of GMT but provides little evidence of its clinical effectiveness.

Another prospective randomized controlled study (58) utilized a problem solving intervention intended to facilitate patients' ability to reduce the complexity of a multistage problem by breaking it down into manageable subgoals. Training was provided 37 patients who were identified as poor problem solvers on formal tests of planning and response regulation. Twenty participants received an intervention directed at remediation of executive function deficits, while 17 participants received an alternative intervention consisting of memory retraining. Patients who received the problem solving training demonstrated significant gains on neuropsychological measures of planning ability as well as improvement on behavioral ratings of executive dysfunction, such as awareness of cognitive deficits, goal-directed ideas, and problem-solving ability.

Rath and his colleagues (59) evaluated the effectiveness of an "innovative" treatment for problems-solving deficits, compared with a "conventional" neuropsychological group treatment for patients with TBI. The patients were described as being "higher functioning" but with documented, persistent impairments in social and vocational functioning (e.g., job loss, marital difficulties), an average of 4 years post-injury. The conventional treatment consisted of group exercises intended to improve cognitive skills and provide support for coping with emotional reactions and changes after injury. The innovative problem-solving intervention focused on the development of emotional self-regulation strategies as the basis for maintaining an effective problem-orientation, along with a "clear thinking" component that included training in problem solving skills using role-plays of real-life examples of problem situations. Both groups showed significant improvement of their memory functioning after treatment. Only the problem solving group treatment resulted in significant beneficial effects on measures of executive functioning, self-appraisal of "clear thinking", self-appraisal of emotional self-regulation, and objective observer-ratings of interpersonal problem solving behaviors in naturalistic simulations.

These three randomized controlled studies demonstrate that training patients with TBI to use formal problem-solving methods can be an effective intervention. The study by Rath et al. (59) suggests that the development of strategies to improve emotional self-regulation may be particularly relevant to the clinical treatment of patients with executive functioning deficits after TBI, and provides the clearest evidence that this intervention may improve patients' performance in everyday situations.

Several studies have attempted to remediate executive function impairments through the development and internalization of strategies for effective self-regulation. According to Luria (60), self-regulation is achieved through the covert, verbal mediation ("inner speech") of purposeful activity. However, simply having the patient repeat the task

instruction is insufficient to re-establish self-regulation (61). Cicerone and Wood (62) used a self-instructional training procedure to encourage planning and self-monitoring, while inhibiting inappropriate behaviors. The training procedure included three stages of self-verbalization, progressing from overt verbalization, through faded verbal self-instruction, to covert verbal mediation of appropriate responses. Over the course of training, there was a dramatic reduction in task-related errors as well as more gradual reduction and eventual cessation of off-task behaviors. Generalization to his functional, real-life behaviors were observed only with additional instruction and practice in the application and self-monitoring of the verbal mediation strategy to his everyday behaviors. A subsequent study (63) replicated this finding with six patients who exhibited impaired planning and self-monitoring after frontal lobe injury. Five of the six patients showed marked reduction of task-related errors and perseverative responses, suggesting that the effectiveness of training was related to the patients' improved ability to inhibit inappropriate responses. Self-instructional training has also been shown to be an effective component of interventions directed at attention (22, 64) or memory (65).

There is a potential paradox in attempts to remediate disorders of executive functioning, in that these disorders effect the processes of self-monitoring and self-regulation that are an inherent aspect of remedial compensations. Successful compensation appears to require some residual capacity to deliberately and consciously apply strategies. A recent, uncontrolled group study (66) of patients with documented frontal lobe damage, severe cognitive impairments and poor self-awareness has demonstrated improvements after four months of treatment in patients' knowledge and use of self-regulatory strategies, and the self-rated effectiveness of strategies in their daily functioning. Several case studies have also described interventions that improved the patients' ability to self-monitor their behavior (67, 68). In each of these studies, the goal of cognitive remediation was not the training of task-specific performance, but the training and internalization of regulatory cognitive processes. In contrast, limited success was observed in two descriptive case studies of patients with orbitofrontal damage that resulted in social cognition and affective regulation. In both cases, the patients were able to improve specific behaviors in the situations in which they had been trained, but could not effectively modify their problematic social and emotional responses in novel, real-life situations, despite extensive treatment (69, 70).

### **Remediation of Pragmatic Communication Deficits**

Deficits in executive functioning may be expressed as a disturbance of the social and affective and pragmatic aspects

of communication, as noted by Eslinger in this volume. Thus, while classic neurologic syndromes of language impairment are not commonly seen after TBI, patients with TBI frequently exhibit impairments of pragmatic communication. These may include the loss of coherence and cohesiveness during narrative discourse, difficulty interpreting subtle, contextual aspects of communication (e.g., humor, sarcasm, irony), and failure to interpret or respond to non-verbal cues in the context of social communications. Helffenstein and Wechsler (71) evaluated the effectiveness of a group intervention designed to improve interpersonal communication skills, in which the central aspect of treatment was to provide patients with systematic review and feedback concerning their interpersonal, communication interactions. Beneficial effects were noted following this procedure, compared with a sample of subjects with TBI who received equivalent treatment contact without the systematic feedback. Specific improvements were noted on self-report measures of self-concept, ratings of interpersonal and communications skills, and the effectiveness of interpersonal communication in non-therapy, social settings. Several uncontrolled group studies (72, 73) and single-case studies (74, 75) have reported improved pragmatics and conversational skills following treatment that included systematic feedback and self-monitoring of interpersonal communications. The focus of the group-based treatment was to improve patients' communication competence in social contexts, including initiation, topic maintenance, turn taking, and active listening. Within each of these skill areas, treatment addressed the subjects' awareness of obstacles to effective communication, practice of effective communication, and generalization to natural contexts. The goal of the generalization phase was to apply the trained skills to relevant activities and settings in each individual's particular community, incorporating practice with parents and peers (72). One case study (76) has indicated that improvements in narrative discourse that were seen in treatment did not transfer to the patients' functional conversations. This lack of generalization was attributed to the "acontextual" nature of the treatment, and can be contrasted with the treatments that included specific interventions to promote the generalization of communications skills to the patients' real-life contexts and activities.

### INTENSIVE-HOLISTIC COGNITIVE REHABILITATION

Cognitive rehabilitation of TBI may best be achieved through a comprehensive, *holistic* approach to the treatment of cognitive, emotional, and functional impairments and disability. Comprehensive-holistic neuropsychological rehabilitation is centered around the goals of fostering patients' awareness of their functional potential and

adapting to the chronic limitations imposed by their injury, in order to alleviate disability in everyday, social functioning. Ben-Yishay was perhaps the first clinician to delineate and advocate the need for a holistic approach to the neuropsychological rehabilitation of individuals with brain injury (77). In discussing the rationale for the holistic, or therapeutic milieu, approach to neuropsychological rehabilitation, Ben-Yishay and Gold (78) emphasized that the neurobehavioral manifestations after traumatic brain injury are dynamic and multidetermined. They suggest that "it is meaningless to make rigid distinctions between higher and lower level cognitive functions or between physiogenic and psychogenic factors in emotional disturbances" after brain injury (p. 194). Thus, neither isolated cognitive remedial exercises to improve attention, memory, and or other "fragmentary" deficits, nor a focus exclusively on traditional psychotherapeutic interventions, are likely to be effective. Instead, an effective rehabilitation program must systematically integrate interventions directed at the remediation of cognitive deficits, functional skills, and interpersonal functions. Improvements in functioning are typically accomplished by an improvement in the effective functional application of residual cognitive abilities, rather than restoration of the underlying cognitive deficits, per se.

An early study of the relationship between holistic cognitive rehabilitation and employability (79) evaluated the effectiveness of a clinical program consisting of three phases. The first phase consisted of individual modules of cognitive remediation and group treatments to improve interpersonal communication, social competence, and awareness and acceptance of the consequences of brain injury. Treatment was provided within the model of a "therapeutic community" which included the engagement of family members and significant others in the treatment process. The second phase of treatment was devoted to structured work trials, and the third stage involved actual work placements. Employability ratings suggested that 84% of the previously unemployed patients were able to engage in some form of productive activity following the neuropsychological rehabilitation program. A subsequent study (80) suggested that patient characteristics related to motivation, affective regulation, and accurate self-appraisal were more closely related to effective functioning after treatment than neurologic or neuropsychological characteristics.

The relative contributions of individualized cognitive remedial interventions and small-group based exercises in interpersonal communication within the context of a holistic neuropsychological rehabilitation program have been explicitly evaluated (81). One group of patients received a mixture of cognitive and interpersonal interventions. A second group of patients received the individualized cognitive remedial interventions but did not receive interpersonal communication training. The third group received

the initial, basic attentional training followed by the interpersonal remediation, while the individualized cognitive interventions were withheld. Only the two groups receiving the individualized cognitive remediation showed improvement on near transfer measures of cognitive functioning, which may have reflected practice effects as these measures were similar to the tasks used in treatment. There was a tendency for patients receiving the interpersonal training to show improvement on measures of affect regulation, self appraisal and self esteem. These findings are consistent with the holistic approach to treatment, indicating that the greatest gains in functioning may be achieved through the integrated treatment of both cognitive and interpersonal functioning.

There have been two prospective, randomized controlled studies of comprehensive rehabilitation for patients with TBI. Both studies are best considered as efficacy studies, in that treatment was provided to selected patients in a highly constrained environment. The first of these studies (82) compared the effects of structured cognitive rehabilitation with treatment providing professional attention and psychosocial support. Participants with moderate-to-severe TBI, one to seven years post-injury, were recruited from the community and “quasi-randomly” assigned to treatment conditions. Potential participants with expressive or receptive language disturbance, significant visual deficits, prior neuropsychiatric disturbance, or poor motivation were excluded from treatment. Subjects in the neuropsychological treatment condition received specific treatments directed at improving attention, memory, visuospatial ability, and problem solving. Subjects in the alternative, psychosocial treatment condition received an equivalent amount of treatment directed at coping skills, interpersonal functioning, and personal development. Both groups improved, but there was little overall difference between the two groups on measures of neuropsychological functioning or emotional adjustment. The findings suggest that non-specific factors (e.g., establishment of a therapeutic alliance and expectations for improvement) contributed to the effects of treatment in both conditions.

Salazar and colleagues (83) evaluated the efficacy of cognitive rehabilitation for 120 people with moderate to severe TBI (an average of 38 days post injury) within a single, military medical referral center. The program was based on the principles of a “therapeutic milieu” modified to meet the needs of patients returning to active military duty. Patients were randomly assigned to receive either a multidisciplinary, in-hospital cognitive rehabilitation program or home-based education and encouragement from a psychiatric nurse. There was no difference between groups on either return to work or fitness for military duty one year after treatment. The groups also did not differ on measures of neuropsychological

functioning, although participants with more severe injuries demonstrated greater improvement after the cognitive rehabilitation program.

In both of these studies, the ability to generalize the results to the typical clinical situation is limited. Length of treatment was relatively brief (eight weeks) in both studies, and significant subject selection biases were apparent. Salazar (83) noted the “extraordinarily high return-to-work rates” and suggested that participants’ high pre-injury education and level of functioning, significant degree of spontaneous recovery, and ready availability of (military) employment after injury might have limited the ability to detect any differential benefits from the cognitive rehabilitation program.

Clinical studies of comprehensive-holistic cognitive rehabilitation have generally reported more positive results. One prospective, non-randomized study evaluated the benefits of either a “standard” program of postacute neurorehabilitation or a more structured and intensive milieu-based rehabilitation program (84). Treatment was provided to 56 patients with primarily moderate-to-severe TBI who had been referred for cognitive rehabilitation, either from acute rehabilitation or from the community. All patients were screened and assigned to one of the treatment programs based on clinician’s judgments regarding the most appropriate treatment. As a result of this selection process, patients who received the more intensive-holistic cognitive rehabilitation program were further post-injury, more likely to exhibit impaired self-awareness, and exhibited lower initial levels of community functioning on admission to rehabilitation. Overall, patients in both treatment conditions showed significant improvements in community integration; the patients who received the intensive-holistic treatment program showed greater improvement despite the fact that they were less functional and further post-injury at the time of admission. Improvements in overall neuropsychological functioning were associated with clinically significant improvement in community integration. Patients’ satisfaction with their cognitive functioning after treatment was also a strong indication of successful community integration, again suggesting the contribution of psychological factors in patients’ ability to benefit from cognitive rehabilitation.

A number of retrospective studies have also reported positive benefits from comprehensive neuropsychological rehabilitation programs, compared with patients who did not receive rehabilitation (85–87). Observational studies in this area have also demonstrated significant improvements in community functioning after treatment (88–90) that persist for many years (91, 92). These clinical studies support the effectiveness of a programmatic approach to cognitive rehabilitation for people with TBI, including those who have been unable to resume effective functioning several years after injury.

## CONCLUSIONS

Cognitive rehabilitation is an integral part of the neurorehabilitation of TBI. The first published case studies on remediating memory deficits in brain damaged individuals appeared in 1977 (28). The clinical practice of cognitive rehabilitation has matured substantially in the ensuing 25 years. Empirical evidence for the effectiveness of cognitive rehabilitation is beginning to catch up with clinical practice. Recent systematic reviews of the literature (3, 93) have identified 20 randomized, controlled trials addressing the remediation of higher cognitive deficits in patients with TBI, with 35% of these published within the last 5 years. In clinical practice, there is general consensus that cognitive rehabilitation (regardless of the specific approach taken) should be directed at improving patients' everyday functioning and quality of life. Most studies of interventions for specific cognitive functions have been limited to assessing the effectiveness of treatment at the impairment level, although several recent studies have demonstrated clinically meaningful improvements in community integration following comprehensive-holistic cognitive rehabilitation.

Efforts to provide patients with the best available treatment, and to evaluate the effectiveness of cognitive rehabilitation, need to consider the complex nature of the interventions, the heterogeneity of patients with TBI, and the need to individualize treatment according to the unique and varied demands of patients' lives. For these reasons, the practice of cognitive rehabilitation will continue to rely upon clinical judgment and experience. Cognitive rehabilitation is not a distinct form of service, or the purview of any single discipline, but a specialized form of rehabilitation that requires adequate professional training in the nature of brain-behavior relationships, the neurologic basis of intact and impaired cognitive function, and the rehabilitation of cognitive disorders (94). It is also essential for clinicians who practice cognitive rehabilitation to maintain their knowledge of the literature and the empirical basis for the effectiveness of interventions as a means of guiding treatment selection and implementation. The increasing emphasis on evidence-based (cognitive) rehabilitation is not intended to supplant clinical judgment, but to inform it through the best available scientific evidence.

The ability to secure adequate reimbursement for cognitive rehabilitation remains a challenge in many cases, sometimes due to the position taken by referral sources and payers that cognitive rehabilitation remains an "investigational" procedure. The increasing evidence for the effectiveness of cognitive rehabilitation, and familiarity with evidence-based recommendations for cognitive rehabilitation by practicing clinicians, should help to facilitate this process. There is already evidence that some major insurance providers are incorporating the current evidence for effectiveness of cognitive rehabilitation in their clinical

policy bulletins. In other cases, clinicians who are providing treatment in accordance with evidence-based recommendations may be able to obtain approval for cognitive rehabilitation through the external claim review process that is available in many states.

From a scientific perspective, the evaluation of the effectiveness of cognitive rehabilitation is, of course, a continuous and ongoing process. There continues to be some debate regarding the most appropriate methodology for conducting research on cognitive rehabilitation. Well-designed single-case studies can provide important information, especially regarding novel or innovative interventions. Highly controlled, clinical trials remain the most sure way to subject an intervention to rigorous confirmation of its efficacy. The selection of an appropriate research methodology will depend on multiple considerations, including the state of the already existing evidence, the ability to standardize the intervention across subjects or settings, and the availability of resources required to conduct the study. Perhaps the most compelling need in this area is the establishment of sustained programs of research that develop and evaluate the effectiveness and utility of an intervention through increasingly rigorous and practical methods, including the replication of findings across settings. This has generally not been achieved in the field of cognitive rehabilitation, with some exceptions (18, 19, 49–51). There is also a need to assess the external validity of cognitive rehabilitation, particularly through the use of outcome measures that are congruent with the research intentions. For example, the use of functional imaging may provide information about the degree of functional plasticity and nature of cerebral reorganization (if any) associated with a specific intervention. However, it can not be assumed that changes in the pattern of cerebral activation, even when present, are related to improvements in the individual's neuropsychological performance or everyday functioning. This will require that these interventions be assessed with an appropriate range of relevant health-outcome measures (e.g., functional limitations, community integration, subjective well-being). It is only through a sustained program of research that cognitive rehabilitation will fulfill its clinical and scientific promise, to improve the quality of lives for people with neurocognitive disability.

## Cognitive Impairments After TBI

*Paul J. Eslinger*

*Anna M. Barrett*

### INTRODUCTION

Traumatic brain injury (TBI) is associated with several types of pathophysiology that damage cerebral cortex and subcortical nuclear structures as well as white matter connections (see chapter by Povlishock and Bullock for more details). The resulting changes in brain anatomy and physiology disrupt the typical functioning of specific structures and the larger neural networks they comprise, leading to subsequent neurological and neurobehavioral impairments. In addition to these direct brain-behavior effects of TBI, there can be many complicating medical and psychological problems that contribute to post-traumatic cognitive, behavioral and emotional impairments. These are detailed in several chapters throughout the text and underscore the complex nature of TBI. Despite their prevalence, cognitive impairments must be carefully evaluated on an individual basis, as they may be influenced by pre-existing conditions (e.g., learning disabilities, attention deficit hyperactivity disorder, substance abuse, prior head trauma), co-morbid conditions (e.g., seizures, major depression, pain, and medication side-effects) and differences in TBI effects and recovery. As an example, recent study identified a significant effect of major depression in lowering cognitive test scores after TBI (1). Hence, a multidisciplinary and comprehensive approach to TBI is necessary for best treatment outcomes.

Attentional and memory problems after TBI are among the most common cognitive impairments reported

by patients, their family members and clinicians (2, 3). Recent study has also emphasized that prominent working memory impairments occur after TBI (4). Such cognitive deficits are frequently accompanied by a spectrum of other cognitive, social, emotional and behavioral changes as well. This chapter provides an overview of cognitive impairments that are commonly associated with TBI in adults. Accompanying chapters by Kreutzer (*Neuropsychological Assessment and Treatment*), Cicerone (*Cognitive Rehabilitation*), Murdoch (*Speech Disorders*), Wehamn (*Vocational Rehabilitation*), Coelho (Language and Communication), Arciniegas and Silver (*Cognitive Psychopharmacology*) and Johnston (*Functional Assessment and Outcome Evaluation*) address important inter-related aspects of cognition and TBI. The importance of these topics stem from the fact that the long-term effects of TBI on personal, social and occupational ability and disability can often be related to cognitive, behavioral and emotional functioning. Indeed, cognitive measures are among the most important predictors of patients' return to work and independent living, even among those with good medical recoveries (4–7).

### NEUROPSYCHOLOGICAL EVALUATION

Neuropsychological assessment encompasses clinical and psychometric testing procedures that survey and

objectively measure the effects of cerebral damage on cognitive, behavioral, social and emotional functioning (8, 9). These procedures typically employ a wide range of standardized cognitive tests and survey instruments, together with comprehensive interview and clinical assessment. Neuropsychological test scores can change in different ways depending upon TBI pathophysiology. To this end, a variety of specific assessment techniques have been developed to evaluate a patient's relative strengths and weaknesses in multiple neurobehavioral domains such as memory, language, attention, spatial cognition, executive functions, and social cognition. Scores are then interpreted in reference to available normative data that provide the typical range and variation in test performance. Interpretation of neuropsychological test scores is meant to identify the type and severity of cognitive impairments that in turn reflect general location and severity of brain injury. While some clinicians employ fixed neuropsychological batteries that administer the same compilation of tests to all patients, most clinicians use a flexible battery approach that focuses on specific problem areas identified through clinical exam and observation. The flexible battery approach also places a very strong emphasis on evaluating the patient's *pattern* of performance; that is, the possible causes for their impaired test score. For example, an impaired memory test score may be reflect attentional and encoding deficiencies, memory consolidation deficits, or poor retrieval of information. Delineating specific processing impairments may provide a more direct and efficient approach to remediation services that target impaired processes. Therefore, neuropsychological assessment, along with assessments provided through medical and diverse therapy services (i.e., physical, occupational, speech and recreational specialists) is geared toward identifying how best to intervene in the remediation of cognitive, behavioral, social and emotional impairments that are caused by TBI (see chapters by Cicerone and by Wehman for further discussion of this interface). The following sections cover specific cognitive processing domains that are particularly important in TBI.

### INFORMATION PROCESSING AND ATTENTION

Information processing measures are typically designed to determine the speed and accuracy of sensory-perception and perceptual-motor responses. These processes are mediated by diverse brain structures that include multiple cortical regions, subcortical nuclei and many white matter connections. The pathophysiology of head trauma may affect information processing in several ways. Sarno et al. (10) recently demonstrated that head trauma was associated with prolonged simple and choice reaction times to visual, auditory and tactile stimuli. Tactile stimuli

presented particular difficulty in comparison to vision and audition (i.e., sensory-specific deficit) as well as in combination with those modalities (i.e., cross-modal deficits). Mathias et al. (11) confirmed that reaction time speed was compromised after mild TBI, particularly as visual task difficulty increased and when inter-hemispheric transfer of information was required. The level of difficulty and transfer deficits were more evident for visual than tactile tasks in their study. Tinius (12) reported that similar to adults with attention deficit disorder, those with mild TBI were impaired on reaction time measures, underscoring the frequent finding of slowed reaction time after head trauma (13). However, reaction time changes interact with the particular type of tasks presented. For example, simple reaction time tasks are often completed in normal fashion after head trauma, but choice or complex reaction time tasks are frequently more difficult and lead to detectable impairments (14–16).

Zoccolotti and colleagues (17) sought to compare multiple information processing and attentional measures in a group of 106 patients with generally more severe TBI drawn from multiple European sites. The sample was tested at least 5 months after injury and 80% of participants suffered coma of 8 days or longer. Patients were presented with 4 computerized tasks with responses limited to button presses to measure accuracy and latency. The first 2 tasks were designed to require *intensive attention* and included measures of: (1) alertness (reaction time with and without a tonal warning) and (2) sustained attention (15 minutes of vigilant observation of horizontal bar movements). The final 2 tasks were considered measures of *selective attention* and hypothesized to be problematic for patients. These included: (3) selective attention (go no-go and design detection tasks) and (4) divided attention (simultaneous visual and auditory tasks, each to detect a specific pattern during continuous stimulus presentations). Patients showed considerably more difficulty in the selective attention tasks requiring go- no go responding (combining working memory with inhibitory control) or divided attention (increasing the working memory load), with up to one-half demonstrating deficits. Some difficulties were also evident in the more straightforward intensive attention conditions, varying between 9–33% of patients. However, coma severity had no statistically significant effects on the intensive attention measures of alertness and vigilance. Analyses also indicated considerable variability in performance amongst patients. This is not unexpected given the diverse trauma and personal characteristics of the sample. At least three subgroups were identified:

- A severely impaired subgroup, with a similar attention deficit profile as the overall sample (greater impairment in selective and divided attention tasks). This subgroup, comprising nearly 50% of the sample,

also had more severe trauma and longer length of coma. While all patients with mild and moderate levels of coma completed the divided attention task, 5% of severe and 26% of very severe coma patients were unable to complete the task.

- A less impaired subgroup with a large dissociation between normal alertness scores and poor divided attention scores. Nearly 44% of the sample showed this pattern of performance that argues against a nonspecific or generalized slowing of performance and supports the possibility of a specific divided attention deficit. We have encountered such deficits commonly in clinical practice, where they can be described as disorganized behavior, losing track of objects, paperwork and activities, and being able to undertake only one activity or task at a time.
- A third possible subgroup (comprising only 7% of the sample) included those with very long reaction times in both alertness and divided attention tasks, suggesting very slowed psychomotor speed.

The prolonged reaction times of TBI patients appear to be influenced by both the type of task and the working memory load that it requires, usually represented by the number of competing stimuli and choices. These cognitive deficits may be a behavioral index of diffuse cerebral damage that subsequently limits speed of information processing particularly as environmental demands increase, becoming either more concentrated or sustained over time. Hence, TBI patients must exert greater mental effort in cognitive and occupational tasks that may have been readily managed prior to injury. This can lead to increased physical and mental fatigue, even headaches, that may be mistaken for stress effects. In these cases, a reduced work load and schedule is usually recommended. In some TBI cases, the degree of attentional change is sufficient to warrant evaluation of attention deficit-type symptoms. This is typically undertaken with a combination of standardized tests of attention (such as the Working Memory Index from the Wechsler Adult Intelligence Scale and continuous performance tasks) and behavioral survey of attentional behaviors (such as the Brown Adult ADD Scale). Treatment of adult TBI patients with low dose stimulants can be of significant benefit to their occupational and daily functioning, particularly when combined with cognitive compensatory strategies.

### UNAWARENESS OF DEFICITS (ANOSOGNOSIA)

Anosognosia (meaning, literally, “without knowledge of disease,” a term introduced by Babinski (18)) is a common behavioral disorder occurring in neurological conditions, characterized by limited acknowledgment or

denial of neurological dysfunction. The symptoms of which the patient is unaware may vary, and include memory and cognitive deficits, hemiparesis, visual and other sensory disturbances, gait disorder and deficits of naturalistic action/limb apraxia (19, 20)

Patients’ inability to recognize functionally-relevant problems is known to be a major barrier to rehabilitation after closed-head injury (21). Disavowal of neurological impairment can take several forms, including lack of emotional concern for acknowledged deficits (anosodiaphoria), verbal denial of deficits that are implicitly acknowledged (e.g. patients claim that they can walk but never actually attempt to get out of bed), combined explicit and implicit denial of deficits, denial of ownership of an impaired body part (asomatagnosia or somatoparaphrenia), and, at the far end of the continuum, dislike or hatred of a dysfunctional body part (miso-plegia) (19, 22). Patients with this disorder can evidence dramatic abnormalities in behavior, such as throwing themselves from their beds “in order to get rid of that awful leg.” Although occurring in conjunction with other clinical syndromes such as spatial neglect, amnesia, and even thought disorders, dissociations of awareness of deficit from each of the associated clinical syndromes are reported, and thus anosognosia may be best characterized as an independent syndrome, at this time without a single neuroanatomic basis.

### Impact of Anosognosia

Although there are no formal studies of the possible contribution of anosognosia to a delay in seeking medical attention after closed head injury, numerous anecdotal reports suggest that unawareness of deficit (sometimes theorized to be partly due to a functional adaptation, e.g. “shock”) may keep patients from presenting promptly to a medical care provider or emergency room after head injury, especially if patients lack other bodily injuries. Currently, no treatments for closed head injury are available that depend critically upon initiation within a short period after an injury occurs, but in the administration of acute thrombolytic therapies after stroke it has been suggested that anosognosia is a barrier to treatment delivery (19).

The most relevant impact of anosognosia on rehabilitation after closed head injury is in patients’ acceptance of the rationale for participation in treatment (engagement in the rehabilitative program), and in their ability to participate in the program once having agreed to do so (19, 22, 23). It is reasoned that patients may put forward inadequate or inconsistent effort, preventing gains in strength and endurance. However, anosognosia and decreased motivation has not in formal studies been universally associated with a poorer rehabilitation outcome (24). The scope of rehabilitation for anosognosic patients may be more limited because of safety and supervision needs, and

fewer challenging tasks may be attempted in order to ensure that patients will not expose themselves to further harm or attempt to perform tasks of which they are incapable. Lastly, anosognosia presents a barrier to studying outcomes in head trauma rehabilitation. After traumatic brain injury, patients consistently report better cognitive, physical and emotional outcomes than do their loved ones and clinicians (25–29). This creates problems in interpretation of patient self-report data, which might under other circumstances be considered to be of greater validity than that of external observers (30).

### Mechanisms of Anosognosia

Proposals to account for unawareness of neurological deficits include: *psychological denial*, *modular dysfunction* at the level of an isolated cognitive or neurological subsystem or in a single semantic domain, *monitoring dysfunction* at a level of superordinate cognitive processing, and *multifactorial* theories postulating dysfunction in several cognitive domains (19, 22).

A detailed discussion of the putative mechanisms underlying anosognosia after brain injury is beyond the scope of this chapter. However, because of the importance of this theory, we will briefly discuss evidence regarding the mechanism of psychological denial. Weinstein and Kahn (31) first proposed that psychological denial may produce inability to acknowledge neurological deficits after stroke such as hemiparesis. Important clinical observations, however, are inconsistent with the psychological defense mechanism hypothesis. A coping strategy should be more utilized as recovery progresses, cognition improves, and chronic losses become apparent. Anosognosia is most apparent immediately post-injury, and gradually improves (19, 21, 22, 27, 30). A denial syndrome should be most severe for deficits posing the greatest potential ego threat, and less marked for deficits not likely to produce disability. However, modular dissociations in anosognosia not clearly based on subjective deficit severity (e.g. unawareness of visual problems but awareness of gait problems) are reported after head injury (22, 32). In subjects without brain injury, anosognosia can be induced by selective hemispheric anesthesia (19), but in the same individuals, this occurs more commonly after right- than left-sided injection. This asymmetry is difficult to explain on a psychological basis. Most critically, in brain-injured patients, it is unclear that anosognosia confers even temporary functional advantage, either in reducing subjective distress (33) or in improving function (34), which is central to the concept of a psychological defense. Schacter and Prigatano (35) wrote an excellent summary of the controversy about this issue:

Although most observers agree that defensive denial of a kind that can be observed in non-brain-damaged patients plays *some* role in the unawareness phenomena exhibited by *some* brain-damaged patients, the nature

and extent of the contribution is still the subject of debate . . . The critical problem . . . is to develop adequate criteria for distinguishing between defensive and nondefensive forms of unawareness and to delineate the underlying bases for them.

### Management and Treatment of Anosognosia

Unfortunately, large controlled trials of specific management and treatment methods for subjects with anosognosia after closed head injury are not yet available. A number of approaches are reported to be symptomatically useful (36–41). These include *explicit* techniques in which therapists have subjects self-assess and then perform straightforward, quantifiable tasks and help them to measure assessment-performance discrepancies, *implicit* techniques in which subjects are asked to perform in both preserved and deficient areas in order to experience the contrast between these abilities, and techniques involving *external and off-line feedback*, such as videotaping and later viewing task performance, and reviewing it in a group setting with performance assessment from other group members. Related to the external/off-line method is *intervention based on third person assessments*, in which patients make judgments about pictured scenarios in which others fail to perform tasks, preselected to resemble their impairments (42). Although reinforcement with these methods has traditionally been behavioral, positive results have been reported when increased accuracy of self-assessment is reinforced with monetary rewards (43).

A general difficulty with these clinical reports, however, is that although patients' awareness of deficit may have improved, the effect on daily living activities has not been well-studied. In at least one instance, there was a failure of the improved self-awareness to generalize to untrained tasks (38). Therefore, further studies are needed to identify the most effective interventions for anosognosia after TBI. In typical practice, such interventions are team-based and often require continued efforts by educated caregivers after hospital discharge.

## INTELLECTUAL FUNCTIONING

Measures of intellectual functioning are frequently employed in the neuropsychological assessment of brain-injured patients to ascertain a broad range of cognitive capacities (44, 45). Although several instruments have been designed for the purpose of evaluating intelligence, the Wechsler scales are currently favored by most clinicians. The Wechsler Adult Intelligence Scale has several important features:

1. It surveys a broad range of verbal and nonverbal cognitive abilities with standardized instructions and materials

2. Test items are presented in ascending difficulty and usually discontinued after a certain number of incorrect responses, allowing for assessment of many different abilities without undue frustration for patients
3. The scale provides multiple scores for comparison such as verbal, performance and full scale IQ, and index scores for verbal comprehension, perceptual organization, working memory and processing speed
4. Interpretation of multiple subtest and composite scores is possible through extensive normative data that provide statistical comparisons, enhancing the strong reliability and validity indicators of the scale.

Interpretation of IQ tests requires highly trained clinical expertise particularly because there is no single or specific profile of intellectual impairment that results from brain damage (46). From available studies, however, it is possible to identify several common patterns of findings related to TBI effects, as follows:

1. A generalized pattern of intellectual decline is most likely to be observed in patients whose TBI is at least moderate to severe (47, 48).
2. The Wechsler Processing Speed Index is particularly sensitive to brain dysfunction, due mainly to the sensitivity of the digit-symbol coding and symbol search subtests. In contrast, other subtests (e.g., Matrix Reasoning, Vocabulary) appear resistant to the incremental effects of TBI (47, 49).
3. A large discrepancy between Verbal and Performance IQ scores is not always synonymous with brain damage; nor does it necessarily imply damage to one hemisphere versus the other. For example, a lower Performance IQ may be related to slowed visuomotor processing rather than right hemisphere damage per se, and a lower Verbal IQ may be related to impaired attention and concentration rather than left hemisphere damage per se. However, discrepancies of 15 points or more deserve close scrutiny for cognitive dysfunction (50, 51) as these differences are reaching statistically improbable levels for typical cognitive functioning. This entails ruling out other premorbid or concurrent causes of test impairment and supporting any inferences about localized brain damage (e.g., left or right hemisphere, frontal or temporal cortical) with additional specific indicators.
4. In reasoning about and explaining any left vs. right hemisphere disparities in intellectual processing, investigators have emphasized that the left hemisphere tends to fundamentally process information sequentially whereas the right hemisphere engages in more simultaneous information processing (51). Thus, left vs. right hemisphere deficits, at least as expressed through verbal vs. performance IQ score differences, should not be interpreted as simply verbal vs. visuospatial differences; rather, they may reflect different levels and approaches to information processing.
5. In studies of localized cerebral damage, left hemisphere injuries often result in lower digit span and arithmetic subtest scores, whereas picture arrangement deficiencies have been associated with right hemisphere lesions (52).
6. Impairment on the block design subtest has been associated with damage to the parietal lobes regardless of the side of cerebral dysfunction (46).
7. Vocabulary and picture completion subtests have been employed in estimating premorbid intellectual functioning because of their robust resistance to brain injury (49, 52).
8. Deficits on the similarities subtest has been associated predominantly with left frontal injury because of its reliance on verbal concept formation and abstraction (51, 53).
9. In interpreting intellectual test scores and patterns, the important contributions of unique personal attributes must be assessed including educational level, premorbid functioning, learning disability, cultural/linguistic factors and others that are likely to affect IQ test scores.

The foregoing summary should not be considered immutable; rather, clinicians engaged in assessing intellectual functioning among TBI patients utilize these principles to guide interpretation and hypotheses about related functional deficits, their causes and their remediation. Similarly, the cognitive strengths observed in IQ testing may point clinicians in the direction of harnessing intact patient abilities to compensate for possible limitations. In our clinical experience, we do not rely on one sign of TBI as being sufficient for rendering diagnosis. Similarly, the presence of atypical IQ scores by itself should not be taken to suggest cerebral impairment without further investigation. For individuals with unusual IQ profile scores, review of their school testing records can disclose significant pre-existing discrepancies in verbal and mathematical/spatial abilities. Competent neuropsychological evaluations take many factors into account as part of understanding TBI effects. IQ scores, therefore, should not be considered in isolation from measures of attention, memory, language, etc; similarly, test data should not be emphasized in the absence of a clear patient history, neurological evaluation and related data from other service providers.

## MEMORY

Learning and memory are among the most fundamental and important capacities that underlie human development

and adaptation. The neurobiological bases of how we acquire and subsequently retain vast amounts of information and experiences remain enigmatic though there is increasing understanding of the neural structures and processes that mediate functional memory systems. In scientific and clinical studies of TBI there is viable evidence for both alterations to memory-related structures and disruption of memory processing. The effects of post-traumatic memory impairments can be disabling and significantly limit an individual's ability to live independently, handle a job, and interact productively with others (54). Subjective complaints of memory impairment after TBI are quite common, even among those with mild TBI and good medical recovery (55). Although not always substantiated by objective memory testing, physiological brain changes underlying such complaints have been verified in some scientific studies but not others. The controversy arises in part from the wide individual variability in the effects of TBI on learning and memory abilities. Differences in patient sampling (e.g., consecutive series vs. patients referred for assessment) and in how learning and memory are assessed may lead to dissimilar results and conclusions. Differences in the length of time post-injury, age, and severity of TBI can also contribute to contrasting outcomes. Complicating effects of chronic pain, sleep disturbance, depression, stress due to loss of income etc. are known to contribute to learning and memory problems, and must be considered in both etiology and treatment plans. Despite these many cautions, reliable correlation has been found between memory performance and brain volumetric measures in the temporal lobe of adults with mild TBI (56). Specifically, decreased hippocampal and temporal white matter volumes were significantly related to memory impairment. Despite normal MRI or CT imaging in 15 of 20 patients with mild TBI, Umile et al. (57) reported that dynamic brain imaging (including SPECT and PET) detected abnormalities in 18 of the 20 patients, with 15 of 20 having abnormalities in the temporal lobe, primarily the hippocampal region. There are also functional imaging data suggesting that the brain activity patterns of TBI patients become altered during tasks of memory retrieval. Specifically, patients engaged increased levels of frontal, anterior cingulate and occipital activity while showing reduced right dorsomedial thalamic activation and attenuated hemispheric asymmetry that was characteristic of controls (58).

### Post-Traumatic Amnesia

Post-traumatic amnesia (PTA) refers to the immediate and dramatic amnesic effects of TBI. Patients can be described as *confused, agitated, repeating questions*, and *disoriented* in this acute/post-acute phase. PTA is defined as the period during which patients are neither encoding nor retaining any new information and experiences, and can

last from a few moments to several weeks and even months after TBI. Although patients are awake and alert during this period, they subsequently recall little to no information regarding the accident and such post-traumatic events as transportation to the hospital, medical evaluation, and even visits of family members. Patients with PTA are disoriented to time, place and reason for hospitalization, and may even think that they are at school or in their hometown. As described previously, they may show anosognosia during this period as well as a range of behavioral difficulties and agitation.

PTA is variable in both extent of amnesia and pattern of recovery. It is considered a general marker of neurological impairment and in most cases gradually improves. Sometimes the term 'shrinking post-traumatic amnesia' is used to refer to the gradual reduction in severity and temporal extent of amnesia (in both retrograde and anterograde spheres). PTA can be assessed with standardized instruments such as the Galveston Orientation and Amnesia Test (59). Recovery of orientation and short-term memory can be reliably predicted from early daily screening and is generally predictive of functional independence upon discharge (60, 61). It is important during this period to rule out contributing effects of sleep disturbance, pain medications, and other complicating factors on post-traumatic attention and memory deficits.

An interesting implication of PTA concerns its relationship to post-traumatic stress disorder (PTSD). That is, does loss of consciousness and memory after TBI necessarily preclude the development of PTSD symptoms that typically involve the re-experiencing of the traumatic events as well as heightened emotion with anxiety and avoidance behaviors. If the event cannot be remembered, can PTSD symptoms still be possible? Turnbull, Campbell and Swann (62) examined the inter-relationship in 53/371 TBI cases. Results indicated that those with traumatic memories of the TBI event ( $n = 26$ ) reported the highest psychological distress followed by those with no traumatic memories ( $n = 14$ ) who reported less severe and non-intrusive symptoms. Reviews by Bryant (63) and Harvey et al. (64) have generally favored the view that PTA and PTSD can co-exist though in ways that may be different than in non-TBI PTSD cases. The latter review underscored a number of caveats, related either to imprecise criteria for TBI and/or limited assessment of stress-related symptoms (PTSD and acute stress disorder). Further research is needed to clarify the causes and management of these co-morbid conditions.

### Information Processing Aspects of Memory

Memory is neither a unitary nor an automatic process. Although there is individual variation in learning styles, cognition and interests that affects subsequent retention, there are several well-standardized tests of learning

and memory that permit identification of specific memory impairments. Information processing approaches to memory and the brain have identified 3 principal aspects: *encoding*, *consolidation* and *retrieval*. Encoding typically refers to the acquisition of new information and experiences through sensory-perceptual and attentional mechanisms. Encoding is believed to be mediated by several cortical/cortical sensory-perceptual systems together with attentional/executive resources that are allocated according to information load, difficulty, prior knowledge etc. Consolidation pertains to biological mechanisms that are necessary to maintaining a memory trace, thought to involve interactive processing between cortical sensory association areas and limbic system structures, particularly the hippocampus and related medial temporal lobe areas. Retrieval refers to the recovery of stored information either through recall or recognition processes. The neural basis of retrieval remains unclear but may involve executive processes mediated by the prefrontal cortex for search and comparison of familiarity. Given this model of memory and the diversity of neural structures and connections that subserves memory, it becomes easier to understand how memory complaints may be so common after TBI, since large scale coordination of attentional, sensory-perceptual, limbic and executive processing systems is usually required.

Studies investigating TBI and memory continue to show diverse results. While some studies have identified principally encoding deficits, others have identified consolidation and retrieval deficits (65, 66). Curtis et al. (67) suggested that subgroups of memory impaired TBI patients can present with mainly consolidation or retrieval deficits. Particularly in patients with mild TBI, memory impairments may not be apparent on some standardized testing and become evident only under certain conditions such as when patients must divide attention during the encoding phase (68). The latter investigators reported that patients with severe TBI can also present with variable memory results, depending upon whether they attended to the target stimuli or distracting stimuli during encoding. There are a number of other cognitive and learning parameters that can affect memory retention in patients. For example, strategies of clustering similar semantic information (e.g., chunking) can improve verbal retention, while spaced repetition of words can also contribute to more effective learning (69). An important clinical guideline that is emerging from extant literature is the realization that interactive effects of processing speed, working memory and episodic memory impairments may combine to influence learning and memory capacities in naturalistic settings (70). In addition to the importance of cognitive remediation strategies for these deficits, some researchers have suggested that pro-cholinergic medications may be helpful in recovery (71, 72).

## CONFABULATIONS AND DELUSIONS
