To investigate differences among these vegetation water indices, we compared the NDWI (1240 nm) and the LSWI (1640 and 2130 nm) formulations over a range of green canopy cover conditions with dry and wet surface soil states (see Figure 8). The NDWI primarily responded to the amount of vegetation moisture, as related to green vegetation cover, and was minimally affected by the wetness condition of the soil surface. The LSWI based on 1640 and 2100 nm bands had higher dynamic ranges and were sensitive to both vegetation moisture and surface soil wetness conditions (Figure 8). The wet soil backgrounds for a given amount of vegetation resulted in higher LSWI values, especially with the 2100-nm index. Hence the use of both NDWI and LSWI would allow soil surface moisture influences to be analyzed separately from those due to vegetation moisture status. All three indices appeared very unstable over bare soil conditions with large variations in values, which may restrict their use in more arid regions. The NDWI values also did not become positive until a 60% green canopy cover was present.

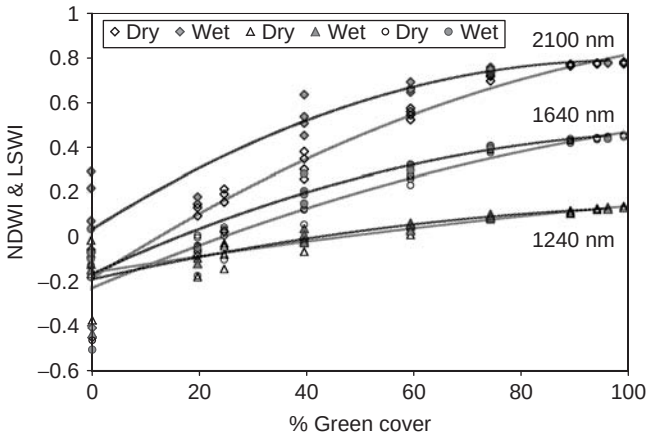

Figure 8 NDWI (1240 nm) and LSWI (1640, 2100 nm) plotted against increasing levels of green cotton cover with dry and wet soil backgrounds

COMBINED MOISTURE AND VEGETATION INDICES

Vegetation water indices employing the 1240-, 1640-, or 2100-nm wavelengths in lieu of the red band used in vegetation indices have recently been used as independent vegetation measures related to canopy moisture condition instead of chlorophyll amount. Although vegetation indices (VIs) have also been correlated with vegetation water content, they are physiologically related to canopy chlorophyll content and absorbed photosynthetically active radiation (Tucker and Sellers, 1986). Thus, VIs generally would depict decreases in plant growth (or senescence) caused by water stress rather than lower water contents. At the Soil Moisture Experiments 2002 (SMEX02) field and satellite campaign, Jackson *et al.* (2004) found the water indices to be superior to VIs in mapping vegetation water content (VWC), as the NDVI was found to saturate, while the water indices continued to show changes in VWC with increasing amounts of green vegetation. Ceccato *et al.* (2002) concluded that VIs were unsuitable for retrieving VWC since relationships between chlorophyll and VWC are specific to each species. Furthermore, decreases in chlorophyll content do not imply a decrease in VWC, and vice versa, a decrease in VWC does not imply a decrease in chlorophyll content.

We combined three vegetation water indices (VWI) with vegetation indices (VI) to ascertain variations specific to each. A combined VI-VWI approach would provide a contextual array of remotely sensed measurements, increasing the measurement domain and reducing the underdetermination problem for assessing soil moisture and vegetation water content (Goward *et al.*, 2002; Zarco-Tejeda *et al.*, 2003). Goward *et al.* (2002) explored this contextual approach for surface moisture studies in the thermal and reflective portions of the spectrum. In Figure 9, the NDWI of soil and vegetation field measurements are plotted with

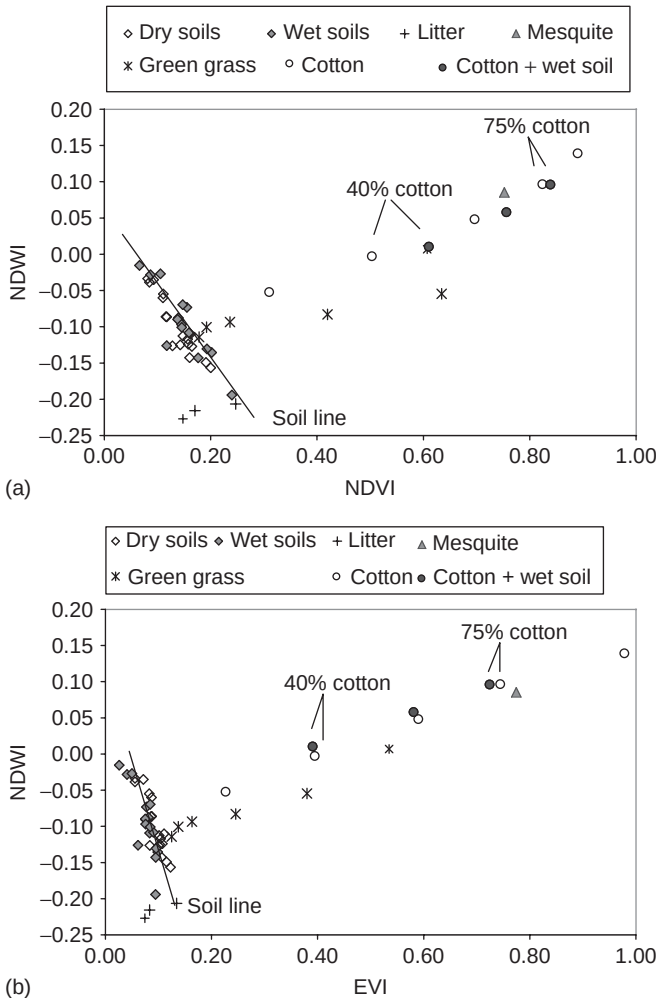

Figure 9 NDWI (1240 nm) plotted against (a) NDVI and (b) EVI for soil and vegetation variations in moisture

the two VIs adopted as standard MODIS products, the normalized difference vegetation index (NDVI) and enhanced vegetation index (EVI),

$$\mathrm{NDVI} = \frac{[\rho_{\mathrm{NIR}} - \rho_{\mathrm{Red}}]}{[\rho_{\mathrm{NIR}} + \rho_{\mathrm{Red}}]} \tag{11}$$

$$\mathrm{EVI} = 2.5\frac{[\rho_{\mathrm{NIR}} - \rho_{\mathrm{Red}}]}{[1 + \rho_{\mathrm{NIR}} + 6\rho_{\mathrm{Red}} - 7.5\rho_{\mathrm{Blue}}]} \tag{12}$$

There is a strong negative, "soil-line" relationship among the dry and wet soil, as well as surface litter, points in the NDWI-NDVI plot. There is also a strong and positive relationship between NDVI and NDWI for the vegetated points, which increasingly separate from the soil line with increasing amounts of vegetation (Figure 9a). Wetting the soil of the 40% green cotton canopy resulted in higher NDVI values with minimal changes to the NDWI. Although the NDWI was spectrally insensitive to the wet soil, the higher NDVI value would result in error in predicting vegetation cover and associated water fluxes. It is worth noting that both indices in Figure 9(a) are needed for maximum discrimination, and hence detection, of variations in soil and vegetation moisture. The NDWI by itself, would not be able to unambiguously distinguish certain bare soils from 40% vegetation canopies as both resulted in NDWI values close to zero.

As the NDVI was strongly correlated to soil variations, we also analyzed the NDWI-EVI relationships and found a clearer separation of soil and vegetation variance (Figure 9b). The EVI was only weakly correlated with the bare soils and the NDWI and EVI values of the vegetated cases were insensitive to soil surface wetness condition. Thus, changes in NDWI and EVI values could be unambiguously related to vegetation, moisture, and chlorophyll, amounts. Although the NDWI was insensitive to soil wetness condition, it exhibited a considerable range in values for bare soils of varying soil types, (Figure 9a,b). This indicates the need for development a soil-adjusted version of the NDWI.

The equivalent cross plots using LSWI, instead of NDWI, are shown in Figure 10. In the NDVI plot, the bare wet soils deviated significantly from the dry bare soils with the wet soils increasing in both NDVI and LSWI values. The same occurs in the vegetated cotton canopy, where wetting the soil increased values of both NDVI and LSWI. This presents a dilemma since this is the same trajectory of increasing NDVI and LSWI values that vegetated pixels would take with increasing amounts of vegetation, limiting the utility of this combined-index cross plot. As with the NDWI plots, the NDVI-LSWI relationships also showed strong negative correlations for bare soils and litter. The LSWI-EVI plot, on the other hand, more clearly shows the LSWI to respond to moisture variations in both soils and vegetation, but in a distinct manner that separates the moisture signal of soil from that of vegetation. Thus, using both LSWI and EVI, one could distinguish between variations in moisture due to soil from those due to vegetation (Figure 10b).

The unique patterns observed between the two moisture indices, NDWI and LSWI, are shown in Figure 11. One can observe an overall correlation, between the two indices, however, dry soil surfaces are clearly separated (steepest slopes) from surfaces with wet soil and vegetation moisture (lower slopes). Wetting the soil of the 40% cotton canopy influences the LSWI but not the NDWI, as expected. As in the previous figures, there is a large variation in bare soil behavior found in both indices that may hinder the assessment of vegetation moisture in sparser and drier canopies. However, in contrast to the previous Figures 9 and 10, the bare wet soils are now separable from the bare dry soils. The sensitivity of these cross plots to vegetation water content, however, remains to be

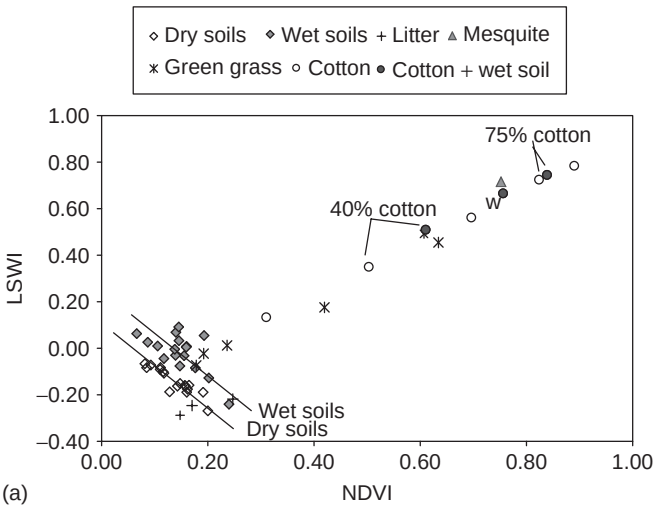

Figure 10 LSWI (2100 nm) plotted against (a) NDVI and (b) EVI for soil and vegetation variations in moisture

tested. These crossplots also do not consider root-zone soil moisture variations and the interactions of soil drying and wetting on chlorophyll versus water content levels in vegetation canopies. The combined use of vegetation indices (VI) and vegetation water indices may yield new insights into the monitoring of soil moisture and separation of moisture signals within a canopy. A combined VI and vegetation water index with thermal or microwave remote sensing approaches would also greatly enhance our understanding of land-surface moisture dynamics.

DISCUSSION

In this paper, we have summarized and also discussed the uses of hyperspectral and optical-based remote sensing techniques for quantitative retrieval of soil properties. Soils are shown to be complex mixtures of numerous absorbing

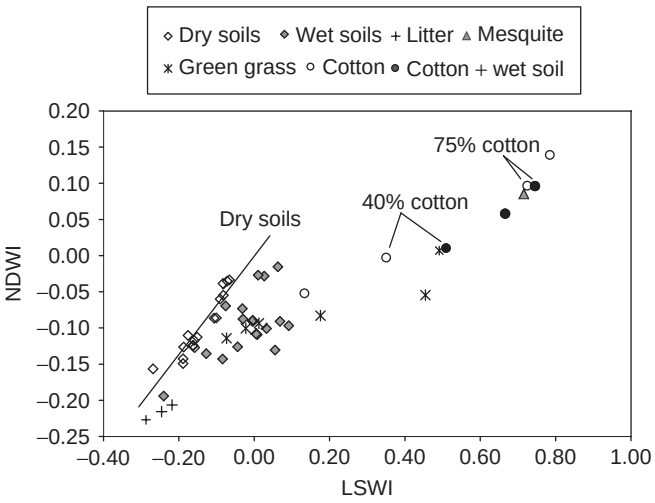

Figure 11 NDWI (1240 nm) plotted with LSWI (2100 nm) for a range of soil and vegetation moisture variations

constituents that require sophisticated methods of analysis to predict and map their abundances. Hyperspectral sensors and advanced spectroscopy and noise removal techniques have greatly improved the feasibility of unambiguously identifying numerous soil and vegetation absorption features, related to mineralogy, organic matter, liquid water, chlorophyll, cellulose, and lignin contents. Hyperspectral remote sensing is used to detect various chemical and physical soil properties either (i) directly from the pure soil pixels, (ii) through advanced spectroscopy methods in mixed "soil-vegetation-NPV" pixels, and (iii) by measurements of the overlying "impacted" vegetated canopy to infer soil properties and moisture status. Soil spectra carry significant information about many soil properties and for the most part, high spectral resolution data are needed over the spectrally active regions of all chemical and physical chromophores to derive soil properties. In most cases, the availability of laboratory or field soil spectra, with physicochemical soil information for calibration purposes, greatly improves upon quantitative retrieval of soil properties.

Although there are strong limitations in the use of remote sensing techniques for soil moisture assessment, optical remote sensing is useful for its spatial coverage and ability to integrate the spatial variability within an area, allowing for scale-dependent studies. Hyperspectral data is increasingly being used to establish relationships between important water absorption features and surface and subsurface soil water status. The water absorption features of both soil and vegetation have been successfully integrated into land-surface-water indices and applied to both hyperspectral and broadband sensor systems. Various water indices have been shown to respond uniquely to soil and vegetation moisture conditions, allowing for the separation of the two sources of variability, and possibly providing a more robust

methodology to assess near-surface, soil moisture conditions. Furthermore, spectral retrieval of both chlorophyll and water contents in vegetation canopies better depict plant physiological status and provide opportunities for improved drought, soil water deficit, and vegetation stress analysis. Much remains to be done, however, in the application of advanced spectroscopy to extract moisture properties of soils and canopies and new models are needed to optimize the water information present in hyperspectral data.

Up until recently, hyperspectral remote sensing was limited to the use of aircraft platforms and field instruments. The first space-borne hyperspectral sensor, Hyperion, was only launched in November 2000 on the Earth Orbiter 1 (EO-1) as part of NASA's New Millennium program. Hyperion is a pushbroom sensor providing 220-, 10-nm bands covering the spectrum from 400 to 2500 nm. Hyperion and AVIRIS imagery have demonstrated their utility in characterizing the ecological variance and complexities of landscapes, including species composition, ecosystem functioning, biogeochemical cycles, and land use, land cover change, and large-scale ecological changes. The success of these applications is providing new impetus for follow-on hyperspectral missions that would provide consistent data in spatial and temporal modes to assess, for example, how soils vary in response to climate and anthropogenic changes.

Combining optical moisture measurements with thermal and microwave measurements in a synergistic mode is also providing powerful new tools for moisture assessments and dynamics at the leaf, soil, and whole ecosystem levels. Various synergy approaches have been used, combining optical and microwave approaches in deriving surface hydrologic fluxes (Kustas *et al.*, 1998; Moran *et al.*, 2002). Microwave data offer improved information on soil, canopy, and landscape roughness useful in soil infiltration, runoff, and erosion models. Thermal measurements provide additional information on plant canopy and soil moisture status, and combined with optical information on soil properties and vegetation amounts, greatly improve hydrologic process studies related to soil moisture. In combination, hyperspectral, thermal, and microwave approaches will provide new insights into complex hydrologic processes, fluxes, and feedbacks among soil moisture, atmosphere moisture, and ecosystem metabolism and development.

60: Estimation of River and Water-Body Stage, Width and Gradients Using Radar Altimetry, Interferometric SAR and Laser Altimetry

CHARON BIRKETT[1], DOUG ALSDORF[2] AND DAVID HARDING[3]

[1] *Earth Science Interdisciplinary Center, University of Maryland, College Park, MD, US*
[2] *Department of Geological Sciences, Ohio State University, Columbus, OH, US*
[3] *Geodynamics Branch, NASA/Goddard Space Flight Center, Greenbelt, MD, US*

Major advances in the application of satellite radar altimetry have led the way to a proven ability to determine surface water height, or stage, for some of the largest rivers, wetlands, and lakes around the world. These developments have come at a time when global water resources are of major concern, and there is a much-noted decline in ground-based monitoring networks. Recent interferometric synthetic aperture radar studies have also demonstrated the ability to retrieve stage changes over a wide expanse of inundated floodplain or wetland. While the performance of these radar instruments is continuously being assessed, focus is also on the potential of satellite-based laser altimetry, which may offer smaller observable targets and improved stage accuracies. With these technological capabilities, we have the capacity to determine inland water stage, and to some degree, river width and gradient.

INTRODUCTION

Today, there are many excellent *in situ* hydrologic monitoring networks in operation, measuring lake and river stage (i.e. the height of the water surface), often on an hourly or twice-daily basis, to centimeter accuracy. Some gauges also have the capability to transmit their findings in near-real time. However, gauge sites can be lacking in remote regions and there is often a total absence of recording within wetlands, braided rivers, and floodplains. In many populated regions, the capacity to retrieve stage measurements is also being affected by economic and political factors. These factors can result in explicit data restriction policies as well as delays in information availability. While there is continuing difficulty in obtaining near-real time data from the developing world, recent reports have additionally highlighted the continuing net loss of recording stations for some regions traditionally endowed with dense networks (Lanfear and Hirsch, 1999; Vörösmarty *et al.*, 2001).

The issue of decreasing ground-based observations is a prime concern considering both the human dimension and earth system issues relating to freshwater. For the former, the assessment and management of water resources is a top priority in relation to population growth. The monitoring, prediction, and mitigation of natural hazards such as droughts and floods is also of concern as are transportation and waste processing issues. Regarding studies of the earth system, determination of the surface water balance is critical in understanding both land/ocean and land/atmosphere interactions. The role of rivers, wetlands, and lakes regarding (i) the transport of nutrients, (ii) storage devices and regulators of biogeochemical cycles, (iii) trace gas exchange mechanisms, and (iv) changes on the timing of continental runoff, are all of prime importance.

The effects of climate change contribute additional uncertainty to all of these issues, making the determination of surface water parameters such as river discharge and volume storage even more critical. River discharge is traditionally inferred by the combined knowledge of river-stage and a stage-discharge relationship (referred to as "rating curves", *see* **Chapter 61, Estimation of River Discharge, Volume 2** for details) for a specific location. Lake

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

volume is determined via synergistic knowledge of stage and bathymetry. Ideally, discharge and volume should be acquired via a long-term, global monitoring program with free and rapid dissemination of all information. In this respect, satellite remote sensing is an obvious solution, enhancing the ground-based network information and providing additional data at ungauged locations. While current satellite sensors cannot measure discharge or storage directly, the ability to measure stage is central to both parameters and can be measured, with some limitations, by current technologies. In addition, there is also the potential for river width and gradient to be measured by satellite.

The ability to measure stage using satellite radar altimetry and interferometry has been briefly discussed before in several review papers (Kite and Pietroniro, 1996; Smith, 1997; Mertes, 2002; Mertes *et al.*, 2004). Discussion of river discharge and wetland and lake extent can also be found in **Chapter 61, Estimation of River Discharge, Volume 2**.

SATELLITE RADAR ALTIMETRY

Historical Perspective

Satellite radar altimetry emerged in the early 1960s with objectives of acquiring accurate sea surface topography. By timing the two-way emission and reflection of microwave pulses see section "Principles of Satellite Radar Altimetry", the spatial and temporal variability of sea surface height could be monitored via the utilization of an exact repeat orbit. The technique led to the National Aeronautics and Space Administration's (NASA) GEOS-3 (1975–1978), and the National Oceanographic and Atmospheric Administration's (NOAA) Seasat satellite in 1978. The NOAA Geosat mission followed a decade later and operated successfully between 1986 and 1989.

With multiple ocean, land, and ice science objectives, the European Space Agency (ESA) launched ERS-1 in 1991, and this was followed by ERS-2 (1995) and ENVISAT (2002). An oceanographic theme was continued by NASA and the Centre National d'Etudes Spatiales (CNES) with the launch of TOPEX/POSEIDON (T/P) in 1992 and its follow-on mission, Jason-1, in 2002. The Geosat follow-on program (GFO) is also the US Navy's initiative to develop an operational series of radar altimeter satellites to maintain continuous ocean observation. The first satellite was launched in February 1998 and became operational in November 2000.

Satellite radar altimetry has thus been a prominent technique spanning several decades of operation and application. Although successful, it is important to note that to date no system has been designed and no mission dedicated solely to the monitoring of inland water stage variations.

Principles of Satellite Radar Altimetry

Pulse-limited satellite radar altimetry has been a validated technique for many years now, and a number of excellent published sources describe the fundamentals in great detail (e.g. Ulaby *et al.*, 1981; Chelton *et al.*, 1988, 2001). The basic principles of this nonimaging technique are briefly described here.

Operating from an altitude of 700–1330 km, a continuous stream of microwave pulses (e.g. frequency Ku band 13.6 GHz) is emitted from a nadir-pointing antenna (Figure 1). The resulting radar echo has an intensity (radar backscatter) and shape defined by the surface characteristics (Figure 2). The distance between the antenna and the surface (the altimetric range) is determined via knowledge of the two-way timing difference between pulse emission and echo reception. The spacecraft altitude is estimated from a combination of other technologies (Section "Height (Stage) Construction"). The surface height then, is defined as the difference between orbital altitude and range and is given with respect to a reference datum, a mathematical concept known as a *reference ellipsoid*. If a transformation to a reference system based on mean sea level is required, knowledge of the local geoid must be additionally known.

When referring to inland water bodies, it is this height above the reference ellipsoid, or geoid, that is associated with the traditional ground-based stage measurement of a lake or river gauge. With continuous operation, such stage measurements can be potentially retrieved for any part of an inland water target that sits directly below the satellite overpass. Typically, the instrument footprint size (a function of surface roughness with pulse-limited

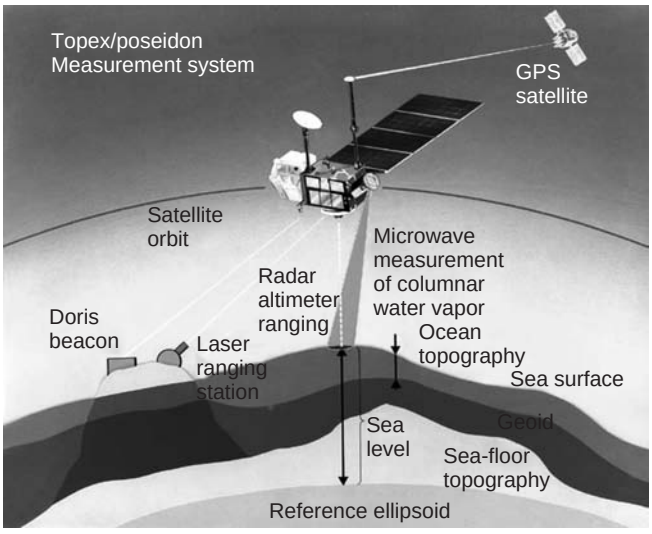

Figure 1 The basic principle of satellite radar altimetry (Image courtesy of the NASA Jet Propulsion Laboratory, California Institute of Technology). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

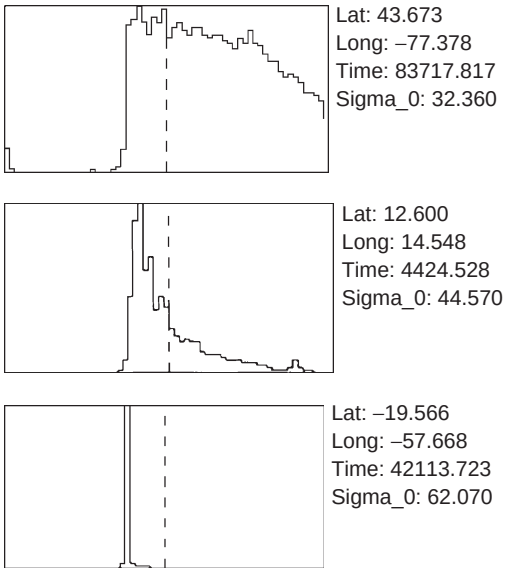

Figure 2 From top to bottom, radar echoes from Lake Ontario, Lake Chad, and the Amazon River during a period of high river stage, demonstrating the effect of differing surface conditions on echo shape and power. Each echo, or waveform, is a representation of power returned as a function of time. Over lakes, waveforms are typically ocean-like, but can become broad-peaked or even narrow-peaked under very calm or icy conditions. Over rivers, floodplains, and wetlands, waveforms are generally narrow-peaked with significant radar backscatter coefficient variability during seasonal inundation

technology) is a few hundred meters to several kilometers wide. Generally, the resulting ground tracks (Figure 3) are repeated to within ± 1 km through each orbit cycle. In reality, there are many limitations to height retrieval but where data is valid, time series of height variations can be constructed during the mission lifetime. If a satellite crosses a river at several locations, then the gradient of a river reach can be estimated if the separation distance between locations is known. Owing to various technological and data-rate limitations (Section "Advantages and Limitations: Accuracy, Resolution, and Target Size"), determination of river width may be more problematic with radar altimetry.

There are complexities to the basic principle outlined here, and instrument design, operation, and data processing may differ between each mission. Over land and inland water, consideration must always be given to the ability to successfully follow (or "track") the rapidly changing fluctuations in elevation and surface complexity. The altimetric range itself is determined from inspection of the echo within a "range window". By continuous inspection of echo power and location, it is the role of the tracking system logic to capture and keep the leading edge, or center of gravity, of each echo within the range window. If the leading edge can be observed, the altimeter is said to be tracking the surface well with surface "lock" being maintained, and the altimetric range can then be derived. Rapid variations in surface roughness and complexity often effect either the ability to retrieve any range value, or the accuracy of the determined range.

The deduced altimetric height must also have a series of corrections applied to take into account various instrument and geophysical factors (Section "Height (Stage) Construction"). It is this postprocessing that allows the reconstruction of the true surface elevation to a sufficient degree of accuracy. In general, ground-processing teams collect and process the telemetered data from the altimeter and auxiliary instruments and redistribute it in raw (Sensor Data Records,SDRs) or processed (Geophysical Data Records, GDRs) form to the user communities. Fast delivery data, with poorer satellite altitude accuracy, may be available within a few hours after satellite overpass. GDR data are often distributed within a month after overpass and contain more precise measurements and corrections. The final stage measurement is associated with a particular time in the mission and is given for a specific geographical location (subsatellite point). It should not, however, be considered as a spot height, rather it is formed via an averaging process that considers all surface heights within the footprint, and the surface heights along a portion of the ground track (to reduce signal to noise). In addition, final stage values will

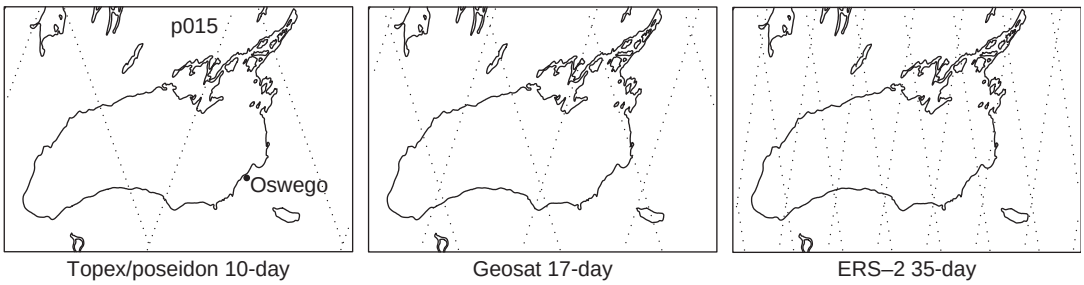

Figure 3 An example of the trade-off between spatial and temporal resolution for differing satellite missions. Dots represent the satellite reference ground track at 1-s intervals. With continuous instrument operation, surface height can be potentially retrieved at any location along these ground tracks. The repeatability of the ground tracks is nominally kept to within ± 1 km

be given at a rate dependant on the delivered mission data. For example, from the T/P GDRs, stage can be constructed every ~580 m along the ground track (10 Hz), while every ~330 m (20 Hz) from the high-resolution ERS datasets.

Height (Stage) Construction

A full discussion of the derivation of altimetric height can be found elsewhere (e.g. Zandbergen, 1990, and various mission data handbooks). A brief description is given here, where relevant to studies of inland water. The height, H, of a non-ocean surface is given by the difference between the satellite orbit altitude, Alt, and the corrected altimeter range, R_{corr}, with a final correction for tidal effects, T.

$$H = (Alt - R_{corr}) - T - [BC] - [G] \quad (1)$$

Both H and Alt are given with respect to a mathematical reference ellipsoid. Tidal effects include corrections for earth, pole, and ocean-loading tides. In general, GDRs and SDRs do not include information pertaining to lake tides or to ocean tidal effects on large rivers. Researchers must seek auxiliary data sets here. Height measurements over the ocean usually include a correction for barometric effects, BC, to take into consideration the response of the sea surface to atmospheric pressure. Although this correction is supplied on some GDRs for some of the largest lakes and inland seas, the correction is not supplied for the smaller lakes. In consideration of the fact that the majority of lakes are small closed systems by comparison with atmospheric pressure systems, BC is often not applied. If heights are to be determined with respect to a mean sea surface, than a correction for the geoid, G, can be applied if such knowledge is available from the GDRs or external sources. The spacecraft altitude, Alt, can be very accurately obtained by a combination of technologies including the Global Positioning System (GPS), Satellite Laser Ranging (SLR), Doppler Orbitography and Radiopositioning Integrated by Satellite (DORIS), Precise Range and Range-rate Equipment (PRARE) and by use of the altimetric heights at orbital "cross-over" locations.

The altimetric range itself must be corrected for various instrumental and physical effects. These include an electromagnetic bias (EM-bias), which takes into consideration the fact that surface wave troughs are better reflectors than wave crests. Other corrections include a center of gravity correction to correct for satellite roll and pitch changes due to solar array motion and a significant wave height-attitude correction (SWH/ATT) for combined surface wave status and spacecraft off-nadir pointing effects. Over inland waters, EM-bias and SWH/ATT must certainly be applied to large unfrozen lakes, but the values become more questionable, and may even be defaulted in the GDRs, over the calmer surfaces of rivers and wetlands.

Range must also be corrected for atmospheric effects. The propagation speed of a radar pulse is reduced because of the effects of various gases and water vapor in the Earth's troposphere. The former is fairly predictable, but the latter is highly variable. An onboard microwave radiometer can provide more accurate estimates of the water vapor over large lakes, but for smaller targets and rivers and wetlands, this correction must be sought from a less accurate meteorological model. The radio pulse propagation velocity is also slowed by the free electrons within the Earth's ionosphere and is proportional to the operating frequency of the altimeter instrument. Over inland water, ionospheric corrections from models or derived from the DORIS instrument are utilized.

The precision of the range estimate is dominated by the error associated with estimating the location in the range window of a predefined point on the leading edge of the returned echo (the retracking point). For an ideal ocean-like echo (Brown, 1977), this point corresponds to the mean height in the instrument footprint. Sometimes the altimeter response to large lakes, and nearly always to rivers and wetlands, is not similar to that over the ocean but varies according to surface conditions. For non-ocean-like radar echoes, there may also be a need for postprocessing of the radar echoes, a technique known as *retracking*. In this case, a range correction has to be estimated to take into consideration variable height biases caused by rapid changes in either surface height, or echo shape and intensity.

Technique and Validation

After the construction of the individual 10- or 20-Hz stage measurements, various filters need to be applied to aid the removal of poor or erroneous stage values stemming from geophysical or instrument effects. In particular, the effects of coastlines and islands need to be eliminated (e.g. Birkett, 1995, 1998).

With valid stage data, the user can then explore the potential for river-gradient determination or look to the creation of a time series of stage variations. The latter requires an intercomparison of stage and location (latitude/longitude) data from all repeat tracks (repeated to ± 1 km), either by a nearest-neighbor approach or by interpolation and coalignment of the tracks. Such a "repeat-track technique" is employed to enable time series of relative stage variations to be deduced over a given time period, and for a given section of satellite ground track. In this method, either one repeat pass over the target or a mean reference pass is nominated as a "reference profile" and height differences between this reference pass and successive repeat passes over the target are determined. A time series of elevation variations is then constructed (Birkett, 1995). With some knowledge of the precision of the technique (Section 2.5.1), estimations of resulting stage accuracy can be made and are

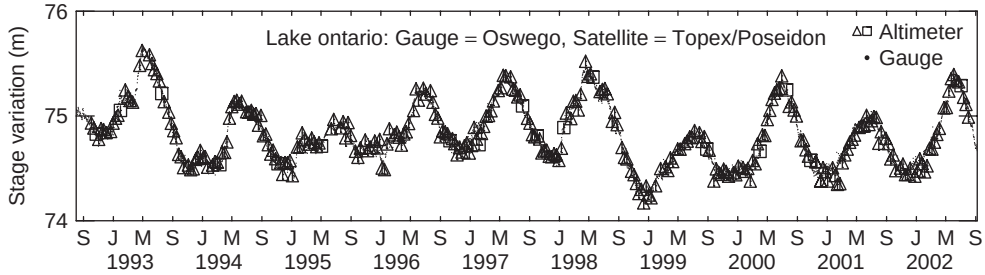

Figure 4 Validation of stage variations over Lake Ontario. Ground-based stage data (dots) are from the Oswego gauge (courtesy of the National Oceanic and Atmospheric Administration/National Ocean Survey). TOPEX/POSEIDON altimeter data from pass015 (Figure 3) are denoted by triangles (NASA radar altimeter) and squares (solid state altimeter). A constant height offset has been applied to the altimetric result. Time steps are in intervals of 4 months (Reproduced from Birkett, 1995 by permission of American Geophysical Union)

further validated by comparisons with ground-based hourly and daily stage data (Figure 4).

Advantages and Limitations: Accuracy, Resolution, and Target Size

The main advantages of this technique include the ability for day/night and all-weather systematic operation with no loss of operation due to cloud coverage. With continuous operation across land surfaces, the instrument behaves like a string of pseudogauges, sampling across lake, inland sea, and wetland surface, and across wide river channels and their floodplains. The presence of vegetation or canopy cover is not a hindrance to this nadir-viewing instrument except at very low inundation levels when dryland conditions are approached. In general, the instruments can observe monthly, seasonal, and interannual variations (Figure 5).

Unlike many gauge networks that operate using a local reference frame, all altimetric height measurements are given with respect to one reference datum, to form a globally consistent, uniform data set that is based on a proven, validated technique. For the most part, the altimeter datasets themselves (DVD, CD-Rom, exabyte, or via ftp) are freely available. There are also several ongoing programs whose objectives are to construct near-real time stage variations for inland waters and place them out in the public domain (Section 2.6). Altimeter instrument design and performance though is not optimized for studies of lakes and rivers. Although there are a number of advantages, the technique is not without its limitations. Two obvious points to note are that the altimetric measurements are constrained by the lifetime of the satellite, and the instruments are nadir-pointing and so do not have a truly global perspective.

Accuracy

The final accuracy of a single altimetric stage value depends on the accuracies of all the parameters and correction terms in equation (1). The satellite altitude and other corrections have root mean square (rms) errors on the order of a few centimeters. The range precision may be poorer, but one way to improve this term is by averaging across the target. In this way, the entire river width, or the full lake crossing extent can be used. The construction of surface height, however, does not take into account the effects of strong or sustained winds, heavy precipitation events, or the presence of lake/river ice. The latter two can hamper the quality and quantity of the range measurement and are sometimes difficult to detect over inland water. Wind setup effects can also effect the mean stage measurement across the lake.

A traditional ground-based gauge offers a height measurement at a defined geographical location, that is, it is essentially a spot height, while an altimeter must rely on the ability to average many echoes along the satellite ground track. The accuracy of a resulting altimetric time series (in comparison with gauge measurements) can vary then according to target size (or crossing extent) and surface roughness. For the largest lakes of the world, validation exercises have shown 3–5 cm rms can be achieved. This degrades though to ten or tens of centimeters rms for smaller lakes (e.g. $\sim$100 km^2) or narrow reservoirs, and holds true for shallow lakes, wetlands, and rivers. This may be considered poor but is clearly acceptable for some science objectives, and is a bonus for those regions around the globe with a total absence of any stage data. With knowledge of the satellite altitude at the 1–2 cm level, the most dominant source of altimetric errors for small lakes and rivers/wetlands is the poor knowledge of the wet tropospheric correction, and the error associated with the extraction of the altimetric range from the narrow-peaked river/wetland echoes.

Resolution and Performance

There is a trade-off between temporal and spatial resolution with each mission (Figure 3), and instrument performance determines the final quantity of retrieved elevation information. The majority of targets will have a single satellite

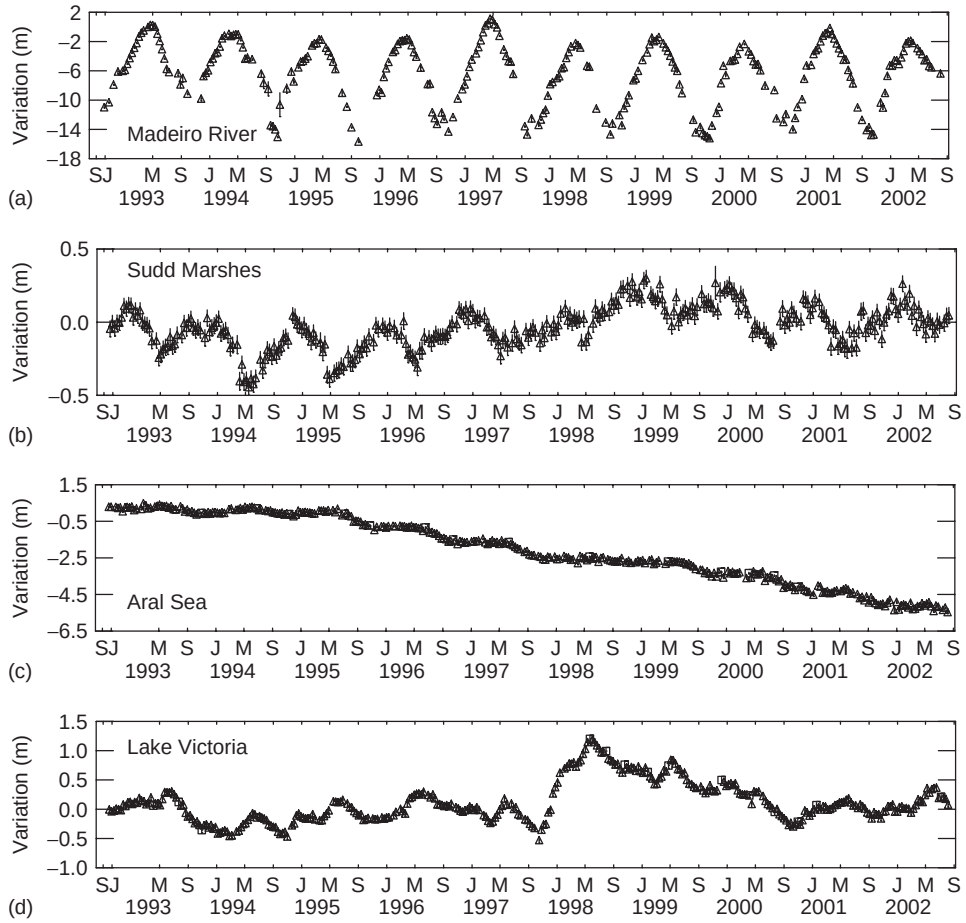

Figure 5 Time series of relative stage variations for a variety of inland water targets; (a) the Madeira River, Brazil, (b) the Sudd Marshes, Sudan, (c) the Aral Sea, and (d) Lake Victoria, Africa. The series was produced using data from the TOPEX/POSEIDON mission archive. Time steps are in intervals of 4 months (Reproduced from Birkett, 1995; Birkett *et al.* 1999, 2002 by permission of American Geophysical Union)

overpass, and thus the temporal resolution or the frequency of the stage measurements will be defined by the satellite repeat period (e.g. one overpass every 10 or 35 days). This is to be compared with the twice-daily, often automated measurement from a gauge. For the largest lakes and inland seas, the satellite temporal resolution will improve depending on the number of differing overpasses and the ability to combine separate time series results.

Spatial resolution is also limited by the narrow field of view. The number of available targets and the location of overpass are predetermined by the satellite orbit that is, its geographical latitude limits and the positioning of its resulting ground tracks. It is thus a case of predetermined target selection depending on the distribution of the inland water basins. Examples can be given for the currently operating ENVISAT and Jason-1 missions. The Mullard Space Science Laboratory Global Lakes Database (Birkett and Mason, 1995) reveals that there are ~1440 large lakes and reservoirs across the globe. With its 35-day repeat period, and ±82° latitude limit, ENVISAT crosses over ~1075 of those listed. With a temporal resolution increased by a factor of three, the number of targets crossed by Jason-1 (10-day repeat, ±66° latitude) is reduced by a factor of three, to only ~360.

Consideration must be given to the performance of the instrument, regarding its ability to track highly varying terrain, and the additional limitations of effective footprint size and GDR data-rate on target size. Surrounding hills, ravines, buildings, riverbanks, lake coastlines, and islands, all offer potential obstacles for the tracking system. The results may be a radar echo too complex to interpret, or the complete loss of surface lock, both effects resulting in the loss of surface height. The effects can be compounded by the presence of multiple water targets within the footprint. The reacquisition of the terrain after loss of surface lock may also take a few seconds, by which time the satellite may have flown past the intended inland water target. The Seasat, Geosat, T/P and Jason-1 radar

altimeters were only designed to track the ocean surface with an assumed sea surface variability and expected wave-height range. The ERS-1 and ERS-2 radar altimeters were designed for both ocean and ice/land measurements and incorporated the ability to switch between two operating modes, ocean- and ice-tracking, to assist with the capture of the radar echoes within the range window (Scott *et al.*, 1994). The ENVISAT radar altimeter, RA-2 has a different tracking system again, with the potential to retain even more land and inland water data.

Target Size

Surface tracking considerations, the effective instrument footprint size, and the averaging of echoes to improve range precision, all place constraints on the minimum size of observable target. The tracking consideration can even be a concern for large targets that have mountainous terrain on the satellite approach path. The footprint size affects the ability to single out a specific river channel or small pool, and determines the ability to separate river channel from inundated floodplain. A final factor is the rate at which stage values are given in the GDR/SDR user datasets. One average height value is given every ~580 m (for T/P, GDR), ~350 m (ERS, ENVISAT), and ~290 m (Jason-1, GDR) along the ground track. Current studies on target size limitation suggest $> 100-300\,\text{km}^2$ (wetlands, lakes) and $>0.5-1$ km river widths, mission dependent. The advent of new tracking techniques and echo interpretation methods, and the potential for increasing the data-rate, may well significantly improve these minimum size limitations.

Applications

The first inland water study was carried out by Brooks (1982) who explored Seasat data over the Canadian lakes for mapping purposes. Rapley *et al.* (1987), Olliver (1987), and Au *et al.* (1989) also used this dataset to perform bathymetric studies on Lake Tanganyika, the Great Lakes, and the Caspian and Black Seas. Guzkowska *et al.* (1990) and Cudlip *et al.* (1992) also utilized these early measurements in several wetland-mapping and river-gradient determination studies. In general, results were hampered by data limitations, technical problems, and the then poor accuracy of the Seasat satellite altitude.

Following the success of the Geosat mission, Guzkowska *et al.* (1990) also presented the first lake level time series for Grand Lac, Cambodia, while Koblinsky *et al.* (1993) explored river-stage accuracies within the Amazon basin. As part of a study dedicated to aridity changes, Birkett (1994) expanded the early Geosat studies to a collection of large ($\geq 100\,\text{km}^2$), closed, and climatically sensitive open lakes. Morris and Gill (1994a) also derived Geosat lake level time series for the Great Lakes and through validation exercise showed the resulting time series were accurate to ~10 cm rms.

The advent of a new satellite mission, TOPEX/POSEIDON (T/P) with excellent knowledge of satellite altitude and a 10-day repeat period, enabled altimetric lake and river stage to be more accurately determined. Morris and Gill (1994b) found rms accuracies of ~3 cm over the Great Lakes when lake tides and wind setup effects were removed. Birkett (1995) examined the contribution of T/P to the continuing study of climatically sensitive lakes, and later (Birkett, 1998) to the study of rivers and wetlands. Dalton and Kite (1995) also examined preliminary T/P data over the Great Lakes, and made low-rate (1 Hz) accuracy comparisons with nearby gauge measurements.

After these early exploratory projects, the application of T/P altimetry to inland water studies became more region-based with science objectives focusing on natural hazards, climate change, and surface water dynamics. Cazenave *et al.* (1997) observed the temporal and spatial variation of the rising and falling waters of the Caspian Sea. Ponchaut and Cazenave (1998) utilized the interannual stage fluctuations of some of the largest lakes in Africa to explore El Niño/Southern Oscillation (ENSO) and recurrent drought connections. The late 1990s saw one of the strongest El Niño's on record in the Pacific and similar reversals of sea surface temperature in the Indian Ocean. Discussion of drought changed to precipitation excess as radar altimetry was used to study the great 1997/1998 flooding events across East Africa (Birkett *et al.*, 1999; Mercier *et al.*, 2002).

The plight of flood or drought and the associated socioeconomic impacts became the focus of several social, remote sensing, and modeling studies concentrating on the water resources of Lake Chad in the Sahel (Birkett, 2000; Sarch and Birkett, 2000). In general, the determination of reservoir storage for irrigation potential is particularly important for all regions with high agricultural demands. With the advent of fast delivery radar altimetry data and validated techniques, operational projects are now underway to assist with the timely delivery of information. One such program (**http://www.pecad.fas.usda.gov/cropexplorer/global_reservoir**) monitors in near-real time the stage variations of nearly a hundred large lakes and reservoirs across the globe using the T/P and Jason-1 datasets.

Temporal fluctuations in river and wetland stage became the focus of two studies in the Amazon basin (Campos *et al.*, 2001; Birkett *et al.*, 2002) and one in the La Plata Basin (Maheu *et al.*, 2003). All three projects examined T/P data at many sites noting the differences of seasonal amplitudes, the time lags of peak periods, and the propagation speeds of the flood waves. The Birkett *et al.* (2002) study (**http://essic8.umd.edu/RALNET-LBA**), part of the Large-scale Biosphere Atmosphere experiment in Amazonia (LBA) project, also utilized the altimetry to reveal the hysteresis characteristics of the Amazon main stem flood

Table 1 Summary of satellite technique capabilities for inland water

Satellite mission	Operation period	Temporal resolution	Spatial resolution	Stage-change accuracy	Minimum target area and width
Radar Altimetry					
ERS-2	1995–2002	35 days	350 m AT	$>$ 9 cm rms	$>$100 km^2 $>$500 m
ENVISAT	Post-2002	35 days	350 m AT	$>$9 cm rms	$>$100 km^2 $>$500 m
T/P	1992–2002	10 days	580 m AT	$>$3 cm rms	$>$300 km^2 $>$1 km
Jason-1	2002–current	10 days	290 m AT	$>$3 cm rms	$>$300 km^2 $>$500 m
InSAR					
SIR-C	October, 2004	1 day	20–90 m PS	$\pm$1.0 cm	0.1 km^2, $\sim$100 m
JERS-1	1992–1998	44 days	20–90 m PS	$\pm$2.4 cm	0.1 km^2, $\sim$100 m
Laser Altimetry					
ICESat	2003–current	91 days	175 m AT	$>$10 cm rms	0.01 km^2, $\sim$100 m

(A) AT = along track (nadir) stage interval, PS = pixel size.
(B) Minimum target area/width for lake or wetland area and river width. For radar and laser altimetry, values given are guidelines based on data-rate and footprint size. Current radar investigations are examining trade-offs between size reduction gains and stage accuracy effects.
(C) Radar and Lidar altimetry can measure stage and stage change over a given time period. The InSAR technique based on double-bounce returns measures only stage change and applies to flooded forest regions.
(D) Stage-change accuracies for radar and laser altimetry are based on comparisons with ground-based gauge data over a given time period. Values can be variable depending on target extent and surface roughness. Values for ERS-2 are based on preliminary validation results in ice tracking mode. Values for ICESat are based on preliminary calibration and validation results.
(E) ICESat temporal resolution: The orbit is a 91-day repeat orbit, but with $\leq 5^\circ$ off-nadir precision pointing capability, repeat profiling is 8 days at 70° lat, or 24 days at the equator.

wave, and to study the temporal and spatial variations of the river gradient.

To summarize, satellite radar altimetry is capable of monitoring stage and stage variations within large lakes, reservoirs, rivers, and wetlands. The current missions are not dedicated to inland water studies, nevertheless, the technique has been successfully utilized within many different interdisciplinary projects and operational programs. It can potentially offer stage measurements at many ungauged locations, but there are limitations to the technique in terms of stage accuracy, target size, temporal, and spatial resolution (see Table 1). Stage accuracy and spatial resolution may be improved for large wetland areas and floodplains by the application of interferometric SAR (Section 3), while lidar altimetry (Section 4) aims to improve both stage accuracy and size limitations for all target types.

INTERFEROMETRIC SYNTHETIC APERTURE RADAR

The ability to only observe stage variations at nadir is a serious limitation of satellite radar altimetry. However, if certain assistance is provided by vegetation, this limitation can be overcome by another satellite-based technique known as *interferometric synthetic aperture radar* (*InSAR*). This extends the capability to a wide image swath and can measure more subtle changes in water level. Across vast wetlands and floodplains this can lead to estimations of significant storage changes. The following sections detail the technological and geomorphic requirements of this methodology as well as its resolutions, advantages, and disadvantages.

Historical Perspective

Interferometric SAR first gained wide recognition with the efforts of Massonnet *et al.* (1993) and Zebker *et al.* (1994) who provided highly detailed maps of ground surface deformation resulting from the Landers earthquake in Southern California. Similarly, Goldstein *et al.* (1993) demonstrated that interferometric processing of SAR imagery could yield velocity maps of flowing glaciers. For the past decade, a tremendous effort has been devoted to this methodology (e.g. review provided by Massonnet and Feigl, 1998), and in fact, the Space Shuttle Radar Topography Mission (SRTM) of February 2000 used interferometric SAR to create the world's first seamless, high-resolution digital elevation model (DEM) (Farr and Kobrick, 2001).

Because SAR systems use an off-nadir viewing geometry, the highly reflective water surface typically causes emitted radar pulses to specularly reflect away from the antenna. Thus, conventional thought suggests that interferometrically measuring water level changes is not possible because of the lack of returned energy. Alsdorf *et al.* (2000, 2001a,b) have now demonstrated that, in the special case of inundated vegetation, radar pulses are returned to the antennae and that it is possible with interferometric processing of the SAR data to produce a centimeter-scale mapping of water level changes throughout inundated vegetation.

Interferometric SAR Principles

To create a map of surface change with interferometry requires two SAR images acquired from nearly identical viewing geometries. The images must be acquired before and after the change phenomenon, for example, an earthquake or floodplain-lake with decreasing storage, thus this approach is called the *repeat-pass* method. After coregistering the images to subpixel accuracy, the complex radar phase and amplitude values at each pixel are subtracted to yield an interferometric phase image with phase values varying between $-\pi$ and $+\pi$. The specific phase value of each pixel is a function of (i) the baseline distance between the two positions of the SAR antennae, (ii) topographic relief, (iii) the degree of correlation between the scattering elements that comprise each pixel (i.e. the "coherence", Li and Goldstein (1990), Zebker and Villasenor (1992)), and (iv) the surface elevation change.

InSAR Baselines

Because of viewing parallax, large baselines are ideal for accurately measuring topography, whereas smaller baselines are desired for mapping changes in surface elevations. To separate these components, either a synthetic interferogram based on a DEM ("two-pass method", Massonnet *et al.*, 1993) or additional SAR interferograms free of displacement phenomenon ("multipass method", Zebker *et al.*, 1994), can be subtracted from the observed phase. Essentially, the observed phase contains both topographic and surface change components. Removal of the topographic component is accomplished by either (i) using a preexisting DEM to construct a model phase based on the known observing geometry or (ii) using additional interferograms with long baselines thus dominated by a topographic signal. Because water surface elevations are constantly changing, the topographic phase cannot be easily extracted using additional SAR images, which suggests that the two-pass method is likely required. The amount of topographic relief captured by one interferometric phase cycle, from $-\pi$ to $+\pi$ is a function of the perpendicular component of the baseline. Short perpendicular components yield more topographic relief per phase cycle than long baselines, thus giving a more reliable estimate of surface change.

The two Amazon demonstrations of this interferometric method discussed in Section 3.5 had perpendicular baselines between satellite acquisitions of +63 m (Shuttle Imaging Radar C-mission,SIR-C, Alsdorf *et al.*, 2000, 2001a) and −118 m (Japanese Earth Resources Satellite, JERS-1, Alsdorf *et al.*, 2001b). These short baselines indicate that 0.5 radians of phase are equivalent to 15 to 20 m of topographic relief, whereas depending on look angle, the same 0.5 radians are also equivalent to about 1 cm of water surface change. Fortunately, in these two cases, the topographic relief across the Amazon floodplain is about 20 m, resulting in the bulk of the interferometric phase signal being related to water level change.

InSAR Coherence

Over land surfaces, where changes in soil moisture, vegetation, and freeze/thaw cycling cause random changes in the structure and dielectric properties of the scattering elements, interferometric coherence typically diminishes with increasing time between SAR acquisitions. Over inundated vegetation, the scattering elements consist of the water surface and vegetation trunks. For short time periods, say 24 h, the water surface is likely to experience a greater change in structure than the trunks of vegetation (i.e. wave action on the water surface). Thus, short-term temporal coherence is probably a function of the stability of the water surface (i.e. dielectric changes in the air-water interface are assumed to be minor). Across seasonal growth periods, however, vegetation changes will also affect coherence. For example, during the 24-h separating SIR-C acquisitions of Alsdorf *et al.* (2000, 2001a), coherence was maintained, and thus it was initially assumed that the heavy Amazon forest canopy prevented wind roughening of the water surface during the 1-day period. Yet given the low vegetation density and large water surface of Lake Balbina (Alsdorf *et al.*, 2001b), it is doubtful that wind and wave action would be similarly subdued for the 44-day temporal baseline of the JERS-1 interferogram. Nevertheless, strong coherence is maintained across the entire JERS-1 image.

Accuracy and Temporal Resolution

The vertical accuracy of the interferometric method is related to coherence and the degree to which the topographic phase can be removed. In cases where the scattering elements of each pixel remain stable, such as a dry desert, and an accurate DEM exists, the resolution of the surface change in the look-direction of the SAR antennae can be less than a centimeter (e.g. Massonnet *et al.*, 1993; Zebker *et al.*, 1994). However, the Amazonian research lacked a DEM, thus based on coherence measurements, vertical accuracies were estimated to vary from ±1.0 cm in the SIR-C case to ±2.4 cm for JERS-1 (see Table 1). Provided that coherence is maintained across the floodplain water body, the spatial accuracy is a standard function of SAR imagery. SAR data typically have pixel sizes between 20 and 90 m, such that many small geomorphic features can be mapped. The number of satellite overpasses varies from 1 day for SIR-C to 44 days for JERS-1. Unfortunately, both of these missions are no longer operating.

Limitations and Advantages

It is must be noted that the InSAR method requires the radar pulse to be returned from the water surface to the antennae, and in the case of the repeat-pass method

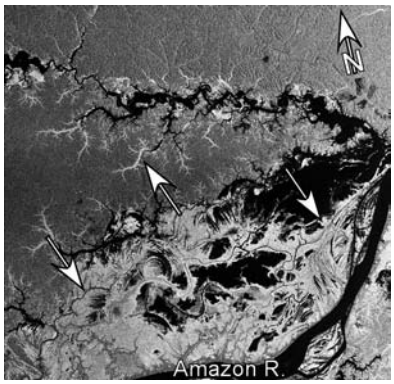
described here, the return does not occur over open water surfaces. Rather, the trunks of vegetation are a demonstrated requirement for measuring changes in water levels. Other features, such as telephone poles, might produce returns, but remain to be proven. Fortunately, the testing ground for this technique, the Amazon floodplain, is about 70% inundated forest (Mertes *et al.*, 1995), suggesting that the geomorphic requirements are met for much of this vast wetland. However, the radar pulse must also penetrate the vegetation canopy in order to reach the underlying water surface. Radar wavelengths of C-band or shorter (~6 cm) do not typically penetrate the dense canopy of the Amazon floodplain at typical off-nadir SAR imaging geometries, whereas L-band (~24 cm) SAR will travel through vegetation cover (e.g. Hess *et al.*, 1995). Research is still required to determine the complete relationship between vegetation habitat, radar wavelength, and look-angle. The strongest advantage of the technique is that it results in a mapping of the centimeter-scale height variations of the water surface across vast wetlands. The spatial resolution of most L-band SAR systems can be used to measure water level changes for ~100-m wide water bodies and greater.

Applications

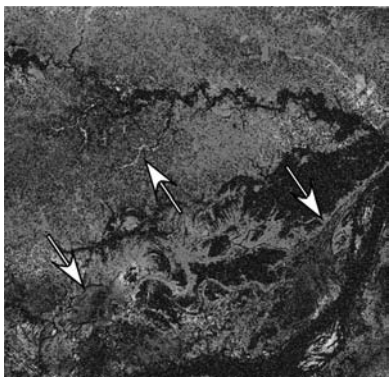
Although the Amazon main channel contains a small number of stream gauges, there are no gauges on the floodplain itself, opening the question of just how much water is flowing through the vast wetland. A Muskingum model based approach by Richey *et al.* (1989) has provided a significant first step toward estimating the storage volume on the floodplain. However, it assumed that water levels on the floodplain were equivalent to the main channel, whereas Alsdorf (2003) used InSAR data to demonstrate that during recessional flow, water levels are not horizontal and floodplain stage changes are not equivalent to those of the main channel.

Figure 6 provides another view of water level changes using interferometric JERS-1 SAR data collected on April 14 and July 11 of 1996, that is, during inundation of the floodplain. Differential variations in water level changes across the floodplain are notable between floodplain channels (western and eastern most arrows), whereas flooded valley lakes (central arrow) also show water level changes. If flow during inundation mimicked a horizontal water surface with fluctuations equivalent to the main channel, then these interferometric phase values would be uniform across the entire floodplain. Instead, the phase transitions are spatially variable suggesting more complex flow hydraulics.

The great advantage of InSAR methods is the spatial distribution of water level change measurements spread throughout an entire wetland area, whereas the requirement of flooded vegetation to return the off-nadir radar pulse is a strong limitation. As noted in Figure 6, some locations



(a)



(b)

Figure 6 The Amazon floodplain during inundation. (a) JERS-1 backscatter intensity from April 14, 1996 and (b) interferogram showing water surface changes from April 14 to July 11, 1996. Images are about 70 km × 70 km and are located about 100 km west of Manaus, over the Cabaliana floodplain. In (a), the main Amazon channel as well as some floodplain channels are marked by low amplitudes, whereas most of the Cabaliana floodplain includes bright ''double-bounce'' returns. In (b), the interferometric phase values show sharp transitions within the floodplain (arrows in b). These sharp transitions are indicative of complex flow hydraulics where some portions of the floodplain are filling differently than immediately adjacent regions. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

such as the Amazon floodplain are abundant with flooded forest and with interferometric phase signatures of changing water levels. Such measurements show for the first time, the spatially rapid variation in floodplain water surfaces thus indicating similarly strong variations in wetland flow hydraulics. A challenge ahead is the integration of the high-spatial resolution elevation-change capabilities of InSAR with profile elevation-change data from radar altimetry. Already some promise has been shown by combining T/P data over a large Amazon lake with InSAR data to show hydrologic volumetric loss and gain (Alsdorf *et al.*, 2001b). In the following section, the advantageous along-track spatial resolution of laser altimetry should allow direct

comparisons with InSAR as well as increasing the global coverage of surface water hydraulics.

LASER ALTIMETRY

An alternative altimetric approach to measuring inland water stage can be provided by airborne and spaced-based laser altimetry. Like radar altimetry, the measurement principal is based on precisely measuring the round-trip travel time of a pulse, in this case a brief laser pulse typically 1 to 10 ns in duration. Converting travel time to distance based on the speed of light yields the distance from the instrument to the reflecting target; corrections for atmospheric effects on propagation speed and refraction are required but these are a significantly smaller than atmospheric effects on microwave propagation. Combining the distance measurement with knowledge of the instrument position typically obtained using the Global Positioning System or microwave and/or optical tracking data, and the orientation of the laser pulse, obtained with gyroscopic and/or star tracker instrumentation, yields the horizontal and vertical position of the reflecting target. Laser altimeters have been used extensively from airborne platforms for topographic mapping of ice sheets (e.g. Krabill *et al.*, 2002), land topography (e.g. Haugerud *et al.*, 2003), and forest canopy structure (e.g. Lefsky *et al.*, 2002) and from satellites for global topographic observations of the Moon (Smith *et al.*, 1997), Earth (Garvin *et al.*, 1998), Mars (Smith *et al.*, 1999), and an asteroid (Zuber *et al.*, 2000).

Advantages and Limitations

Although not yet used extensively for observing inland water, characteristics of laser-based altimeter measurement (Bufton, 1989) hold the promise for important lake and river observations. A prime advantage is that the tightly collimated laser pulse enables operation with smaller instrument footprints and thus higher spatial-resolution sampling than traditional radar altimetry (see Table 1).

With submilliradian beam divergence, submeter footprints can be achieved from airborne platforms while footprints as small as tens-of-meters can be achieved from orbital altitudes. With these small-diameter footprints, a laser altimeter is not limited to observing just the sub-satellite nadir point. Laser altimeters can thus acquire data at off-nadir orientations, permitting cross-track scanning to map water surface elevations within a swath. In addition, targeted data acquisitions can be made for water bodies and rivers located on either side of the satellite's ground track. A limitation to off-nadir measurements though is imposed by loss of backscatter signal strength (a function of off-nadir angle and surface roughness, Bufton *et al.*, 1983) caused by specular reflection of the laser pulse from the water surface. Smooth water surfaces under calm wind conditions can thus be difficult to observe at angles that are more than several degrees off-nadir. Also, geolocation of the laser footprints requires accurate knowledge of the laser-pointing vector, at the arc-second level for orbital implementations, requiring greater instrument complexity than a radar altimeter.

An additional benefit of laser altimetry over radar altimetry is the absence of coherent fading. While radar altimetry has to average many echoes, each individual laser pulse provides a unique, elevation measurement with centimeter- to decimeter-level accuracy. High-repetition rate lasers can achieve contiguous footprints along the ground track at orbital velocities, or within scanned swaths at aircraft velocities, providing complete sampling of surface elevations at high-spatial resolution. Because short duration pulses are used, submeter resolution of vertically distinct surfaces such as water and overlying vegetation in a flooded forest can be achieved using the backscatter signal from a single laser pulse, where sufficient gaps in the vegetation allow illumination of the water surface. The water returns correspond to the elevation of the water surface because the near-infrared laser pulses used by most systems negligibly penetrate into the water column.

Operating at optical wavelengths, cloud cover imposes a significant limitation upon laser altimeters, reducing the quantity and accuracy of stage measurements obtained with an orbital system. However, unlike passive optical systems, by using range-gating techniques, laser returns from the Earth's surface can be acquired through thin to moderately dense clouds, up to an optical depth of approximately two. Reduced signal strength and multiple-scattering effects in the presence of clouds do, however, degrade vertical accuracy (Duda *et al.*, 2001; Mahesh *et al.*, 2002).

These characteristics of laser altimeter systems provide the potential to measure the stage of inland water including small water bodies and narrow rivers unresolved by radar altimetry. In addition, small-diameter, contiguous footprints provide a means to determine the bank-to-bank extent of the water surface, even where obscured by vegetation cover, and measure surface gradients induced by flowing water and/or wind.

Applications

To date, laser altimeter measurements of water surfaces in general have focused on calibration of instrumental biases, assessment of vertical accuracy, and characterization of ocean wave structure. Acting essentially as a reference surface while conducting platform attitude maneuvers, lake returns have been used to establish pointing and timing biases for airborne (Vaughn *et al.*, 1996; Ridgway *et al.*, 1997; Hofton *et al.*, 2000) and orbital (Luthcke *et al.*, 2000, 2001, 2002) instruments. After validation exercises over Crowley Lake in Long Valley, California, Hofton *et al.* (2000) achieved a standard deviation from the mean lake level of 2.9 cm for 2500 laser-determined elevations acquired along a 5-km flight path. The gradient induced

in the lake surface by the local gravity potential (i.e. geoid) of 8 cm over 5 km was also observed. By using a radar altimetry mean sea surface model, Luthcke *et al.* (2002) calibrated time-varying instrumental biases for the Shuttle Laser Altimeter (SLA) by minimizing laser range residuals with respect to the open ocean surface. The vertical accuracy of the SLA instrument, described by the rms ocean surface range residuals after calibration, was ~1 m. SLA vertical accuracy, limited by its ranging precision, nonoptimal means to determine Shuttle orbit and attitude, and unmodeled instrumental biases, is an order of magnitude worse than that expected for an optimized orbital laser altimeter system (Luthcke *et al.*, 2002). Hwang *et al.* (2000, 2002) used an airborne scanning system to map three-dimensional ocean wave structure, assess the spectral properties of wave fields, and quantify the distribution of breaking waves. Carter *et al.* (2001) used a similar system to measure the height and slope of sheet flow water in the Florida Everglades with 4 cm vertical precision. In this study, the intensity of the laser backscatter signal was used to identify specular nadir returns from the smooth water surface, thus eliminating returns from overlying grasses.

These initial studies demonstrate some of the potential for laser altimeter measurements of inland surface water characteristics, with prospects for data of high-spatial resolution and centimeter-level precision from future systems designed specifically to address hydrologic monitoring objectives.

FUTURE OUTLOOK

With regards to satellite radar altimetry, the performance of the newly designed RA-2 instrument onboard the ENVISAT satellite will be examined to check on expected tracking continuity (Resti, 1993) over various inland waters. Such a capability may provide surface water height in complex or rugged regions for which previously there was much loss of elevation information. Projects are also underway that are examining various retracking options in lieu of range (and thus) stage determination and accuracy. The future of interferometric SAR for measuring water level changes will continue to rely on vegetation to provide the required scattering centers for returning the radar pulse to the antennae. This also limits the effectiveness of shorter wavelength pulses such as C-band and smaller. In fact, research is still needed to carefully define the vegetation habitats capable of providing this returned echo.

In the near-term, ICESat is providing an opportunity to assess orbital laser altimeter capabilities over water bodies. This NASA Earth Observing System mission was launched in January, 2003 and acquires globally distributed profiles with the Geoscience Laser Altimeter System (GLAS). Observations of ice sheet elevation change, cloud and aerosol heights, land topography, and vegetation characteristics are being made (Zwally *et al.*, 2002). Recording the backscattered infrared laser energy from ~70 m diameter footprints spaced ~175 m along the ground tracks, the predicted elevation accuracy (1 sigma) is 15 cm for flat surfaces. The spacecraft attitude is controlled to point the laser beam to within 35 m (1 sigma) of a specified ground track, enabling selected features to be profiled. Kwok *et al.* (2004) used ICESat data to measure the extent and elevation of open water leads within Arctic sea ice. To assess backscatter strength and water stage accuracy as a function of off-nadir angle, ICESat observations are being acquired for reservoirs and rivers with *in situ* gauge measurements at a variety of angles up to 5°. Methods for automated identification of laser pulses returned from inland water surfaces are being evaluated, and data from flooded forests are being examined to assess waveform retrieval of water surface elevations beneath vegetation. Experience gained from ICESat will thus aid in the design of the next generation of orbital laser altimeters optimized for measurement of inland water stage, extent, and slope.

The application of satellite radar altimetry, laser altimetry, and interferometric SAR to the determination of inland water stage and its variation, has presented the scientific communities with some interesting challenges and thoughts for the future. All instrument types were not specifically designed with inland water applications in mind, but have shown sufficient potential to pave the way for future dedicated missions with modifications to suit the hydrological communities (Vörösmarty *et al.*, 1999; Vörösmarty *et al.*, 2001; Alsdorf *et al.*, 2003; Alsdorf and Lettenmaier, 2003). Almost certainly the ability to acquire further river and lake parameters, such as river width, river discharge, and lake volume would greatly assist both the routine ground monitoring networks and significantly contribute to some of the main science questions (e.g. of the Earth System Science, Land Hydrology, and Water Cycle Divisions within NASA). In this respect, several new groups have emerged under the ESA and NASA auspices (e.g. **`http://www.swa.com/hydrawg`**) to continue to examine the status of current ground-based networks, identify the major science issues and parameter requirements, and promote the advancement of new sensor techniques.

61: Estimation of River Discharge

S LAWRENCE DINGMAN[1] AND DAVID M BJERKLIE[2]

[1]*Earth Sciences Department, University of New Hampshire, Durham, NH, US*
[2]*United States Geological Survey, Hartford, CT, US*

River discharge, the volume flow rate through a river cross section, is perhaps the most important single hydrologic quantity. It is a major link in the global hydrologic and geologic cycles and a critical component of climate, and represents the rate at which nature makes water available for human use and management. In the form of floods, it constitutes one of the most destructive natural hazards. Measurement of river discharge thus provides vital information for science and society. Measurement by conventional ground-based methods is expensive and is declining globally. Using various combinations of active and passive imagery and sensors mounted on satellites or aircraft, it is possible to obtain direct quantitative information on several hydraulic variables, including channel configuration and the area, width, elevation, and velocity of the water surface. Computations using conventionally obtained data indicate that this information can be used in various combinations with statistical models and topographic information to generate quantitative time- and location-specific estimates of discharge. Thus, it appears feasible to produce useful river-discharge information via remote sensing, especially for locations that are remote or otherwise difficult to observe conventionally. However, it is likely that this capability will be useful only for relatively large rivers and that, even for these, measurement accuracy will be considerably lower than is possible with ground-based measurements. Given the scientific and societal importance of river-discharge observations, and the present discharge-measurement network and unlikely prospects for its expansion, further development and testing of these approaches, development of concurrent sets of pertinent remotely sensed variables, and a more complete evaluation of the spacing and timing of observations possible with satellite systems is warranted.

INTRODUCTION

This article focuses on the measurement of river discharge via remote sensing, that is, obtaining quantitative time- and location-specific estimates of river discharge using only information provided by ground-, aircraft-, or satellite-mounted sensors not in contact with the water. Thus, it does not include discussion of (i) up-links to satellites from river-based sensors of velocity, width, depth, or water level; or (ii) estimates of river discharge developed from hydrologic models that use remotely sensed information on precipitation, soil moisture, snow, or other hydrologic state variables.

RIVER DISCHARGE

Definition

River discharge, Q, is the volume rate of flow [$L^3\ T^{-1}$] through a stream cross section (Figure 1). It is the product of the cross-sectional area of the flow, A, and the cross-sectional average velocity, U; A is the product of the water-surface width, W, and the cross-sectional average depth, Y. Thus,

$$Q = A \cdot U = W \cdot Y \cdot U \quad (1)$$

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

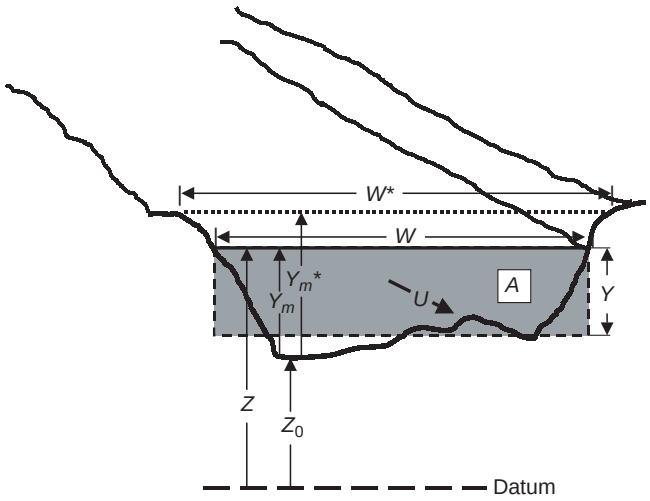

Figure 1 Definitions of quantities involved in river-discharge measurement. $W \equiv$ water-surface width; $Y \equiv$ average depth; $Y_m \equiv$ maximum depth; $U \equiv$ average flow velocity; $A \equiv$ flow cross-sectional area (shaded); $Z \equiv$ water-surface elevation (stage); $Z_0 \equiv$ zero-flow stage. Asterisks denote bank-full quantities

Importance

Global Hydrologic and Geologic Cycles

On the global scale, the time-integrated hydrologic cycle can be depicted as in Figure 2 – the world's oceans receive about 385 000 $km^3\,year^{-1}$ in precipitation and lose 425 000 $km^3\,year^{-1}$ in evaporation, while the continents receive 111 000 $km^3\,year^{-1}$ in precipitation and lose 72 000 $km^3\,year^{-1}$ via evapotranspiration. River discharge is the link that balances the global cycle, returning about 40 000 $km^3\,year^{-1}$ from the continents to the oceans (*see* **Chapter 2, The Hydrologic Cycles and Global Circulation, Volume 1**).

River discharge is also a major link in the global geologic cycle, delivering some 13.5×10^9 T $year^{-1}$ of particulate material and 3.9×10^9 T $year^{-1}$ dissolved material from the continents to the oceans (Walling and Webb, 1987). The dissolved material is an important determinant of ocean chemistry and constitutes the major source of nutrients for the oceanic food web.

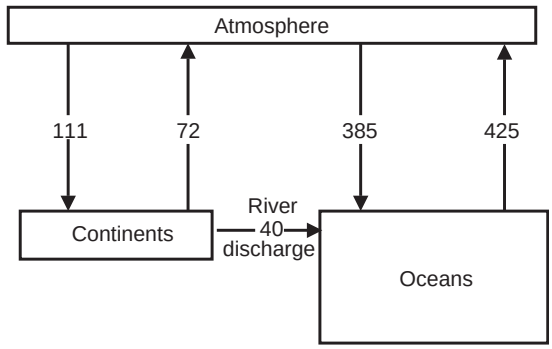

Figure 2 The spatially and temporally aggregated global hydrologic cycle. Fluxes are in 1000 $km^3\,year^{-1}$

Climate

River discharge plays a critical role in regulating global climate. Its effects on sea-surface temperatures and salinities, particularly in the North Atlantic Ocean, drive the global thermohaline circulation that transports heat from low to high latitudes. River inflows also maintain relatively low salinity in the Arctic Ocean, which makes possible the freezing of its surface; the reflection of the sun's energy by this sea ice is an important factor in the Earth's energy balance.

River discharge is also a sensitive indicator of climate change. A simple model can be developed that relates the relative change in discharge, q, ($q \equiv$ ratio of discharge after climate change to discharge before climate change) to the relative change in precipitation, p (Wigley and Jones, 1985):

$$q = \frac{p - (1 - w) \cdot e}{w} \qquad (2)$$

where w is the proportion of precipitation that runs off (a function of local geology and climate) and e is the relative change in evapotranspiration. This model shows that q is always greater than p; for example, with a 10% increase in precipitation ($p = 1.1$) and no change in evapotranspiration ($e = 1$), $q = 1.2$ (20% increase) where $w = 0.5$ (humid regions) and $q = 1.5$ (50% increase) where $w = 0.2$ (semiarid regions). Observations of long-term trends in precipitation and streamflow consistently show this amplification effect (e.g. Karl and Riebsame, 1989).

Water Resources and Flood Hazards

At all spatial scales, from small watersheds to continents, river discharge constitutes all or most of the residual of precipitation minus evapotranspiration, and hence is the rate at which nature makes water available for human use. Water flowing in streams provides a habitat for fish and other organisms of ecological and commercial importance and it is utilized for a wide range of vital purposes, including the transport and treatment of human and industrial wastes, commercial navigation, generation of hydroelectric power, recreation, and esthetic enjoyment. River flow is also the principal source of water withdrawn for human consumption, irrigation, cooling of thermoelectric power plants, and other commercial and industrial uses. Demand for water for all these purposes is growing with population, and roughly 1/3 of the world's peoples currently live under moderate-to-high water stress (Vörösmarty *et al.*, 2000). Long records of river discharge are essential tools for water-resource management because regional water availability is assessed by analyses of the time distribution of discharge in the region.

River flooding is one of the most destructive natural hazards globally. In the United States, flood damages average about $\$4 \times 10^9\,\text{year}^{-1}$ and are increasing rapidly because of the increasing concentration of people and infrastructure in flood-prone areas (van der Vink *et al.*, 2004). Assessment of flood hazards, and of the economic, environmental, and social benefits and costs of various strategies for reducing future flood damages at a riparian location are based on frequency analyses of extreme river discharges at that location. Thus, time-series records of discharge are an essential component of flood-hazard management. Satellite images of current locations of riverine flooding around the globe can be viewed at **www.dartmouth.edu/artsci/geog/floods** (G.R. Brakenridge, Department of Geography, Dartmouth College).

Validation of Hydrologic Models

River discharge is the time- and space-integrated output of the regional hydrologic cycle. And, because river flow is generally concentrated in channels, discharge can in principle be measured with considerably more accuracy and precision than can precipitation, evapotranspiration, or any other component of the hydrologic cycle. For these reasons, measurements of river discharge, in addition to providing direct information about climate, water-resource availability, and flood hazards, are also invaluable for validating the hydrologic models that are the only means of forecasting the effects of land use and climate change on water resources.

Conventional Measurement Techniques

Specialized Methods

Small flows in channels less than a few meters in width can be measured directly (i) volumetrically, (ii) by dilution gaging, and (iii) in weirs or flumes. Volumetric measurement involves diverting the flow and measuring the time required to fill a container; clearly this is feasible only for extremely small flows. In dilution gaging, a known concentration of a conservative tracer is introduced into the flow and the time distribution of its concentration is measured at a downstream location. This technique is suitable for small, highly turbulent streams where complete mixing occurs over short distances (see White, 1978; Dingman, 2002).

In relatively small research watersheds, discharge can be accurately monitored by directing the flow through specially designed weirs or flumes. These devices provide stable relations between water level and discharge, which in many cases can be derived from hydraulic theory (White, 1978; Herschy, 1999a). Generally, however, calibration by volumetric or velocity-area measurement (see "velocity area method") is required over at least some ranges of discharge.

Velocity-Area Method

In streams with widths greater than a few meters, discharge is almost always measured by the velocity-area method (Figure 3). In this method, observations of depth, Y_i, and average velocity, U_i, are made at successive locations, X_i, in a cross section, and discharge is calculated as

$$Q = U_1 \cdot Y_1 \cdot \frac{|X_2 - X_1|}{2} + \sum_{i=2}^{N-1} U_i \cdot Y_i \cdot \frac{|X_{i+1} - X_{i-1}|}{2} + U_N \cdot Y_N \cdot \frac{|X_N - X_{N-1}|}{2} \tag{3}$$

where X_1 and X_N are located at the edges of water at either end of the cross section. Usually $N = 25$ to 30, and the average velocity at each location is estimated from velocity measurements taken at prescribed depths (see Buchanan and Somers (1969), Herschy (1995), or Dingman (2002) for more detailed discussions).

A recent modernization of the velocity-area method uses an Acoustic Doppler Current Profiler (ADCP) to simultaneously measure and integrate the depth and velocity across a channel section, thereby obtaining all of the elements of equation (3) in one pass (Simpson and Oltman, 1992; Morlock, 1996). The ADCP unit is mounted on a boat or raft that traverses the cross section and measures depth via sonar and velocity via the Doppler shift of acoustic energy pulses. This system greatly reduces the time necessary to make a discharge measurement and allows measurements at stages when wading is precluded and at locations lacking stream-spanning structures. However, because this method requires the instrument to have direct water contact, it is not considered a "remote" data-collection system.

The velocity-area method provides quasi-instantaneous measurements of discharge. Continuous records of discharge are developed by relating periodic velocity-area measurements to measured water-surface elevation (stage) to develop a stage-discharge "rating" for the cross section. The stage-discharge rating relation takes the general form

$$Q = a \cdot (Z - Z_0)^b \tag{4}$$

where the coefficients a and b are empirical values characteristic of the specific cross section, and Z_0 is the elevation of zero flow at that location (Rantz *et al.*, 1982; Herschy, 1995). In many cases, the values of a and b change for different ranges of discharge at a given reach.

For the periods between measurements of Q, the stage (Z) is recorded continuously or at frequent intervals and Q is inferred from the rating relation. (Methods of stage measurement are described by Herschy (1999b).) Since the value of Z_0 represents the elevation of zero flow, the term $(Z - Z_0)$ may be viewed as equivalent to the maximum flow depth (Y_m); thus the standard rating curve provides an estimate of discharge from the flow depth. In most situations, the rating relation is subject to change over time due to erosion and/or deposition in the measurement reach,

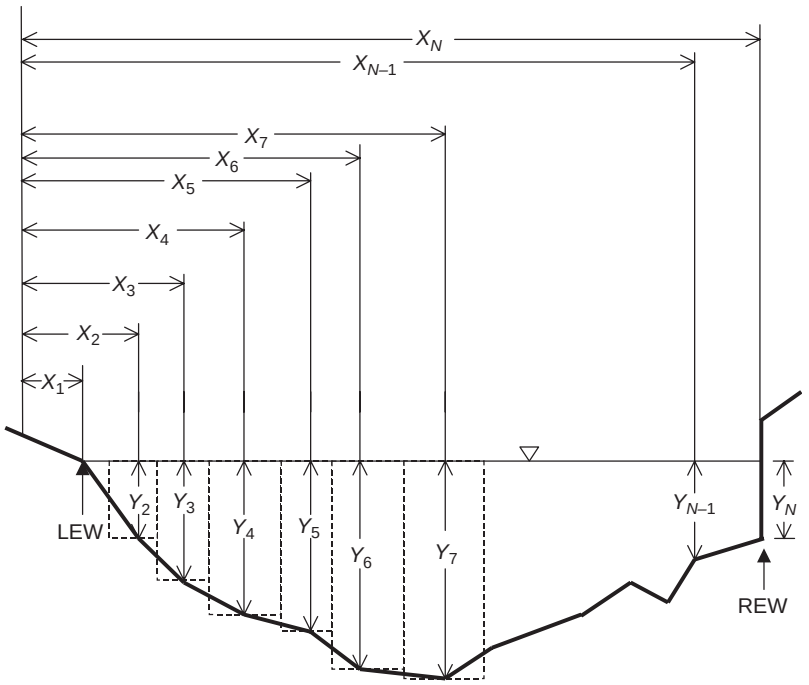

Figure 3 Definitions of terms involved in velocity-area discharge measurement (equation 3). Dashed lines indicate individual subsections, numbered consecutively $i = 1, 2, \ldots, N$. Left and right edges of water (LEW and REW) are defined for an observer facing downstream. (After Buchanan and Somers (1969))

so that periodic velocity-area measurements are required to maintain an accurate rating curve as well as to extend its range.

Most stream gages maintained by the United States Geological Survey (USGS) are now satellite-linked so that "real-time" observations of stage and discharge can be readily accessed via the Internet. This is an important advance in access to river-discharge data, but since the data are collected by conventional methods it is not considered a hydrological application of remote sensing.

Slope-Area Method

The discharge of a recent peak flow in a river reach can be estimated from observations of high-water marks by the slope-area method. This method involves surveying the slope of the water surface, S_s, as revealed by the high-water marks, the reach-averaged wetted perimeter, P, and cross-sectional area, A, beneath the marks. These observations are used to determine the hydraulic radius, R, where $R \equiv A/P$, and to estimate discharge, Q, via the Manning equation:

$$Q = \frac{u \cdot A \cdot R^{2/3} \cdot S_e^{1/2}}{n} \qquad (5)$$

In this equation, u is a unit-conversion factor (=1.00 for S.I. units and 1.49 for English units); the energy slope, S_e, is calculated from the water-surface slope and the reach geometry and generally differs little from S_s; and the reach-resistance factor, n, is estimated by the observer.

Values of n reflect the overall flow resistance of the reach and depend principally on boundary roughness (bed-particle size and bed forms), obstructions, variations in channel geometry, bed and bank vegetation, channel curvature, and slope. The value of n is usually selected based on the observer's judgment guided by tables (e.g. Chow, 1959), photographs (Barnes, 1967; Hicks and Mason, 1991; Coon, 1997), or formulas (Cowan, 1956). The detailed methodology is described by Dalrymple and Benson (1967), Ponce (1989), and Dingman (2002), among others.

Accuracy and Precision

In many situations, the allocation of water resources is governed by laws, treaties, regulations, or contracts. Hence measurement of river discharge often has significant legal, economic, and diplomatic implications, and measurement precision within a few percent is required, particularly when the flows are relatively low.

The precision of a velocity-area measurement depends principally on the regularity of the measured cross section, the number of observations (N), and the method used to determine average velocity. If $20 < N < 30$, accuracies of 5% to 8% can be achieved for individual measurements (i.e. 95% of the measurements will be within 5% to 8% of the true value) (Carter and Anderson, 1963). Precision and accuracy obtainable in slope-area measurements are generally considerably worse, largely because of the uncertainty involved in estimating n in equation (5) and because the

cross section at the time of the flow may be different than the measured cross section due to scour or fill (Kirby, 1987). Herschy (1995) indicated that the typical error range in slope-area estimates is 10% to 20%.

In addition to the factors affecting the precision and accuracy of individual velocity-area measurements, the accuracy of long-term gaging-station records is affected principally by the stability of the measurement cross section and the effects of ice on the stage-discharge relation. The USGS rates measurements at gaging stations as "excellent" (95% of measured values with in 5% of true value), "good" (95% within 10% of true), "fair" (95% within 15% of true), or "poor". Records at most long-term stations are rated "good"; "excellent" measurements can generally be obtained where discharge is measured via calibrated weirs or flumes. Dickinson (1967) concluded that the accuracy of estimates of discharge from a conventionally established rating curve range from about $\pm 12\%$ at the 80% confidence level and about $\pm 20\%$ at the 95% confidence level. Winter (1981) estimated that the uncertainty of long-term average values of streamflow at a gaging station is on the order of 5%.

Cost

The costs of establishing and maintaining a conventional long-term gaging station are considerable. Typical values used by the USGS are \$8000 to \$10 000 to establish a long-term monitoring station and \$6400/year (2003 US$) for operation and maintenance of each station, not including administrative overhead costs (B. Mrazik, USGS, personal communication).

Status of River-discharge Monitoring

Despite the importance of river-discharge information, expansion and maintenance of a comprehensive global river-monitoring network using conventional measurement methodologies face numerous technological, economic, and institutional obstacles (Rodda, 1999). As a result, gaging stations and access to river-discharge information have been declining since the 1980s (Vörösmarty *et al.*, 1999). The International Association of Hydrological Sciences (IAHS, 2001) reports that the density of long-term stream gages is well below WMO-recommended levels in many regions, particularly in Africa, and has declined significantly in the states of the former Soviet Union, Canada, and the United States. The number of stations reporting discharge data to the World Meteorological Association (WMO) Global Runoff Data Center (GRDC) declined by 90% during the period 1995–2000 (IAHS, 2001). Currently, less than 60% of the runoff from the continents is monitored at the point of inflow to the oceans (Fekete *et al.*, 1999) and the distribution of runoff within the continents is even less well monitored.

Hydrographic data obtained from satellites and other remote sources offer the possibility of broad and frequent coverage of river-discharge estimates (Barrett, 1998) and the potential to maintain or even increase the global streamflow-monitoring network. Ultimately, this may be a cost-effective method to obtain the required river-discharge data on a global scale.

REMOTE SENSING OF RIVER DISCHARGE

Introduction and Previous Work

Since discharge cannot be directly measured remotely, it must be determined from predictor variables that can be remotely observed. The feasibility of remote sensing of river discharge thus depends on (i) the accuracy and precision with which predictor variables can be remotely measured, (ii) the uncertainties inherent in models used to convert measurement of predictor variables to discharge estimates, (iii) the spatial and temporal distribution of observations of predictor variables, and (iv) the costs involved in obtaining measurements of predictor variables.

The use of remotely sensed information, including water surface elevation (Z), water-surface velocity (U_s), and water-surface area (A_s), to track changes in river discharge has been shown to be feasible and potentially useful where ground-based data are difficult to obtain (Kuprianov, 1978; Koblinsky *et al.*, 1993; Birkett, 1998; Brakenridge *et al.*, 1994; Brakenridge *et al.*, 1998; Horritt *et al.*, 2001; Birkett *et al.*, 2001). These studies suggest that remotely sensed river hydraulic data could be used to directly estimate the discharge at a specific location, if ground-based discharge measurements are used to develop discharge ratings in conjunction with the remotely observed variable(s).

Estimating discharge in rivers from remotely sensed hydraulic information obtained from aerial and satellite platforms has been explored and summarized by Smith *et al.* (1996), Smith (1997) and Bjerklie *et al.* (2003). Currently deployed satellite-based sensors and other remote data sources can be used to determine channel and water-surface width and water-surface area, water-surface elevation, channel slope, and channel morphology (planform) (Table 1). The surface velocity of rivers can also be observed remotely using various forms of Doppler radar or lidar (Plant and Keller, 1990; Vörösmarty *et al.*, 1999; W. Emmitt, Simpson Weather Associates, personal communication, 2000; Costa *et al.*, 2000; Goldstein *et al.*, 1994; D. Moller, NASA-JPL, personal communication, 2003) mounted on aircraft; however, measuring surface velocity from satellites has not been demonstrated. The key hydrographic variables that cannot be directly measured from aerial and satellite-based sensors are average depth (Y) and average cross-sectional velocity (U). Thus, these variables will need to be estimated from stage and surface velocity, respectively, as will be described later.

Table 1 Summary of capabilities of remote sensing modes potentially usable for obtaining river-discharge estimates

Mode	Platform	Data Type	Resolution	Limitations
Photography	Aircraft, satellites	Surface features including planform, sinuosity, and so on; bank-full and water-surface width. Stereoscopy can provide slope.	Depends on scale and lens and film properties; can be as fine as 1 m.	Cloud cover
Visible and infrared digital imagery	Aircraft, satellites	Surface features including planform, sinuosity, and so on; bank-full and water-surface width.	Depends on sensor, platform, and orbital characteristics. Aerial imagery can be as fine as 1 m; satellite imagery typically 10 m (LandSat 7) or coarser.	Cloud cover
Synthetic-aperture radar (SAR)	Aircraft, satellites, ground vehicles	Surface features including planform, sinuosity, and so on; bank-full and water-surface width. Interferometry can provide slope. Doppler techniques can provide surface velocity.	Space-based SAR 10 to 30 m; aerial SAR 5 m. Velocity from aerial SAR 0.1 m s^{-1} (not verified).	Interpretation can be difficult (e.g. locating edge of water).
Radar altimetry	Aircraft, satellites	Water-surface elevation at discrete points, giving stage and possibly slope.	Typically 0.5 m, but 0.1 m possible from satellites; higher resolution from aircraft.	Footprint size.
Ground-penetrating radar (GPR)	Ground vehicles, cableways, helicopters	Width and depth.	Comparable to conventional water-contact measurements.	Spatial coverage.
Lidar	Aircraft, satellites	Surface velocity, stage, possibly slope.	Elevation to 0.5 m, velocity to 0.1 m s^{-1} (not verified).	Cloud cover.
Topographic maps, DEMs, GIS	None	Static channel dimensions and morphology; ground slope.	Depends on scale.	No time-varying information.

In a proof-of-concept experiment, Costa *et al.*, (2000) measured river depth and width (cross section) using GPR mounted on a cableway, and surface velocity via a microwave Doppler-radar system mounted on a stationary ground vehicle on the river bank. The mean cross-sectional velocity of flow was estimated from the surface-velocity measurements using a single correction factor of 0.85 (Rantz *et al.*, 1982), and enabled the discharge to be computed from equation (1) to an accuracy comparable to conventional ground-based measurements.

The experiment conducted by Costa *et al.* (2000) demonstrates that ground-based remote data-collection systems can replace in-stream handheld measurement methods without significant loss of accuracy. However, this ground-based measurement system is site-specific and therefore would require periodic maintenance visits similar to conventional gaging stations. The Costa *et al.* (2000) experiment also demonstrated that surface-velocity measurements can be reliably used to estimate the mean velocity. Thus in principle, it should be possible to use aerial or satellite measurements of surface velocity to estimate the mean cross-sectional velocity. However, measuring the mean depth from satellites or aerial platforms remains problematic (see discussion below).

Bankside remote-observation systems provide measurement advantages by potentially increasing the frequency of measurements, especially where access is difficult, and by minimizing the risks to observers by reducing the need for direct in-stream work using conventional handheld instruments or ADCP. In rivers that have difficult accessibility and high costs for obtaining ground-based discharge measurements, satellite and aerial platforms can be used to supplement the ground-based network. In addition, because of the potential for relatively frequent global coverage by

satellites, a satellite-based, discharge-measurement system can provide much-needed understanding of the spatial distribution of discharge across the continents.

Satellite or Aircraft-based Measurement of Hydraulic Variables

Water-surface Area and Width

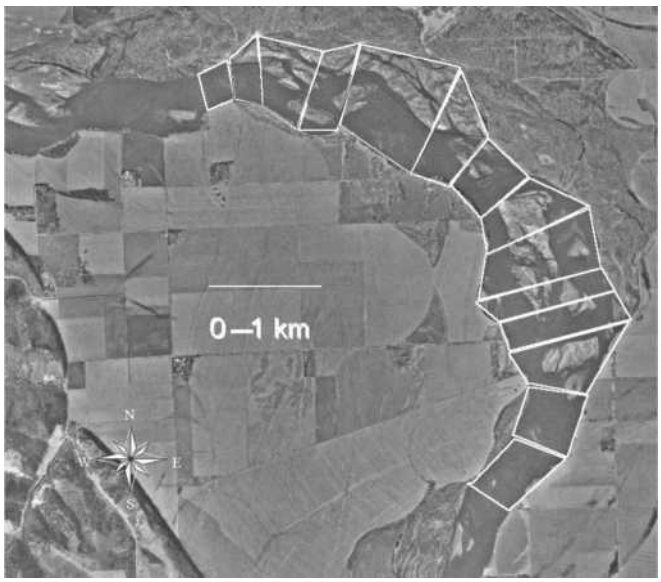
Both bank-full channel water-surface area, A_s^*, and current water-surface area, A_s, of a reach can be measured via a variety of sensors and imagers mounted on satellites and aircraft, including panchromatic and infrared imagers, digital photography, and synthetic-aperture radar (SAR) (Barrett,1998; University of Wisconsin Environmental Remote Sensing Center, 2001). Reach length, L, can also be determined via these sensors, and thus one can compute the reach-average, bank-full width, W^*, and current water-surface width, W, as $W^* = A_s^*/L$ and $W = A_s/L$ respectively. Spatial resolution as fine as 1 or 2 m can be obtained from visible spectrum and near-infrared imagers, and currently deployed SAR imagers have resolutions as fine as 10 m (University of Wisconsin Environmental Remote Sensing Center, 2001). Unlike visible spectrum and infrared imagers, SAR imagers can observe through cloud cover.

The accuracy of measuring surface area and width is only partly a function of the resolution. Measuring along a reach length increases accuracy by averaging errors associated with pixel identification, and also provides a reach-averaged width estimate by averaging local variability in width (Figure 4). Delineating width is also subject to errors associated with vegetation obscuring the water's edge and, in the case of SAR, wet ground, vegetation, wind roughening, and rocks can also confound observation of the water-surface extent. This is a particular problem for the Amazon River, where the water surface extends under forest canopy for a significant part of the year.

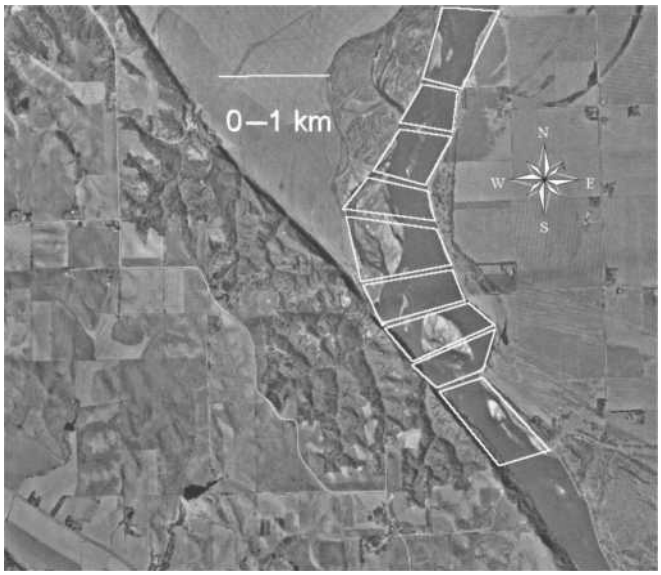
Orbital orientation may also affect the accuracy of satellite observation of water-surface width and area, because the geometric relation between the sensor and the river must be accounted for in image processing, particularly for radar and lidar imagers. This issue could be addressed by linking the processing to geographic information-system (GIS) coverages that contain information about river orientation.

Flood-inundation Area

The water-surface area of flooded and in-bank reaches, used to estimate a mean flow width, can be tracked using a variety of satellite-based sensors including the LandSat MultiSpectral Scanner (MSS), Thematic Mapper (TM), TERRA MODIS, and other visible/infrared spectrum sensors, as well as SAR. MODIS provides daily information, but at relatively coarse resolution (500 m), while TM provides finer spatial resolution but with less frequent overpass; only SAR is capable of observing through clouds.



(a)



(b)

Figure 4 Missouri River near Elk Point South Dakota, showing digitized polygons delineating the maximum channel surface area (Source: 3.75-minute DOQs for Elk Point (a) and Ponca (b) South Dakota, National Digital Orthophoto Program (NDOP))

Measurement of flood-inundation areas from satellite imagery has been summarized by Smith (1997), and such areas are currently measured and tracked globally by G.R. Brakenridge of the Dartmouth Flood observatory (**www.dartmouth.edu/artsci/geog/floods**) using the MODIS sensor mounted on the TERRA satellite. Brakenridge *et al.* (1994) used SAR images from ERS-1 to delineate a flood-inundation area coupled with topographic information to determine water-surface elevations

during the 1993 Mississippi floods. Horritt (2000), Bates and DeRoo (2000), and Horritt *et al.* (2001) have used satellite-mounted SAR imagery to delineate flood boundaries and calibrate river hydraulic models.

Water-Surface Elevation (Stage)

Koblinsky *et al.* (1993) used GEOSAT altimeter data to track elevation changes at several locations in the Amazon River basin with an accuracy on the order of 0.7 m. In that study, the altimeter footprint ranged from 0.2 to 2 km, indicating that the target must be at least that wide to obtain a return unique to the water body. Birkett (1998) measured water-surface elevation changes in several rivers around the globe (including rivers in the Amazon Basin, the Okavango River, the Indus River, and the Congo River) using the TOPEX/POSEIDON altimeter (Figure 5). The accuracy of these measurements ranged from 11 to 60 cm depending on local topography. The theoretical minimum river width that can be observed using the currently deployed TOPEX/POSEIDON altimeter ranges from 0.58 km to 1.16 km (Birkett *et al.*, 2001). However, smaller footprints can be achieved with improved processing algorithms (E. Rodriguez, NASA-JPL, personal communication, 2001). New generation laser altimeters, such as the GLAS altimeter (NASA, 1997) that is deployed on ICESAT, can provide higher resolution and accuracy.

Depth

It is not possible to directly measure water depth using currently available remote sensors. However, it may be possible to obtain useful estimates of average flow depth based on an estimate of bank-full width, W^*, from imagery and successive concurrent observations of water-surface elevation, Z, and water-surface width, W, via altimetry and imagery respectively. This approach is based on the assumption that the channel cross section can be approximated via a power-law relation:

$$Z = Z_0 + 2^b \cdot \left(\frac{Y_m^*}{W^{*b}}\right) \cdot |x|^b \tag{6}$$

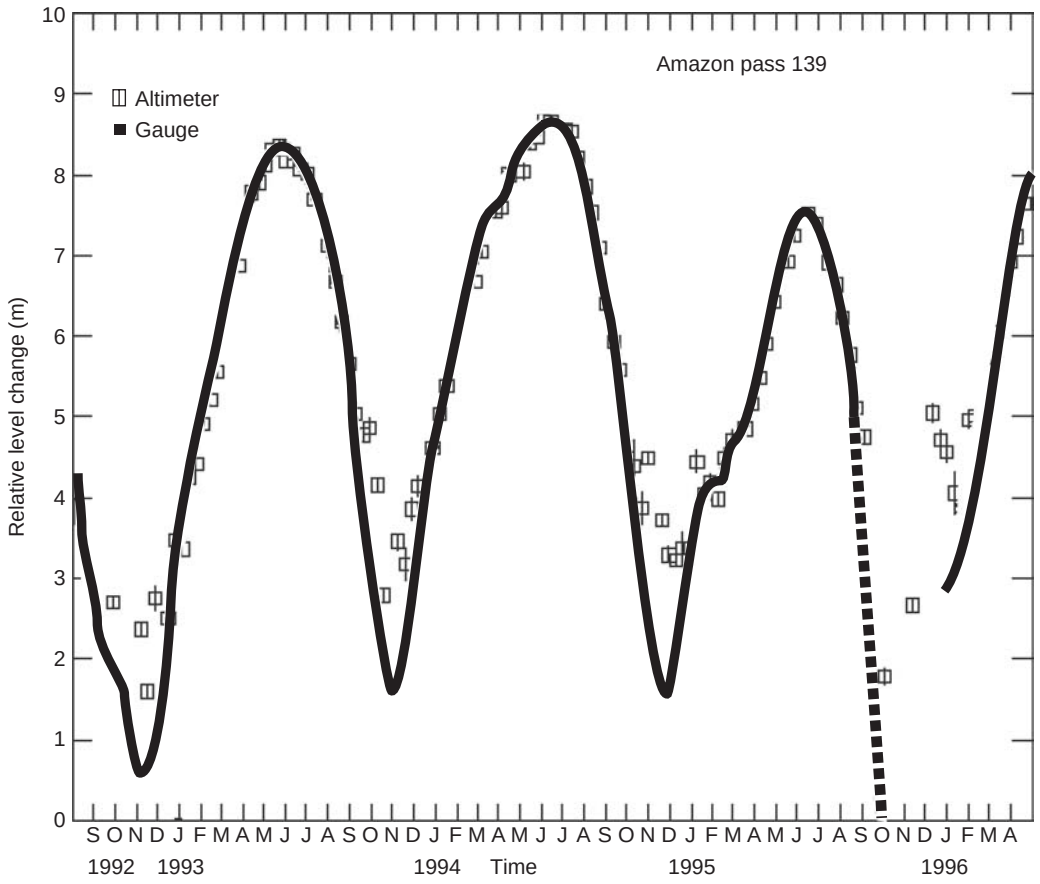


Figure 5 TOPEX/POSEIDON radar-altimetric track for the Amazon River. The time series of relative river water-surface height was derived from two satellite passes over the main branch. Observations are compared against standard river-stage data from a ground-based conventional gauge (Reproduced by permission of C. Birkett from Birkett *et al.*, (2001). *Surface water dynamics in the Amazon Basin: application of satellite radar altimetry.* Presented at 2nd International LBA Scientific Conference, Manaus, Amazonas, Brazil, 7–10 July 2001)

where x is horizontal distance from the channel center, Z_0 is elevation of the lowest (central) point, $Y_m{}^*$ is the bank-full maximum depth, and b is an exponent. Many hydraulic analyses have indicated that a value of $b = 2$ (parabola) closely describes many natural channels (e.g. Leopold *et al.*, 1964), but values as high as $b = 5$ may be appropriate in some cases.

Taking $x = W/2$ and specifying b, the values of Z_0 and $Y_m{}^*/W^*$ can in principle be determined by regression analysis using equation (6) as the regression model. (Alternatively, one could use the model with b unspecified and determine b via nonlinear regression.) Then maximum depth, Y_m, and stage are related as $Y_m = Z - Z_0$, and average depth, Y, is related to maximum depth as

$$Y = \left(\frac{b}{b+1}\right) \cdot Y_m \tag{7}$$

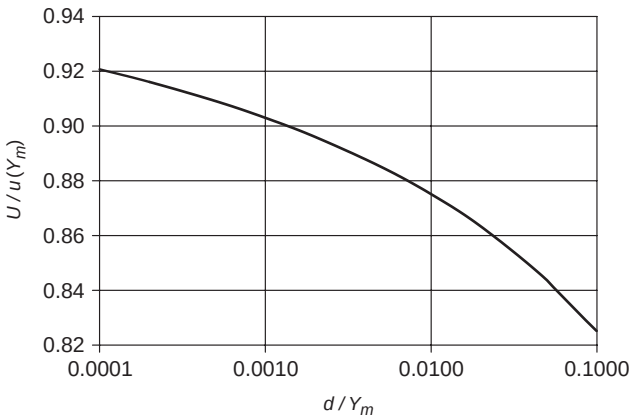

Figure 6 Ratio of average velocity, U, to surface velocity, $u(Y_m)$, as a function of the ratio of bed-material size, d, to flow depth (Y_m) as computed from the Prandtl-von Karman vertical-velocity profile

Velocity

Overall accuracies and observing limitations have not been fully evaluated for remote velocity-measurement techniques. The surface velocity in rivers is potentially measurable from aircraft and satellites with Doppler lidar or radar (Vörösmarty *et al.*, 1999; W. Emmitt, Simpson Weather Associates, personal communication, 2000; Goldstein *et al.*, 1994; D. Moller, NASA-JPL, personal communication, 2003). Wind-generated waves can significantly interfere with the measurement; however, in some circumstances the estimates can be corrected on the basis of the knowledge of the surface wind speed and direction (Kinsman, 1965).

Figure 6 shows the ratio of average vertical velocity to maximum (surface) velocity as a function of the ratio of bed-particle size to flow depth, based on the Prandtl-von Karman vertical-velocity distribution. In most rivers of sufficient size to be remotely observed, the particle size will be small compared to depth, and the average velocity can be estimated as about 0.85 times the surface velocity, as done by Costa *et al.* (2000).

Figure 7 shows estimates of water-surface velocity for a reach of the Missouri River obtained from the aircraft-mounted NASA-JPL AirSAR imager. The estimates were corrected for surface wind using the Bragg correction technique (Bragg, 1913; Kinsman, 1965). The mean channel velocity estimated from this image for those sections of the river flowing towards the sensor was $0.88\,\mathrm{m\,s^{-1}}$ (Moller, NASA, personal communication, 2003). Downstream mean velocity measured by the USGS at a narrower point in the river (with presumably higher velocity) during periods of comparable discharge ranged from 0.96 to $1\,\mathrm{m\,s^{-1}}$. An important limitation of the AirSAR imager is that reliable surface-velocity measurements can only be obtained from river reaches oriented towards the sensor. Thus, although surface velocity can be measured from remote bankside platforms and from aircraft, it is unclear whether this limitation can be overcome to enable the satellite observation of velocity.

Slope

Water-surface slopes over long reaches of the Amazon River have been measured by Mertes *et al.* (1996) and Dunne *et al.* (1998) using altimeters mounted on SEASAT, by Birkett *et al.* (2001) using the TOPEX/POSEIDON altimeter, and by Hendricks *et al.* (2003) using data from the Shuttle Radar Topography Mission (SRTM). While these measurements may be hydraulically meaningful for the Amazon, it is by no means clear that this would be true for smaller rivers because of changes in discharge, hydraulic geometry, and local slopes over the measurement reach.

Measuring hydraulically meaningful water-surface slopes using altimeters would be possible if two water-surface elevations could be obtained at nearly the same time from two closely spaced locations on the river surface. Achieving this measurement objective would require that the altimeter have pointing capability and greater measurement accuracy than the expected 10 to 20-cm accuracy suggested by Birkett (1998). Given a typical river slope in the range of 0.001 to $0.0001\,\mathrm{m\,m^{-1}}$, an observed reach length of 1 to 10 km, and altimeter accuracy of ± 10 to 20 cm, the measured slope could range from negative to several times the actual value. This suggests that slope information obtained from the current generation of altimeters would not provide sufficient spatial resolution to be hydraulically meaningful. Interferometric SAR techniques (Alsdorf *et al.*, 2000; Alsdorf *et al.*, 2001) and laser altimeters may ultimately provide a means to estimate slopes more accurately, but averaging the values obtained from a large sample of water-surface slope measurements in a given reach may be the most meaningful

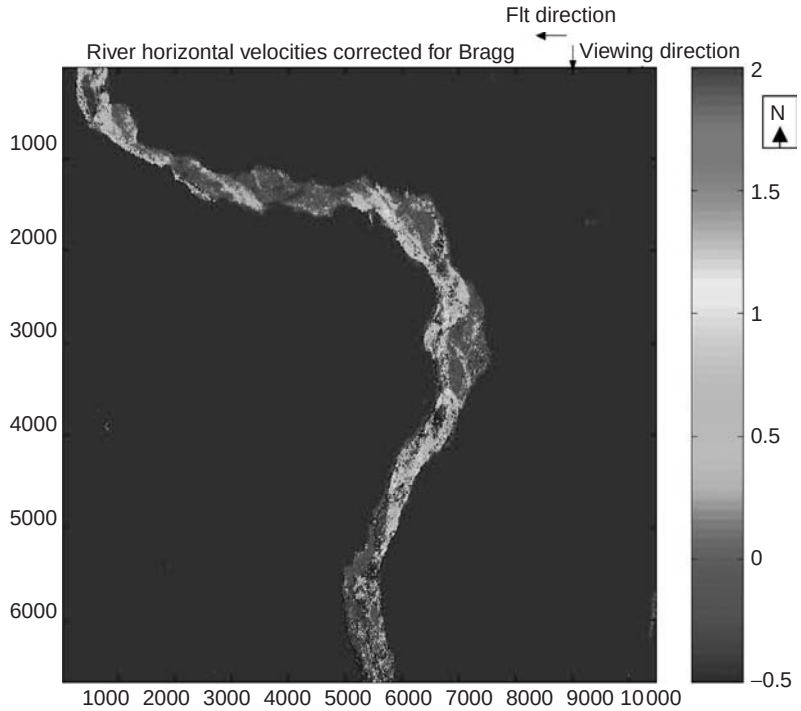

Figure 7 SAR image of the Missouri River near Elk Point South Dakota showing surface-velocity distribution. Scale units are $m\,s^{-1}$ (Reproduced by permission of D. Moller, NASA-JPL). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

remotely sensed slope information that can be considered reliable (Bjerklie *et al.*, 2003).

However, remote measurement of dynamic water-surface slopes may not be necessary. Bjerklie *et al.* (2003) have shown that when estimating discharge with a general slope-resistance equation, the topographic channel slope will provide estimates with accuracy similar to that obtained using a ground-measured dynamic slope over a wide range of rivers. This suggests that a characteristic constant channel slope is hydraulically meaningful for a given river reach.

Channel Morphology

Valley and channel features such as the channel sinuosity and planform, channel slope, meander length, and meander radius of curvature can be observed from a variety of data sources including visible and infrared spectrum images, SAR images, digital elevation models (DEMs), and topographic-map information. Since these features are usually relatively stable over at least decadal time frames, the frequency and timing of observations is not a limiting factor, and therefore high-resolution panchromatic images could be used to measure them when weather conditions permit. As shown in the Smith *et al.* (1996) study discussed in the following section, such information is potentially useful in refining models for remote estimation of discharge.

Remote Estimation of Discharge

Discharge Estimation via Continuity Relation

The previous discussion indicates that there is a possibility that all of the hydraulic elements of equation (1) can be measured or inferred from simultaneous satellite observations. If so, discharge could be calculated directly, with an accuracy dependent on the accuracy and precision of the individual measurements of water-surface width, surface velocity, and stage and of the estimations of mean velocity and mean depth from observations of surface velocity and stage. However, all of these variables, particularly depth, may not be measured or reliably estimated simultaneously. In these situations, general functions that correlate discharge to one or more measured variables would be required.

Discharge Estimation via Single-variable Relations

In principle, it would seem that discharge ratings based on any one of the variables of continuity (width, depth, or velocity) might be developed for a wide range of rivers, because these variables generally increase with increasing discharge (Figure 8). However, because of irregular cross-sectional shape and wide variation in slope, one or more of these variables may change very little or in an unpredictable way with discharge in individual river reaches, so that use of general single-variable ratings would often introduce large estimation errors.

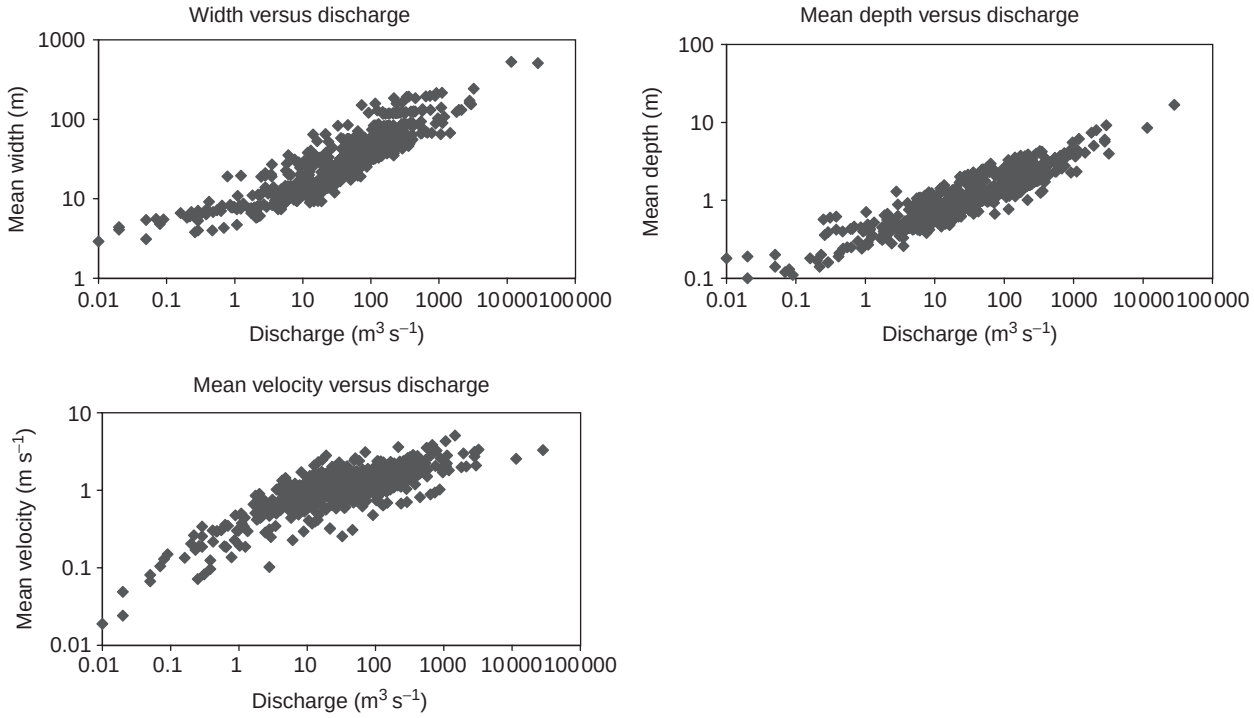

Figure 8 Reach-averaged hydraulic variables versus discharge for 569 velocity-area discharge measurements in 81 rivers

Smith *et al.* (1996) correlated the mean water-surface width, W, estimated from the water-surface area obtained from RADARSAT SAR imagery, with ground-measured discharge in three braided river reaches (lengths on the order of 10 km) to derive power-function discharge ratings. They derived a single best-fit power function for all three rivers, but reported that estimates based on this general rating would be expected to have an accuracy only within a factor of 2. The accuracy of the width-discharge ratings varied between the three rivers, and Smith *et al.* (1996) found that channel sinuosity was a useful additional predictor variable. Figure 9 shows that inclusion of sinuosity, ξ, in a multivariate rating function ($Q = c \cdot W^x \cdot \xi^y$; where c, x, and y are determined by regression) yields a more accurate general predictive equation. This result suggests that multivariate rating functions that include additional hydraulic or morphologic features of a river channel will improve accuracy compared to single-variate functions.

Discharge Estimation via Multivariate Relations

Recent work by Dingman and Sharma (1997) and Bjerklie *et al.* (2003) indicates that statistically derived or general multivariate discharge-estimating equations can be developed and used to estimate discharge for within-bank flows in a wide range of rivers with accuracy comparable to estimates made from slope-area measurements. These equations use the variables of river hydraulics (width, depth, velocity, and slope) in various combinations to estimate discharge. Bjerklie *et al.* (2003) proposed four discharge-estimating equations:

$$Q = k_1 \cdot W^a \cdot Y^{b\cdot} S_c^c \tag{8}$$

$$Q = k_2 \cdot W^d \cdot U^e \cdot S_c^f \tag{9}$$

$$Q = k_3 \cdot W^g \cdot U^h \tag{10}$$

$$Q = k_4 \cdot W^{*i} \cdot Y^{*j} \cdot Y^k \cdot {S_c}^l \tag{11}$$

where S_c is channel slope; W^* and Y^* are the bank-full width and bank-full mean depth respectively; W, Y, and U are as previously defined; and a–l are empirically or theoretically determined exponents. The discharge coefficients k_1 through k_4 reflect components of flow resistance that are not functions of channel adjustments to flow, such as bed material and vegetation (see discussion of equation (5)).

Bjerklie *et al.* (2003) derived values for the coefficients and exponents in equations (8)–(11) via regression analysis. Figure 10 shows discharge predicted from these equations compared with observed discharge for 506 individual flows in 102 rivers with a maximum (bank-full) width

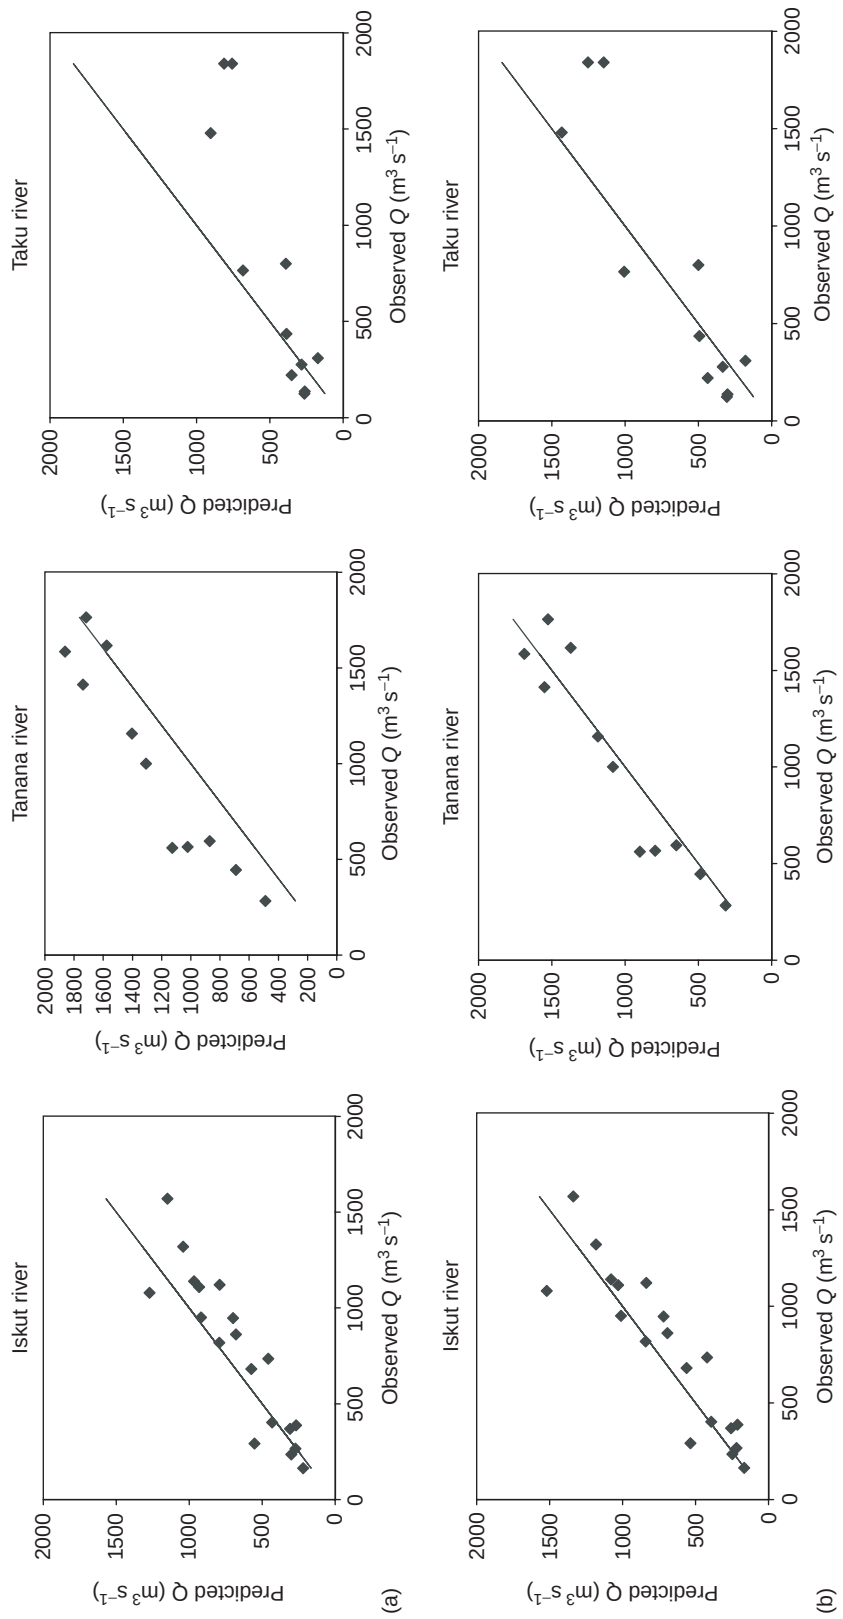

Figure 9 (a) Discharge predicted from remotely observed width versus observed discharge for the Iskut, Taku, and Tanana Rivers, Alaska. Discharge is poorly predicted for all three rivers. (b) Discharge predicted from remotely observed width and sinuosity versus observed discharge for the Iskut, Taku, and Tanana Rivers, Alaska. Discharge predictions cluster more generally around the 1 : 1 line than in (a), indicating that inclusion of sinuosity improves the predictive relation. (Data from Smith *et al.* (1996))

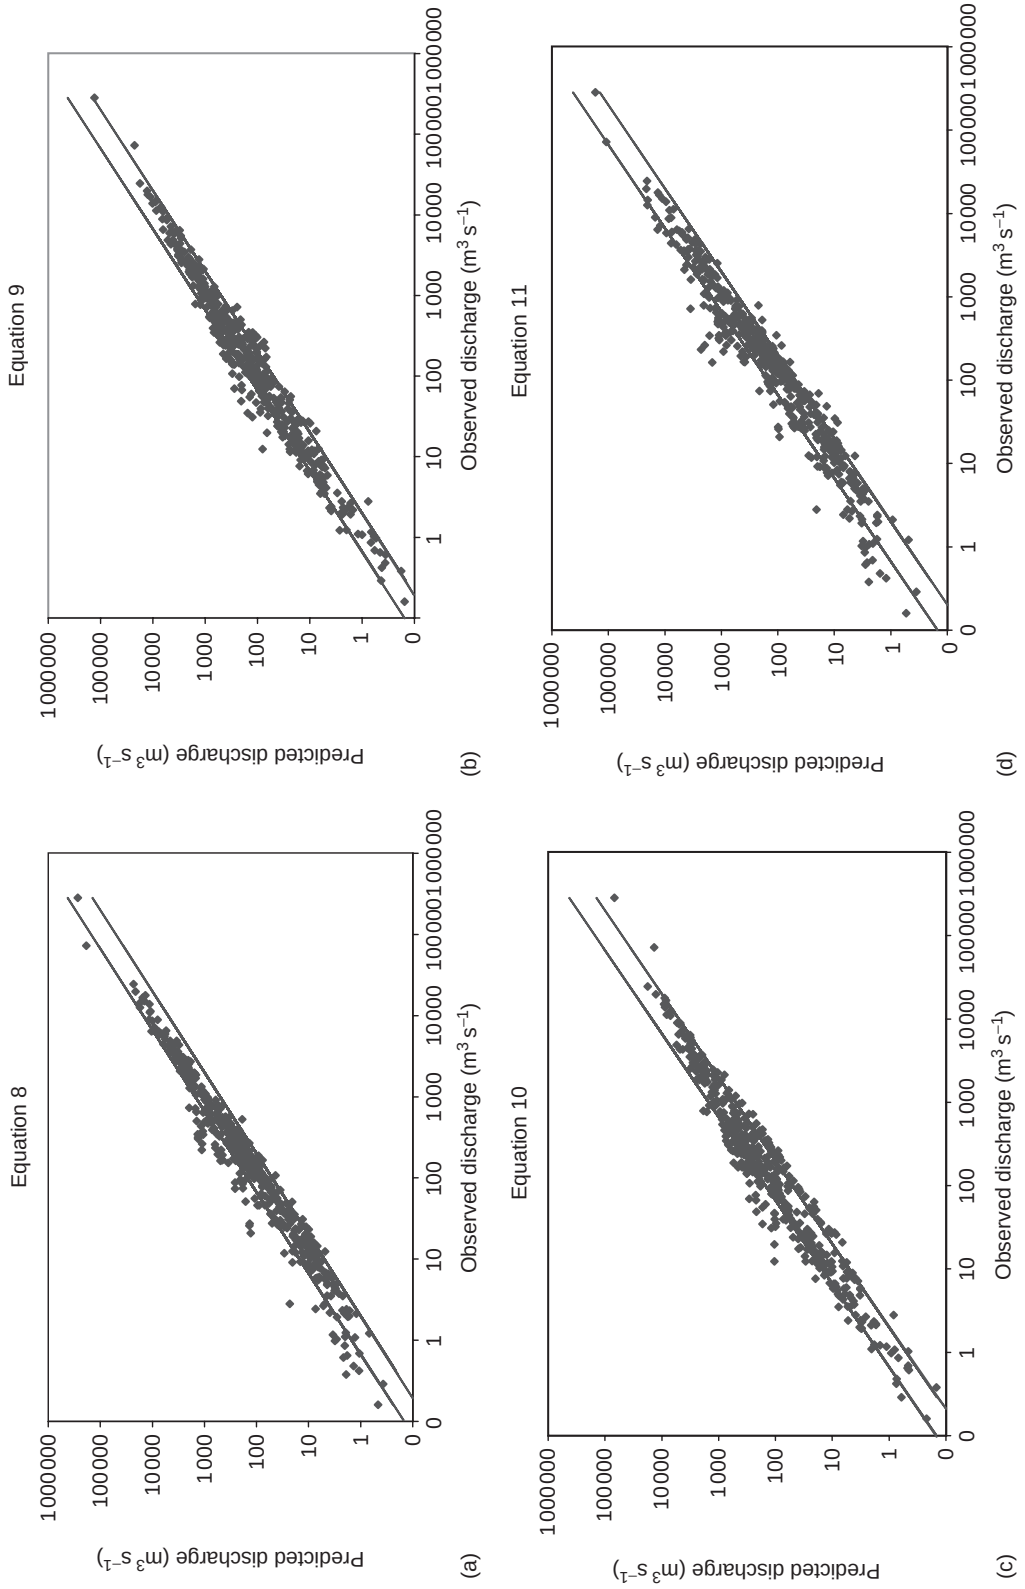

Figure 10 Discharge predicted from regression-derived forms of (a) equation (8); (b) equation (9); (c) equation (10); and (d) equation (11). The upper and lower lines are the plus- and minus-50th-percentile error bars, respectively. (From Bjerklie (2004))

exceeding 30 m, including several of the world's largest rivers (e.g. the Amazon, Yukon, and Mississippi rivers). The accuracy of the four equations varied, but all four produced discharge estimates that were within ±50% of the observed values at least 70% of the time. These results suggest that relations of the form of equations (8)–(11) can provide generally applicable predictions with useful accuracy.

Bjerklie *et al.* (2003) also examined the effects of measurement uncertainty of the hydraulic variables in equations (8)–(11) on discharge-prediction accuracy. They found that prediction error is greatest at lower discharges due to the proportionally larger effect of measurement error and because the equations have larger statistical uncertainty at lower discharges. Thus, generalized prediction equations such as (8)–(11) will tend to be more accurate for larger rivers.

The results of Bjerklie *et al.* (2003) suggest that remotely measured hydraulic variables have the potential to provide useful estimates of discharge for within-bank flows in moderate-sized to large rivers. Equations (8), (9), and (11) require information on the (constant) local channel slope, which can generally be determined from topographic maps and/or DEMs. Use of equations (9) and (10) assumes that surface-velocity measurements can be used to estimate mean velocity. Equations (8) and (11) can be used if the depth of flow can be estimated from a remotely measured stage as discussed earlier (equations 6 and 7), and equation (11) requires information on bank-full width and average depth that may be obtainable from repeated imagery or altimetry at a given reach.

For overbank flows, the relationships analogous to equations (8)–(11) may not exist. Jacobs and Wang (2003) have suggested that the resistance of floodplain vegetation and other obstructions to the flow can be evaluated remotely from ground-cover characteristics in the same manner that surface roughness is estimated for atmospheric modeling. Reliable estimates of floodplain resistance would allow use of traditional resistance equations such as the Manning equation (equation 5 or calibration of prediction equations such as (8)–(11) to specific floodplain characteristics). With this approach, the discharge in inundated areas could also be estimated if topographic information was used to determine floodplain depths, provided areas of stagnant water or nondownstream flow could be identified from surface-velocity observations (Brakenridge *et al.*, 1994).

Discharge Estimation via Remotely Established Rating Relations

As discussed previously, assuming a regular geometric channel shape coupled with an observational history of width and stage provides the basis for converting stage to channel depth (equations 6 and 7). An alternative approach to utilizing stage information to improve prediction accuracy is to predict discharge from remote observations of width, velocity, and slope using equations of the form of (9) and (10), and observe stage remotely via altimetry. One can then develop a stage-discharge rating equation using the observed stage and the model-estimated discharge. Such a rating would average out much of the predictive error and, once the rating was established, enable stage to be the primary discharge-tracking variable.

We have conducted a proof-of-concept test of this approach using data for the USGS gage on the Mississippi River at Thebes, Illinois. In this test we assumed that the ground-measured widths and velocities are representative of measurements made from aircraft- or satellite-mounted sensors and that the ground-measured stages are representative of satellite-altimeter measurements. Rating relations are then established between the observed stage and the discharge estimated from generalized versions of equations (9) and (10). Figure 11 compares these ratings with the USGS rating relation for the Thebes gage. The estimated discharge is taken as the average of the values given by the two equations, and the estimated and observed discharges are compared in Figure 12. The mean relative error of the estimate is 0.01 (+1%) and the standard deviation of the relative error is 0.11 (11%) (i.e. approximately 95% of the estimates are within 22% of the true values).

Frequency of Satellite Observation

As noted earlier, the practical value of remotely sensed observations of river discharge depends on the spatial and temporal frequencies of observation as well as the precision with which predictor variables can be observed and the errors associated with prediction models. Temporal observation frequencies are difficult to generalize because they are functions of the orbital characteristics of satellites, the frequency of signal capture, whether the sensors can see through clouds, and the presence of ice cover. However, general estimates of the spatial frequency of observation can be based on simple quantitative characterizations of the planar aspects of stream networks.

Given a region of area A_D, the drainage density, D, is defined as $D \equiv \Sigma L / A_D$, where ΣL is the total length of streams in the region. From simple geometry, the characteristic (minimum) distance between streams, X, is the inverse of the drainage density. Referring to Figure 13, a random straight-line path crosses adjacent streams at a random angle θ, so the pathwise distance between stream crossings, Δx, is given by

$$\Delta x = \frac{X}{\cos\theta} = \frac{1}{D \cdot \cos\theta} \tag{12}$$

Assuming that all values of θ ($0 \leq \theta \leq \pi/2$) are equally likely and that D has a characteristic fixed value in a region, Sellmann and Dingman (1970) showed that the average

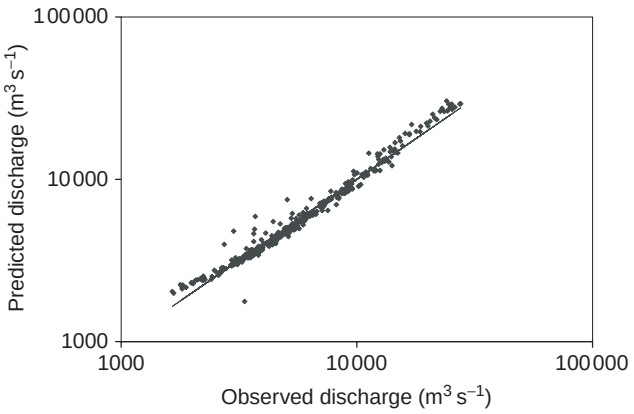

Figure 12 Discharge predicted as average of values predicted from equations (9) and (10) versus velocity-area measurements of discharge at the USGS gaging station for the Mississippi River at Thebes, IL

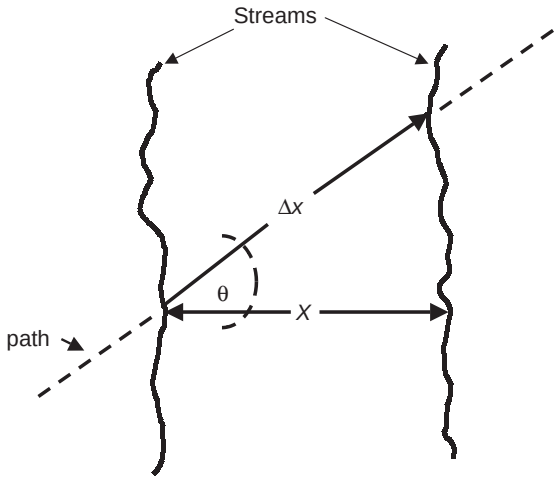

Figure 13 Definitions of terms in equation (12)

number of streams encountered per unit path length, $E(n)$, is given by

$$E(n) = \left(\frac{2}{\pi}\right) \cdot D = 0.637 \cdot D \tag{13}$$

The bifurcation ratio, R_B, in a stream network is the ratio of the number of streams of order ω, $N(\omega)$, to the number of streams of order $\omega + 1$, $N(\omega + 1)$:

$$R_B \equiv \frac{N(\omega)}{N(\omega + 1)} \tag{14}$$

and the length ratio, R_L, is the ratio of the average length of streams of order $\omega + 1$, $L(\omega + 1)$, to the average length of streams of order ω, $L(\omega)$:

$$R_L \equiv \frac{L(\omega + 1)}{L(\omega)} \tag{15}$$

Defining $R \equiv R_B/R_L$, Rodríguez-Iturbe and Rinaldo (1997) showed that the total length of streams in a drainage basin of order Ω, ΣL, is

$$\Sigma L = L(\Omega) \cdot \frac{1 - R^{\Omega}}{1 - R} \tag{16}$$

where $L(\Omega)$ is the length of the main stream. Values of R_B are generally between 3 and 5 and average about 4, and values of R_L are typically $\approx$2 (Rodríguez-Iturbe and Rinaldo, 1997).

Assuming a nearly constant relation between stream size (e.g. width) and stream order in a region, a given remote observing system will be able to extract useful information from streams of order greater than or equal to a "minimum observable order", ω^*. It can be shown that the total length of streams of this or larger order, $\Sigma L(\omega^*)$, is

$$\Sigma L(\omega^*) = L(\Omega) \cdot \frac{1 - R^{\Omega - \omega^* + 1}}{1 - R} \tag{17}$$

Thus in any path in a basin of order Ω, the frequency of encountering a stream large enough to observe, $f(\omega^*)$, is

$$f(\omega^*) = \frac{\Sigma L(\omega^*)}{\Sigma L(\Omega)} = \frac{1 - R^{\Omega - \omega^* + 1}}{1 - R^{\Omega}} \tag{18}$$

Finally, the average number of observable streams encountered per unit path length, $E(n^*)$, is given by the product of equations (13) and (18) as:

$$E(n^*) = 0.637 \cdot f(\omega^*) \cdot D \tag{19}$$

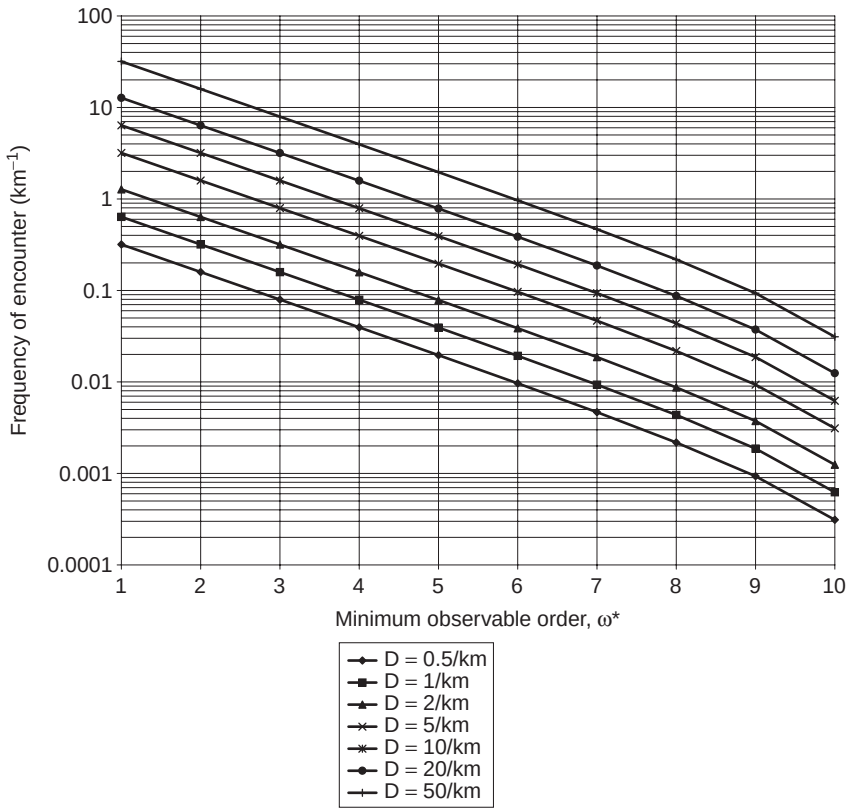

Figure 14 Relations between frequency of stream encounters and minimum observable order, ω^*, as a function of drainage density, D, assuming $R = 2$ and $\Omega = 10$ (equation 19)

Figure 14 shows $E(n^*)$ as a function of D assuming $R = 2$ and $\Omega = 10$. For example, in a basin with $D = 2\,\mathrm{km}^{-1}$ and a system that can observe streams of order $\omega^* = 6$ and larger, we find $f(\omega^*) = 0.030$ and $E(n^*) = 0.039\,\mathrm{km}^{-1}$, or about 4 streams per 100 km of observation path.

Summary and Discussion

Numerous studies have demonstrated the use of remotely sensed hydraulic data in tracking dynamic changes in river-flow conditions. However, few have used remotely sensed information to quantitatively estimate river discharge. One reason for this is that concurrent data sets of remotely sensed width, slope, and either stage or velocity are not generally available at present.

As discussed in this article, analyses using conventional ground-measured data indicate the feasibility of several approaches to developing quantitative discharge estimates using hydraulic data measured from remote platforms. These approaches should be developed further and their accuracy and precision tested as such data sets become more available. Further experience in the remote measurement of river hydraulic variables and the use of hydraulic relations to estimate discharge from these data will probably result in robust estimating methods.

Aircraft- and satellite-based measurement systems specifically designed to monitor rivers and estimate discharge are potentially cost-effective when large areal coverage is required. In the large portions of the world where ground-based measurements are not feasible for political or economic reasons, such systems appear to be the only option for obtaining quantitative river-discharge information.

The needed accuracy and precision of discharge measurements are functions of the intended use, and would be expected to improve over time as large data sets are developed and calibration methods improve. However, because of inherent uncertainties in remote observation and inherent limitations of resolution, it is unlikely that remote measurements of river discharge can replace the need for ground-based measurements for many water-resource assessment needs, particularly in developed countries where ground-based networks already exist. Although the cost of a satellite or aerial measurement system would be relatively high compared to ground-based systems, the large coverage that could be obtained could ultimately contribute significantly to our knowledge of regional and global hydrology and water resources.

Acknowledgments

The authors' research on remote sensing of river discharge has been supported in part by NASA grants NAG5-7601 and NAG5-8683. We thank Charon Birkett (NASA Goddard Space Flight Center) and Delwyn Moller (California Institute of Technology Jet Propulsion Laboratory) for providing information from their current research, and Charles Vörösmarty (Institute for the Study of Earth, Oceans, and Space, University of New Hampshire) for guidance, insight, and ideas that contributed to this article. Comments by Dennis Lettenmaier (Department of Civil Engineering, University of Washington) on earlier drafts of this article were most helpful.

Remote sensing techniques can be use to monitor water quality parameters (i.e., suspended sediments-turbidity, chlorophyll, temperature). Optical and thermal sensors on shoreline booms, boats, aircraft, and satellites provide both spatial and temporal information needed to monitor changes in water quality parameters for developing management practices to improve water quality. Recent and planned launches of platforms equipped with improved spectral and spatial resolution sensors should lead to greater use of remote sensing techniques to assess and monitor water quality parameters. Integration of remotely sensed data, GPS, and GIS technologies provides a valuable tool for monitoring and assessing waterways. Remotely sensed data can be used to create a permanent geographically located database to provide a baseline for future comparisons. The integrated use of remotely sensed data, GPS, and GIS will enable consultants and natural resource managers to develop management plans for a variety of natural resource management applications. This review paper identifies current knowledge regarding the assessment of water quality, and identifies promising techniques for high resolution assessment.

INTRODUCTION

Current concerns for the effects of global change and sustainable development of the global environment have overshadowed what many see as the equally important problems associated with the progressive degradation of the global soil resources and the impact of increased sediment and nutrient mobilization on fluvial and aquatic ecosystems (Lal, 1994, 2001; Walling, 1999; Ritchie *et al.*, 2003a). Changes in water quality (*see* **Chapter 91, Water Quality, Volume 3** and **Chapter 92, Water Quality Monitoring, Volume 3**) are the most visible manifestation of this progressive degradation. Water quality is most often defined in terms of physical, chemical, thermal, and/or biological characteristics that affect the properties of water. Good or poor water quality depends on the end use of the water; however, there is general agreement that surface water quality has deteriorated in recent decades. Substances from natural and/or anthropogenic sources have contributed to deterioration of water quality in freshwater and estuarine ecosystems of the world (Dekker *et al.*, 1995). The impacts of these substances include water pollution, reservoir sedimentation, degradation of aquatic habitats, alterations of trophic levels in aquatic food chains, and increased cost of water treatment. Globally, the economic cost of the on-site and off-site impacts of pollutant movement has been estimated at ca. $400 billion per year (Pimentel *et al.*, 1995).

Rapid techniques for monitoring and assessing water quality are critical if surface waters are to be managed to maintain or improve their quality. *In situ* measurements provide accurate information for a point in time and space, but these measurements are difficult, expensive, and often inaccurate for understanding either the spatial or temporal patterns of water quality needed for accurate assessment or management of water bodies (Curran and Nova, 1988; Boyer *et al.*, 2002). These limitations of *in situ* measurement techniques to provide information on the spatial and temporal patterns of water degradation across the landscape restrict our ability to develop cost-effective land management strategies. Such limitations point to the need

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

to investigate other techniques to supplement current techniques for monitoring and quantifying water quality patterns in space and time. Assessment of the magnitude of these problems and the formulation of effective management and control strategies require more reliable data, an improved understanding of the spatial and temporal patterns involved, and faster retrieval of information. Recent reviews have emphasized the potential of remote sensing techniques to monitor water quality (Curran and Novo, 1988; Cracknell, 1999; Ritchie, 2000; Ritchie and Schiebe, 2000; Ritchie *et al.*, 2003b). The purpose of this chapter is to provide an overview of the application of remote sensing techniques and sensors for monitoring and assessing suspended sediments and chlorophyll (algae) components of water quality. These are certainly the most visible manifestations of water quality.

BACKGROUND

Electromagnetic radiation from the Sun is either transmitted into the water or reflected (backscattered) from the water surface. Remote sensing techniques for monitoring water quality are based on the ability to quantitatively measure changes in quality and quantity of the backscattered or emergent radiation characteristics of the surface water (Jerlov, 1976; Kirk, 1983) and to relate these measured changes by empirical or analytical models to the water quality parameter of interest. The optimal sensor/wavelength used to measure a water quality parameter depends on the substance being measured, its concentration, and the sensor characteristics.

Suspended sediments (turbidity), colour (i.e. chlorophylls, carotenoids), chemicals (i.e. nutrients, pesticides, metals), dissolved organic matter (DOM), thermal releases, aquatic organisms including zooplankton, emergent and submergent plants, bacteria, viruses, and oils are key factors affecting water quality. Remote sensing techniques can measure the energy spectra of reflected solar and/or emitted radiation from surface waters caused by suspended sediments, chlorophylls, DOM, oils, aquatic plants, and thermal releases. Most chemicals do not directly change the spectral or thermal characteristics of surface waters so they can only be inferred indirectly from measurements of other water quality parameters (most often chlorophyll) that are affected by these substances. Remote sensing techniques provide spatial and temporal data on surface water parameters thus making it possible to monitor the landscape effectively and efficiently, identifying and quantifying water quality parameters and problems.

Research using remote sensing techniques to measure surface water properties began in the early 1970s. This research used sensors in the laboratory and on boats, airplanes, and satellites to make measurements of the spectral backscattering characteristics of water surfaces. Empirical relationships between spectral properties and *in situ* water quality parameters were established. Ritchie *et al.* (1974) using *in situ* measurements from boats and others (i.e. Klemas *et al.*, 1975; Bowker and Witte, 1975; Johnson, 1976) using aircraft and satellite sensors developed empirical approaches to estimate suspended sediments and chlorophyll from spectral measurements. The general forms of these empirical equations are:

$$Y = a + bX \quad \text{or} \quad Y = ab^X \tag{1}$$

where Y is the remote sensing measurement (i.e. radiance, reflectance, energy) and X is the water quality parameter of interest (i.e. suspended sediments, chlorophyll). a and b are empirically derived coefficients relating measured spectral properties and measured water quality properties. Information about the spectral/optical characteristic of the water quality parameter can often be used to help select the best wavelength(s) or best model in this empirical approach. The empirical nature of these relationships limits their applications to estimating water quality parameters for water bodies with similar properties and conditions. A number of modifications to these linear modeling efforts have been developed; however, all rely on utilizing unique spectral characteristics to estimate the desired component.

These limitations in empirical approaches led to attempts to use analytical approaches based on optical properties of the water and the water quality parameters to develop physically based models of the relationship between spectral and physical characteristics of surface water studied. These physically based reflectance models have been successfully applied for estimating suspended sediment concentrations (Schiebe *et al.*, 1992; Harrington *et al.*, 1992; Dekker *et al.*, 1995). Similar relationships have been developed to estimate phytoplankton chlorophyll in marine and estuarine systems (Gitelson *et al.*, 1986; Vos *et al.*, 1986; Gitelson, 1992; Gitelson *et al.,* 2000; Mittenzwey and Gitelson, 1988; Mittenzwey *et al.*, 1992; Millie *et al.*, 1992; Quibell, 1992; Dekker, 1993; Gitelson *et al.*, 1993a,b, 1994a; Goodin *et al.*, 1993; Matthews and Boxall, 1994; Han *et al.*, 1994; Richardson *et al.*, 1995; Richardson and Zimba, 2002; Rundquist *et al.*, 1995, 1996; Yacobi *et al.*, 1995; Schalles *et al.*, 1997, 1998).

This article will review the use of remote sensing technology to measure suspended sediments and chlorophyll (color). These are the two key pollutants listed by United States Environmental Protection Agency who estimated that approximately 40% of the United States waters do not meet minimum water quality standards (US Environmental Protection Agency, 1998). Similar estimates have been made for waters of other countries. A short discussion of *in situ* sensors for remote measurement is also included since these are essential for measuring water quality parameters related

to colour that cannot be measured with remote sensing techniques and for collecting data to calibrate remote sensing models for determining water quality.

SUSPENDED SEDIMENTS

Suspended sediments (*see* **Chapter 83, Suspended Sediment Transport – Flocculation and Particle Characteristics, Volume 2**) are inorganic particles suspended in water and are the most common pollutant both in terms of weight and volume in surface waters of freshwater systems (Robinson, 1971; Lal, 1994) and are a serious problem in coastal waters (Cracknell, 1999). *In situ* measurements made either by collecting samples and filtering or by using a turbidity meter while providing accurate measurements for a point in time and space cannot account for the high spatial variability in suspended sediments found in most aquatic systems.

Suspended sediments increase the radiance reflected or emergent from surface waters (Figure 1) in the visible and near-infrared proportion of the electromagnetic spectrum (Ritchie *et al.*, 1976). Remote sensing instruments measure the difference in the electromagnetic spectrum in the visible and near-infrared wavelengths from the surface water related to the concentration of suspended sediments. *In situ*, controlled laboratory, aircraft, and satellite measurements have shown that surface water radiance is affected by amount, type, texture, and color of the suspended sediments (Novo *et al.*, 1989), sensor view angle, sun angles (Ritchie *et al.*, 1974, 1975), water depth (Blanchard and Leamer, 1973), and the atmospheric conditions (Curran and Novo, 1988). Spectral sensors on boat, aircraft, and satellite platforms have all been used to study suspended sediment patterns in freshwater and coastal aquatic systems.

Significant relationships between suspended sediments and radiance or reflectance from spectral wavelengths or combinations of wavelengths on satellite and aircraft sensors have been found. Ritchie *et al.* (1974, 1976) using *in situ* measurements found the highest correlations between suspended sediments and radiance or reflectance at wavelengths between 700 and 800 nm. Curran and Novo (1988) in a review of remote sensing of suspended sediments found that the optimum wavelength was related to suspended sediment concentration. Most studies have shown that radiance measured from the water surface increases linearly between 30 and 120 mg l^{-1} of suspended sediments then becomes asymptotic (Whitlock *et al.*, 1982; Novo *et al.*, 1989). The point where the curve becomes asymptotic is related to both the wavelength and the suspended sediment concentration. The greater the wavelength the higher the concentrations of suspended sediments before the curve becomes asymptotic (Figure 2).

This asymptotic relationship between suspended sediments and radiance or reflectance (Ritchie *et al.*, 1976, 1990) means that the amount of reflected radiance tends to saturate as suspended sediment concentrations increase. If the range of suspended sediments is between 0 and 50 mg l^{-1}, reflectance from almost any wavelength will be linearly related to suspended sediment concentrations. As the range of suspended sediments increases from 50 mg l^{-1} to 150 mg l^{-1} or higher, the use of curvilinear relationships becomes necessary. At these higher suspended sediment concentrations, wavelengths between 700 and

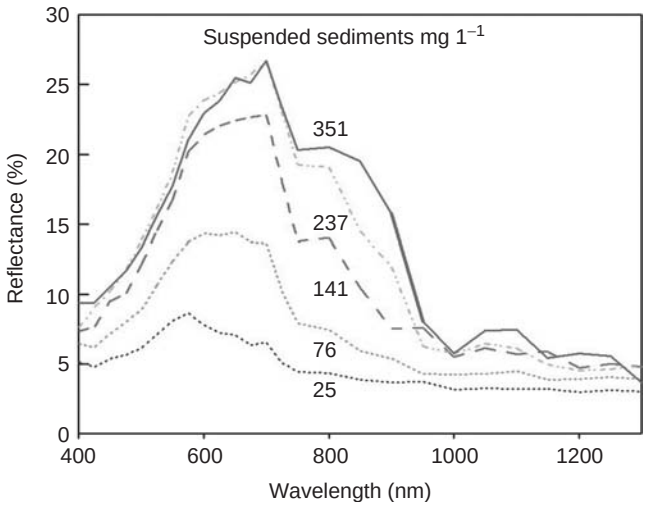

Figure 1 The relationship between reflectance and wavelength as affected by the concentration of suspended sediments (Ritchie *et al.*, 1976). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

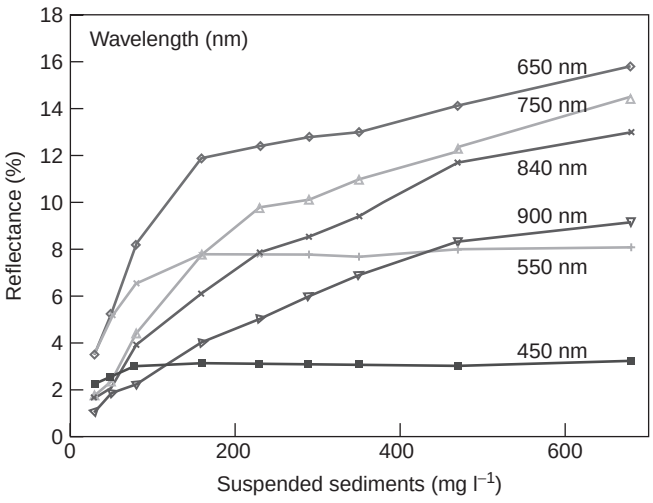

Figure 2 Relationship between reflectance and suspended sediments by wavelength showing nonlinear relation between suspended sediment concentration and reflectance (Adapted from Whitlock *et al.*, 1982). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

900 nm are best for estimating suspended sediment concentrations. Schiebe *et al.* (1992) developed a physically based reflectance model and used it to estimate suspended sediment concentrations in Lake Chicot, Arkansas. Most researchers have concluded that surface suspended sediments can be mapped and monitored in large water bodies using sensors available on current satellites. Figure 3 shows an example of mapping suspended sediments in Lake Chicot, an oxbow lake in Arkansas, USA next to the Mississippi River, using Landsat Thematic Mapper data. Suspended sediments were mapped in ranges defined by a management plan proposed for the lake.

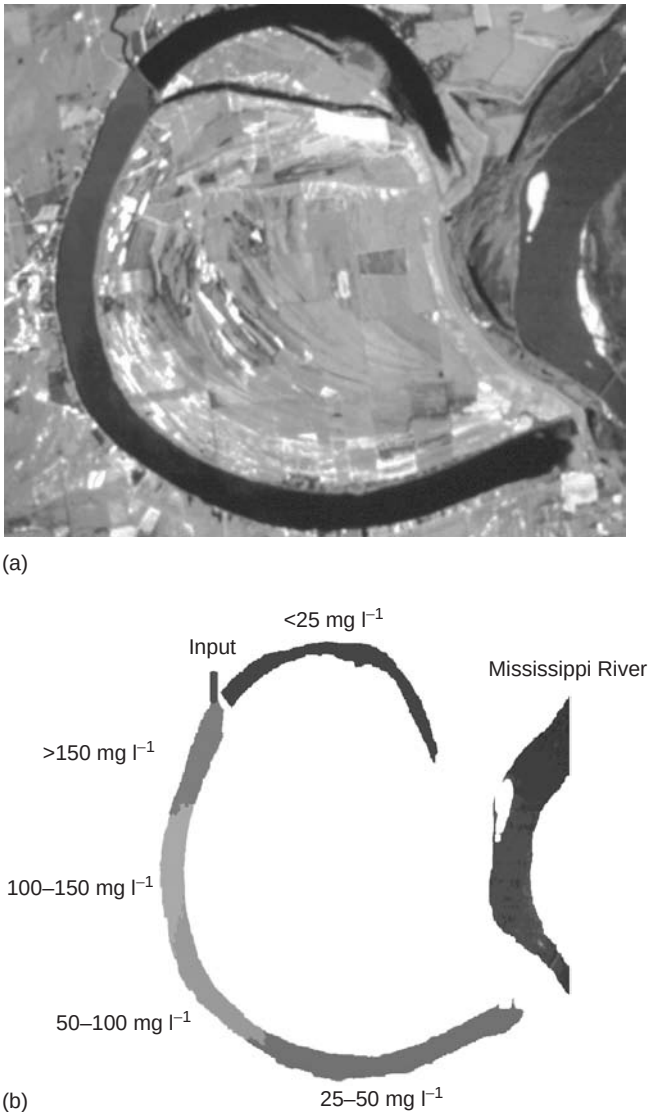

Figure 3 (a) Landsat Thematic Mapper (TM) image of Lake Chicot, Arkansas and (b) a derived image showing categories of suspended sediments mapped in Lake Chicot based on the radiance in the TM image. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Many studies have developed empirical relationships (algorithms) between the concentration of suspended sediments and radiance or reflectance for a specific date and site. Few studies have taken the next step and used these algorithms to estimate suspended sediments for another time or place (Curran and Novo, 1988). Ritchie and Cooper (1988, 1991) showed that an algorithm developed for one year was applicable for several years. Once developed, an algorithm should be applicable until some watershed event changes the quality (i.e. size, color, mineralogy, etc.) of suspended sediment particles delivered to the lake. While most researchers and managers agree that suspended sediments can be mapped with remotely sensed data, the current spatial and temporal resolution of satellite data (Ritchie and Schiebe, 2000; Ritchie *et al.*, 2003b) does not allow the detail mapping of water bodies or measurements in or from streams needed for management decisions. As new satellites come on line with higher resolution spatial and spectral data, greater application of satellite data for monitoring and assessing suspended sediments will be possible.

ALGAE/CHLOROPHYLL

Remote sensing provides a means for estimating chlorophyll (Chl) at local, regional, and even global scales. Several algorithms for remote estimation of chlorophyll concentration in marine, estuarine, and inland waters have been developed (Figure 4a–c). They are all based on reflectance in the red and near-infrared (NIR) range of the spectrum, since other portions of the spectrum are not useful for chlorophyll in productive, coastal, and freshwater ecosystems (Gitelson *et al.*, 1986, 2000; Vos *et al.*, 1986; Gitelson, 1992; Mittenzwey and Gitelson, 1988; Mittenzwey *et al.*, 1992; Millie *et al.*, 1992; Quibell, 1992; Dekker, 1993; Gitelson *et al.*, 1993a,b, 1994a; Goodin *et al.*, 1993; Matthews and Boxall, 1994; Han *et al.*, 1994; Richardson *et al.*, 1995; Richardson and Zimba, 2002; Rundquist *et al.*, 1995, 1996; Schalles *et al.*, 1997, 1998; Yacobi *et al.*, 1995; Zimba and Thomson, 2002). The basic concept of these algorithms is the inclusion of the spectrum range, which shows the maximal sensitivity to changes in chlorophyll concentration and the range with the minimum sensitivity to variation of chlorophyll concentration (Gitelson *et al.*, 1986, 1993a,b, 1994a, 2000; Yacobi *et al.*, 1995). The latter accounts for nonpigmented suspended matter that causes variation in the reflectance as detailed in the previous section of this chapter. The magnitude and position of the reflectance peak near 700 nm (R_{700}) is most sensitive to chlorophyll concentration (Gitelson, 1992), whereas the reflectance at 670 nm (R_{670}) is the least sensitive to changes in algal density, especially for chlorophyll concentrations less than 15 to 20 mg m^{-3} (Figure 4a). For chlorophyll concentrations above 20 mg m^{-3}, changes in the reflectance at

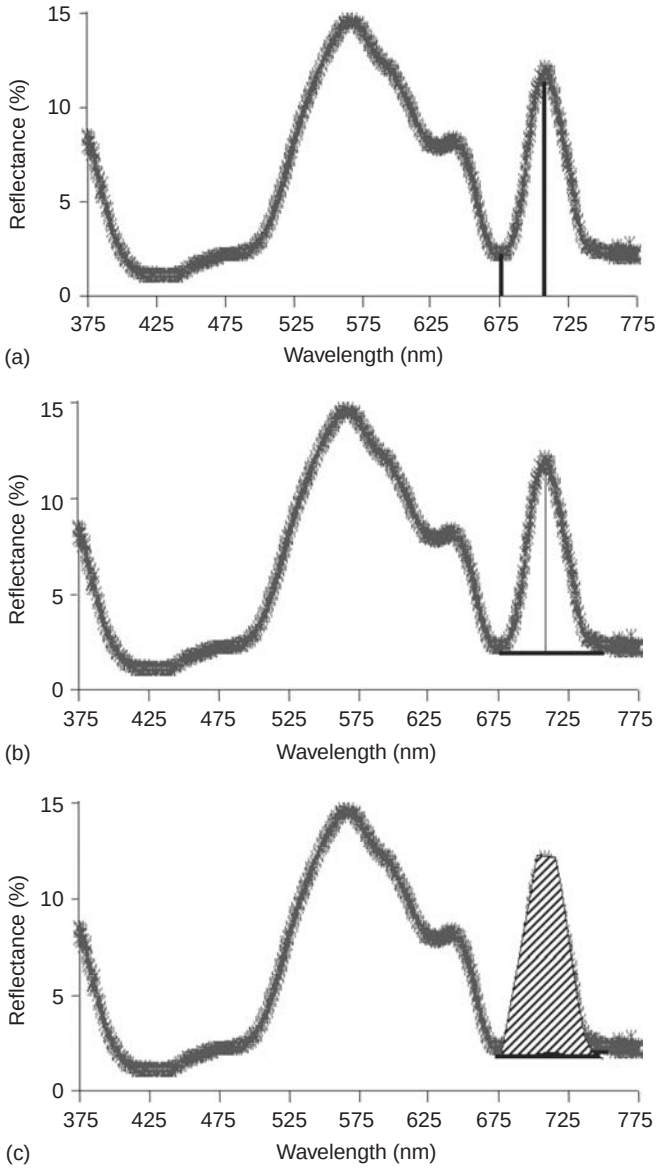

Figure 4 Examples of the three methods commonly used to estimate chlorophyll *a* concentrations- (a) Ratio of reflectance at the peak around 700 nm to reflectance at 670 nm; (Yacobi and Gitelson, 2000) (b) Reflectance height above the baseline between 670 and 800 or 900 nm; (c) Area above the baseline between 670 and 750 nm. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

R_{670} primarily depend on the concentration of nonorganic suspended matter (Gitelson *et al.*, 1993a, 1994b; Dekker, 1993; Yacobi *et al.*, 1995). Reflectance above 750 nm (R_{750}) depends on both organic and nonorganic suspended matter concentrations and is relatively insensitive to algal pigments (Han *et al.*, 1994). The variation of R_{750} is comparatively small because of strong water absorption in the NIR range. The slope of the baseline between 670 and 750 nm depends primarily on scattering by water constituents, and is less dependent on chlorophyll absorption. With variation in the amount of nonorganic and nonpigmented organic suspended matter concentration, the slope of the baseline changes but it has minimal influence on the height and area of the 700-nm peak above the baseline (Figure 4b and c). Therefore, the height of the peak and the area above the baseline between 670 and 750 nm depends mainly on chlorophyll concentration and is most often used as its quantitative measure.

These algorithms work well in systems having low turbidity associated with nonalgal suspended material, such as Lake Kinneret, Israel (Mayo *et al.*, 1995; Yacobi *et al.*, 1995) and Carter Lake, Nebraska (Schalles *et al.*, 1997). These trophically diverse systems illustrate the existence of robust relationships between chlorophyll concentration and variables of reflectance. However, chlorophyll concentrations have to be estimated against a background of high and variable inorganic suspended matter. Measured reflectance spectra in Mississippi catfish ponds typify these variable environments (Figure 5). Turbidity ranged from 40 to 350 FAU (Formazin Attenuation Unit), whereas field chlorophyll samples ranged from 8 to 600 $\mu g\, l^{-1}$. Measured reflectance of algae-laden waters prior and after addition of known clay concentrations (Figure 6a and b) show that for the same chlorophyll concentration, increases in inorganic suspended matter caused an increase in the magnitude of the reflectance peak (R_{700}). Thus, to retrieve accurately measured chlorophyll concentrations against a background of high and variable inorganic suspended matter an improvement of algorithms is required. This is particularly evident when concentrations of suspended inorganic material (montmorillonite clay in this example) exceed 200 $mg\, l^{-1}$ (Figure 6b).

The three algorithms (Figure 4) used for chlorophyll assessment performed poorly in water bodies with very high concentrations of inorganic suspended matter. As previously shown (Figure 6), scattering by inorganic particles affected the magnitude of the peak around 700 nm in the same way as chlorophyll concentration: magnitude of the peak above the baseline between 670 and 750 nm increased with total suspended solids (TSS) increase. Reflectance spectra (Figure 5) showed spectral features of chlorophyll (trough at 676 nm) as well as phycocyanin (trough at 624 nm). The peak around 700 nm corresponds to a minimum in absorption by algae and water and is representative of chlorophyll (Gitelson, 1992). These spectral features are of use for retrieval of chlorophyll and phycocyanin concentration from remotely sensed data. In contrast to productive waters, reflectance around 670 nm varied widely, showing the variation of inorganic suspended matter concentrations encountered.

Gitelson *et al.* (2003) and Dall'Olmo *et al.* (2003) have recently shown that reciprocal reflectance is a proxy of

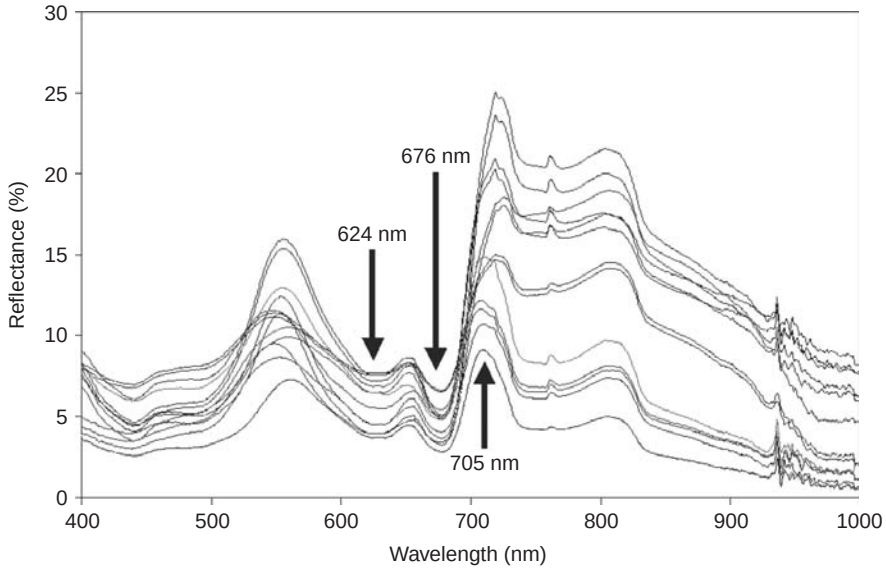

Figure 5 Representative reflectance spectra collected July 2002 from Mississippi channel catfish ponds showing variable suspended solids (705 nm) and algal biomass (chlorophyll *a* trough at 670 nm, phycocyanin trough at 624 nm). Measurements were made using a dual head Ocean Optics SD2000 operated with University of Nebraska CALMIT software (CDAP)

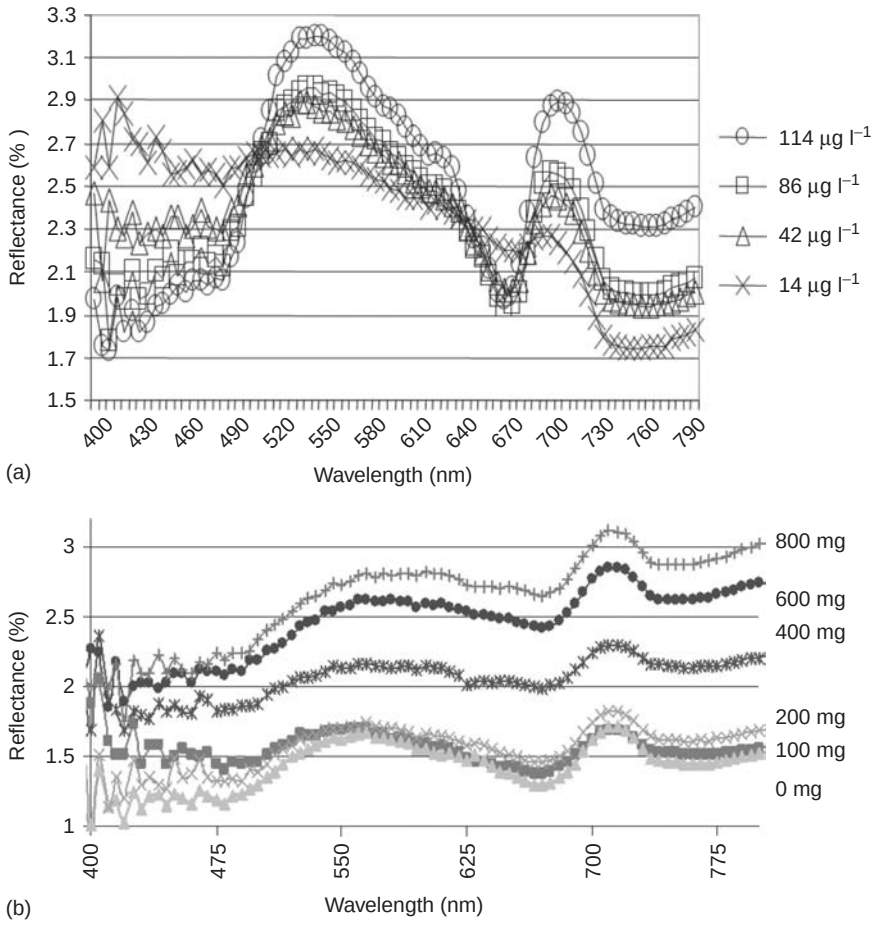

Figure 6 Effect of differing algal biomass (a) and montmorillonite clay additions (b) on reflectance of *Scenedesmus* cultures. Measurements made using a dual head Ocean Optics US2000 spectrometer operated with CDAP (University of Nebraska CALMIT) software. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

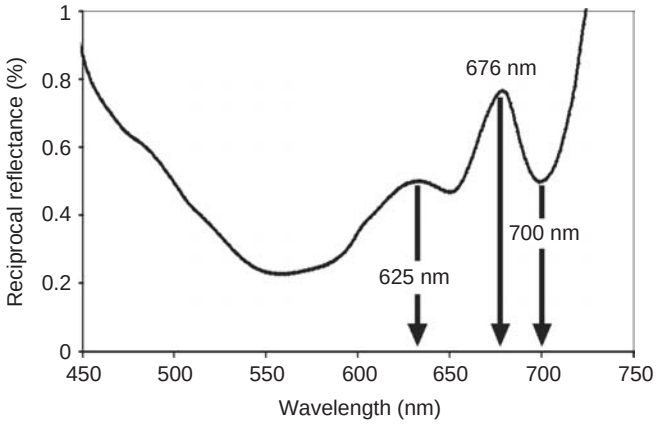

Figure 7 Reciprocal reflectance from Mississippi catfish production ponds sampled in July 2002. Measurements made using a dual head Ocean Optics SD2000 spectral radiometer. Note prominent algal biomass and solids peaks (as in Figure 5)

the ratio a/b, where a and b are absorption and scattering coefficients of the medium. Reciprocal reflectance of these turbid, eutrophic ponds (shown in Figure 7) shows three pronounced spectral features: peak at 625 nm (absorption by phycocyanin), peak at 676 nm (absorption by chlorophyll *a*), and minimum around 700 nm that manifests the minimal absorption by algae and water in this spectral range. Using the spectral features of chlorophyll *a*, Gitelson and colleagues have suggested a new approach for chlorophyll assessment. They subtracted reciprocal reflectance at 700 nm (that is proportional to scattering by all suspended matters) from reciprocal reflectance at 675 nm (that is proportional to absorption by chlorophyll *a* and scattering by all suspended matters as well). As a result, the model $(R_{675})^{-1}$-$(R_{700})^{-1}$ described chlorophyll *a* concentrations better than known algorithms. The resulting image also better fit the field truthed data (Figure 8).

The rationale for this approach is similar to that used in classification of crop health using NDVI (Normalized Difference Vegetation Index) and assessment of CASE 1 waters (i.e. Rouse *et al.*, 1974; Morel and Prieur, 1977). However the inversion method used by Gitelson and coworkers (Gitelson and Kondratyev, 1991; Gitelson *et al.*, 2003a,b; Merzlyak *et al.*, 2003; Dall'Olmo *et al.*, 2003) is an innovative approach to decompose diffusive spectral reflectances and estimate chlorophyll in both terrestrial and aquatic systems having different spectral absorption and backscattering constituents. This technique has the further advantage of removing effects of suspended solids from the chlorophyll estimation and appears to be a unifying concept that will shift methodologies from the left wall as described by Gould (1996).

In systems having highly variable suspended solids and algal biomass, increased temporal coverage is required. Aerial overflights have been effective in monitoring these systems (Millie *et al.*, 1992; Zimba and Thomson, 2002). Millie *et al.* (1992) demonstrated the utility of aerial overflights to identify total algal biomass in ponds. In subsequent analyses, (Millie *et al.*, 1995) were unable to predict algal biomass from aerial overflights collected one month apart. Confounding factors contributing to these models include the sampling frequency relative to the algal division rate, sediment resuspension from abiotic and biotic factors (e.g. wind resuspension, fish feeding), as well as the alteration of pigment composition by algae in response to altered physiological state (Falkowski and Raven, 1997). Zimba and Thomson (2002) used low-altitude remote sensing methods to assess the utility for detecting harmful algal taxa present in 18 catfish ponds. Concurrent field samples were collected weekly for six weeks and the relationship between digital imagery numbers and chlorophyll was stable for over a month period. The carotenoid pigment myxoxanthin, found in coccoid cyanobacteria, was highly correlated with the digital numbers, presence of chlorophyll, as well as the harmful algal species *Microcystis.* Approaches such as digital camera imagery are still in the developmental stage but may provide necessary information for temporally variable systems. Use of cut-band filters to target specific spectral bands of interest will be critical for selectivity.

The ability to discriminate between different algal groups is required for accurate assessment of harmful algal species (Millie *et al.*, 1995; Zimba and Thomson, 2002; Bazzani and Cecchi, 1995). Spectral features unique to these algae must be used to characterize algae in terms other than chlorophyll *a*. Spectral features that have not been exploited include the phycobilin signatures of cyanobacteria, as well as unique carotenoid compositions of phylogenetic groups. For example, Millie *et al.* (1995) identified a unique biomarker (gyrodinium diester) in the bloom forming dinoflagellate *Gymnodinium (Karenia) breve*. This alga causes reoccurring toxic blooms off the Florida west coast, and has expanded in the Gulf of Mexico recently to Alabama, Mississippi, and Texas coast. As an initial identification tool, Millie *et al.* (1995) used fourth derivative analyses of absorbance to discriminate unialgal and mixed assemblages containing this alga. The amount of signal variance explained by such approaches is trivial, but as a first approximation it is a useful concept. Zimba and coworkers (Zimba *et al.*, 2001; Zimba and Thomson, 2002; Zimba and Grimm, 2003) have demonstrated the co-occurrence of the carotenoid myxoxanthin and presence of *Microcystis*, a genus known to produce harmful secondary metabolites, including the off-flavor compound *beta*-cyclocitral and the toxin microcystin. A peak near 504 nm was also identified by Richardson and Zimba (2002) as indicating presence of coccoid cyanobacteria in Florida

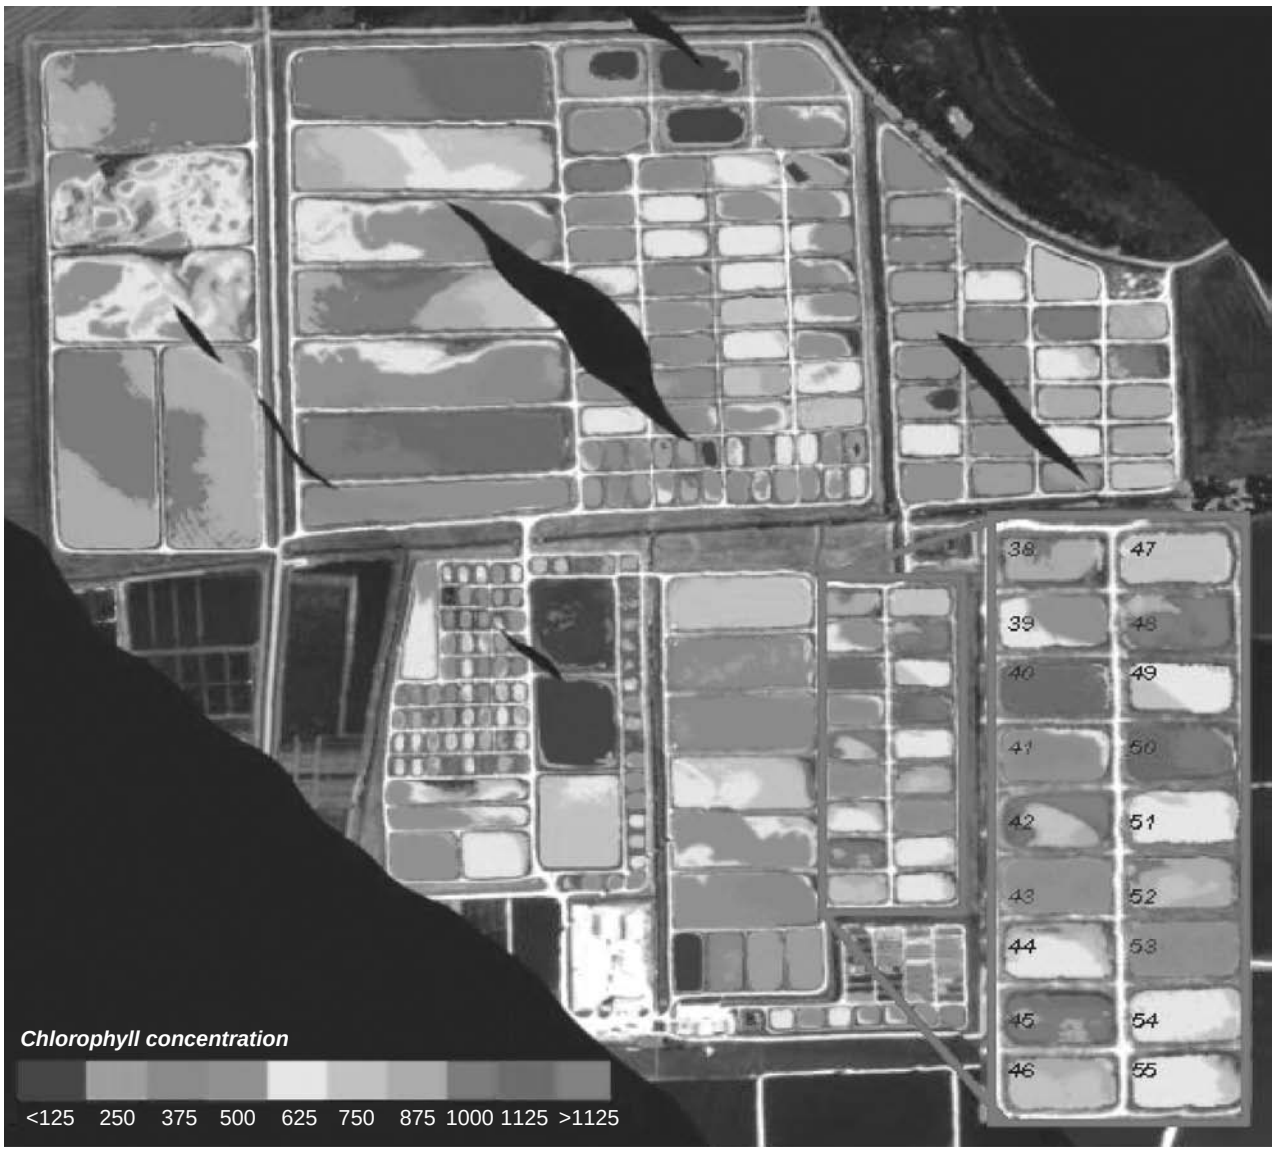

Figure 8 Chlorophyll concentration estimated from Mississippi catfish ponds sampled in July 2002. Imagery captured using an AISA hyperspectral scanner operated by University of Nebraska CALMIT personnel. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Bay, Florida. Phycobilin signatures appear useful in identifying harmful cyanobacterial blooms in catfish production systems in Mississippi.

The development of miniaturized sensor equipment requiring simpler platforms than satellites provides greater opportunities for optimization of methodologies, increased frequency of sampling events, and lower operating costs. Airborne sensor systems are useful to assess optimal bandwidths and thereby build the foundation for incorporation in future satellite designs. Additionally, the resolution of airborne systems (as compared to satellites) may provide greater sensitivity in assessing dynamic features of algal growth, particularly in upwelling areas, riverine plumes, as well as in closely monitoring bloom development within small lakes, reservoirs, and rivers. The rapid development of miniaturized handheld spectral units also will contribute to optimization of assessment methodologies.

CONCLUSIONS

Remote sensing techniques for measuring suspended sediments and algae have improved greatly since the 1970s and presently have many actual and potential applications for assessing water resources and for monitoring water quality. However, limitations in spectral, spatial, and temporal resolution of sensors on current satellites restrict wide scale

application of satellite data for monitoring water quality. New satellites and sensors (hyperspectral, high spatial resolution) already launched or planned to be launched over the next decade may provide the improved spectral and spatial resolution needed to monitor water quality parameters in surface waters from space platforms. However, there may be many cases requiring the use of airborne or even handheld sensors so that temporal and spatial data can be collected on fast developing pollution events (i.e. algae bloom, sediment laden water from storm events).

The integration of remotely sensed data, GPS (Global Positioning Systems), and GIS (Geographic Information Systems) technologies provides a valuable tool for monitoring and assessing surface waters. Remotely sensed data provide a permanent geographically located image database as a baseline for future comparisons. The integrated use of remotely sensed data, GPS, and GIS will enable consultants and natural resource managers to develop management plans for a variety of natural resource management applications. Improvements in software for imagery or reflectance signal processing will also improve the near-real time ability to use these data for management decisions.

63: Estimation of Precipitation Using Ground-based, Active Microwave Sensors

MATTHIAS STEINER

Princeton University, Princeton, NJ, US

Ground-based radar measurements have provided a wealth of information about precipitation systems, how they evolve and organize themselves. Advances in Doppler and polarimetric radar technology, in particular, have yielded unprecedented insight into the dynamics and microphysics of precipitation formation. This paper summarizes the basic components and principals of radar measurements, and discusses how radar can be used to identify different types of precipitation particles as well as recognize nonmeteorological radar echoes, and obtain quantitative precipitation estimates.

INTRODUCTION

Quantitative information about precipitation is of major concern to meteorologists, hydrologic scientists, water resources managers, and environmental legislators. Yet, accurate measurement of precipitation over the relevant space and time scales remains a challenge. Active remote sensors, such as *radar* (*RA*dio *D*etection *A*nd *R*anging), have proven essential in capturing information about precipitation at scales of less than one to several hundred kilometers. For example, modern radar technology enables estimation of precipitation rates and distinction between different types of precipitation. In addition, information about the severity of storms and the associated wind field may be obtained. The quantitative estimation of precipitation, however, is a complex procedure that involves issues of radar hardware and signal processing software design, propagation of electromagnetic waves through the atmosphere and their interaction with precipitation particles, physics of precipitation production, data quality control, rain (and wind field) retrieval, and uncertainty analyses.

The relevant aspects of the radar-based precipitation measurement are highlighted in this article. More detailed information may be obtained from the relatively easy to comprehend textbooks by Battan (1973), Rinehart (1999), and Lhermitte (2002), or the more mathematically comprehensive books by Doviak and Zrnić (1993) and Bringi and Chandrasekar (2001). An excellent review of polarimetric radar measurements is given by Illingworth (2003). The challenges of (operational) radar measurements of precipitation in complex terrain are illustrated by Germann and Joss (2003). The monograph edited by Atlas (1990) provides an overview of the early days of radar meteorology and its evolution over approximately five decades. Skolnik (1988) elaborates on hardware and technical details.

BASIC RADAR PRINCIPLES

The main components of the radar are an active source for emission of electromagnetic radiation (i.e. *transmitter*) and a *receiver* designed to detect and amplify the return signals. The transmitter and receiver are collocated for monostatic radar systems (typical for weather radar) or separated by some distance for bistatic (or multistatic) radar systems. The transmission and reception of electromagnetic signals is facilitated by the *antenna*, a device that is usually combined with a parabolic reflector to focus the energy and guide it away from the radar in a particular direction. Typical gains of focusing the transmitted energy over an isotropic source of radiation are on the order of 20 to 50 dB (i.e. increases of 10^2 to 10^5). The shape and size of the reflector determine the antenna beam pattern. For simplicity, the term radar antenna will refer to both the antenna and the reflector combined. The transmitter is controlled by a modulator that regulates how often a pulse is sent out and provides the correct waveform and

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

duration for the transmitted pulse. Most radar transmit a few thousand Watts (1 W = 1 Joule per second) to more than a Megawatt (10^6 W) of power and are capable of detecting returned powers as small as 10^{-14} W or less. If the same antenna is used for transmission and reception (i.e. monostatic radar system), a highly insulated switch is needed to protect the sensitive receiver from the high power output of the transmitter. Computers are used to control the transmission of the radar signals, the direction the radar antenna is pointing, and the processing and display of the received signal.

In the earth's atmosphere, electromagnetic waves travel approximately at the speed of light ($c = 3 \times 10^8\,\mathrm{m\,s^{-1}}$) and are characterized by a frequency f in Hertz (1 Hz = 1 cycle per second) that is related to the radar wavelength λ through

$$f = \frac{c}{\lambda} \tag{1}$$

Typical values of radar wavelengths are compiled in Table 1. There are tradeoffs to consider when determining the appropriate wavelength and size of the radar antenna. For a given wavelength, a larger antenna results in a narrower beam (i.e. better focusing the radiated energy). For a circular parabolic antenna, the *beamwidth* ϑ (in degrees), defined as the angular width where the transmitted power is half the maximum power centered along the antenna pointing axis, is determined by the ratio of radar wavelength λ and antenna diameter d_a (both given in the same units),

$$\vartheta = \frac{180}{\pi}\frac{\lambda}{e_a d_a} \tag{2}$$

where e_a is the antenna aperture efficiency (typically $e_a \approx 0.8$ or less). Desirable beamwidths are on the order of 1 degree or less. A radar operating at a 10-cm wavelength, therefore, requires an antenna with diameter of approximately 10 m to achieve that. Increasing the size of a radar antenna, however, dramatically increases its weight and cost. For practical purposes, therefore, ground-based weather radar, equipped with a steerable antenna that can rotate in azimuth and elevation, employs transmitters with wavelengths in the S, C, or X band. Mobile radar platforms, such as those mounted on trailers, trucks, or airplanes, are typically based on X or K band transmitters, although some C and S band radars are in use also. Longer wavelengths (L, VHF, and UHF bands) are employed in fixed, vertically pointing installations (so-called *wind profilers*) to measure the vertical profile of the horizontal wind speed and direction. Shorter wavelengths (K and W bands) are used for observation of nonprecipitating clouds. A notable exception is the K_u band precipitation radar aboard the Tropical Rainfall Measuring Mission (TRMM) satellite.

Table 1 Standard nomenclature (band designation) for radar wavelengths and frequencies

Band designation	Nominal wavelength	Nominal frequency
HF	10–100 m	3–30 MHz
VHF	1–10 m	30–300 MHz
UHF	0.3–1 m	300–1000 MHz
L	15–30 cm	1–2 GHz
S	7.5–15 cm	2–4 GHz
C	3.75–7.5 cm	4–8 GHz
X	2.5–3.75 cm	8–12 GHz
K_u	1.67–2.5 cm	12–18 GHz
K	1.11–1.67 cm	18–27 GHz
K_a	0.75–1.11 cm	27–40 GHz
W	1–7.5 mm	40–300 GHz

Radar-transmitted signals are described by either a pulse duration τ (if measured in units of time) or a pulse length h (if expressed in units of distance). Weather radars measuring precipitation typically employ simple (i.e. not coded) pulses of durations ranging from 0.2 to 2 μs (1 μs = 10^{-6} s), corresponding to pulse lengths of 30 to 300 m. The pulse duration, together with the beamwidth, provide a measure of the spatial resolution of the radar measurements. The radar sends out signals on a regular basis. The unambiguous distance $r_{\max}$ a pulse can travel to a backscattering target and return to the radar before the next pulse is sent out is determined by the *pulse repetition frequency* (*PRF*)

$$r_{\max} = \frac{c}{2PRF} \tag{3}$$

Typical *PRF* values range from 300 to 3000 Hz, corresponding to unambiguous ranges of 500 and 50 km, respectively. Signals returning to the radar from a distant target after the next pulse has been released cannot be distinguished from a signal more quickly returning from a nearby target and are thus depicted closer to the radar than they actually are. This feature is called *range folding*. Range-folded radar echoes are recognized by their apparent low intensity, radially elongated shape, and reduced vertical extent compared to correctly located storm signatures.

So far we have assumed that the target remains at a fixed distance r from the radar. A target moving relative to the radar causes a shift in frequency of the radar signal, known as the *Doppler effect*. For the radar to detect a frequency shift, the phase ϕ of the returned signal has to be compared to the phase ϕ_0 of the signal sent out, where

$$\phi - \phi_0 = \frac{2r}{\lambda} \tag{4}$$

The change of phase with time from one pulse to the next is given by

$$\frac{\mathrm{d}\phi}{\mathrm{d}t} = \frac{2}{\lambda}\frac{\mathrm{d}r}{\mathrm{d}t} = \frac{2v}{\lambda} \tag{5}$$

where v is the speed of the target relative to the radar. Note that the radar can only measure the velocity component of

a moving target in the radial direction. The ability of a Doppler radar to detect small phase shifts depends critically on either the stability of the transmitter frequency and phase from one pulse to the next (achieved by coherent transmitters such as klystron tubes) or the capability of the radar to remember the frequency and phase of each pulse sent out so that they can be compared to the returned signal (requires a stable local oscillator).

Radial velocity measurements can be ambiguous. The radar cannot distinguish between a target that has traveled half a wavelength towards the radar within the time from one pulse to the next and a target that has traveled a similar distance away from the radar. The maximum velocity $v_{\max}$ that can be determined unambiguously is called the *Nyquist velocity* and is given by

$$v_{\max} = \frac{\lambda}{4} PRF \tag{6}$$

Velocity folding is often characterized by abrupt changes in the radar-indicated velocity (near the Nyquist velocity) around the aliased region. Doppler radar operations are thus faced with the choice of either maximizing the unambiguous velocity or the unambiguous range measurements. This is known as the *Doppler dilemma* and is expressed by combining equations (3) and (6)

$$v_{\max} r_{\max} = \frac{c\lambda}{8} \tag{7}$$

We can increase $r_{\max}$ and $v_{\max}$ by employing longer wavelengths, which in turn requires bigger radar systems and increased costs, as detailed earlier. If instead the *PRF* is increased, the unambiguous velocity will increase yet the unambiguous range decreases. An acceptable compromise must be determined for each radar system and desired application. Alternatively, emerging techniques based on using multiple *PRF*s or staggered pulse release times may ease the unambiguous velocity problem.

RADAR PARAMETERS AND THEIR METEOROLOGICAL INTERPRETATION

Radar Equation for Distributed Scatterers

Weather echoes obtained by individual radar pulses are constantly changing (fluctuating), because precipitation particles are not homogeneously distributed in space and they rearrange themselves relative to each other and relative to the radar. Thus, echoes from multiple radar pulses are averaged to obtain a more accurate measure of a storm's intensity. The number of independent pulses to be averaged for a good measure of the signal strength depends on how quickly samples decorrelate with time, which is a function of the radar wavelength and scanning, the size distribution of hydrometeors, and the wind shear or turbulence within the radar sampling volume. Decorrelation times are shorter for shorter radar wavelengths and broader hydrometeor size distributions. Typically many tens of radar pulses are averaged for a given point in space.

Assuming a circular parabolic antenna with a Gaussian-shaped beam pattern, it can be shown that the received power P_r backscattered from an ensemble of precipitation particles in a sample volume illuminated by the radar at a distance r is related to the transmitted power P_t through the radar equation

$$P_r = P_t \frac{G^2 \lambda^2 \vartheta^2 h}{1024 \ln(2) \pi^2 r^2} \sum_{\text{Vol}} \sigma_i \tag{8}$$

where G is the antenna gain, λ the radar wavelength, ϑ the angular beamwidth, h the pulse length, and σ_i the backscattering cross-sectional area of particle i. For spherical particles of diameter D, the backscattering cross-sectional area is

$$\sigma = \frac{\pi^5}{\lambda^4} |K|^2 D^6 = \frac{\pi^5}{\lambda^4} \left| \frac{m^2 - 1}{m^2 + 2} \right|^2 D^6 \tag{9}$$

where K is a parameter related to the complex refractive index m. The value of $|K|^2$ depends mainly on the target's composition and to a lesser extent on temperature and radar wavelength. For most commonly used radar wavelengths (S, C, and X band), $|K_w|^2 = 0.93$ for water at temperatures from 0° to 30 °C and $|K_i|^2 = 0.176$ for solid ice particles at temperatures as low as −20 °C. Equation (9) is valid when the size of the sphere is significantly smaller than the radar wavelength, $D < \lambda/10$, which is known as the *Rayleigh approximation*. For spherical particles much larger than the wavelength, $D > 10\lambda$, the backscattering cross-sectional area approaches the geometric area, $\sigma = \pi(D/2)^2$, and optical scattering behavior dominates. The Mie scattering, or resonance region, falls in between the Rayleigh and optical regions. Combining equations (8) and (9) yields the radar equation for spherical particles using the Rayleigh approximation

$$P_r = P_t \frac{\pi^3 G^2 \vartheta^2 h}{1024 \ln(2) \lambda^2} \frac{|K|^2}{r^2} \sum_{\text{Vol}} D_i^6 = C \frac{|K|^2}{r^2} \sum_{\text{Vol}} D_i^6 \tag{10}$$

where the radar-specific parameters have been grouped together to form the "radar constant" C. From (10) it can be seen that radar employing shorter wavelengths are more sensitive than radar based on longer wavelengths. For example, for a given transmitted power, antenna gain, and beamwidth, a 3-cm wavelength radar will receive approximately one order of magnitude more backscattered power from a target than a 10-cm wavelength radar.

Radar Parameters

A variety of radar parameters can be defined, depending on the radar's hardware and signal processing capabilities, as presented below. Parameters based on the received power are discussed first, followed by those that are based on Doppler information. The meteorological relevance of these parameters will be exemplified in a subsequent section.

For raindrops (i.e. spherical particles) and conditions of Rayleigh scattering, a *radar reflectivity factor* Z can be defined as

$$Z = \frac{\lambda^4}{\pi^5 |K_w|^2} \int N(D)\sigma(D)\,\mathrm{d}D = \int N(D)D^6\,\mathrm{d}D \quad (11)$$

where $N(D)$ is the raindrop size distribution and D is the drop diameter with backscattering cross-sectional area $\sigma(D)$ as given in (9). The integration is performed over all diameters present in the radar sample volume. The radar reflectivity factor Z provides a measure of a storm's intensity and is related to the received power P_r through

$$Z_e = P_r \frac{r^2}{C|K_w|^2} \quad (12)$$

obtained by combining equations (10) and (11) and assuming the radar is illuminating raindrops. Because in practice we cannot be sure that the radar is looking at spherical particles or raindrops only, Z is more appropriately termed equivalent radar reflectivity factor Z_e. Z (or Z_e) is given in units of $\mathrm{mm}^6\,\mathrm{m}^{-3}$, but is often expressed in logarithmic terms as $\mathrm{dBZ} = 10\log(Z)$. Small raindrops ($D \leq 1\,\mathrm{mm}$) qualify as spherical particles, whereas bigger raindrops appear on average more elliptical, with a horizontal axis exceeding the corresponding vertical axis. The effect of elliptical drops on the radar parameters is discussed in the following paragraphs.

Electromagnetic waves are polarized (i.e. the coupled electric and magnetic fields occupy well-defined orthogonal planes) perpendicular to the direction of propagation of the wave. The radar may transmit (and receive) either linear or circular polarized waves depending on the hardware. For simplicity, we concentrate on linear polarized electromagnetic waves only and, more specifically, on waves that are either horizontally (subscript h) or vertically (subscript v) polarized. Using the Rayleigh–Gans theory enables calculation of the backscattering cross sections for ellipsoids with minor axis a (vertical) and major axis b (horizontal) as

$$\sigma_{h,v} = \frac{\pi^5}{9\lambda^4} \left| \frac{m^2 - 1}{1 + (m^2 - 1)A_{h,v}} \right|^2 D_{\mathrm{eq}}^6 \quad (13)$$

where D_{eq} is the diameter of a spherical drop of an equivalent volume, and A_h and A_v are geometrical (shape) factors defined as

$$A_v = 1 - 2A_h = \frac{1}{\varepsilon^2} \left\{ 1 - \sqrt{\frac{1 - \varepsilon^2}{\varepsilon^2}} \frac{1}{\sin(\varepsilon)} \right\} \quad (14)$$

with the eccentricity ε of the elliptical cross section given by $\varepsilon^2 = 1 - (a/b)^2$. Note that for $a/b \to 1$ (spherical), the geometric factors become $A_h = A_v \to 1/3$ and the backscattering cross-sectional areas $\sigma_h = \sigma_v \to \sigma$ as shown in (9). On the basis of this analysis, a *differential reflectivity* Z_{DR} (in decibels or dB) can be defined as

$$Z_{\mathrm{DR}} = 10\log\left(\frac{Z_{hh}}{Z_{vv}}\right) = 10\log\left\{ \frac{\int N(D_{\mathrm{eq}}) \left| \frac{m^2 - 1}{1 + (m^2 - 1)A_h} \right|^2 D_{\mathrm{eq}}^6\,\mathrm{d}D}{\int N(D_{\mathrm{eq}}) \left| \frac{m^2 - 1}{1 + (m^2 - 1)A_v} \right|^2 D_{\mathrm{eq}}^6\,\mathrm{d}D} \right\} \quad (15)$$

where Z_{hh} and Z_{vv} are the radar reflectivity factors with horizontal and vertical polarization, respectively. Note, the double subscript of Z denotes the polarization of transmission (first index) and reception (second index) – for example, Z_{hh} is the (co-polar) radar reflectivity factor obtained for both horizontally polarized transmission and reception. The differential reflectivity Z_{DR} provides a reflectivity-weighted measure of the mean shape of particles in the radar sampling volume. The physical particle shape becomes particularly visible for liquid (raindrops) or wet-coated (melting) precipitation particles. As particle density and complex refractive index m decrease, however, the true particle shapes may no longer be revealed; for example, Z_{DR} is approximately zero for dry, low-density ice particles (snow). The measurement of differential reflectivity Z_{DR} typically requires a radar to be capable of switching the polarization of the transmitted wave from pulse to pulse. The latest technological developments now allow for simultaneous transmission (and reception) at different polarizations.

The polarization properties of radar waves reflected by precipitation particles (or other targets) may be altered by the backscattering process from nonspherical or canted particles. It is of interest, therefore, to assess how much of the transmitted signal power is depolarized by backscattering from targets. This has led to consideration of the *linear depolarization ratio* L_{DR} (in dB), defined as the ratio of the received cross-polar signal power (Z_{hv} or Z_{vh}) to the co-polar power (Z_{hh}) either by

$$L_{\mathrm{DR}} = 10\log\left(\frac{Z_{hv}}{Z_{hh}}\right) \quad (16)$$

or

$$L_{\mathrm{DR}} = 10\log\left(\frac{Z_{vh}}{Z_{hh}}\right) \tag{17}$$

depending on the radar hardware. Formulation (16) is appropriate for a radar that cannot switch polarizations from pulse to pulse, while (17) requires this capability. The cross-polar (depolarized) signals are usually much lower than the co-polar signals yielding very small L_{DR} values. Elevated L_{DR} values, indicating a significant signal depolarization, are typically seen for wet tumbling oblate particles, such as melting snowflakes or hail, and ground clutter echoes.

The amount of radar echo fluctuations from pulse to pulse contains meteorologically useful information. The (zero-lagged) correlation between the time series of successive estimates of Z_{hh} and Z_{vv}, termed the *co-polar cross-correlation* $|\rho_{hh,vv}(0)|$, depends on particle shape, variability (e.g. breadth of axis ratio distribution), and orientation (canting). $|\rho_{hh,vv}(0)|$ varies from 0 to 1, with $|\rho_{hh,vv}(0)| = 1$ if all particles were identical. A reduced correlation (< 0.9) results from a mixture of particle types and shapes within the radar pulse volume such as seen in the melting layer, where melting snow aggregates and raindrops coexist. Irregularly shaped hydrometeors (e.g. hail) and particle canting angles having a probability distribution of finite width can cause lower co-polar cross-correlation signatures as well.

Doppler technology provides ground for many more radar parameters. In general, the nth moment of the (reflectivity-weighted) Doppler velocity spectrum is given by

$$\langle v^n \rangle = \frac{\int N(D)D^6 v^n(D)\,\mathrm{d}D}{\int N(D)D^6\,\mathrm{d}D} \tag{18}$$

where $v(D)$ is the size-dependent fall velocity component of particles in the direction of the radar, containing also a radial component of the three-dimensional wind field. Two widely used radar parameters are the *mean Doppler velocity* $\langle v \rangle$, the first moment of the Doppler velocity spectrum, defined as

$$\langle v \rangle = \frac{\int N(D)D^6 v(D)\,\mathrm{d}D}{\int N(D)D^6\,\mathrm{d}D} \tag{19}$$

and the *Doppler spectral width* σ_{vel} defined as

$$\sigma_{\mathrm{vel}} = \sqrt{\langle v^2 \rangle - \langle v \rangle^2} \tag{20}$$

The former indicates the (reflectivity-weighted) mean radial velocity of the hydrometeors in the radar sampling volume, while the latter provides a measure of the associated velocity dispersion and turbulence. In addition, both the mean Doppler velocity and Doppler spectral width contain valuable information for detection of (stationary) ground returns seen by ground-based radar, aiding data quality control procedures.

For Doppler radar that also incorporate polarimetric flexibility, valuable information may be obtained by measuring the difference in phase of the backscattered signals, the so-called *differential phase*

$$\phi_{\mathrm{DP}} = \phi_{hh} - \phi_{vv} \tag{21}$$

where ϕ_{hh} and ϕ_{vv} are the co-polar phase shifts at horizontal and vertical polarization accumulated over the round trip from the radar to the targets and back. At 10-cm wavelength, phase differences between horizontally and vertically polarized signals accumulate primarily as a result of the forward scattering associated with the radar signal propagating through precipitation composed of nonspherical particles. Differences in phase shifts typically grow monotonically with increasing distance from the radar and become apparent especially in intense rainfall. The range derivative of ϕ_{DP} is called the (two-way) *specific differential phase* K_{DP} (in $\mathrm{deg\,km^{-1}}$) and defined by

$$K_{\mathrm{DP}} = \frac{\phi_{\mathrm{DP}}(r_2) - \phi_{\mathrm{DP}}(r_1)}{r_2 - r_1} \tag{22}$$

where $\phi_{\mathrm{DP}}(r_1)$ and $\phi_{\mathrm{DP}}(r_2)$ are the differential phase values at range r_1 and r_2, respectively. K_{DP} shows promise for radar rainfall estimation, because it is approximately proportional to the product of liquid water content times median diameter of the raindrops present in the radar sampling volume (which is closely related to the rainfall intensity). Phase measurements are attractive because they are immune to radar calibration problems and unaffected by signal attenuation. Moreover, they appear little affected by the presence of randomly tumbling hail or partial blocking of the radar beam. However, phase differences between horizontally and vertically polarized radar returns are typically small (much smaller than phase shifts caused by target motions relative to the radar), causing ϕ_{DP} measurements to be noisy. In order to reduce uncertainty, K_{DP} should be estimated from measurements spaced over many (typically tens of) radar resolution volumes in radial direction, depending on the precipitation intensity.

Meteorological Interpretation

The *amplitude, phase*, and *polarization* of backscattered signals received by the radar are key measures containing information on the illuminated targets, such as the *size distribution* of the precipitation particles within the radar sampling volume, particle *shape* (axis ratio) and

orientation, thermodynamic *phase* (solid, liquid, or a mixture of both) and *density*, and particle *fall speed* and *behavior* (spin, wobble). In order to interpret radar signals in meteorologically useful terms, one must consider the radar signal as well as the environment in which it is obtained. For example, environmental conditions (such as temperature, humidity, wind, and turbulence, or storm electric fields) may affect both the propagation of the radar signal and the particles' shape, phase, fall behavior, and orientation.

For all practical purposes, interpretation of radar signals *relies on many assumptions* due to a lack of detailed information about the precipitation particles and environmental conditions. Nonetheless, radar observations have yielded unprecedented insight into storm structure and precipitation formation processes and have assisted in measuring rainfall on large space and time scales. The radar reflectivity factor Z provides a direct measure of the intensity of precipitation (e.g. 10, 25, 40, and 55 dBZ correspond roughly to rainfall rates of 0.1, 1, 10, and 100 mm h^{-1}, respectively; see section on precipitation measurement for details) and has been instrumental in revealing details about the three-dimensional structure and organization of clouds and precipitating storm systems. Radar observations build the basis for characterization of different types of precipitation (convective versus more widespread or stratiform rainfall) and assess their potential to cause severe damage (e.g. heavy rainfall, hail, strong winds, and tornadoes). Moreover, elaborate analyses of the three-dimensional Doppler velocity field may be used to retrieve information about the thermodynamic properties of weather systems. The purpose of this section is to highlight some of the benefits of various polarimetric and Doppler parameters for characterizing meteorological and nonmeteorological radar echoes.

Figures 1 and 3 provide a horizontal, multiparameter depiction of convective storm systems developing near the Colorado–Kansas border. A series of convective storms evolving along a frontal boundary (visible as

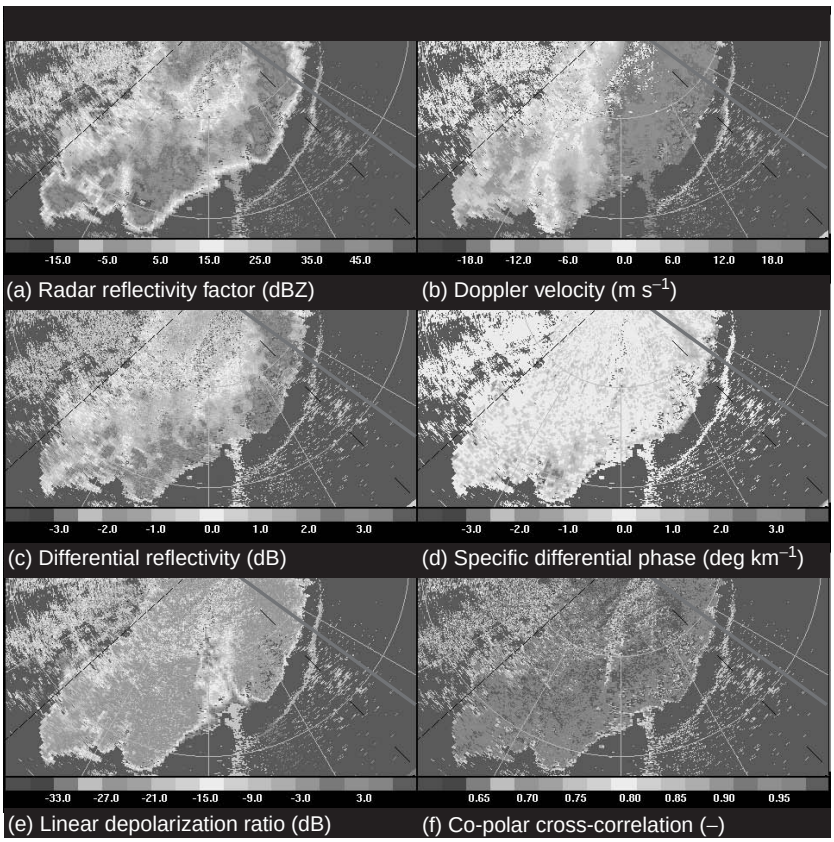

Figure 1 Pseudohorizontal cross section (surveillance scan at 0.5 degree elevation) through a series of convective storms developing at the Colorado–Kansas border, as observed by the National Center for Atmospheric Research (NCAR) multiple-polarization S-Pol radar on 11 June 2000 at 2355 UTC. Shown are (a) radar reflectivity factor Z, (b) radial Doppler velocity $\langle v \rangle$, (c) differential reflectivity Z_{DR}, (d) specific differential phase K_{DP}, (e) linear depolarization ratio L_{DR}, and (f) co-polar cross-correlation $|\rho_{hh,vv}(0)|$. Range rings are 50 km apart, and the red-outlined azimuth indicates the direction of the vertical cross section shown in Figure 2. Figure 2 Vertical cross section in the direction of 126 degree azimuth through storms shown in Figure 1. The same parameters are shown as in Figure 1. Range rings are 20 km apart. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

thin low-intensity line ahead of the convective storms) is shown in Figure 1. The corresponding vertical cross section through that storm system is shown in Figure 2. This type of organized convection is also known as *squall line*, exhibiting a leading line of intense and deep convective cells, trailed by more moderate widespread rainfall with a layered (stratified) structure – hence the name stratiform precipitation. The thin horizontal line of enhanced backscatter seen approximately 2.5 km above ground in the vertical cross section (to the left in Figure 2a) marks the so-called *bright band* that indicates the melting layer. This enhancement in radar reflectivity factor is a consequence of the increased likelihood of aggregation of snow particles near the 0 °C level (resulting in larger particles) and the approximately a factor-of-five increase in backscattering intensity (caused by a larger complex refractive index m) as the particles begin to melt and become wet coated. The large snow aggregates will eventually collapse into smaller raindrops upon complete melting. Moreover, because raindrops fall faster than snowflakes, these particles tend to spread out quickly in the vertical decreasing the precipitation particle number density in the radar sampling volume and thus, combined with the reduced particle size, decrease the backscattered signal strength. Figure 2(a) shows fall-streaks within the stratiform portion of precipitation visualizing the vertical shear in the environmental flow, as depicted in Figure 2(b) (note the red colors near the ground indicating flow away from the radar and in green above that flow towards the radar).

The storm depicted in Figures 3 (horizontal cross section) and 4 (vertical cross section) shows a severe, potentially long-lasting convective storm *(supercell)* that may produce heavy rainfall and damaging hail, strong winds, and often tornadoes. This storm was also triggered by a frontal boundary visible ahead of the convective storm. The vertical cross section of this supercell storm (Figure 4a) is markedly different from the vertical cross section through the squall line (Figure 2a). Supercells exhibit a characteristic overhanging intense updraft core (shown in gray indicating radar reflectivity factors in excess of 57 dBZ) where large particles may be suspended and carried aloft (note the storm-relative upsloping flow into that core of high reflectivity in Figure 4b), and potentially get recycled. In this case, precipitation particles grow through collection of supercooled

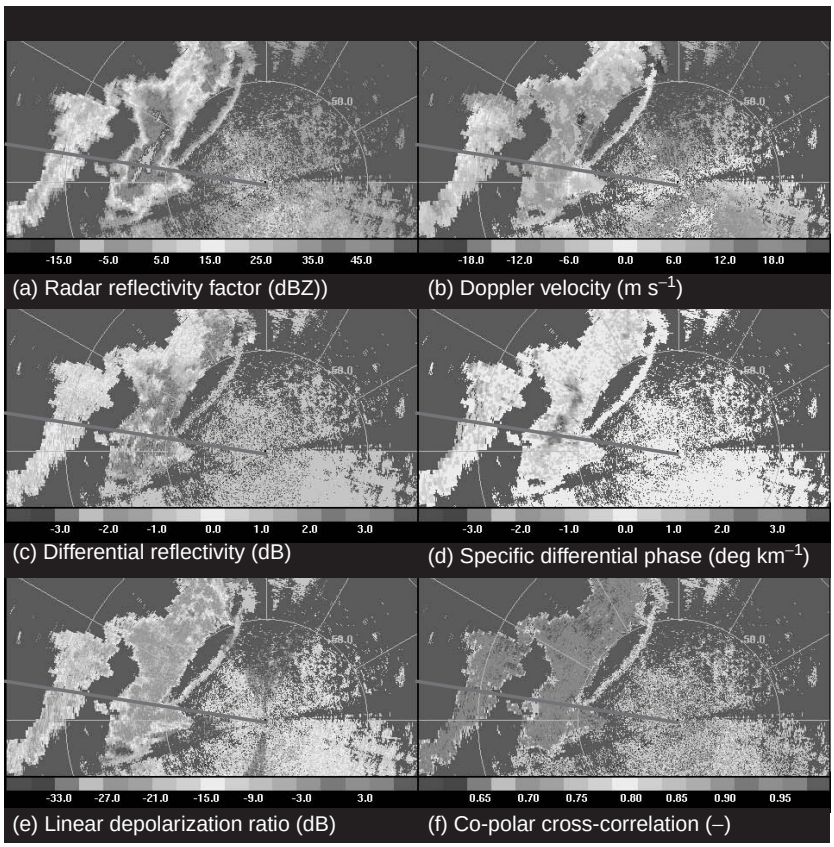

Figure 3 Pseudohorizontal cross section (surveillance scan at 0.5 degree elevation) through convective storms developing at the Colorado–Kansas border, as observed by the NCAR multiple-polarization S-Pol radar on 22 June 2000 at 2315 UTC. The same parameters are shown as in Figure 1. Range rings are 50 km apart, and the red-outlined azimuth indicates the direction of the vertical cross section shown in Figure 4. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

water droplets that freeze onto the already frozen ice particles (a process called *accretion* or *riming*) and thus may grow into high-density graupel or large hailstones. Details about the dynamics and microphysics of such storms may be found in textbooks by Houze (1993) or Doswell (2003).

In contrast to the radar reflectivity factor, the differential reflectivity Z_{DR} is independent of the radar constant (e.g. radar calibration) and is a good measure of the (reflectivity-weighted) mean axis ratio of particles. This parameter is not very sensitive to the particle size distribution. As the density and index of refraction of the particles decrease, the radar reflectivity factor (at any polarization) becomes weaker and less sensitive to shape and orientation, causing the differential reflectivity to approach zero. Therefore, Z_{DR} provides valuable information to distinguish solid (ice) from liquid (rain) particles and aids in quantitative rainfall estimation. The largest values of Z_{DR} (3–5 dB) are associated with individual big raindrops falling from the leading edge of storms or may be found towards the bottom of the melting layer in stratiform precipitation, where a high refractive index is compounded by a large axis ratio of water-coated (wet), melting snowflake aggregates just before collapsing into raindrops.

The big raindrop Z_{DR} signature can be clearly seen in the horizontal cross sections through the squall line (Figure 1c) and the supercell (Figure 3c), associated with regions of high value of radar reflectivity factor. In the vertical cross sections, the distinction between ice (low Z_{DR} values) and rain (moderate to high Z_{DR} values) is very pronounced, and a bright band signature is also recognizable in the stratiform portion of the squall line precipitation (Figure 2c). A core of low Z_{DR} value all the way to the ground is visible in the vertical cross section through the supercell storm (Figure 4c, range 57 km). This low Z_{DR} core associated with high radar reflectivity factor is characteristic for significant hail falling out of the storm. The high Z_{DR} values seen under the overhang, in contrast, are likely produced by smaller hail and graupel that melt and reach the surface as big raindrops. Note also the velocity folding signature at the top of the anvil in Figure 4(b), where the colors go from blue through purple into the red and yellow shades.

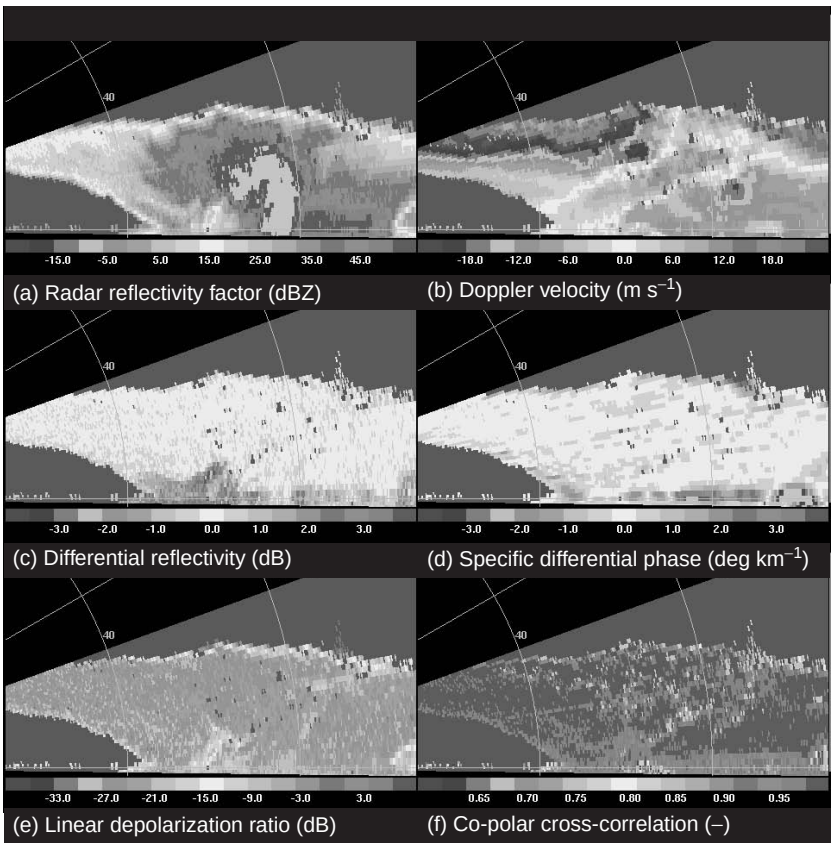

Figure 4 Vertical cross section in the direction of 279 degree azimuth through storms shown in Figure 3. The same parameters are shown as in Figure 1. Range rings are 20 km apart. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Observations and simplified analytical analyses have revealed that increased linear depolarization ratios L_{DR} occur when spheroidal hydrometeors fall with their major or minor axis neither aligned nor orthogonal to the polarization of the transmitted radar signal. Moreover, irregular-shaped hydrometeors and wobbling high-density particles that display a distribution of canting angles tend to cause signal depolarization, especially when they are wet. The lowest measurable signal depolarization is typically on the order of −30 dB or less. Elevated L_{DR} values (−20 dB or higher) are seen for wet ice particles in the melting layer or for large wet hail due to the increased refractive index. The linear depolarization ratio therefore appears to be a good indicator for the fall behavior of particles and particularly for wet (melting) ice particles.

The melting signature of L_{DR} can easily be recognized in the vertical cross sections of the squall line's stratiform precipitation (Figure 2e). The highly elevated L_{DR} values under the overhang of the supercell (Figure 4e) suggest melting of smaller hail and graupel particles (consistent with Z_{DR} features), although a potential contamination from antenna sidelobe effects in the low-reflectivity zone may have to be considered. A melting signature is also visible in the co-polar cross-correlation $|\rho_{hh,vv}(0)|$, for example, associated with the melting layer depicted in the vertical cross section of the squall line (Figure 2f), where partially melted large snow aggregates coexist with smaller raindrops resulting from ice particles that have already completely melted.

Radial Doppler velocity has been widely used to derive vertical profiles of the horizontal wind field, detect shearing winds, storm outflow, and frontal boundaries, and strong rotational signatures such as tornadoes. Doppler spectral width is used less commonly, but may indicate strong turbulence. Analyses based on a single Doppler radar may have to rely on significant assumptions about the homogeneity of the wind field, while data collected by multiple Doppler radar illuminating the same volume in space and time can yield quite detailed information about the three-dimensional wind (and thermodynamic) field. Differential phase and especially the specific differential phase observations have shown some value for rainfall measurement, particularly for higher intensities (see the associated signatures in Figures 1d and 3d, and Figures 2d and 4d, respectively), in the presence of hail within the radar sampling volume, or regions of partial beam blockage.

Table 2 Typical radar parameter values for various types of precipitation particles and nonmeteorological targets as observed at 10-cm wavelength

Particle type	Z_{hh} [dBZ]	Z_{DR} [dB]	$\lvert\rho_{hh,vv}(0)\rvert$	K_{DP} [deg km^{-1}]	L_{DR} [dB]
Drizzle	<25	0	>0.99	0	< −34
Rain	25 to 60	0.5 to 4	>0.97	0 to 10	−34 to −27
Snow, dry low density	<35	0 to 0.5	>0.99	0 to 0.5	< −34
Crystals, dry high density	<25	0 to 5	>0.95	0 to 1	−34 to −25
Snow, wet melting	<45	0 to 3	0.7 to 0.95	0 to 2	−18 to −13
Graupel, dry	40 to 50	−0.5 to 1	>0.99	−0.5 to 0.5	< −30
Graupel, wet	40 to 55	−0.5 to 3	>0.99	−0.5 to 2	−25 to −20
Hail, small <2 cm wet	50 to 60	−0.5 to 0.5	>0.95	−0.5 to 0.5	< −20
Hail, large >2 cm wet	55 to 70	< −0.5 to >3	>0.96	−1 to 1	−15 to −10
Rain and hail	50 to 70	−1 to 1	>0.9	0 to 10	−20 to −10
Ground clutter	10 to 70	−5 to 5	<0.7	0	> −10
Clear air and insects, birds	<25	−3 to 10	<0.5 to 0.8	0	> −10

Besides precipitation echoes, Figures 1 and 3 also show radar returns from clear air and ground targets. For example, ground clutter echoes are recognizable behind the squall line storm (top left corner of panels) by their moderate to high yet noisy reflectivity signature (Figure 1a) and zero radial velocity (Figure 1b). The weak clear air returns from a deep boundary layer depict the approximately south-southeasterly environmental flow field (Figure 3b) ahead of the supercell storm – note the change in color at the radar location from green (towards radar) to yellow (away from radar). There are also some embedded ground clutter echoes recognizable within 25-km range from the radar by their elevated backscatter (Figure 3a) and corresponding zero radial velocity (Figure 3b). Moreover, note the values of differential reflectivity ($Z_{DR} > 4$ dB, shown in gray), linear depolarization ratio ($L_{DR} \geq -10$ dB), and co-polar cross-correlation ($|\rho_{hh,vv}(0)| \ll 0.9$) within the boundary layer that differ markedly from the signatures associated with precipitation echoes. These radar signatures are typical for boundary layer air that is heavily contaminated by insects.

Values that are commonly observed for these radar parameters are compiled in Table 2. This information can be used to design algorithms for precipitation particle type identification and recognition of nonmeteorological radar echoes. Applications thereof range from cloud physics to rainfall estimation and from radar data quality control to hazardous weather detection for aviation safety, and radio communication. In addition, entomology and ornithology may benefit from polarimetric radar measurements.

PRECIPITATION MEASUREMENTS AND ASSOCIATED UNCERTAINTIES

Radar Rainfall Measurement

The radar reflectivity factor Z (mm^6 m^{-3}), defined by (11), is highly correlated with the rainfall rate R (mm h^{-1}), expressed as

$$R = \frac{6\pi}{10^4} \int N(D) D^3 v(D)\, \mathrm{d}D \tag{23}$$

where $v(D)$ represents the vertical fall velocity (m s^{-1}) of a raindrop of size D (mm). Both Z and R depend on the raindrop size distribution $N(D)$ (mm^{-1} m^{-3}), albeit weighted by a different power of the drop diameter. Raindrop spectra can be described by a gamma distribution of the form

$$N(D) = N_0 D^{\mu} \exp(-\Lambda D) \tag{24}$$

where N_0, μ, and Λ are three coefficients that scale the number concentration of drops, curvature (shape), and slope of the drop size distribution. The relationship between the radar reflectivity factor Z and rain rate R is conveniently expressed by a power-law form

$$Z = \alpha R^{\beta} \tag{25}$$

The coefficients α and β depend on the raindrop size distribution and range approximately $100 < \alpha < 1000$ and $1 < \beta < 1.8$. Typical values are $\alpha = 300$ and $\beta = 1.5$. For certain rainfall conditions, these coefficients can be interpreted in terms of the number density of drops and a characteristic drop size. However, for most situations the relationship (25) is merely of a statistical nature – that is, $\langle Z \rangle = \alpha \langle R \rangle^{\beta}$ where the $\langle\rangle$s denote expectations. This is particularly true for empirically derived relationships between radar reflectivity factor and rainfall rate. Typically, α and β vary from storm to storm, but can vary also within storms. Convective rainfall, for example, exhibits significantly different drop size distributions than stratiform rainfall, as reflected by the drop number density (Figure 5c) and mean drop size (Figure 5d). Distinct differences in raindrop spectra have also been found between oceanic and continental precipitation regimes. This great variability in

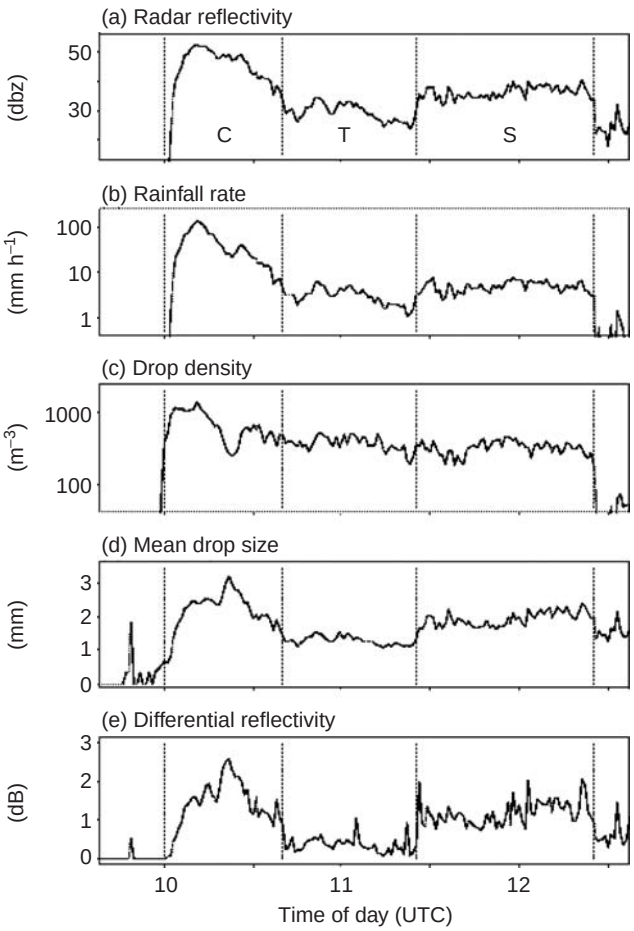

Figure 5 Depiction of a squall line moving over the Goodwin Creek research watershed in northern Mississippi on 27 May 1997. Shown are (a) the radar reflectivity factor, (b) rainfall rate, (c) drop number density, (d) mass-weighted mean drop size, and (e) differential reflectivity, as derived from raindrop size distributions collected by a Joss-Waldvogel disdrometer. This storm was characterized by three distinct phases: a convective leading line (C), a period of stratiform rainfall (S), and a transition (T) from one into the other

drop size distribution resulted in a myriad of $Z-R$ relations reported in the literature (e.g. see Battan, 1973) and may cause appreciable uncertainty (30–50%, sometimes more) in radar-based rain rate estimates. In addition, the conversion of the radar-measured reflectivity factor (a state parameter) into a rainfall rate (a flux parameter) is affected by vertical air motions. For example, an updraft of $2\,\mathrm{m\,s^{-1}}$ may cause a 50% overestimate and, conversely, a downdraft of $2\,\mathrm{m\,s^{-1}}$ may result in a 25% underestimate of the rainfall rate. Because regions of significant up- and downdrafts tend to be spatially and temporally limited, however, such air-motion related uncertainties are often neglected.

For practical purposes, especially operational applications of radar rainfall estimation, a climatological (i.e. default) $Z-R$ relationship is often used to retrieve rain rates from the observed radar reflectivity factor, and the radar-estimated rainfall amounts are subsequently adjusted based on contemporaneous rain gauge observations. This adjustment should take place only after all other corrections (e.g. calibration, attenuation, vertical structure) have been accommodated as necessary or possible. Various methods have been proposed to accomplish this merging of radar and rain gauge information, and it may be done on different space and time scales depending on the application. However, comparably little difference remains among the results based on various adjustment procedures once the mean difference (bias) between the collocated radar rainfall estimates and the gauge observations has been removed. The effect of space and time differences in the radar and gauge observations is very significant on short time scales but diminishes with increasing averaging (i.e. time integration). Under good (i.e. research) conditions, the root-mean-square (*RMS*) differences between gauge-adjusted radar-estimated and gauge-measured rainfall amounts may be as low as 10–20% on a storm-total or daily time scale. The *RMS* differences for operationally obtained radar rainfall estimates, in contrast, may amount to a factor of two or three. *RMS* differences typically increase with increasing spatial and temporal variability of precipitation, and decreasing time integration.

The advent of polarimetric radar observations has enabled new approaches to the radar rainfall measurement. The promise has been that additional radar parameters are obtained that yield information useful for reducing the uncertainty compared to rainfall estimates based on a single parameter (i.e. Z). For example, the combination of radar reflectivity factor Z and differential reflectivity Z_{DR} observations allows for estimation of two coefficients of the raindrop size distribution (24): Z_{DR} provides an estimate of the mean raindrop size in the radar sampling volume (see Figures 5d and 5e), while Z assists in deriving the drop number density. This appears to work particularly well under the assumption of exponential ($\mu = 0$) raindrop size distributions, but has also been used for gamma distributions, although the distribution shape factor μ must be specified (values of μ typically range from 2 to 10). Recent results based on using an additional constraining relationship between the curvature μ and slope Λ of gamma raindrop size distributions demonstrate that pretty reliable raindrop spectra and associated rainfall estimates can be obtained.

Alternatively, the specific differential phase K_{DP} has shown promise for rainfall estimation, especially for high rain rate conditions, when randomly tumbling hail may be present in the radar sampling volume, or under partial beam blockage. A combination of three approaches may be applied, therefore, where rainfall is estimated from radar reflectivity factor Z, differential reflectivity Z_{DR}, and

specific differential phase K_{DP} with increasing weight on the polarimetric radar parameters for increasing precipitation intensity. The respective empirical relationships, however, contain coefficients that may need to be tuned for a given situation, similar to the coefficients in (25). Moreover, the polarimetric radar parameters Z_{DR} and K_{DP} are not fully independent and rely on a number of assumptions about the raindrops, such as their shape with size (axis ratio), orientation and oscillation about the mean state, and fall behavior in a highly dynamic environment. For rainfall estimation purposes, therefore, the added complexity of the measurement and the achievable accuracy may offset the potential benefits of the additional information available. For example, measurement accuracies of $\leq$1 dBZ for the radar reflectivity factor Z, 0.1–0.2 dB for the differential reflectivity Z_{DR}, and $\sim$0.5–1deg km^{-1} for the specific differential phase K_{DP} are needed for rainfall rate estimates to be accurate to approximately 25%. Such accuracies for Z_{DR} and particularly K_{DP} are difficult to achieve. Nonetheless, these parameters may provide valuable information to constrain the rainfall retrieval. Moreover, the polarimetric radar capability pays off in terms of data quality control (e.g. radar calibration, attenuation correction, ground return detection) and identification of precipitation type (including hail discrimination and bright band detection).

Uncertainty of Radar Rainfall Estimates

Variability in raindrop size distribution and vertical air motion cause uncertainty in radar-estimated rainfall amounts, as discussed in the previous section. Although this may be a significant uncertainty, other sources of uncertainty can be much larger. For example, no matter how sophisticated the radar measurements are, they are always affected by the propagation of electromagnetic waves and the *earth's curvature*. Significant gradients in atmospheric humidity, temperature, and pressure may result in nonstandard propagation of electromagnetic waves, causing the radar to "look" at a different altitude above the earth's surface than anticipated. Although the radar signal may intersect ground targets (e.g. trees, buildings, or the terrain) at known locations, *anomalous propagation* may significantly increase ground returns in unexpected places. Furthermore, ground clutter echoes caused by anomalous signal propagation may have an appearance similar to real precipitation echoes, though typically only the lowest elevation scans are contaminated. Automated recognition of such contamination in radar reflectivity data remains a challenge today. One of the great benefits of polarimetric radar information is its value for radar data quality control: nonmeteorological radar echoes (e.g. ground clutter, insects, or birds) are non-Rayleigh scatterers exhibiting signatures significantly different from precipitation (see Figures 1 and 3).

Even under standard propagation conditions, the radar beam widens with increasing distance from the radar (i.e. the radar sampling volume increases) and the center of the beam increasingly rises above the ground, eventually intercepting the melting layer and entering the ice phase of a precipitating cloud system. This may result in *inhomogeneous beam filling* effects or possibly the overshooting of shallow echoes at far ranges. Therefore, the radar information seen aloft must be related to surface rainfall by considering the *vertical structure* of precipitation. A coarse resolution of radar observations at greater ranges prevents obtaining vertical structure information locally though. In this case, one may resort to using a "typical profile" for the anticipated type of precipitation (e.g. convective or stratiform). The radar reflectivity can decrease appreciably with height (up to 8 dB km^{-1}), depending on the type of precipitation. Significant vertical gradients are typically observed in stratiform rainfall, where the reflectivity decreases rapidly with height above the melting layer (i.e. bright band). Weaker gradients are normally seen in deep and intense convective cores, although in a very moist environment effective growth of precipitation particles occurs at low levels that the radar may not capture at farther ranges. Significant evaporation below cloud base can result in negative gradients at lower levels. Accounting for the vertical structure (to the extent possible) when relating radar observations made aloft to surface rainfall is thus very important.

Other concerns relate to the visibility of the radar and the stability of the radar hardware. Major terrain features or obstructions close to the radar can block the radar's view thus creating blind sectors, where no observations can be obtained – at least at lower elevations. Clever placement of the radar is key to guarantee coverage of a desired area although it may be difficult in complex terrain. *Visibility* is of greater importance in site selection than ground clutter concerns – modern signal processing techniques can be used to account for clutter problems, but little can be done to retrieve precipitation echoes in radar-blind sectors. In the latter case, one may have to resort to observations made at some altitude above the ground and relate them to surface rainfall by using information about the precipitation's anticipated vertical structure, as mentioned before.

Stability of the radar hardware is crucial to quantitative radar measurements. Systematic radar calibration offsets can be detected and corrected (e.g. through internal consistency checks using redundant polarimetric radar information), but if the hardware (e.g. transmitted power) varies with time, it is much more difficult. Modern radar systems, therefore, monitor the various components for quality assurance. Well-calibrated radar systems may be accurate to within 1–2 dB and achieve a measurement precision on the order of 1 dB or less. Note that for a typical $Z - R$ relationship, $Z = 300R^{1.5}$, 1.5 dB uncertainty in Z

translates into 1 dB uncertainty in R, which is approximately 25%.

In precipitation-free regions, attenuation due to atmospheric gases (oxygen and water vapor) should be considered. The magnitude of such attenuation accumulated over some distance may be comparable to the accuracy of the radar reflectivity measurements. *Attenuation* of the radar signal as it travels through rain is another source of uncertainty that is particularly relevant for shorter ($\leq$5 cm) wavelengths. Severe signal attenuation (>20 dB) can be caused by intense rainfall (>100 mm h^{-1}) observed at X-band wavelengths, especially when melting high-density ice is present in the radar sample volume. This is demonstrated, for example, in the vertical cross section of radar reflectivity factor (Figure 6b) through a squall line approaching the radar (the horizontal view is depicted in Figure 6a). The corresponding Doppler velocity (Figures 6c and 6d) and spectral width fields (Figures 6e and 6f) are displayed as well. Significant attenuation (and possibly shifts in signal phase) may also occur at the radar itself, when the radome (i.e. the antenna cover) is coated by a variably thick film of water during heavy rainfall. Weaker attenuation (<5 dB) by intervening rainfall may possibly be corrected, but wet radome attenuation is rather difficult to account for. Signal attenuation affects particularly the radar reflectivity factor measurements. Moreover, the difference in attenuation between horizontally and vertically polarized reflectivity observations can be significant at shorter wavelengths (e.g. C and X band) and thus affect the differential reflectivity measurements as well. These are some of the reasons why shorter wavelength radars are less often used for operational rainfall estimation.

If the received radar signals from melting particles or hail, or ground targets, are used for rainfall retrieval, a significant overestimation may result. In contrast, improper conversion of radar signals from the snow phase to rainfall will cause underestimation. (The quantitative measurement

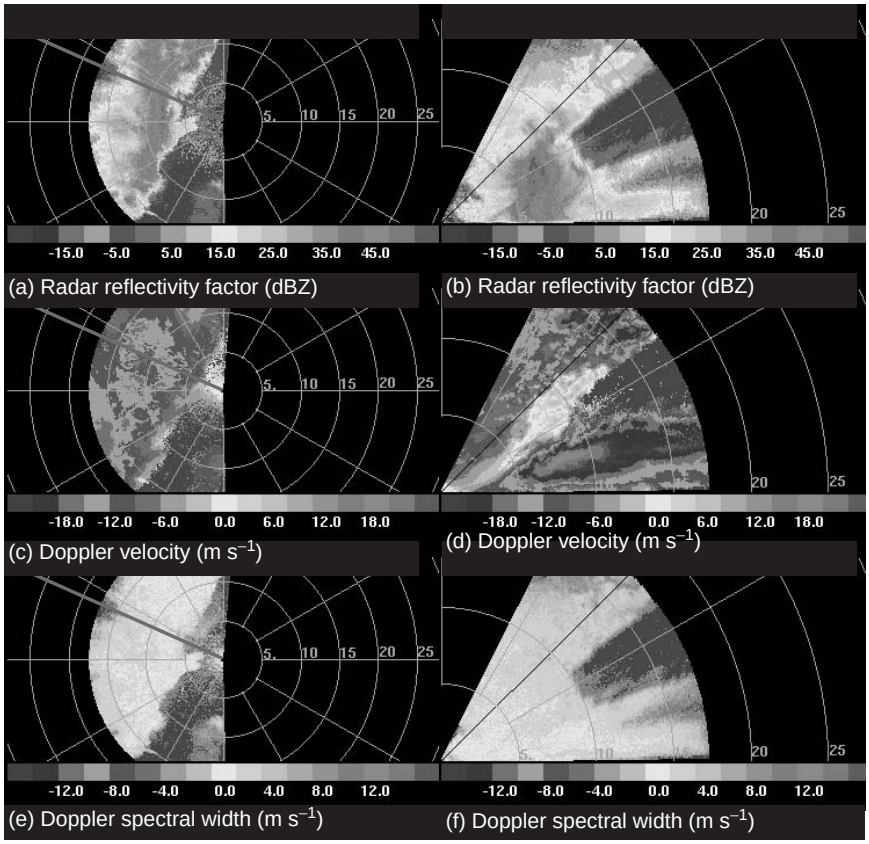

Figure 6 Horizontal (left panels) and vertical (right panels) cross sections through an intense line of convection passing over the Goodwin Creek watershed in northern Mississippi, as observed by the University of Oklahoma Doppler-on-Wheels (DOW) mobile X-band radar on 4 April 2001 at approximately 2314 UTC. Shown are the radar reflectivity factor Z (top panels), radial Doppler velocity $\langle v \rangle$ (middle panels), and Doppler spectral width σ_{vel} (bottom panels). Range rings are 5 km apart, and the red-outlined azimuth in the left panels indicates the direction of the vertical cross section shown in the right panels. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

of snowfall is much more complex than that of rainfall, because of the variable density of ice particles and their great range of shapes and sizes.) The polarimetric capabilities of modern radar can alleviate some of these problems through a classification of the dominant precipitation particle type present in the radar sample volume. Other, less frequent problems can arise from nonmeteorological targets such as birds or artificial targets (e.g. chaff dispersed by military actions).

USE OF RADAR FOR HYDROLOGIC APPLICATIONS

Ground-based radar measurements have provided a wealth of information about precipitation systems, how they evolve and organize themselves. Advances in Doppler and polarimetric radar technology have yielded unprecedented insight into the dynamics and microphysics of precipitation formation. However, the technology and knowledge transfer from research to operational applications has been slow. It comes at no surprise, therefore, that most radar-based rainfall estimation still heavily relies on simple $Z-R$ relationships to obtain rainfall rate estimates from reflectivity observations. It is not uncommon for such rain rate estimates, made at spatial and temporal resolutions of $1-2$ km and $5-10$ min, to be uncertain by up to a factor of two or more. Operational radar rainfall estimation is particularly challenging, because only a limited amount of rain gauge information may typically be available in real time for comparison to the radar rainfall amounts.

On the other hand, radar measurements of rainfall have had a substantial impact on hydrologic applications, such as (flash) flood monitoring and warnings. Unlike typical coarse rain gauge networks, radar observations can reveal the significant variability of rainfall over spatial scales of only a few kilometers that is often associated with extreme weather events. The spatial and temporal organization of rainfall, and the motion of storms relative to watersheds play a fundamental role in the *hydrologic response* of a basin. For example, a large fractional coverage of high rainfall rates for durations corresponding to the basin response time will result in maximum river peak discharges. Also, storm motion relative to a catchment may either amplify or dampen a flood wave, depending on whether the storm moves down the basin or in upstream direction, respectively. Algorithms exist for operational identification and tracking of storm cells, and the resulting rainfall centroids and storm motion vectors may be overlaid on topographic and hydrologic information using GIS-based software. Moreover, radar rainfall estimates are ingested to spatially distributed hydrologic models for runoff and river discharge predictions.

Looking ahead, the anticipated upgrade of the U S network of operational weather radars to incorporate polarimetric capability will facilitate adaptation of advanced Doppler and polarimetric technology into the operational arena.

Acknowledgments

The writing of this review was supported by the National Science Foundation (NSF) through Grants EAR-9909696, ATM-9906012 and ATM-0223798, and the National Aeronautics and Space Administration (NASA) Earth Science Enterprise through Grants NAG5-9891 and NAG5-13624. The thoughtful comments and suggestions by Drs. Anthony Illingworth, Edward Brandes, and Remko Uijlenhoet are greatly appreciated.

64: Satellite-based Estimation of Precipitation Using Microwave Sensors

GEORGE J HUFFMAN

Science Systems and Applications, Inc. and NASA/Goddard Space Flight Center Laboratory for Atmospheres, Greenbelt, MD, US

Satellite-borne sensors provide critical input to estimating precipitation over the vast majority of the Earth's surface that lacks adequate in situ observing systems. This article reviews the legacy of sensors, satellites, and data archives that have accrued throughout the Space Age, and that largely governs the precipitation estimates that are available to the hydrological community, both currently and over the long term. Tables of publicly available, quasi-global, satellite-based precipitation data sets are introduced, examples are provided, data quality is considered, and future prospects are outlined. One major theme throughout the article is to raise the key issues that users should consider in determining whether a particular set of precipitation estimates is appropriate for their particular application.

INTRODUCTION

Precipitation is one vital input to numerous hydrological studies and applications, yet extensive research is still needed to establish accurate global estimates of the mean and time-dependent record of precipitation (see Figure 1). Precipitation has strong small-scale variability and highly nonnormal statistical behavior, which makes it much more difficult to characterize than, for example, atmospheric temperature. Such attributes require frequent, closely spaced observations to accurately quantify the precipitation pattern, but these requirements cannot be met by surface-based observations over much of the globe, particularly in oceanic, remote, and developing regions. In response, atmospheric scientists have developed a variety of satellite-borne sensors to obtain the requisite information for estimating precipitation on a global basis. As researchers have gained experience with the individual sensors and the performance of single-sensor algorithms for estimating precipitation, they have increasingly moved to using combinations of sensors for improved accuracy, coverage, and resolution. This article focuses on publicly available, quasi-global, operational data sets that are the most likely to be widely useful for hydrological research and applications. None of the current data sets satisfies requirements for both fine-scale space/time detail and a long continuous record. Fortunately, recent and planned developments in the recovery of old data sets and additions to the fleet of satellite sensors promise to enrich the available precipitation database in the early twenty-first century.

SATELLITES, SENSORS, AND DATA

Satellites have been used as platforms for the remote sensing of hydrologically relevant data since the dawn of the Space Age. The first Television-Infrared Observation Satellite (TIROS-1) was launched by the United States in April 1960, providing the first global images of clouds. TIROS already exhibited many characteristics of modern meteorological satellites. Its orbital plane was nearly perpendicular to the Equator (a "polar orbit") and the orbital altitude was relatively low ("low earth orbit" or LEO), causing TIROS to circle the globe about every 90 min. From this vantage point, TIROS could only see a small portion of the globe at any one time, but viewed most of the Earth's surface over the course of 12 h (either on the ascending or descending part of the orbit). TIROS imaged the Earth in visible and infrared (IR) frequency bands that are not

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

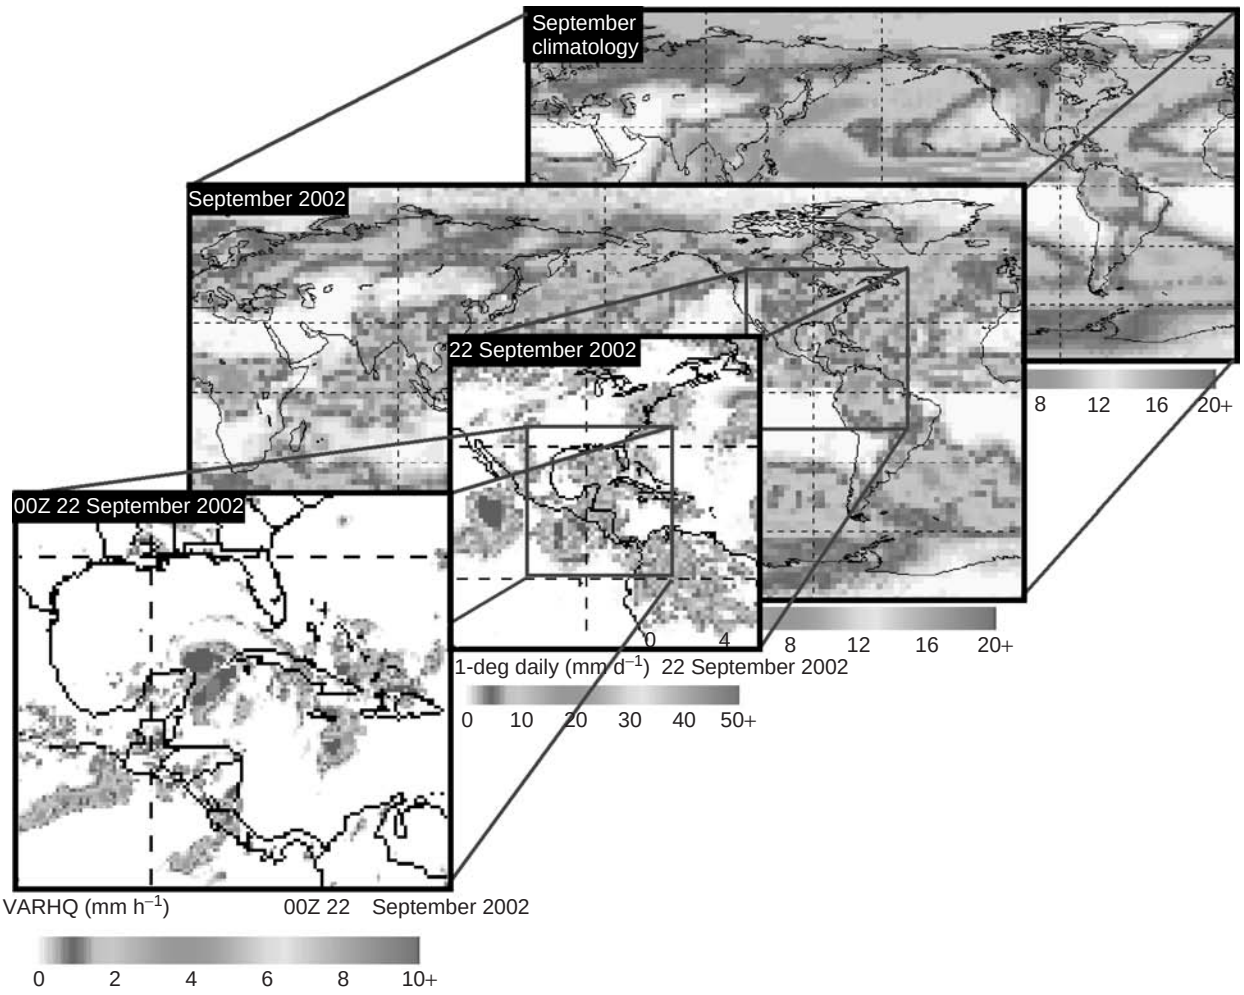

Figure 1 Examples of modern global precipitation estimates at various time resolutions: September Climatology from GPCP Monthly SG, September 2002 from GPCP monthly SG, 22 September 2002 subsetted from GPCP 1DD, and 00Z 22 September 2002 subsetted from TRMM 3B42RT. See Tables 2 and 3 for product details. Hurricane Isadore is located off the tip of the Yucatan peninsula at 00Z 22 September 2002. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

strongly affected by atmospheric effects, other than clouds and dust (so-called "window channels"). Finally, the sensor was "passive", recording the radiant energy that was emitted (IR) or reflected (visible) by the Earth's surface, then modified by a scene-dependent sequence of reflection (for visible), emission, and scattering by atmospheric constituents, including clouds, as the energy upwelled toward the satellite.

Another important milestone for precipitation work came with the launch of the first geostationary Earth orbit (GEO) meteorological satellite in 1974 by the United States. A GEO satellite orbits some 35 400 km above the Equator and takes a day to circle the Earth, so its motion is synchronous with a fixed point on the Earth's surface. Further, notable firsts include the first passive microwave-frequency sensor in 1972, and the first active microwave instrument (i.e. radar) in late 1997 on board the Tropical Rainfall Measuring Mission (TRMM). Interested readers may consult Kidd (2001) for an excellent summary of satellite sensor development related to precipitation. This five-odd decades of work has produced a legacy of sensors, satellites, and data archives that critically governs the precipitation estimates that are available to the hydrological community.

Sensors

Precipitation-related satellite sensor development work has historically focused on just a few channels in the electromagnetic spectrum (*see* **Chapter 47, Sensor Principles and Remote Sensing Techniques, Volume 2**):

IR

The IR channel around 11 microns is a window channel, typically showing the surface, except when clouds are present. Most clouds are optically thick in the IR, meaning that they are very effective at absorbing upwelling radiant energy, which is then reemitted with energy levels characteristic of the temperature of the emitters. This measured energy is termed the *brightness temperature* (T_b). As a result, IR mostly reveals the presence and temperature (and so, implicitly, the height) of clouds. (Typically, temperature is a decreasing function of height in the troposphere, so the IR-estimated cloud temperature can be related to cloud-top height.) For sufficiently large time-space averages, high-level cloudiness is well-correlated to precipitation in the tropics, but the correlation declines dramatically for averages covering less than $2.5° \times 2.5°$ of latitude/longitude and 12 h (Richards and Arkin, 1981; Arkin, 1979). Furthermore, outside the tropics, the occurrence of dense, nonprecipitating cirrus in frontal zones makes the IR-rainfall relationship considerably less reliable for estimating precipitation.

Visible

The visible channel is similar to IR in responding to the surface and cloud tops, but the radiant energy involved is reflected sunlight, rather than emission by the Earth's surface and atmosphere. This reflectance is a complicated function of the viewing and solar illumination angles, and is limited to daylight hours. At present, there are no routinely operational precipitation algorithms that use visible data.

Passive Microwave at ''Emission'' Frequencies

Channels located at passive microwave (PMW) frequencies at and below 37 GHz mostly respond to radiant energy emitted by the Earth's surface, and modified by cloud water and liquid hydrometeors within the intervening atmosphere. Information on the atmosphere's liquid water content is closely related to liquid precipitation at the surface, and is preferable to either IR or the PMW scattering channels (below). The main limitation at these frequencies is that a useful retrieval is only possible when the Earth's surface within the given satellite field of view is entirely covered by water, which has a relatively low and uniform emissivity. Any land or surface ice produces surface emissivities that are higher and exhibit such strong heterogeneities that quantitative precipitation estimates are not currently possible.

Passive Microwave at ''Scattering'' Frequencies

Channels located at PMW frequencies above 37 GHz exhibit emission signals similar to the lower frequency channels over nonprecipitating regions, but once clouds start to develop precipitation-sized frozen hydrometeors, the ice strongly scatters the upwelling radiant energy out of the line of sight of the sensor. This produces a characteristic low T_b embedded in a higher-T_b region. Frozen hydrometeors have a better instantaneous relationship to surface precipitation than IR T_b's, but the relationship is generally not as good as for the liquid hydrometeors sensed by emission channels. Scattering signals are not significantly degraded by land surface in the pixel's field of view, but surface ice (including frost) prevents reliable retrievals whenever such conditions occur.

Passive Microwave at ''Sounding'' Frequencies

The PMW channels chosen to retrieve soundings, that is, to estimate vertical profiles through the atmosphere, saturate in the atmosphere and (mostly) cannot see the surface. Thus, sounding channels do not suffer the same surface effects as the other PMW channels. Sounding channels generally employ frequencies close to water vapor absorption bands and respond to the presence of hydrometeors, making it possible to infer precipitation in snowy situations. Such channels began to enter operational use for estimating precipitation in the early 2000s.

Radar

In contrast to the integrated signal that passive devices sense, active devices such as radar send out short pulses of energy at one or more specified frequencies, creating return signals that have information about conditions at different distances from the remote sensor. Until recently, the power and antenna requirements for radars were not considered economically practical on meteorological satellites. The current state of satellite-borne radar technology only provides a narrow swath of data that is primarily useful for calibrating other sensors' precipitation estimates, for accumulating climatological statistics, and for providing detailed views of specific events that a radar overpass happens to catch.

Satellites

The legacy of satellite types and sensors is the second factor governing precipitation estimation. An unbroken record of IR data from LEO satellites is available from 1979 to the present, principally from the United States National Oceanic and Atmospheric Administration (NOAA) series, with contributions from China and Russia. IR observations from GEO satellites started in earnest in 1981, with nearly full coverage beginning in 1983 from an international constellation provided by Europe, Japan, and the United States The primary shortfall was a persistent gap over the Indian Ocean sector until mid-1998, and various temporary outages for other regions caused by the failure of individual sensors.

A nearly continuous record of PMW scattering and emission channels starts in mid-1987 with the United States Special Sensor Microwave/Imager (SSM/I), which has been carried aboard the Defense Meteorological Satellite Program (DMSP) platforms. Starting in the late 1990s

additional PMW sensors were launched, as well as the TRMM Precipitation Radar (PR).

All of the preceding development work has yielded an unprecedented set of global observations. Five GEO satellites – two Meteorological Satellites (METEOSAT) from Europe, two Geostationary Operational Environmental Satellites (GOES) from the United States, and one Geostationary Meteorological Satellite (GMS) from Japan – provide visible and IR data, as well as other channels. By international agreement, each satellite images the full disk of the Earth as seen from its position for each three-hourly synoptic time (00Z, 03Z, ..., 21Z), together with more-frequent images of operationally chosen sectors. As for the LEO satellites, two to three United States NOAA-series satellites provide visible, IR, and PMW sounding (Advanced Microwave Sounding Unit; AMSU) data. Two to three United States DMSP satellites provide ongoing SSM/I PMW coverage, with additional PMW coverage provided by research satellites, namely, the *TRMM Microwave Imager* (TMI) on TRMM and the Advanced Microwave Scanning Radiometer – Earth Observing System (AMSR-E) on the United States Aqua satellite. Finally, TRMM also hosts the PR. All of the LEO satellites provide near-global coverage from polar orbits, except the TRMM orbit, which only covers the latitude band 36 °N–36 °S for PR and 38 °N–38 °S for the wider-swath TMI.

One subtlety is that most of the LEO satellites are flown in sun-synchronous polar orbits, meaning that they overfly each point on Earth at roughly the same local a.m. and p.m. time each day. Such an orbit introduces a likely bias in estimating precipitation, since the diurnal cycle in precipitation varies with location, synoptic situation, and surface type, and typically is not a simple function of time of day. The alternative is a LEO satellite whose orbit precesses through the day, but this precession usually takes so many days to cover the diurnal cycle that stratifying the observations by time of day is only meaningful for accumulations over months of data. As an example, the TRMM satellite takes 46 days to precess through one day at any one location on the Earth's surface. Regardless of the orbit, it is estimated that eight evenly spaced samples are needed to adequately characterize the daily precipitation (Adams *et al.*, 2002). This can be achieved at any particular site by use of a GEO satellite or by a sufficiently large fleet of LEO satellites. Note that *global* coverage requires a constellation of satellites, whether GEO or LEO. In the case of PMW sensors, which are only available on LEO satellites at present and which have somewhat narrow swaths of data, the "sufficiently large" constellation translates to a requirement for eight satellites.

Data Archives

The third major factor governing remotely sensed estimates of precipitation is access to the data. At present, the bulk of the workhorse satellite observations, namely the PMW and IR, are posted on-line in near-real time or reproduced on tape within a month or so of the observation time. However, before the late 1990s, this was not the case for the IR, and it is still not entirely true for other channels. Instead, long-term operational precipitation algorithms depend on a legacy of subsetted and averaged IR data summaries, and the earlier the era, the less detailed the summary. For example, the Global Precipitation Climatology Project (GPCP) Version 2 monthly Satellite-Gauge (SG) product (Adler *et al.*, 2003) depends on:

- Outgoing Long-wave Radiation (OLR) values computed from LEO IR and then averaged to a $2.5° \times 2.5°$ grid for five-day (pentad) intervals during the period 1979–1985;
- GEO IR T_b data binned into 16 T_b intervals, most of them 5K wide, on a $2.5° \times 2.5°$ grid for five-day (pentad) intervals during the period 1986–1996, with fill-in by 3-T_b-bin histograms of LEO IR data; and
- GEO IR T_b data binned into 24 T_b intervals, most of them 5K wide, on a $1° \times 1°$ grid for individual three-hourly observation times during the period 1997–present, with a parallel grid of LEO IR-based GOES Precipitation Index (GPI; Arkin and Meisner, 1987).

See "Future Prospects" below for notes on possible improvements to the archive issue.

Strengths and Weaknesses

As noted above, GEO IR data exhibit excellent sampling, but are only weakly related to instantaneous precipitation rates and to precipitation outside the tropics. PMW data have an excellent correlation to precipitation over oceans and a good correlation over land, except in regions with frozen land surface, but PMW technology is currently limited to LEO satellites, thereby introducing temporal sampling issues. Radar data have both excellent correlation to precipitation and range-resolved information, but the very narrow data swath, power requirements, and cost severely limit the number of sensors ever likely to be flown at the same time.

In addition, all satellite-based precipitation estimates face some generic problems. Most importantly, the physical problem is under-determined, so that it is clear in advance that simply recording more observations from the same sensor cannot force the error in the estimate to zero. A closely related issue is inhomogeneity in the precipitation scene across an individual pixel, referred to as the beam-filling problem. Such inhomogeneities interact with the nonlinearities in the radiative processes to force the retrieved precipitation value for the pixel away from the true average. Finally, there are dropouts in the various estimates

due to issues in satellite operations, data transmission, and data archiving.

At this juncture, the reader should note that any real system for producing precipitation estimates is subject to weaknesses. Numerical models require computational approximations, most particularly the parameterizations for the precipitation microphysics; experience initialization errors; and can transfer errors from other parts of the model to the precipitation estimates. Surface-based radar suffers calibration uncertainties, beam blockage by surface objects, bright-band uncertainties, and anomalous propagation. Even rain gauges, which are usually considered the gold standard, carry a large list of caveats, led by the fundamental problem of converting point gauge values to areal averages. Other significant gauge problems include losses due to aerodynamics around the gauge orifice, evaporation, side-wetting, splashing, and unrepresentative siting.

This summary of strengths and weaknesses underscores the need for users to question the suitability of any precipitation data set for their particular use. Different sensors, both satellite- and ground-based, observe different aspects of precipitation. We now turn to the estimation schemes, which typically seek to emphasize strengths and minimize the weaknesses of the input data sets that they utilize.

TRANSFORMING OBSERVATIONS INTO ESTIMATES

Each type of sensor mentioned in the previous section has some advantage for estimating precipitation, and a number of algorithms have been developed to exploit that sensor's unique information. Increasingly, researchers have worked to combine observations or precipitation estimates from multiple sensors to achieve better accuracy and/or wider coverage. Of the large number of research algorithms that have been developed, only a few have found operational application on a quasi-global basis. The data sets thus generated are the most likely to be useful to the nonspecialist, and so the discussion here is limited to those archives with

Table 1 Summary of publicly available, quasi-operational, quasi-global precipitation estimates from a single sensor. Where appropriate, the algorithms applied to the individual input data sets are mentioned. The TMI GPROF and PR are also available as separate products from the GDAAC. ''Latency'' gives the typical interval between the end of the observational period and release of the product[a]

Algorithm	Input data	Space/time scales	Areal coverage/start date	Update frequency	Latency	Archive location[b]

reasonable coverage and continuity. Kidd (2001) points to numerous other examples still in the research stage. For the sake of clarity and compactness, we summarize the publicly available, quasi-global precipitation estimates into: single-sensor satellite data sets (Table 1), combination satellite data sets (Table 2), and combination satellite data sets that incorporate gauge data (Table 3). While space limitations preclude a detailed discussion of each approach, the major themes and issues are outlined in the following subsections. See the Appendix for full expansions of the acronyms used in the tables to conserve space. The reader is referred to **Chapter 35, Rainfall Measurement: Gauges, Volume 1** for a similar discussion of rain gauge observations. Well-calibrated, carefully analyzed rain gauge data sets are critical to the development and routine calibration of remote sensing estimates of precipitation.

PMW-Based Data Sets

The various PMW algorithms may be characterized as predominately statistical, including the National Environmental Satellite Data and Information Service (NESDIS)/Fleet Numerical Meteorological and Oceanographic Center (FNMOC) and Wilheit-Chang algorithms, or physical, such as the Goddard Profiling algorithm (GPROF). In either approach, the under-determined problem is implicitly closed by assuming climatological behavior at critical steps.

As one might expect, various algorithms respond differently to errors and failures in the input data. The 85-GHz channels on the first SSM/I, launched in July 1987, progressively failed during 1989–1991. The Wilheit-Chang results were unaffected because they only depend on the lower frequencies (and correspondingly only provide estimates over oceans), while the NESDIS/FNMOC scheme shifted to a lower-accuracy fall-back algorithm during the failure and the GPROF algorithm exhibited progressively larger errors.

Under normal circumstances, NESDIS/FNMOC is primarily a scattering algorithm, while GPROF uses both emission and scattering signals over ocean and only scattering over land. None of the PMW algorithms is capable of estimating precipitation over frozen/icy surfaces.

One potentially confusing aspect of the PMW algorithms is that multiple algorithms have been developed for each sensor, *and* the same algorithm is sometimes applied to data from different sensors. Another source of confusion is that successive versions of an algorithm can exhibit rather different characteristics. Thus, it is important for users to be clear about which particular sensor-algorithm-version combination is producing the PMW estimates under study.

Table 2 Summary of publicly available, quasi-operational, quasi-global precipitation estimates that are produced by combining input data from several satellite sensors. Many of the input data sets are preprocessed into precipitation estimates. The TCI is also available as a separate Level 2 (satellite swath coordinates) product from the GDAAC. ''Latency'' gives the typical interval between the end of the observational period and release of the product[a]

Combination Algorithms

Compared to combination data sets that depend only on satellite data (Table 2), approaches that routinely use gauge information in some way (Table 3) should have less bias where the gauges exist. However, users need to be aware of possible nonindependence between the with-gauge combinations and validation data sets built from gauge data. In addition, gauge analyses can introduce local errors into the combination. For example, Nijssen *et al.* (2001) have pointed out that the GPCP Version 2 monthly SG product has a systematic low bias in the Pacific Northwest of the United States, most likely due to preferential gauge siting in valleys in that region of complex terrain.

One important issue in constructing combinations is how to deal with known or suspected biases in the individual input precipitation data sets. For example, the TRMM Multisatellite Precipitation Analysis (MPA) calibrates each of the different PMW estimates to a single standard estimate using histogram matching of coincident precipitation rates. The calibration standard in the real-time MPA is the set of TMI-based GPROF estimates, while in the post-real-time version, the standard is the TRMM Combined Instrument (TCI) data set, which combines TMI and PR data. The IR-based Variable Rainrate Precipitation (VAR; Huffman *et al.*, 2003) algorithm is subsequently calibrated from these adjusted PMW estimates separately for each month and grid box. Similar PMW-IR calibration concepts are applied in the GPCP Monthly SG and GPCP One-Degree Daily (1DD) data sets. The Climate Prediction Center (CPC) Merged Analysis of Precipitation (CMAP) takes the alternative view that biases are largely unknown and declines to select a standard. Rather, a semiobjectively weighted combination is formed from multiple individual satellite estimates, including the GPI (Xie and Arkin, 1996). The GPCP Pentad data set is a mixture of approaches, since the occurrence of precipitation is computed as in CMAP,

but the amounts are scaled to the GPCP Monthly SG (Xie *et al.*, 2003).

When calibrations are carried out for data fields that are only intermittently nonzero, such as precipitation, it is important that both data sets be averaged to the same spatial grid before calibration. Otherwise, when the finer-scale of the two estimates is averaged to the coarser scale, it will have a higher fractional coverage of nonzero precipitation than the original coarse-grid data set due to averaging zero and nonzero grid boxes around the edges of precipitation systems. At the same time, the averaged fine-scale data will lack the necessary high-end values because of averaging with near-by, lower values. These comments apply both to histogram-matched calibrations between precipitation fields and to histogram-matched precipitation-T_b calibrations for IR schemes.

IR-Based Combination Data Sets

Precipitation estimates based on IR data constitute a special class of combinations because there is no "pure" IR-based precipitation estimate in the sense that one cannot specify a precipitation scene and compute the resulting IR signal. Rather, calibration by some source of precipitation estimates is always necessary between the cloud-top information that the IR provides and the corresponding precipitation. IR techniques that require no additional information use a static calibration. For example, the GPI was calibrated using several months of data from the Global Atmospheric Research Program (GARP) Atlantic Tropical Experiment (GATE) in the summer of 1974 off West Africa. The advantage of static calibration is that the estimate only depends on a single sensor for computing new estimates, which is why the GPI and OLR Precipitation Index (OPI) are included in Table 1. Calibrations that are routinely updated with coincident precipitation data may be termed "dynamic", and require both IR and precipitation information in the calibration step, even if the estimation step only requires IR data. This is the basis for including such combinations in Table 2. One interesting question posed by dynamic calibration is how frequent the updates to the calibration should be. Monthly updates are very stable, but may fail to adequately represent changes in the weather regime, while overpass-by-overpass updates favor sensitivity over stability. This is a matter of current research and diverse practice, so users should be aware of the update interval in data sets that they plan to use.

One popular approach to dynamic IR calibration is histogram matching between coincident sets of precipitation estimates and IR T_b data. This approach assigns the highest precipitation rates to the coldest IR T_b's and successively lower precipitation rates to successively warmer IR T_bs. Figure 2 illustrates the result of such a calculation for (roughly) January 2003 from the VAR technique, which matches IR T_bs to merged, intercalibrated PMW estimates

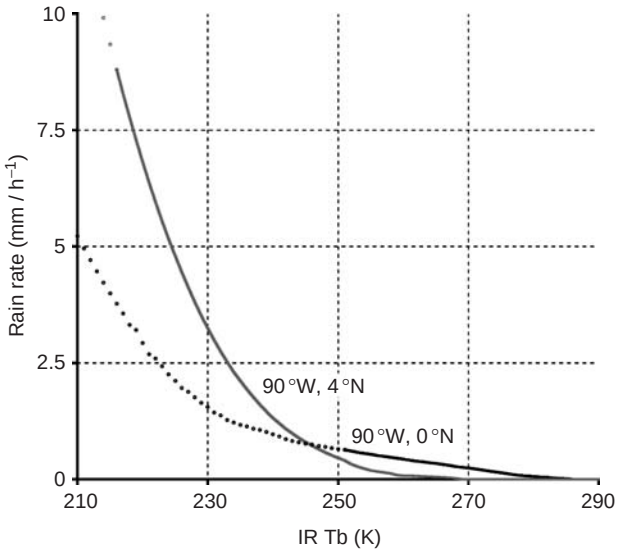

Figure 2 Examples of IR T_b – rain rate calibration curves for instantaneous, 0.25° × 0.25°-latitude/longitude grid estimates, as computed in TRMM 3B41RT for the 30-day accumulation ending 4 February 2003. The red (black) line is for the location 90 °W, 4 °N (90 °W, 0 °N), which is in the core (southern edge) of the ITCZ. The solid curves correspond to the range of data recorded in the accumulation, while the dots correspond to a climatologically based continuation to colder T_bs. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

separately for each month and grid box. Note that the relationship in the heavy rain area of the eastern Pacific Intertropical Convergence Zone (ITCZ) has a lower threshold, and assigns higher precipitation rates to temperatures that are colder than any found in the dry region just 4° of latitude south. Both curves estimate nonzero precipitation at a warmer IR T_b than the GPI threshold of 235K, both because rain tends to occur from relatively warm clouds in that region, compared to the GATE area, and because VAR works with 0.25° × 0.25° latitude/longitude gridbox-average values, while the GPI works with individual 4-km pixels. Note that the VAR threshold over land is frequently colder than the GPI threshold in heavy rain areas.

To summarize, modern combination data sets generally provide the best general-purpose estimate, but users should be aware of possible artifacts and should ask the data set producers questions about the specific performance that they are observing. In such cases, it should be possible to determine which input data set or analysis step is governing the behavior of the final combination.

EXAMPLES

The 23-year average of the GPCP Version 2 monthly SG precipitation estimates is shown in Figure 3. The regional

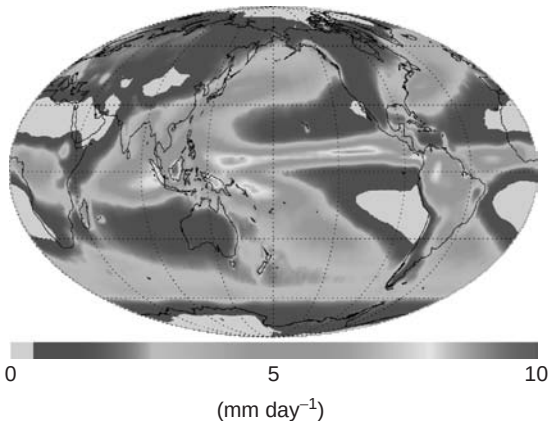

Figure 3 Annual precipitation climatology from 23 years (1979–2001) of GPCP Version 2 Monthly precipitation estimates. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

features are similar to other such climatologies, particularly over land. The goal at this point for precipitation researchers is to continue refining estimates at finer time and space scales, a by-product of which is that the overall climatology should be improved as well. The corresponding time series of the global average appears in Figure 4. The ocean, land, and total averages are shown separately, with thin (thick) lines depicting the month-to-month (running 12-month) global averages. The major dips in the smoothed land time series have a strong negative lead-in-time correlation with the occurrence of El Niño events, likely due to major declines in precipitation in the maritime continent in advance of the El Niño. Some of the year-to-year maxima in the smoothed land time series are related to La Niña events, but there is still a fair amount of interannual variation that seems unrelated to El Niño – Southern Oscillation (ENSO) events. Overall, the interannual variation of the total time series tracks with that of the ocean due to the large fraction of the Earth's surface covered by water. Nonetheless, the combination of an ocean time series with modest positive correlation to ENSO and a land time series with marked negative correlation to ENSO yields a total time series with nearly zero correlation. The overall secular change in the time series of global total is modest, but it is considered premature to trust the absolute calibrations across several important data boundaries in the current version of the data set.

As another example, Hovmöller diagrams for the latitude band 10 °N–10 °S and the period February–December 2002 were constructed for the GPCP Pentad data set, GPCP 1DD, and the then-operational TRMM Real-Time MPA (Figure 5). Given rather different algorithms, as well as time and space resolutions, the agreement is qualitatively impressive. Several eastward-moving (slanting down to the right) Madden–Julian Oscillation events are depicted in the Pacific during the spring, while westward-moving cloud clusters (slanting down to the left) continue unabated in the Atlantic Ocean The weakness of the 2002–2003 El Niño is demonstrated by the lack of significant precipitation in the Equatorial eastern Pacific, although in the climatological ITCZ location north of 10 °N, the precipitation *was* enhanced.

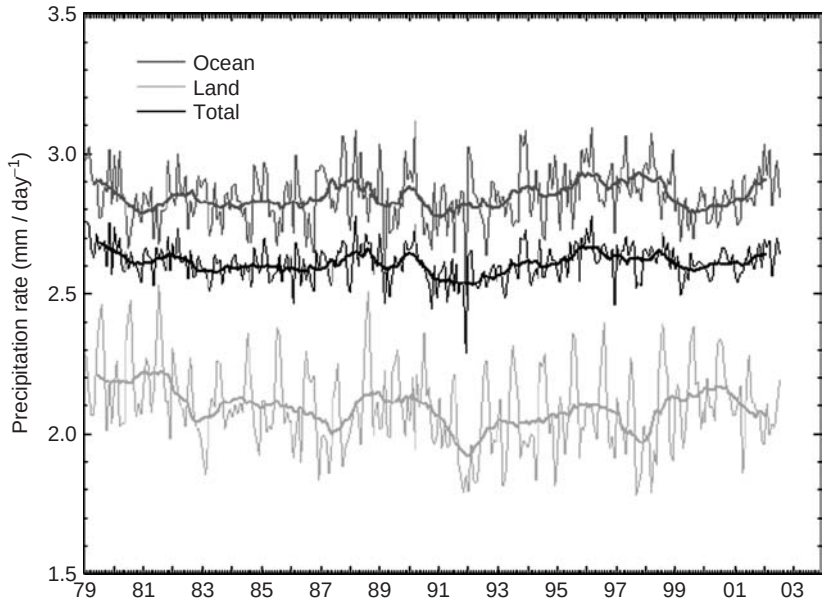

Figure 4 Time series of global-average precipitation for ocean (blue), land (green), and all (black) regions contained in the record of GPCP monthly SG estimates. Thin and thick lines depict original monthly and 12-month-running-mean values, respectively. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

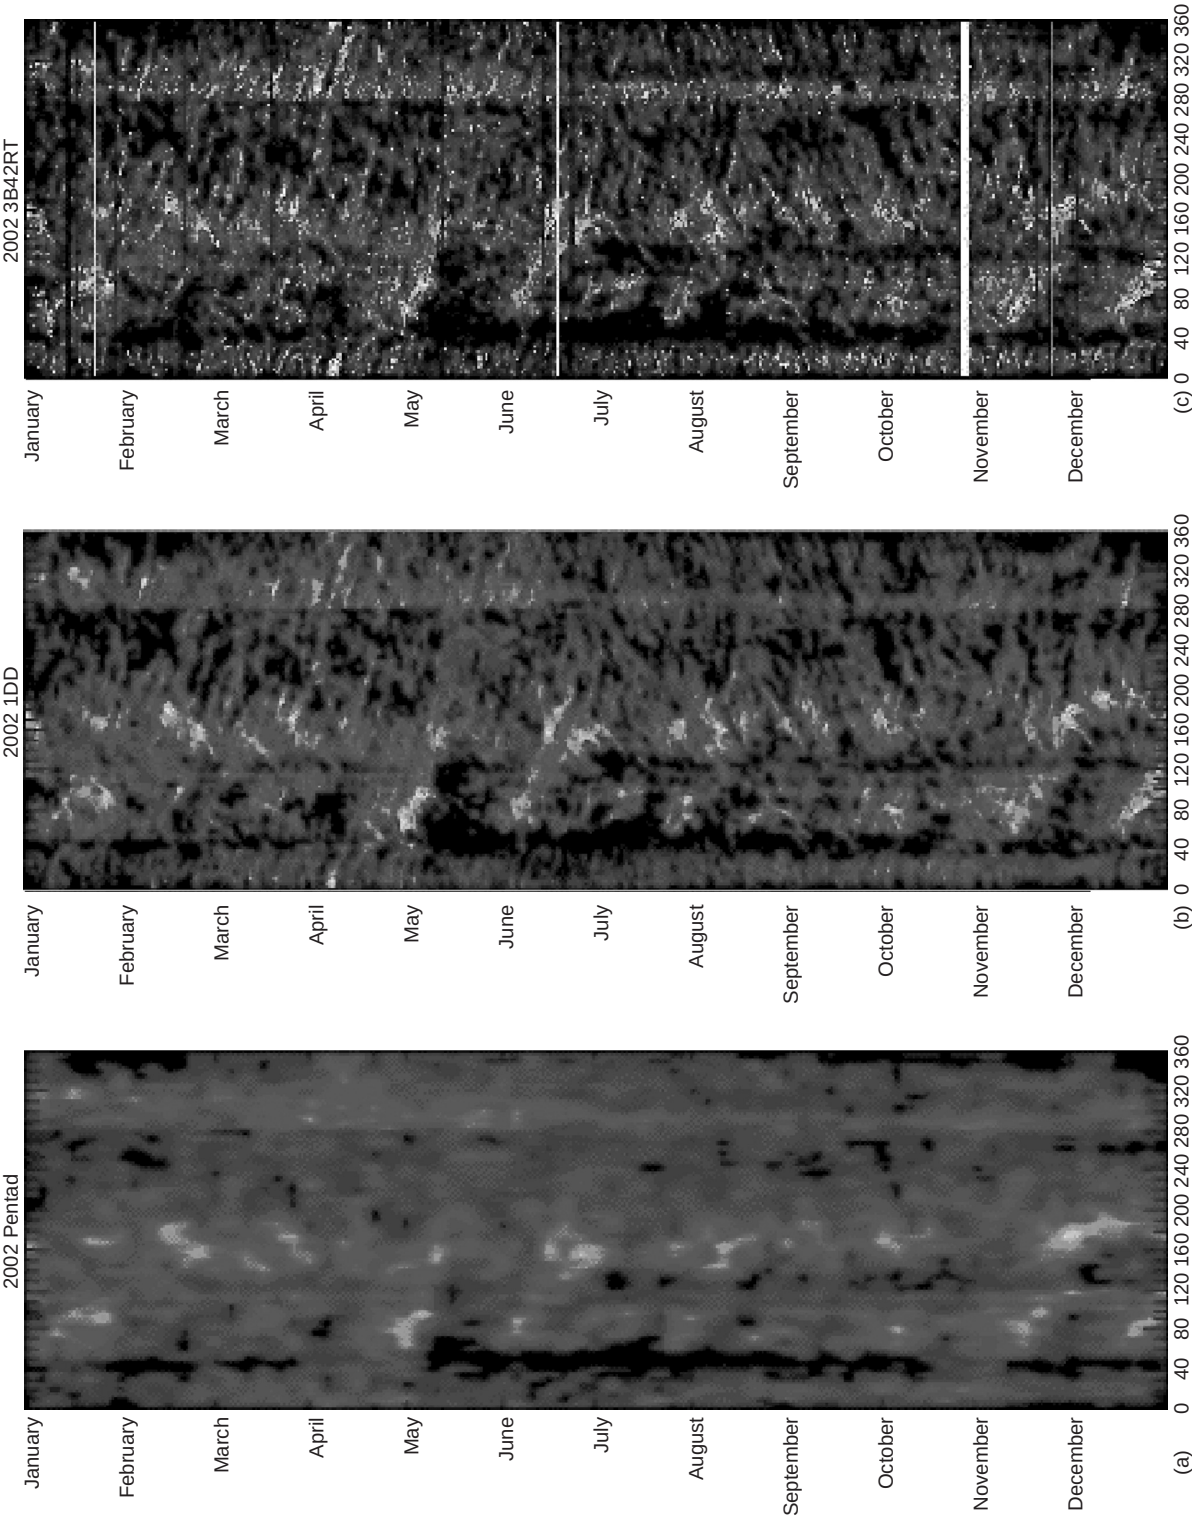

Figure 5 Example Hovmöller diagrams of estimated Equatorial precipitation for the year 2002 from three modern algorithms: GPCP Pentad (a), GPCP 1DD (b), and TRMM 3B42RT (c). In each panel, the data are averaged over the latitude zone 10°N–10°S for each longitude (along the horizontal axis) for each time (along the vertical axis), then regridded to be comparable to the other data sets. Black or white horizontal lines denote missing data. See Tables 2 and 3 for product details. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

At the finest scales, satellite-based estimates facilitate monitoring for extreme events and putting each event in its meteorological context, even when a portion of the overall storm pattern is offshore, beyond the view of radar and gauge coverage. For example, Figure 1 depicts a number of rain bands off the Pacific coast of Central America, even while attention was focused on Hurricane Isadore off the tip of the Yucatan peninsula at the time. These bands provided important antecedent information for the subsequent heavy rains over southern Mexico that appear in the September 2002 field in Figure 1.

EVALUATION

The preceding discussion has already introduced the two major factors that determine the accuracy of precipitation estimates, namely errors due to instrument and algorithm problems, and errors due to sampling. Instrument/algorithm errors are primarily driven by limitations in the retrieval process discussed above, while sampling errors are related to the very small decorrelation distances and times for individual events. Such correlation structure is a direct result of the physics of precipitation, which is generated on the microscale and results in a time series of data values that are nonnegative and only occasionally nonzero (see, for example, Krajewski *et al.*, 2000). One of the major challenges in validating the satellite estimates is accounting for the instrument/algorithm and sampling errors that are latent in the ground truth data. It is extremely rare to have a sufficiently dense, well-calibrated gauge network that covers a reasonably large area, so algorithm validation is usually focused on a few sites that are chosen to span as many climatic regimes as possible. Gebremichael *et al.* (2003) demonstrate the effects of reducing rain gauge density on the estimate of uncertainty in validating precipitation estimates. In regions without adequate gauge coverage, the errors associated with a particular algorithm must be parameterized in terms of the satellite observations themselves (Li *et al.*, 1998; Huffman, 1997). These first studies only parameterize the random part of the error in monthly precipitation estimates, and a comparable representation of bias has not been developed. Furthermore, note that the current generation of error parameterizations does not include whatever diurnal or geographically related biases may be introduced by the sampling pattern in a particular data set. Likewise, none of the current error parameterizations is designed to account for the multiscale nature of errors at submonthly timescales (outlined below).

In the 1990s, a series of intercomparison projects sought to evaluate the then-current precipitation algorithms in a variety of settings. The three Algorithm Intercomparison Projects (AIP-1, -2, and -3; Ebert *et al.*, 1998) and three Precipitation Intercomparison Projects (PIP-1, -2, and -3; Barrett *et al.*, 1994; Smith *et al.*, 1998; Adler *et al.*, 2001 respectively) tested monthly and single-overpass performance in a variety of global locations. It proved to be easy to identify flawed algorithms, but relatively hard to rank the rest. Important results from these studies include: Combination algorithms generally show improved performance compared to single-sensor schemes; PMW estimates are better than IR at short intervals; and all sensors falter in light or cold-season precipitation cases. At present, researchers working under the Coordination Group for Meteorological Satellites International Precipitation Working Group (CGMS-IPWG) are leading a validation effort for the current generation of precipitation algorithms. Most of the algorithms being evaluated are multisensor combination approaches at relatively fine time/space scales (including many of the entries from Tables 2 and 3). Routine daily validation statistics at $0.25° \times 0.25°$ resolution for Australia, the United States, and Western Europe may be accessed through the CGMS-IPWG web site **`http://www.isac.cnr.it/~ipwg/IPWG.html`**.

It is still a matter of research to fully validate precipitation estimates at the finest scales using rain gauges. The error variance is large, mostly due to the lack of accuracy in the satellite estimates, and, less importantly, resulting from uncertainties introduced by approximate time match-ups, navigation uncertainties, and geometric offsets in various satellite footprints, and the point-to-area interpolation uncertainties in the gauge analyses. As well, there can be a seasonal variation in the validation statistics that likely reflects the change in climatic regime between convective activity and more stratiform events. One early study of real-time MPA estimates (Katsanos *et al.*, 2004) employed 12-h accumulations from 73 gauges in the eastern Mediterranean region. The reliability of low and moderate rainrates was good, but high rain rates in the MPA tended to suffer a low bias. Of particular interest to hydrologists, Hossain and Anagnostou (2004) conducted a simulation study of flood prediction driven by satellite estimates. They demonstrated that sparse but high-quality precipitation estimates (having microwave-grade statistics) generated uncertain but relatively unbiased estimates of extreme stream flow, while the use of frequent but lower-quality precipitation estimates (having IR-grade statistics) produced streamflows that had a smaller random error but were biased against large events.

Another approach to assessing precipitation quality at fine scales is to intercompare satellite estimates, for example, PMW-calibrated IR precipitation estimates and the original PMW estimates. Difference maps from this study demonstrate that errors in the histogram-matched IR estimates are not simply a random shuffle of precipitation under a solid cloud canopy. On the one hand, we know that in convective situations, the occurrence of the coldest IR cloud tops lags the peak precipitation rates by as much as an

hour or more. On the other hand, at midlatitudes, the coldest IR cloud tops tend to form clusters ahead of fronts, while the PMW estimates tend to depict linear precipitation features more closely aligned with the frontal zone. Both structures are synoptically consistent patterns, but unfortunately, they do not yield the same precipitation pattern. This result is both a caution for data users and a strong impetus for algorithm developers to seek additional PMW estimates.

It is clear that a great deal of the uncertainty at the fine scales is random, because averaging over progressively larger space/time scales successively reduces the error (see the examples in Serra and McPhaden, 2003). However, the error exhibits multiscale correlations, so averaging eliminates the error more slowly than if the error were a simple random variate at the finest scale. Steiner *et al.* (2003) employ precipitation estimates from ground-based radar data over the central United States to explore the effects of subsampling in time and averaging in time and space. They find power law relationships for the expected inverse dependence of precipitation uncertainty on the time/space averaging area and precipitation rate, as well as for the direct dependence on sampling interval. They note that absolute calibration is not critical for determining the relative uncertainty in a data set of precipitation estimates, but is critical for intercomparing multiple estimates.

At the monthly timescale, the combination data sets provide reasonable behavior, particularly when gauge data are included, although some regions with complex terrain are an exception, as noted above. For example, McCollum *et al.* (2000) and Nicholson *et al.* (2003a,b) show that the individual satellite estimates tend to have a high bias compared to a special dense gauge collection in West Africa, while the GPCP Version 1 monthly SG was relatively unbiased, even though the operational gauge array used in the SG was quite sparse. Subsequent work shows similar results for Version 2. Several Version 5 TRMM products were compared over the Oklahoma Mesonet in Fisher (2004), with particular emphasis on gauge analysis uncertainty and the once-a-day sampling that occurs near TRMM's turning latitudes. Elsewhere, in regions that lack gauges, including the vast expanses of the oceans, the monthly variance is higher, and it is a matter of ongoing research to verify that the biases are small. Although oceans are not the prime focus of hydrologists, the Adler *et al.* (2003) and Bowman *et al.* (2003) studies in the tropical Pacific (GPCP SG against atoll data and TMI and PR against buoy data, respectively) demonstrate the care needed to minimize noise because of spatial and temporal mismatches between sparse gauges and satellite estimates. For all data sources, experience shows that the least reliable monthly estimates are located in polar and high mountain regions, where the precipitation is generally light and frequently frozen, the Earth's surface is frequently frozen, and there tend to be few or no gauge sites due to sparse population.

In the face of the high uncertainty at the fine scales and better statistics for averaged data, it may seem that hydrologists should confine their studies to large basins and multiday, or even monthly periods. However, one should also expect success for algorithms and models that explicitly or implicitly perform some level of averaging, such as a soil wetness model. At the large scales, where random errors are not a factor, biases remain, and in regions for which rain gauge analyses are problematic or absent, it is not yet possible to assess an absolute calibration of the precipitation field. As an alternative, it is sometimes useful to express the precipitation as deviations from the data set's average conditions, even if the record is too short to justify identifying the average as a "climatology". The quantification of biases is a major focal point for the latter part of TRMM and the early phases of the Global Precipitation Measurement (GPM) project.

FUTURE PROSPECTS

The first decade of the twenty-first century is seeing rapid advances in precipitation estimation from space, including more-frequent overpasses by PMW sensors, routine opportunities for intercalibration of precipitation estimates from all satellites, and implementation of channels and algorithms that provide useful information on frozen hydrometeors. Furthermore, the ongoing expansion of computer resources makes it more likely that computationally intensive retrievals and combinations will be routinely performed and posted on the Internet for use, comparison, and possible validation. Although not strictly a satellite issue, current tentative steps to develop regional daily gauge analyses around the globe are key to improving the accuracy of and our understanding of the fine-scale estimates that are being produced. It continues to be the case that many regions lack the gauge density to perform a straightforward daily gauge analysis, particularly when the diversity of definitions for the day's starting hour is taken into account.

On the algorithm side, it is likely that increasingly sophisticated neural networks relating PMW precipitation estimates to IR T_bs could lead to algorithms that exceed the performance of the current deterministic algorithms. The algorithm known as *Precipitation Estimation from Remotely Sensed Information using Artificial Neural Networks* (PERSIANN; Sorooshian *et al.*, 2000) is the first such algorithm to be computed quasi-operationally. A second intriguing alternative is morphing. In this approach, the motion of features on successive IR images is used as a first guess for the motion of the realistic precipitation features depicted by successive PMW

images. Once the motion and change of shape of the PMW features is established, they can be intelligently interpolated at a uniform temporal interval. The first morphing estimate was provided by the CPC Morphing algorithm (CMORPH; Joyce *et al.*, 2004). Although neural networks have a longer history, there is a tremendous amount of room for development in both neural networks and morphing.

By the end of the decade, it is expected that the GPM project will have organized the infrastructure, international data agreements, and basic algorithms to acquire, intercalibrate, process, and distribute three-hourly PMW data, including sounding channels for estimating frozen and cold-land precipitation (Adams *et al.*, 2002). One key piece of the GPM operation will be a two-frequency precipitation radar, which will continue routine intercalibration checks with other sensors, as well as building the climatological record that would likely be the first to reveal any systematic changes in the nature of precipitation systems that might arise as part of global change. Moving ahead another decade or so into the future, it is conceivable that PMW sensors will be mounted on GEO satellites, providing the necessary fine time resolution. Until GEO PMW is provided, precipitation estimates will have to depend on GEO IR (plus perhaps other channels) to provide fine time resolution, even if only as an input to a morphing scheme.

Yet another future activity involves the past. Specifically, the nearly complete record of original full-resolution, multichannel GEO and LEO data sets from Europe, Japan, and the United States was almost entirely rescued in the years around 2000. This massive collection of data sets must be accessed, summarized according to modern algorithm requirements, and then processed. It is likely that the first step will be to process the International Satellite Cloud Climatology Project B1 data set (Schiffer and Rossow, 1985), which contains all of the original internationally available satellite data sets, except subsampled by a factor of two in each direction and once every three hours. This set of tasks is quite messy, given the diversity of formats, operational blemishes, and sheer volume involved. However, from the users' perspective, the use of detailed GEO IR back to 1983 and detailed LEO IR back to 1979 would yield significant benefits in estimating precipitation.

CONCLUSION

Satellite estimates constitute the bulk of the data at our disposal for characterizing the global record of precipitation since the late 1970s. The longest records of precipitation have relatively coarse gridding in space and time and suffer from several significant data boundaries, yet they present a relatively coherent picture. Shorter records for more-recent years are available at finer time and space scales. Unfortunately, the IR data that form the bulk of these estimates are only loosely correlated to rainfall at these fine scales. Thus, users are urged to verify that the uncertainty in the fine-scale estimates is compatible with their application. In particular, averaging in space and/or time should be beneficial in improving the error statistics of the resulting estimates.

Looking towards the future, important additions to the observing system are expected, including more PMW satellites and new channels capable of supporting estimates of frozen precipitation and precipitation over icy/frozen surfaces. At the same time, reprocessing of the rescued full historical record should facilitate a much longer record of higher resolution estimates.

65: Estimation of Water Vapor and Clouds Using Microwave Sensors

SUSANNE CREWELL

Meteorological Institute, University of Munich, Theresienstr, 37, 80333 Munich, Germany

Both water vapor and clouds play important roles in the energy and water cycle, and their accurate observation is required. Several techniques to measure water vapor distributions and cloud properties exist with each of them having their specific limitations. Measurements in the infrared and visible spectral range are strongly influenced by clouds and cannot be used to observe water vapor under cloudy conditions. Information about cloud properties is limited to the cloud top and base depending on the use of a space- or ground-based system. Microwave techniques can provide information about water vapor and liquid water also under cloudy conditions, but satellite observations are limited to retrievals above ocean surfaces. Therefore, the combination of different measurements needs to be further pursued in order to gain insight into the three-dimensional distribution of water vapor and cloud properties as well as their temporal variability. Recently, information about the cloud vertical structure including the occurrence of multiple cloud layers and cloud overlap has become available at a few ground-reference sites through sensor synergy including active and passive instruments. In the near future, the first global measurements of this kind will be carried out from satellites.

INTRODUCTION

Only a small fraction of the water in the atmosphere is visible in the form of liquid cloud droplets or cloud ice crystals. Most of the water (more than 99%) is contained in the form of invisible water vapor with a global average of about $25\,\mathrm{kg\,m^{-2}}$ in an atmospheric column. Water vapor is part of a continuous cycle starting with the evaporation and transpiration from the ocean and land surfaces. In the atmosphere, water vapor is transported by complex atmospheric motions leading to a highly variable distribution with fractional amounts of the total mass of air between 0 and 5%. Under certain conditions saturation occurs and water condenses to form clouds. Because the phase transition is connected with the release of latent heat, the transport of water vapor is linked to the energy cycle. Microphysical processes within the clouds eventually lead to the development of precipitation in the form of rain, snow, or hail completing the water cycle with a typical duration of about 10 days. The full hydrological cycle also includes its terrestrial branch (*see* **Chapter 2, The Hydrologic Cycles and Global Circulation, Volume 1**).

Because of its absorption of solar and infrared radiation at several wavelengths, water vapor is the most important greenhouse gas. Clouds strongly modulate incoming solar and outgoing thermal radiation. Thus, both are key elements in the water and energy budget of the atmosphere and their accurate observation is required for a number of applications ranging from climate studies to numerical weather prediction. The accurate global measurement, modeling, and long-term prediction of water vapor is the primary goal of the Global Energy and Water Cycle Experiment (GEWEX) and Global Water Vapor Project (GVaP). The project demonstrated a large uncertainty in global averaged water vapor column estimates from models *in situ* and satellite measurements, as well as combined data sets with values between 23.4 and $28.7\,\mathrm{kg\,m^{-2}}$ (Randel *et al.*, 1996). For cloud water, no comparable solid database has been developed indicating a much larger uncertainty for estimates of cloud water content.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Traditionally, passive remote sensing methods, which rely on the observation of natural radiation emitted by either the sun or the Earth/atmosphere system, are used for the observation of water vapor and clouds. Owing to the strong interactions of water and clouds with radiation throughout the electromagnetic spectrum, observation techniques exist which make use of absorption and/or scattering of solar radiation, thermal infrared, and microwave radiation. One fundamental problem in remote sensing is that the inversion of the direct measurement (radiances) to the atmospheric state is ambiguous; often no unique solution exists. Consequently, the vertical structure cannot be resolved with high precision. The retrieval, also called *inversion problem*, is often approached by employing simplified regression or neural network models to fit the observable to the variable of interest. More physically based retrieval procedures involve the use of optimal estimation theory. A profound description about geophysical retrieval techniques can be found in Rodgers (2000).

Currently, active techniques that use an artificial source of radiation such as lidar and radar are emerging. These observations can provide a much better vertical resolution than passive methods. The trade off is that global observations from space are difficult to perform because of their high power consumption. Furthermore, they do not provide good spatial coverage, as scanning is only possible to a very limited degree with currently available technology. In principal, only vertical slices through the atmosphere are observed. With CloudSat (Stephens *et al.*, 2002) scheduled for launch in 2005, the first observations from a spaceborne cloud radar will be available.

WATER VAPOR

Traditionally, radiosonde ascents performed a few times per day at about 1000 stations unequally spaced over the globe, have provided the humidity information for atmospheric studies. However, the need for high temporal and spatial resolution, and high-accuracy measurements has pushed forward remote sensing technologies both for ground-based and for spaceborne applications. WMO has set the requirements to an accuracy better than 10% and a vertical resolution of 1–2 km for satellite soundings. Recently, the International H_2O Project (IHOP_2002) field experiment tried to improve the characterization of the four-dimensional (4-D) distribution of water vapor and exploit this information for a better understanding and prediction of convection. The experiment took place over the Southern Great Plains (SGP) of the United States in May/June 2002 and involved a large number of *in situ* and remote sensing instruments. An overview about the experimental setup and some preliminary highlights are given by Weckwerth *et al.* (2004).

A number of different units are used to describe the amount of water vapor in the atmosphere. The *water vapor density* [$\mathrm{kg\,m^{-3}}$] (also known as the *absolute humidity*) describes the water vapor mass per volume. Often the *specific humidity* (ratio of water vapor mass to total mass of air) or *mixing ratio* (ratio of water vapor mass to dry-air mass) are used ($\mathrm{g\,kg^{-1}}$). The *relative humidity* is the fractional amount of vapor in the air relative to the equilibrium vapor pressure of water as measured over a plane liquid surface. Additionally, the *dew point temperature* (K) is used that gives the temperature to which air has to be cooled in order to achieve saturation. To convert between the different humidity measures, knowledge of temperature and pressure is needed. Several remote sensing methods can only derive the total column amount of water vapor which is the vertically integrated water vapor density (IWV) also called *precipitable water* (PW). It is either given in units of mass per unit area ($\mathrm{kg\,m^{-2}}$) or dividing by water density to give the equivalent height of the water column (mm).

Water vapor has distinctive absorption characteristics in all parts of the electromagnetic spectrum relevant in the atmosphere. Thus different techniques – active and passive – exist, which utilize electromagnetic radiation in different spectral regions (Table 1). In the microwave range, the atmosphere is semitransparent and variations in the rotational absorption lines enable the passive remote sensing of water vapor in all weather conditions from different platforms (ground-based, air, and spaceborne). The Global Positioning System (GPS) satellites can be used to estimate water vapor contents from the additional delay of the low-frequency microwave GPS signal caused by atmospheric water vapor (Businger *et al.*, 1996). In the infrared part of the electromagnetic spectrum, thermal radiation emitted by water vapor can be used. However, severe limitations arise when clouds are present. Recently, the infrared technique has been extended to perform high-resolution interferometry to provide water vapor profiles with moderate vertical resolution from recent and future space-based instruments like the Atmospheric Infrared Sounder (AIRS) (Aumann *et al.*, 2003). Solar radiation is absorbed by water vapor at different wavelengths. By directly looking at the sun, a ground-based sun photometer can determine the integrated water content using absorption lines in the near-infrared portion of the solar spectrum. The differential absorption of reflected sunlight measured by satellites can also be used to derive the water vapor column in cloud-free conditions. Currently, LIDAR (Light Detection and Ranging) techniques are emerging, which can yield the water vapor profile with high vertical resolution. However, so far, only one operational water vapor lidar exists worldwide. Detailed descriptions of the different methods are given below.

Table 1 Overview of techniques to observe the integrated water vapor and their limitations

Method	Platform	Parameter	Principle	Strengths and weaknesses
Microwave radiometry	Ground-based	IWV	Water vapor emission at 22.235 GHz rotational line	High temporal resolution time series in all weather conditions except precipitation
		Profile $\Delta z = 0.5-2$ km	Pressure broadening of rotational line	Dense surface networks are too costly
	Spaceborne SSM/I, TMI, AMSU, AMSR	IWV profile $\Delta z = 2-3$ km	As for ground-based	From polar-orbiting satellites with at least daily coverage for all weather conditions, over ocean surfaces only with coarse resolution of about $50 \times 50\,\text{km}^2$
Global positioning System	Ground-based	IWV	Delay of GPS signal caused by water vapor	Inexpensive surface networks for all weather conditions, real-time products have less accuracy
Thermal infrared	Spaceborne GOES, MSG	IWV	Differential emission at 11 and 12 μm (split window)	Good spatial and temporal in cloud-free situations only
	HIRS, GOES	Profile	Channels along 6.7 μm line	Limited accuracy
	AIRS, IASI	Profile	High-resolution spectroscopy	High vertical resolution and accuracy
Sun photometer	Ground-based	IWV	Extinction of direct sunlight at 0.95 μm absorption band	Sun tracking is only possible during daylight and cloud-free conditions
Reflected sunlight	Spaceborne	IVW	Difference of reflectances at 0.95 μm and at close by window wavelengths	High spatial (1×1 km) resolution
	MODIS, MERIS, POLDER			Only in cloud-free situations ore above clouds
Lidar	Ground-based	Profile $\Delta z < 100$ m	Raman backscatter of water vapor	Best during night
			Differential absorption at two channels	Non operational

Microwave Radiometry

In the microwave region of the electromagnetic spectrum, atmospheric emission is due to water vapor, oxygen, and cloud liquid water (Figure 1). Radiative transfer is simplified as scattering by atmospheric constituents (with the exception of rain drops) and can be neglected (*see* **Chapter 46, Principles of Radiative Transfer, Volume 2**). Ground-based, airborne, or spaceborne microwave radiometers measure the thermal emission which is typically given as brightness temperatures (TB) in Kelvin. Water vapor has distinct spectral features at 22.235 and 183 GHz. Since the introduction of satellite remote sensing, dual-channel methods have made use of the rotational line at 22.235 GHz to derive the vertically integrated water vapor over oceans (Grody, 1993). Within this method one channel measures at a frequency close to the line center where water vapor absorption is almost independent of height. The observed brightness in temperature is approximately proportional to IWV. The second channel is located in a window region where water vapor and oxygen absorption are low (e.g. 31.4 GHz). Since microwave emission of clouds increases approximately with the square of the frequency (Figure 1), the second channel can be used to characterize the cloud's contribution to the intensity observed at the first frequency. This combination is extremely powerful as the IWV and the liquid water path (LWP), which is the vertically integrated liquid water density, can be retrieved simultaneously. For the past few decades this principle has been used for ground-based instruments (Westwater, 1978), as well as on the first satellites employing microwave radiometers at similar frequencies. Specifications of the accuracy vary between 0.3 and $1\,\text{kg}\,\text{m}^{-2}$. Sometimes microwave IWV measurements from the ground are used to scale radiosonde or lidar measurements. The experiences of the Atmospheric Radiation Programme (ARM) in respect to scaling are described by Revercomb *et al.* (2003). Limitations of the method are the radiometer uncertainty and the underdetermined retrieval problem as more than one atmospheric state can lead to the same set of brightness

Table 2 Overview of techniques to observe the cloud properties and their limitations. Future space missions are not listed

Method	Platform	Parameter	Principle	Strengths and weaknesses
Microwave radiometry	Ground-based	LWP	Cloud emission proportional to water content and frequency	Most accurate method, high temporal resolution time series
	Spaceborne	LWP	As for ground-based	Over ocean surfaces only with coarse resolution of about $50 \times 50\,km^2$
	SSM/I, TMI, AMSU, AMSR			Inhomogeneous beamfilling in case of precipitation
Cloud radar	Ground-based	Reflectivity and velocity profile $\Delta z < 100\,m$	Backscatter of cloud droplets, Doppler shift gives fall velocity	Vertical structure can be resolved, conversion to liquid (ice) water content is highly uncertain, information about phase
Thermal infrared	Ground-based	Cloud-base temperature	Cloud emission of cloud base	High temporal resolution, atmospheric correction for water vapor emission
	Spaceborne	Cloud-top temperature	Cloud emission of cloud top	High temporal and spatial resolution from geostationary satellite
	GOES, Meteosat, AVHRR, MODIS	Cloud-top pressure		
Reflected sunlight	Spaceborne	Optical depth	Reflectance at non absorbing channel (0.65 μm) and near-infrared absorption	Good global coverage, high spatial $1 \times 1\,km^2$ resolution for MODIS
	MODIS, MERIS, AVHRR	Effective radius LWP		Representative for upper cloud part only
Lidar	Ground-based	Backscatter profile $\Delta z < 100\,m$	Backscatter of cloud droplets	Best during night polarization for phase detection

temperatures. Slight improvements in accuracy can be made by using additional frequencies to further constrain the retrieval problem (Crewell and Löhnert, 2003). From the ground, microwave radiometers can provide unattended measurements of IWV at high temporal resolution during all weather conditions (Figure 2), except during precipitation when water on the antenna/radome emits microwave radiation and disturbs the measurement. Comparisons between different microwave radiometers have shown systematic differences of about $1\,kg\,m^{-2}$ mainly caused by the use of different gas absorption models in the retrieval process. Existing ground-based microwave radiometers have very different designs and specifications and are far more expensive than GPS receivers. However, technological progress has been made within the last few years and long-term time series of IWV now can be gathered and investigated (e.g. Güldner and Spänkuch, 1999).

Because the emission from land surfaces is too high and too variable within the field of view, satellite measurements can provide IWV over the oceans only. At the large microwave wavelengths, diffraction effects of the antenna yield a relatively coarse horizontal resolution at the Earth's surface of about $50 \times 50\,km^2$. By scanning across the satellite track, swaths of about 2000 km can be observed. A comprehensive tutorial about satellite observing techniques in the microwave region can be found at **http://www.meted.ucar.edu/ist/poes2/.** Currently, measurements from the Special Sensor Microwave/Imager (SSM/I), the Advanced Microwave Sounding Unit (AMSU-A), the Tropical Rainfall Measurement Mission (TRMM) Microwave Imager (TMI), and the Advanced Microwave Scanning Radiometer (AMSR) provide good global coverage over the oceans. Real-time water vapor fields for the tropics can be accessed at **http://www.ssd.noaa.gov/PS/TROP/trop-atl.html.**

Water vapor profiles are derived from microwave profilers that measure the atmospheric emission at several frequencies along the wings of pressure-broadened rotational lines. From the ground the 22.235 GHz line is used, whereas from space the strong 183 GHz water vapor line is more suitable (Figure 1). The reason is the high atmospheric opacity at 183 GHz, which prohibits measurements from the ground but which partly eliminates the problem of the unknown surface emission for satellite measurements. The contribution of a certain atmospheric layer to the signal

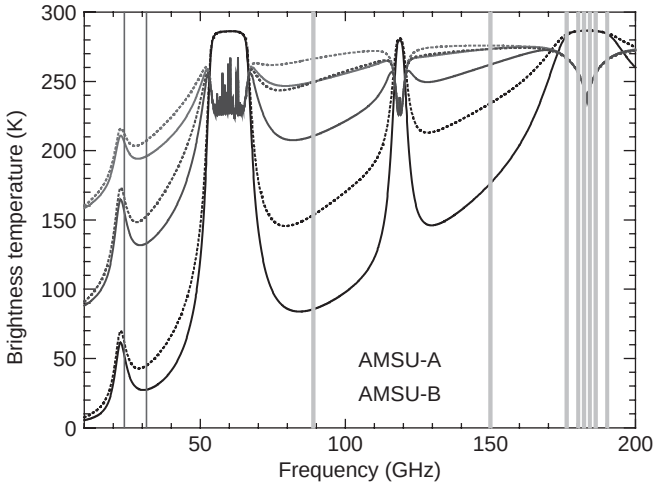

Figure 1 Brightness temperatures in the microwave spectral range simulated for a midlatitude summer atmosphere (IWV = 20 kgm − 2) for ground-based observation (a) and satellite observations over the ocean. As the emission of the ocean surface is polarization dependent, the results are shown for vertical (c) and horizontal (b) polarization. Brightness temperatures were calculated for clear sky (solid) and cloudy (dotted) conditions. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

as observed at the receiver is described by its weighting functions. The reader is referred to Janssen, (1993) for a comprehensive review on microwave remote sensing including details on weighting functions. For ground-based observations the weighting functions at the different frequencies all decrease continuously with height. The satellite weighting functions show marked and well-separated peaks for strongly absorbing frequencies (Figure 3). Channels close to the line center are already saturated in the upper troposphere and do not get contributions from lower layers. For frequencies further away from the line center, atmospheric transmission increases and signals from lower atmospheric layers are observed. The vertical resolution of the ground-based water vapor measurement is estimated to be 0.5–2.0 km; it decreases with altitude and is best close to the surface in the planetary boundary layer (Güldner and Spänkuch, 2001). Measurements made by either AMSU-B or SSM/T-2 can provide low-resolution vertical profiles that are more accurate in the lower troposphere, although measurements over land should be limited to the mid and upper troposphere.

Microwave spectroscopy is also used to observe the water vapor profile in the stratosphere and mesosphere. This is achieved by measuring the inner part (e.g. 1–2 GHz) of the 22 GHz line with high spectral resolution (2 MHz), and consequently deconvoluting the pressure-broadened spectrum. To avoid the complication of the tropospheric contribution obscuring the stratospheric signal, observations are preferably performed where moisture is low, for example, on high mountains or in polar regions.

GPS

Originally designed for navigation purposes, the Global Positioning System can also be used to determine atmospheric water vapor when the position of the GPS satellites and the GPS receiver are precisely known. Since this method has emerged, the number of ground-based GPS receivers organized within networks to derive columnar water vapor is increasing, as well as the use of GPS receivers on Low-earth Orbiting (LEO) satellites for water vapor profiling. An overview about current GPS activities is given in Bengtsson *et al.* (2003).

The time the GPS signal needs to travel from the GPS satellite to the GPS receiver is longer than the time calculated from the distance and the velocity of light in a vacuum. The time difference converted to distance, the so-called delay, is the original GPS measurement from which the water vapor column is derived. The ratio between the speed of light in the atmosphere and the speed of light in a vacuum is the index of refraction. At microwave frequencies the refractivity depends on the free electron density of the ionosphere and a neutral contribution. The ionosphere can cause delays of several tenths of meters but can be corrected using a dual-frequency method, for example, using two GPS signals at 1.2 and 1.5 GHz. The neutral contribution can be further separated into the hydrostatic delay (which can account to 2.3 m but is easily corrected by knowing atmospheric pressure) and the wet delay, the most variable contribution to the GPS signal. Correcting for ionospheric and hydrostatic effects, the wet delay can be determined with good accuracy. In order to take the elevation of the GPS satellite into account, the wet delay is converted to a zenith direction. The zenith wet delay (ZWD) is closely related to the integrated water vapor with a ratio of IWV/ZWD, corresponding approximately to 0.15 (Businger *et al.*, 1996). Further improvements in the accuracy can be obtained by incorporating the effective atmospheric temperature, which can be approximated from the ground-level temperature, in the IWV estimation. Several intercomparison studies have been performed and have demonstrated their potential to measure IWV with a good accuracy of $1-2\,\mathrm{kg\,m^{-2}}$.

As GPS receivers are relatively inexpensive and require low maintenance, they are used in large networks within Europe and the United States (**`http://www.gst.ucar.edu/gpsrg/realtime/`**). Currently, their potential for climate monitoring, atmospheric model evaluation, and data assimilation is being investigated. However, for the latter application, real-time data are necessary. Unfortunately, the exact information about GPS satellite

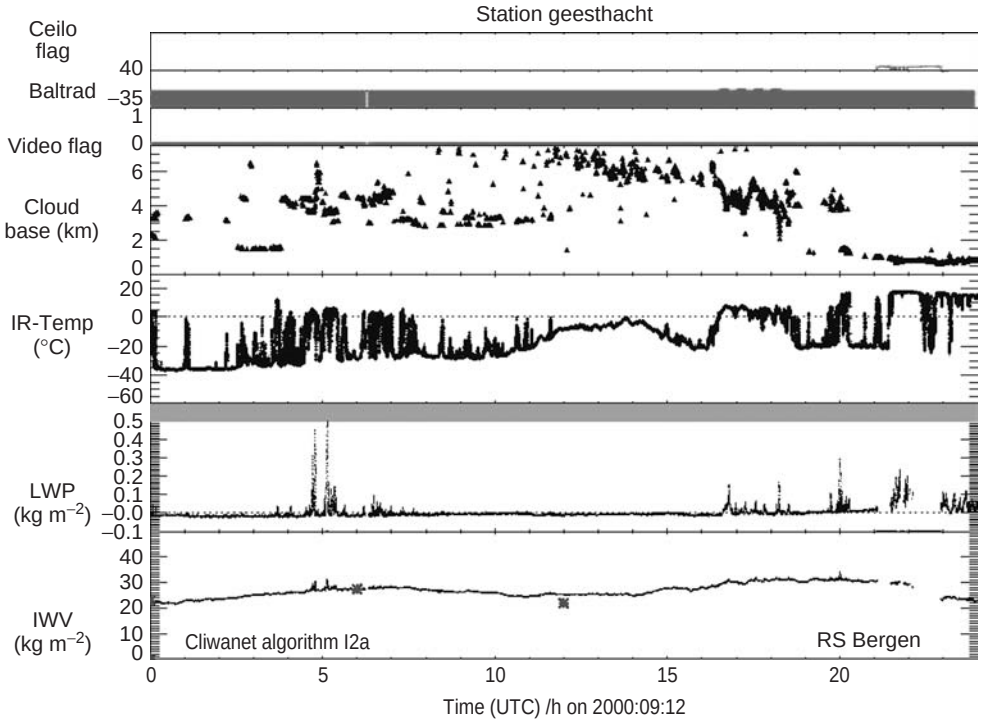

Figure 2 Times series of integrated water vapor (IWV) and liquid water path (LWP) derived from multispectral microwave radiomeasurements, infrared temperature, and cloud-base height derived from lidar ceilometer measured on 12 September 2000 at Geesthacht, Germany. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

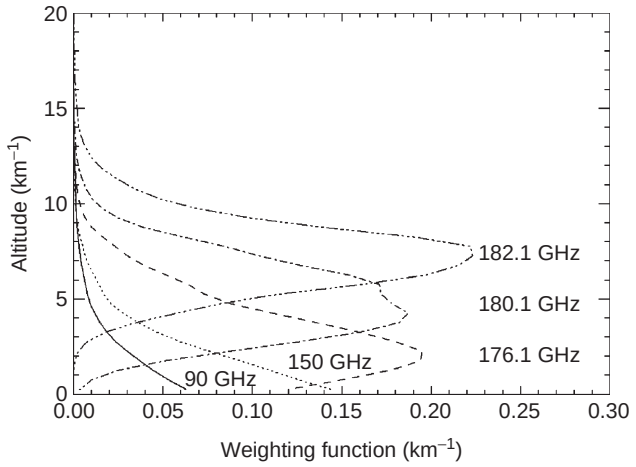

Figure 3 Weighting functions for the frequencies corresponding to the five AMSU-B channels (see Figure 1). The frequencies close to the center of the water vapor line at 183.1 are already saturated in the upper troposphere. The frequencies further away from the line center receive radiation from lower atmospheric levels. Therefore the window frequencies at 90 and 150 GHz also include information from the ground

positions is difficult to provide in real time. Therefore the accuracy for online values (employing predicted orbits) is lower compared to reprocessed data. When high-density network of GPS receivers are used, tomographic techniques can be applied to derive the four-dimensional structure of water vapor in the lower atmosphere (Flores *et al.*, 2001). The same observation principle as with GPS can also be applied to Very Long Base Line Interferometry (VLBI) with large telescopes used in space geodesy.

GPS receivers operated on LEO satellites can determine water vapor profiles via the so-called radio occultation technique. When these satellites rise and set relative to a GPS satellite, the GPS signal frequency changes as a result of the Doppler shift. From the frequency measurement the bending angle of the radio waves can be calculated. The bending angle is determined by the atmospheric refractivity and thus related to the water amount. Encouraging results have been obtained, for example, by the Challenging Minisatellite Payload (CHAMP) satellite (Wickert *et al.*, 2004) and future missions are planned to increase the number of profiles observed per day. One aspect to be clarified, however, is the occurrence of humidity biases especially in the tropics.

Thermal Infrared

Numerous absorption lines and bands exist in the infrared part of the electromagnetic spectrum. The typical temperatures of the Earth/atmosphere system lead to a

maximum emission of infrared radiation at about 10 μm. Exactly in this region – between about 9 and 12 μm – is a so-called window region with high atmospheric transmissivity. What little absorption remains in this spectral region is because of water vapor (and to a minor degree by ozone). However, the signal measured by a satellite in the atmospheric window is mainly dominated by emission from the Earth's surface. Therefore it is possible to simultaneously derive the integrated water vapor and the land surface temperature by the so-called Split-window (SW) technique from measurements at 11 and 12 μm. The method is limited to cloud-free scenes as clouds strongly absorb in this spectral region. The SW algorithm is derived from a perturbation form of the radiative transfer equation (*see* **Chapter 46, Principles of Radiative Transfer, Volume 2**) that is simplified through a parameterization to retrieve bulk layer parameters rather than profile information. This method is applied to the measurements from the Geostationary Operational Environmental Satellite (GOES) and the recently launched Meteosat Second Generation (MSG) satellite and can therefore provide good temporal and spatial coverage. The accuracy of this method has been evaluated in comparison to radiosondes and ranges from about $2.0-7.0\,\mathrm{kg\,m^{-2}}$. Further information about the SW technique and its validation for GOES can be found in Suggs *et al.* (1998).

By using several infrared channels along the wing of the water vapor absorption band (6.7 μm) where each channel receives radiation from a different altitude range, low-resolution water vapor profiles can be derived. For example, GOES has three channels 7.43, 7.02, and 6.51 μm, which give information about low-level, midlevel and upper-level moisture respectively. Near real-time soundings of water vapor and temperature can be accessed for the GOES coverage area at **`http://orbit35i.nesdis.noaa.gov/goes/soundings/skewt/html/skewtus.html`.** Similar infrared channels are used in the High-resolution Infrared Sounder (HIRS) flown as part of the Advanced TIROS Operational Vertical Sounder (ATOVS) package on the polar-orbiting NOAA satellites beginning with NOAA-15. The AMSU instrument described in the previous section is part of the ATOVS packages so that the limitation of the infrared method to cloud-free cases is compensated by the microwave technique. The accuracy of the operational ATOVS humidity soundings is 3 to 6 K in dew point temperature at 2-km vertical resolution (Li *et al.*, 2000).

While the infrared methods described above are based on the observation of a couple of channels, high-resolution interferometry of the infrared spectrum has the potential to retrieve water vapor with a much higher accuracy and vertical resolution, but again in cloud-free conditions only. This sort of instruments resolves the atmospheric emission between approximately 3 and 20 μm with a wavenumber resolution of $0.5\,\mathrm{cm^{-1}}$. The recorded spectra contain a large number of spectral features because of carbon dioxide, ozone, water vapor, and other minor trace gases. Similar to microwave radiometry the radiative transfer equation needs to be inverted to simultaneously retrieve the water vapor and temperature profiles. It should be noted that even with the high number of individual points, the retrieval problem is still ill defined as the channels are strongly correlated. Thus constraints are needed to prevent the inversion from becoming unstable. For the ground-based Atmospheric Emitted Radiance Interferometer (AERI) used by ARM, it was demonstrated that continuous observation of water vapor profiles can be achieved with approximately 5% accuracy in absolute water vapor in the lowest 3 km. A detailed description of the instrument and its validation is given by Feltz *et al.* (2003). The Earth Observing System (EOS) Aqua satellite launched in 2002 has the first high-spectral-resolution infrared sounder for operational weather forecasting onboard. The AIRS (**`http://www-airs.jpl.nasa.gov/index.html`**) performs observations at 2378 channels, while the Infrared Atmospheric Sounding Interferometer (IASI) instrument on the future METOP satellite will provide 8000 channel measurements. IASI will observe temperature and humidity profiles with a vertical resolution of 1.5–2 km and an accuracy of 1 K and 10% respectively to meet the WMO requirements (Lerner *et al.*, 2002).

Sun Photometer

A sun photometer measures the integrated water vapor by the extinction of direct solar irradiance. For this purpose exact tracking is necessary to point the collimator toward the center of the solar disk. A filter wheel rotates in front of the detector to obtain a sequence of measurements at typically 10 different spectral bands. The sun photometer also performs scanning across the sun to detect the presence of thin cirrus clouds that are typically for nonuniform scenes. Scanning is also necessary to derive the prime products: The aerosol size distribution and phase function are determined by inverting sky brightness temperature and incorporating radiative transfer routines. The integrated water vapor is derived from the strong near-infrared absorption band at 0.94 μm. As the strength of the solar transmission is known, and its extinction is described by Bouguer–Lambert–Beer's law (*see* **Chapter 46, Principles of Radiative Transfer, Volume 2**) a simple exponential relation between transmission and IWV can be assumed. This method is limited to cloud-free conditions and daylight. The uncertainty of this method is about 10% and is mainly caused by uncertainties in the knowledge of water vapor spectroscopy. For details see Schmid *et al.* (2001).

Reflected Sunlight from Satellite

From satellites the near-infrared (about 0.95 μm) water vapor absorption band can also be exploited. In contrast to the sun photometer where the direct sunlight provides a reference value, measurements in at least two channels are necessary to derive precipitable water from reflected sun light to account for surface reflectivity. Solar reflectance is measured at one window channel and at a second channel that experiences stronger water vapor absorption. The method can only be applied in regions with a reflective surface, for example, over land and over sun glint regions during daytime only. IWV can be measured with an accuracy of 5–10% from a number of polar-orbiting satellites employing these channels. The Moderate Resolution Imaging Spectrometer (MODIS) onboard the TERRA satellite (in orbit since 1999) uses four channels close to the water vapor absorption region to achieve a higher dynamic range. By using ratios of different channels, the effects of variations in surface reflectivity with wavelength are partially removed. MODIS provides high-resolution (1×1 km) IWV fields during daytime. Details on the remote sensing of water vapor and clouds are given by King *et al.* (1992). In the case of clouds, their high reflectance can be exploited and the water vapor column above the cloud deck can be estimated. The analysis of POLDER (Polarization and Directionality of the Earth Reflectances) measurements showed a mean root mean square (rms) error of 1.8 kg m^{-2} over the ocean and 2.0 kg m^{-2} over land (Albert *et al.*, 2001).

Lidar (Raman Lidar and DIAL)

Two different lidar techniques that provide high vertical resolution profiles of water vapor are emerging: Raman lidar (RL) and Differential Absorption Lidar (DIAL). Both lidar techniques work by emitting pulses of laser light and determining the range to the backscattering object by measuring the travel time of the respective pulse. Vertical resolutions better than 100 m can be achieved. Raman lidar measures the elastic backscatter from molecules and aerosols at the laser wavelength, as well as the Raman backscattered light at the two distinctive wavelengths that represent the Raman (wavelength) shift of nitrogen and water vapor molecules, respectively. The signal in each Raman channel is proportional to the number density of the backscattering molecule. Because nitrogen is uniformly mixed, the mass of nitrogen per kilogram of dry air is constant with altitude. Therefore the ratio between the number densities of water vapor and nitrogen (the ratio between the backscatter signal of both channels) is proportional to the water vapor mixing ratio – the mass of water vapor per mass of dry air (g kg^{-1}). The performance of Raman lidar systems is best during nighttime, in the absence of the daytime solar background. To allow daytime operation, a narrow band interference filter and a narrow field of view are used for the water vapor detection channels. Limiting factors in accuracy are the uncertainties in Raman cross sections and optical transmissions requiring an external calibration. However, this is a single height-independent calibration factor, which is mostly derived from radiosondes or microwave radiometers. The Raman lidar is able to measure upper tropospheric humidity with approximately 5% absolute accuracy. In the lower atmosphere, imperfect alignment can effect the measurement. Most of the presently operating systems cannot – or with strongly reduced performance – be operated during daytime. There is only one system (ARM, Oklahoma) worldwide that can operate unattended all day around the clock (Turner and Goldsmith, 1999).

DIAL measurements are made at two different wavelengths. One wavelength is chosen in a region of high water vapor absorption cross section, whereas at the second wavelength the gaseous absorption should be minimal. If aerosol scattering properties (backscatter and extinction) are the same at both wavelengths, water vapor density can be calculated assuming that the differential water vapor absorption cross section is known. The accuracy of DIAL measurements is specified to be better than 5% in the whole troposphere (Wulfmeyer and Bösenberg, 1998). The main difficulties which were encountered in the application of DIAL to water vapor measurements were associated with the narrow line width of the near-infrared absorption lines, which require tunable laser sources with extremely high frequency stability and narrow bandwidth, and, in particular, with extremely high spectral purity. Daytime measurements of water vapor using DIAL give superior results over RL in terms of resolution (in time and height) and accuracy, and have the advantage of being intrinsically calibrated. RL and DIAL should be regarded as complementary techniques.

Conclusions: Water Vapor

A number of different methods for observing water vapor and its vertical structure exist, each with its own special strengths and weaknesses. From the ground, microwave radiometers and Global Positioning Systems provide unattended all-weather measurements with high temporal resolution but coarse vertical resolution. Under cloud-free conditions high-resolution vertical structures can be observed by lidar. However, the lidar technique is far from the point of being used in operational surface networks. From space the integrated water vapor over the oceans can be observed with good global coverage in all weather conditions using microwave radiometry. Infrared methods from geostationary and polar-orbiting satellites provide a better horizontal resolution also over land but only in cloud-free conditions. Vertical profiles from satellite

soundings in the infrared and microwave regions have a coarse vertical resolution. A major improvement of the vertical resolution is expected by the new generation of infrared spectrometers. Since the methods have complementary benefits, major research is being carried out to integrate the different observations to obtain better products. Some of these approaches will be presented in the Section "Integrated approaches" devoted to sensor synergy.

The specification of accuracy of the different remote sensing methods provides a major challenge. Traditionally, radiosonde soundings are used for this purpose. Differences can be expected because a radiosonde measures the water vapor along its trajectory, for example, at different positions during its ascent. Unfortunately, the quality of standard radiosonde humidity measurements has also been found insufficient to serve as a reference, especially in the upper troposphere. Improvements are possible by employing chilled mirror hygrometers but these lead to much higher costs. The ARM program has performed several water vapor intensive observation periods (IOP) at its central facility in Oklahoma. An overview and initial accomplishments are described by Revercomb *et al.* (2003). The comparison included radio sondes, microwave radiometer, AERI, sun photometer, GPS, Raman lidar, DIAL, and *in situ* sensors. Unfortunately, it is still not possible to constrain the column amounts to better than 2% as biases between the different instruments are too high. More detailed error analysis is required since none of the instruments can be regarded as an absolute reference at any time. In the upper troposphere it was found that Raman lidar and GOES estimates agree much better with each other (10%) than radiosoundings (40% differences) (Soden *et al.*, 2004).

CLOUDS

Owing to a strong influence on atmospheric radiation, clouds are the limiting factor for several methods to derive atmospheric water vapor. On the other hand the strong interaction of clouds and radiation enables remote sensing techniques to infer cloud properties (Table 2). Information about the interior of water clouds, however, is only possible using microwave techniques active as well as passive because clouds are semitransparent in this spectral range. Ice clouds can be probed by optical lidar.

Water clouds consist of a large number of droplets of varying sizes. The number of all droplets within the unit volume is the total number density (m^{-3}). The drop-size distribution (DSD) describes the number density as a function of the droplet radius. Because of the complex microphysical processes within clouds, DSDs are highly variable in time and space. In contrast to raindrops, cloud droplets are perfect spheres. Thus, all cloud microphysical parameters can be calculated from the DSD. For example, the cloud liquid water content (LWC) ($kg\,m^{-3}$) is given by the droplet volume and the density of water. Because the volume of a sphere is proportional to the radius cubed, LWC is also called the *third moment of the DSD*. It comprises one of the most interesting properties of clouds and is the prognostic variable in most numerical weather prediction and climate models to describe clouds, but hardly any observations are available for the validation of the model results. Within these models treatment of ice clouds is even less advanced and prognostic schemes for the ice water content (IWC) are currently under development. For ice particles the observation of their properties becomes more difficult as they can exist in complicated shapes as hexagonal columns and plates, dendrites, needles, and so on. In general, clouds can either occur in a pure liquid or ice phase but also as a mixture of both.

In describing the radiative properties of clouds and their effect on the energy budget of the atmosphere, cloud opacity (also called *optical thickness or optical depth*) is the most important parameter. Cloud opacity τ is a dimensionless measure of the light attenuation caused by scattering and absorption of solar radiation by atmospheric particles. The transmission through the cloud is given by $\exp(-\tau)$, for example, a cloud with an optical depth of 5 has a transmission less than 1%. The effective radius of the cloud is needed for some applications, for example, solar radiative transfer models. It is defined as the third moment of the DSD divided by the second moment, meaning it is a ratio of droplet volume to droplet surface area.

To observe the complete microphysical properties, for example, the DSD and the complex shape of ice or mixed cloud particles, major efforts employing aircraft and balloon measurements are necessary. Traditionally, remote sensing methods have focused on the observation of macroscopic cloud properties such as cloud boundaries and the cloud fraction in a certain area. Currently, a number of synergistic approaches combining active and passive instruments (radar, lidar, and radiometer) are being pushed in an attempt to increase knowledge about cloud microphysics.

Pioneering work has been done within the International Satellite Cloud Climatology Project (ISCCP), which infers cloud properties from operational satellites in geostationary and polar orbit. Established in 1982 as part of the World Climate Research Programme (WCRP), ISCCP collects and analyzes satellite radiance measurements to infer the global distribution of clouds, their properties, and their diurnal, seasonal, and interannual variations from a data set of nearly two decades. The ISCCP products based on harmonized algorithms are cloud cover fraction, optical thickness, cloud-top temperature and its mesoscale variability, cloud-top pressure, and several more. The cloud type

(cumulus, stratus, etc.) is derived from a cloud classification on the basis of optical thickness and cloud-top pressure. A general overview about ISCCP can be found in Rossow and Schiffer (1999). The project web site (Rossow and Duenas, 2004) **http://isccp.giss.nasa.gov/** provides access to data since 1983. In the following section a brief outline about the basic principles in deriving cloud parameters from measurements in the different spectral regions, as well from the ground as from space is given.

Microwave Radiometry

The liquid water path can be estimated from atmospheric emission measurements in the microwave region because in this spectral region the cloud contribution strongly increases with frequency (Fig.1). The standard dual-channel principle has been described above for the determination of precipitable water. For the retrieval of LWP the channel close to the water vapor absorption line corrects for the changing water vapor concentration of the atmosphere. Such observations are, with the exception of expensive and rather limited aircraft measurements, the most accurate method to observe LWP with an estimated accuracy of better than $30\,g\,m^{-2}$. A rough estimate shows that about $10\,g\,m^{-2}$ are caused by the measurement error while the rest can be attributed to the underdetermined retrieval problem. The additional use of the 90 GHz channel can further constrain the problem and improve accuracy to less than $15\,g\,m^{-2}$ (Crewell and Löhnert, 2003).

Satellite measurements (SSM/I, AMSU, TRMM, AMSR) have been available for more than two decades. Their main disadvantage is that reasonable estimates can only be made above the oceans and only with poor (several 10 km) resolution. The high variability of clouds can cause errors in LWP as a result of inhomogeneous beam filling of the satellite field of view, especially in the case of precipitation. Over land the ground-based microwave radiometers can observe LWP with high temporal resolution at one point (Figure 2). First attempts to set up a network of ground-based microwave radiometers have been performed within the BALTEX Cloud Liquid Water Network (Crewell *et al.*, 2002) in north central Europe to evaluate and improve the forecast of clouds in atmospheric models.

Ice clouds are transparent at low microwave frequencies. With increasing frequency the scattering efficiency of ice clouds increases and cirrus clouds reduce the upwelling brightness temperature significantly. Because of the strong water vapor absorption in the submillimetre, the surface is screened from the satellite view. The observed reduction in brightness temperature is closely related to the ice water content and the characteristic particle size. Thus, suggestions for future spaceborne missions have been made (Evans *et al.*, 2002) to observe ice clouds from measurements in the range between 200 and 700 GHz. The frequencies need to be selected carefully as a large number of atmospheric trace gases have emission lines in this region. Currently, the capabilities of this method are being analyzed by investigating the radiative transfer of irregular shaped ice crystals in this frequency range and by aircraft demonstration of the instruments.

Cloud Radar

Radiowave Detection and Ranging (Radar) basically employs the same principle as lidar techniques, but involve radiation in the microwave range. While weather/precipitation radars operate at microwave frequencies below 10 GHz, cloud radars typically transmit radiation at window regions (35 and 95 GHz) to avoid attenuation by water vapor (Figure 1). Because attenuation increases with frequency in the microwave region, cloud radars still suffer from significant attenuation and are limited in their operation range. Ground-based cloud radars typically point vertically and gather time-height series (Figure 4). The vertical resolution of ground-based cloud radars is comparable to lidars with less than 100 m. Future spaceborne radars (Stephens *et al.*, 2002) will have a vertical resolution of about 500 m. Like precipitation radar they mostly operate in the Rayleigh regime, for example, the particle size is small compared to the wavelength. Because cloud droplets ($\sim$10 μm) are much smaller than rain drops ($\sim$1 mm), a higher frequency (shorter wavelength) is used in cloud radars. In the Rayleigh regime the backscatter from cloud droplets is proportional to the sixth moment of the DSD and thus, the derivation of the liquid water content, proportional to the third moment of the DSD, is highly uncertain. Even the presence of one single large drop can dominate the whole measurement. This effect is often evident when clouds start to precipitate only a few drops that evaporate before they can reach the ground (drizzle). In this case the few, but large drops will generate a significant signal and the cloud base would be estimated too low. A detailed description on the use of cloud radar and ceilometer for cloud height estimation is provided by Clothiaux *et al.* (2000). Many relations to convert the radar reflectivity factor Z to the liquid water or ice water content via so-called Z-LWC or Z-IWC relations have been developed. The reader is referred to Sassen and Liao (1996). As indicated above the uncertainty is relatively high. Fox and Illingworth (1997) give an error of 50% for a single LWC retrieval in a nondrizzling stratocumulus cloud.

Liquid water attenuates microwave radiation and can lead to an underestimation of more distant cloud layers. The attenuation is roughly proportional to the liquid water content. As the attenuation increases with frequency, dual wavelength techniques can be used to derive the attenuation and the liquid water content profile, respectively (Gaussiat *et al.*, 2003). Vertical-pointing radars can make use of the Doppler (frequency) shift of backscattered radiation and determine the fall velocity of the cloud particles. While

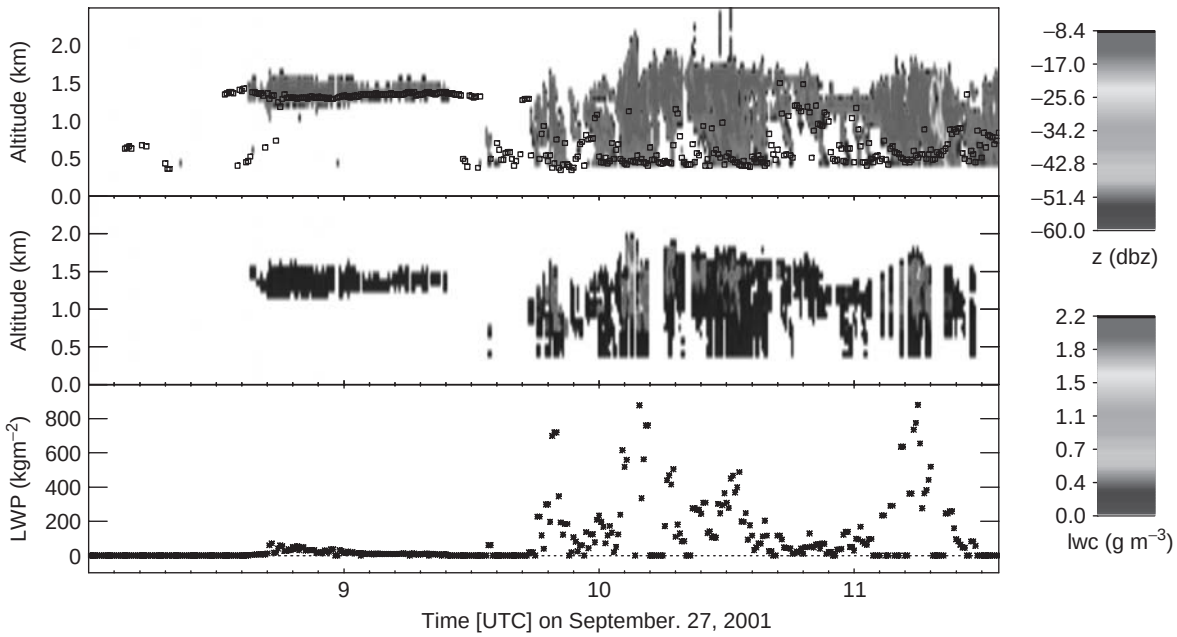

Figure 4 Time series of the radar reflectivity profile measured by a 95 GHz cloud radar on September 27, 2001 at Cabauw, The Netherlands. Squares show the cloud-base height as observed by a lidar ceilometer. The profile of liquid water content was derived from a cloud radar, multifrequency microwave radiometer and auxiliary measurements using the integrated profiling method. The liquid water path is the vertical integral of the profile shown above (courtesy of U. Löhnert). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

cloud droplets do not move vertically, the measurement can identify regions of significant precipitation. Furthermore, snow precipitates much slower than liquid precipitation and the fall velocity can be used as an indicator for precipitation phase. Some radars can also measure polarization quantities. As ice particles cause depolarization due to their irregular shape, this information can be used for phase distinction.

Thermal Infrared

Most water clouds have an emissivity in the infrared spectral region, which is close to one, and thus can be regarded as blackbodies. Therefore, the emitted infrared radiation is directly proportional to the temperature of the cloud boundary via Plancks law. If the atmospheric temperature profile is known, the observed temperature can be converted to cloud height and cloud pressure. The measured radiance may be influenced by water vapor absorption, which however, is low in the atmospheric window between 9.5 and 11.6 μm. In humid conditions the contribution of water vapor between the cloud and the receiver may be as large as a few kelvin. This principle to derive cloud boundary temperature is used from satellites as well as from the ground. Observations from the ground (see Figure 2) show the strong sensitivity of the infrared radiometer; for example, cloud-base temperature can be reliably determined even for clouds with low LWP values (little water) around 4 UTC (in Figure 2). The observations cannot distinguish between water and ice clouds as supercooled clouds can occur down to 233 K, and clouds between 233 and 273 K could be either water, ice, or a mixture.

Very few thin water clouds and many ice clouds have an emissivity significantly below one and as consequence, radiation can penetrate through the cloud, for example, it is semitransparent. Then, a certain part of the measured radiance originates from radiation transmitted through the cloud and the measured signal contains a mixture of both, the radiation behind the cloud and the cloud itself, for example, satellite observations would include the contribution from the warm surface (or a warmer cloud below) leading to a warm bias in the estimated cloud temperature. To avoid this problem observations at several wavelengths are used. Because the wavelength channels are distributed along the wing of a strong absorption band (mostly the CO_2 absorption band centered at 15 μm), the channels have responses from different altitudes. The so-called CO_2 slicing method is applied for instance to MODIS data and derives cloud-top pressure by measuring several channels between 13.3 and 14.2 μm along the strongly absorbing CO_2 band. The more absorbing the band, the more sensitive the channel is to higher clouds. A low cloud will not be visible in measurements from a strongly absorbing channel that is effectively sensitive to higher regions in the atmosphere. If one takes two nearby channels along the band, cloud emissivity can be assumed constant and thus, cancel out if

the ratio of the two channels is taken. The same method is possible using the O_2A-band in the visible spectral range. Cloud-top pressure can be derived with good accuracy from such ratios for mid and high-level clouds. Problems arise in the cold, polar regions.

Reflected Sunlight

Nearly all meteorological satellites employ channels in the visible part of the electromagnetic spectrum where clouds have a high reflectivity, making them so important for the atmospheric energy budget. The measured radiances are mostly converted to reflectances whose values range from 0 to 1. In order to detect the presence of clouds within one satellite pixel, knowledge about the surface reflectivity is required, for example, surface reflectivity maps are generated beforehand under cloud-free conditions. This can be done because changes in surface reflectivity normally are slow (vegetation changes) compared to reflectivity changes due to clouds. The reflectance at a nonabsorbing wavelength, for example, at 0.65 μm, is primarily a function of cloud optical thickness. The reflection function of a near-infrared absorbing band (2.14 μm) is primarily a function of cloud effective radius as small droplets (or ice crystals) reflect more radiation than larger particles. For opaque clouds the simultaneous retrieval of cloud opacity and effective radius from visible and near-infrared reflectivity is well defined (Nakajima and King, 1990). It should be noted, however, that the retrieved effective radius is representative of that portion of the cloud from which the radiation emanates. For an optically thick cloud, this would correspond to the upper portions of the layer. For the retrieval of both optical depth and effective radius, *a priori* information about cloud phase is required, and in the case of ice clouds, assumptions regarding the cross-sectional area for a given crystal size and mass must also be made. Different methods for phase separation are possible. The refractive index of pure water and ice is well separated around 1.7 μm. At this wavelength radiative transfer calculations show that ice crystal reflectivity is approximately constant with wavelength while water cloud reflectivity strongly increases with increasing wavelength. Therefore, high spectral resolution measurements can distinguish cloud phase. Simpler methods compare reflectivities at 1.6 μm and 0.75 μm. Optical depth τ and effective radius r_e can be used to estimate LWP of water clouds by applying the relationship $\mathrm{LWP} = 2\tau\ \mathrm{r}_e/3$ from. If no suitable measurement for deriving the effective radius exists, a value of 10 μm is often assumed. Many more techniques for phase distinction, but also effective radius, liquid water content, and so on exist, which make use of reflected solar radiation and/or infrared brightness temperatures. For example, the retrieval of cloud products from MODIS, which involves channels in the visible and infrared is described in King *et al.* 1992.

Lidar

Cloud particles strongly scatter and absorb the lidar signal at wavelengths in or near the visible part of the spectrum. A water cloud is immediately visible in the measured backscatter profile. Thus, also simple low-power lidar systems – so-called ceilometers – operating unattended (often at airports) can be used to derive the cloud-base height with high accuracy. For this purpose the backscatter signal is converted to the extinction profile, and an extinction threshold is used to estimate cloud-base height. The conversion of the attenuated backscatter signal to extinction is again an underdetermined problem and mostly a constant ratio between lidar backscatter and extinction is assumed.

From the ground the combination of an infrared radiometer and a lidar ceilometer (Figure 2) can provide information about the temperature and the height of the cloud base and therefore gives one point in the temperature profile. The high opacity of water clouds causes the ceilometer signal to be attenuated within the first few hundred meters of the cloud. Therefore higher clouds cannot be detected in the presence of lower water clouds from the ground and vice versa for satellite applications. The lidar backscatter is proportional to the second moment of the DSD. In other words, the backscatter depends on the total cross-sectional area of that the particles in the DSD present to the radiation stream. The cloud radar described above is very sensitive to larger particles (proportional to the sixth moment of the DSD) when the cloud particles are small compared to the radar wavelength (Rayleigh approximation), while the lidar signal is dominated by smaller particles. Therefore the cloud base derived from radar and lidar often does not agree. In the presence of large, precipitating droplets, the radar cloud base (Figure 4) will be lower than the one from the lidar. It should be noted that lidars are more sensitive to thin clouds with small droplets and very often observe clouds that fall under the detection threshold of the radar. It is not uncommon for lidar to observe significantly higher cloud tops in cirrus than cloud radar because of the predominance of small particles near the tops of cirrus layers.

Within the ice clouds the extinction of the lidar signal is much lower. Therefore, the observations have the potential for the derivation of ice cloud properties (particle size, ice–water content). A major difficulty is the correction of uncertainty, given the uncertainty in the extinction-to-backscatter signal. The phase of cloud particles can be detected easily by transmitting linearly polarized light and detecting parallel and orthogonal polarizations in the backscatter. Spherical water drops cause little depolarization, whereas ice particles create depolarization ratios of typically 50%. Information on the derivation of microphysical properties derived from lidar polarization are given by Sassen and Benson (2001).

Conclusions: Clouds

Meteorological satellites have been observing the basic cloud properties, for example, cloud amount, height, and opacity, for several decades by using thermal infrared and reflected solar radiation measurements Long-term products are available by the ISCCP project. Satellite observation of the polar regions is problematic due to the difficulty in separating clouds from the surface. Infrared techniques suffer from the cold temperatures and strong temperature inversions, while the high reflectivity of snow and ice makes clouds difficult to detect from reflected sun light. In general, observations during the night are problematic as only infrared measurements are available. The use of more wavelength channels improves the estimation of cloud phase, particle size, effective radius, and liquid water path. However, this information is mostly limited to the upper part of the cloud. Information about the interior of water clouds is only possible by microwave techniques, as well as active (cloud radar) as passive (radiometer). Owing to the complex microphysical structure, the exact description of the cloud properties can only be gained by sensor combination, which is described below.

INTEGRATED APPROACHES

The description of the various methods used to observe water vapor and clouds given the above discussion reveals the limitations of single instrument techniques. Recently, increased efforts have been made to combine measurements from different instruments. This is true as well for ground-based observation as satellite missions and a combination of both.

In order to observe the atmospheric state as completely as possible, ground-based atmospheric observatories compile a large number of advanced remote sensing and *in situ* sensors. Examples are the Cloud and Radiation Testbeds (CART) of the ARM program in Southern Great Plains, the Tropical Western Pacific, and the North Slope of Alaska, as well as the Coordinated Enhanced Observing Period (CEOP) reference sites like Cabauw (The Netherlands) or Lindenberg (Germany).

On satellites, complementary instruments are operated simultaneously in order to overcome the limitations of single systems. For example, infrared humidity profilers are supplemented by microwave profilers, which have a coarse resolution but provide all weather information. Because measurements of solar radiation have a superior spatial resolution, they can be used to provide subpixel variability of the highly variable cloud field for the other methods. The AIRS sounding suite on NASA's EOS Aqua spacecraft is intended to be used to create global three-dimensional maps of temperature, humidity, and clouds in the Earth's atmosphere with unprecedented accuracy. For that purpose, the AIRS interferometer itself is complemented with a 4-channel visible/near-infrared imaging module, a 15-channel microwave temperature sounder, and a 4-channel microwave humidity sounder (Aumann *et al.*, 2003). To exploit the sensor synergy it is crucial to align the instruments with each other and scan the atmosphere in a synchronized way, as the observation target is highly variable in time and space.

Instead of combining retrieval products derived from single instruments, the direct observables can be integrated in one retrieval system. Here an example for the combination of advanced ground-based measurements including microwave measurements will be given. Both *active* and *passive microwave remote sensing* provide information about microphysical properties of clouds. While the radar provides vertical structure information, microwave radiometers can accurately determine the vertically integrated liquid water content. In the past methods have been developed to combine colocated microwave radiometer and cloud radar measurements to infer LWC and effective radius profiles (Frisch *et al.*, 1998). In principal, such methods use the microwave-derived LWP to scale the LWC derived from the cloud radar reflectivity measurements at each height. However, this involves assumptions about the shape of the DSD and its vertical structure. Multispectral microwave measurements contain additional information on the vertical profiles of temperature, humidity, and to a very limited degree, LWC. Using an Integrated Profiling Technique (IPT) (Löhnert *et al.*, 2004), which applies the optimal estimation theory (e.g. Rodgers 2000), profiles of temperature, humidity, and LWC can be simultaneously retrieved. In contrast to the other methods mentioned above, IPT directly combines 19 microwave brightness temperatures with 95 GHz cloud radar reflectivity profiles, lidar ceilometer cloud base, ground-level measurements of temperature, humidity and pressure, nearest-by radiosonde profiles, and a LWC *a priori* profile obtained from a microphysical cloud model. The advantage of this technique is that the retrieved profiles are physically consistent. This is accomplished by the fact that the retrieved profiles are constrained to the ground-level measurements, they fulfill the condition of saturation within the detected cloud boundaries from ceilometer (base) and cloud radar (top), and their forward-modeled brightness temperatures are constrained to the measured values within their error bars. Momentarily the method is, however, limited to cases of pure water clouds with negligible precipitation (Figure 4). A fundamental requisite in this method is the correct error characterization of the single observations as they determine the degree of how strongly the instruments contribute to the retrieval product. Unrealistic errors in one type of approach might distort completely how other information is used in retrievals. Therefore, much effort needs to be put in the "validation" of error estimates.

Owing to their fine vertical and horizontal resolution, active instruments, in particular, radar and lidar, can be well matched and are uniquely able to provide essential information on the vertical profile. It has already been mentioned that both can provide complementary information about cloud-base height as the lidar is not affected by drizzle. On the other hand, attenuation of the lidar signal is strong and most clouds cannot be penetrated. Therefore cloud-top height derived from cloud radar is more reliable. The complementary nature of lidar and radar not only provides a more complete description of cloud boundaries than either instrument alone but simultaneous lidar and radar retrievals for profiling mean particle size and water content in cirrus clouds are also currently developed (Donovan and van Lammeren, 2001). Ice cloud characteristics can also be derived by combining lidar observations with infrared radiometer observations via the so-called lidar-radiometer (LIRAD) method of ground-based sensors. The method and its application are described in Platt *et al.* (1998).

In addition to the combination of instruments operated on one platform, the synergy between space and ground-based instruments is being pursued. While satellite instruments mostly have good observing capabilities in the middle and upper troposphere, ground-based systems have better resolution in the planetary boundary layer (PBL). Processes in the PBL can change the thermodynamic structure rapidly, which can be well observed in the time series from the ground. Satellite revisit times are less frequent and may be sufficient to detect the development in the upper atmosphere. Clouds block infrared and solar radiation effectively, and the synergy of ground-based and space-borne sensors can provide information above and below the cloud as well as the properties of the cloud boundaries. However, in the simultaneous presence of high and low clouds, information about the midtroposphere can be only gained by employing microwave techniques. An example for this kind of synergy is the blending of ground-based AERI Raman lidar measurements at the ARM CART site with GOES hourly temperature and water vapor retrievals to give high-resolution water vapor profiles (Turner *et al.*, 2000).

CONCLUSIONS

Several remote sensing methods exist to derive water vapor and cloud properties from either the ground or space. However, each of these methods has their limitations and major gaps still exist in the current observing system. Passive sensors generally smooth vertical profiles more than active sensors but provide a better global coverage from space. Infrared and solar techniques can yield good horizontal resolutions but are limited to cloud-free regions. Microwave observations on the other hand can penetrate clouds but have coarse resolutions. In order to overcome the limitations of the different systems, the synergy of different sensors is exploited. For global observations performed from satellites, this is accomplished by combining a complementary suite of instruments on one satellite or arranging complementary satellites in close constellation. In the future, the new generation of sounding interferometers (AIRS, IASI), lidar (CALIPSO), and cloud radar (CloudSat, EarthCare) are expected to provide unprecedented high-quality, high vertical resolution humidity and cloud property measurements from space.

The first spaceborne radar is scheduled to be launched in 2005 within the CloudSat mission (Stephens *et al.*, 2002). It will fly in constellation with four more satellites (Aqua, CALIPSO, PARASOL, and Aura) known as the *A-train*. While Aqua, which has on board MODIS, AIRS, and AMSR, will lead CloudSat by less than 120 s, CALIPSO, which will fly a dual wavelength depolarization lidar, will lag CloudSat only by 15 s. The combined information should give an almost complete picture of the three-dimensional properties of water vapor and clouds. The use of active instruments will for the first time give insight into the vertical cloud structure on the global scale, that is, the occurrence of multilayer clouds, their properties, and their impact on the radiative budget can be investigated.

On the ground, very few, well-equipped reference stations with advanced remote sensing instrumentation exist which are well suited for satellite validation, process studies, and long-term monitoring. To achieve area-wide coverage, much denser networks are needed. Unfortunately, many of the techniques are too costly for this purpose and future work needs to focus on low-cost and low-maintenance operation. Further improvements in observing water vapor and cloud variations are expected to be observed by scanning microwave radiometers and scanning lidars. In order to fully exploit the synergy of the different sensors new algorithms need to be developed. Several retrieval algorithms already exist which combine data from two or three instruments, however, unified retrieval systems that can make use of all available instruments at one site and provide profiles of all meteorological variables and their associated errors are necessary.

It should be noted that most remote sensing methods strongly rely on the accurate knowledge of the radiative transfer in the atmosphere. The need for more accurate models to describe the absorption by the water vapor continuum in the visible, infrared, and microwave range has been the outcome of several studies (Revercomb *et al.*, 2003; Schmid *et al.*, 2001). Potential model improvements will immediately enhance the quality of remote sensing methods.

Acknowledgments

The author would like to thank Dr. Jörg Schulz (DWD) for many helpful discussions and Dr. Ulrich Löhnert for

providing Figure 4. The paper benefited from the comments of many other colleagues and the two reviewers.

PART 6

Soils

66: Soil Water Flow at Different Spatial Scales

JAN W HOPMANS AND GERRIT SCHOUPS

Department of Land, Air and Water Resources, University of California, Davis, CA, US

A major challenge in hydrological sciences is the modeling of flow and transport processes and their measurement across a range of spatial or temporal scales. Such needs arise, for example, when watershed processes must be determined from soil hydrological data collected from a limited number of in situ field measurements or analysis of small soil cores in the laboratory. The scaling problem cannot be solved by simple consideration of the differences in space or timescale, for several reasons. First, spatial and temporal variability in soil hydrological properties create uncertainties when changing between scales. Second, flow and transport processes in vadose zone hydrology are highly nonlinear. As a result, vadose zone properties are nonunique and scale-dependent, resulting in effective properties that vary across spatial scales and merely serve as calibration parameters in hydrologic models. Therefore, their estimation for heterogeneous materials can only be accomplished using scale-appropriate measurements and models. We present examples of soil water flow at the pore, local, and regional scales. The inherent complexity of flow in heterogeneous soils, and the need to integrate theory with experiment, requires innovative and multidisciplinary research efforts to overcome limitations imposed by current understanding of scale-dependent soil water flow and transport processes.

INTRODUCTION

The unsaturated zone is bounded by the soil surface at one end and merges with the groundwater in the capillary fringe at the lower end. The distinction between groundwater and the unsaturated zone is usually made within a hydrologic context, emphasizing water as the agent of change of the subsurface and the main driver for transport of chemicals between the atmosphere and groundwater. To emphasize the profound influence of soil chemical and biological processes on water flow and chemical transport, one may generally refer to the unsaturated flow domain as the vadose zone.

The upper part of the vadose zone is the most dynamic, and changes occur at increasingly smaller time and spatial scales when moving from the groundwater towards the soil surface. The most upper part of the vadose zone is subject to fluctuations in water and chemical content by infiltration and leaching, water uptake by plant roots (transpiration), and evaporation from the soil surface. Water is the main ingredient leading to soil formation from the weathering of parent material such as rock or transported deposits, with additional factors, such as climate, vegetation, topography, and parent material, determining soil physical properties. Generally, the soil depth is controlled by the maximum rooting depth (generally within a few meters from the soil surface). However, the vadose zone can extend much deeper than the surficial soil layer and includes unsaturated rock formations and alluvial materials to depths of 100 m or more, determined by hydrologic, topographic, and lithographic characteristics. In the last few decades, research interest in the deeper vadose zones has increased, instigated by the need to sustain quality of groundwater and resources for drinking water and ecological purposes. Scientists are becoming increasingly aware that soil is a critically important component of the earth's biosphere, not only because of its food production function, but also as the safekeeper of local, regional, and global environmental quality. For example, it is believed that management strategies in the unsaturated soil zone will offer the best opportunities for preventing or limiting pollution, or for remediation of ongoing pollution problems. Because chemical residence times in groundwater aquifers can range from years to thousands of years, pollution is often essentially irreversible. Prevention or remediation of soil and groundwater

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

contamination starts, therefore, with proper management of the vadose zone.

Transient isothermal unsaturated soil water flow is generally described by the so-called Richards' equation,

$$\frac{\partial \theta}{\partial t} = \nabla \cdot [K(\theta)\nabla(h_m + z)] + S(t) \qquad (1)$$

which solves for the soil water matric potential (h_m), water content (θ), and water-flux density as a function of time and space, using one, two, or three-dimensional flow models. In equation (1), $S(t)$ represents a sink/source term that is routinely used to describe plant root water uptake, K is the unsaturated hydraulic conductivity tensor (L T^{-1}), and z denotes the gravitational head (L) to be included for the vertical flow component only. The relationship between h_m and θ is determined by the soil water retention function, of which the slope, $C(h_m)$, is the so-called soil water capacity. Boundary conditions must be included to allow for specified soil water potentials and fluxes at all boundaries of the soil domain, whereas user-specified initial conditions and time-varying source/sink terms need be specified. Both the soil water retention and unsaturated hydraulic conductivity relations (in combination referred to as soil hydraulic functions) are highly nonlinear, with both h_m and K varying many orders of magnitude over the water content range of significant water flow.

Many analytical and numerical mechanistic flow models have been developed to solve equation (1), for specific agricultural or environmental applications. In short, the dynamic water flow equation is a combination of the steady state Darcy expression and a mass balance formulation. Using various solution algorithms, the soil region of interest is discretized in finite-size elements that can be one, two, or three-dimensional. Numerical solution requires that mass balance be maintained within each small volume element within the soil domain at all times. Richards equation is typically a highly nonlinear partial differential equation, and is therefore extremely difficult to solve numerically because of the largely nonlinear dependencies of both water content and unsaturated hydraulic conductivity on the soil water matric potential (h_m). Both the soil water retention and unsaturated hydraulic conductivity relationships must be known *a priori* to solve the unsaturated water flow equation. Although soil water retention measurements are time-consuming (Dane and Hopmans, 2002), unsaturated hydraulic conductivity data are even much more difficult to obtain from measurements (Klute and Dirksen, 1986). Functional unsaturated hydraulic conductivity models, based on pore size distribution, pore geometry, and connectivity, require integration of soil water retention models to obtain analytical expressions for the unsaturated hydraulic conductivity. The resulting expressions relate the relative hydraulic conductivity K_r, which is defined as the ratio of the unsaturated hydraulic conductivity K to the saturated hydraulic conductivity K_s, to the effective saturation to yield a macroscopic hydraulic conductivity expression. Pedotransfer function models (*see* **Chapter 76, Models for Indirect Estimation of Soil Hydraulic Properties, Volume 2**) have been developed to estimate soil hydraulic parameters for various functional models (**http://www.usyd.edu.au/su/agric/acpa/software/multistep.htm**).

Soil hydraulic functions that characterize flow and transport processes at larger spatial scales are mostly obtained from relatively small measurement scales. For example, prediction of soil water dynamics at the field scale is routinely derived from the measurement of soil hydraulic properties from laboratory cores, collected from a limited number of sampling sites across large spatial extents, often using large sampling spacings. Typically, the measurement scale for soil hydraulic characterization is in the order of 10 cm, with a sample spacing of 100 m or larger. Soil hydrological parameters obtained from these centimeter-scale measurements are subsequently included in numerical models with a grid or element size ten times as large or larger, with the numerical results extrapolated to field-scale conditions. Because of the high nonlinearity of the soil hydraulic functions, their application across spatial scales is inherently problematic. Specifically, the averaging of processes determined from discrete small-scale samples may not describe the true soil behavior involving larger spatial domains. In addition, the dominant hydrological flow processes may vary between spatial scales, so that potentially different models need to be used to describe water flow at the soil pedon, field scale, or watershed scale. In 1991, the US National Research Council (NRC, (1991)) identified the scaling of dynamic nonlinear behavior of hydrologic processes as one of the priority research areas that offer the greatest expected contribution to a more complete understanding of hydrologic sciences.

Many field experiments have confirmed that soil heterogeneity controls the hydrology of flow and transport, including preferential flow such as through cracks by soil shrinkage (*see* **Chapter 67, Hydrology of Swelling Clay Soils, Volume 2**). Although some hydrological studies successfully applied a deterministic approach, other studies showed the need for either distributed physically based modeling or stochastic modeling at the watershed scale, mostly because deterministic models require an enormous amount of data to accurately represent the multidimensional soil heterogeneity. Alternatively, the conceptual characterization of flow at the large scale may be simplified by modeling the key flow mechanisms for representative elementary areas (REA's) within the larger domain, using REA-appropriate effective hydrological parameters (Blöschl *et al.*, 1995). The need to incorporate the spatial organization of these key properties,

such as the soil hydraulic functions, is now also recognized in soil science. Specifically, we refer to the treatise by Roth *et al.* (1999), outlining a conceptualization of the control of soil heterogeneity and its spatial organization on soil flow and transport processes, using the so-called scaleway approach. In this approach, the three-dimensional field domain is defined by structural and textural elements. The various identified structural elements describe the dominating physical features that affect the hydrological mechanisms operating at the larger spatial scale, whereas the textural patterns within the structural units merely cause perturbations of these main hydrological processes. This hierarchical notation of structure and texture within a hydrological context should not be confused with soil texture and soil structure, although it can be argued that soil properties such as soil structure and texture may have a dominant control on soil hydrology. Thus, characterizing soil hydraulic variability is predicated on identifying those soil hydrological units that cause major differences in soil water regime at the spatial scale of interest. In soil hydrological studies, these structural units across the landscape may be defined by soil map units (Ferguson and Hergert, 1999). The smaller spatial scale level of textural information within the larger structural units can be determined either deterministically or stochastically, for example, through scaling of soil hydraulic properties from laboratory soil cores (Hopmans and Stricker, 1989). The upscaling from the textural to the structural scale level may result in effective, scale-appropriate soil hydraulic functions that may differ in form and parameter values between spatial scales, but serve a similar function in equation (1). Much of the issues associated with spatial scaling of soil hydrological processes were presented in Hopmans *et al.* (2002a). It is also the focus of this treatise to review the current state-of-the-art of solving the unsaturated water flow equation (1) across spatial scales.

SCALE-DEPENDENCY OF SOIL PROPERTIES AND PROCESSES

Upscaling requires integration and aggregation of spatial information into larger spatial units, for example, as in the estimation of an effective field soil water retention or conductivity curves from small-scale laboratory core measurements. As pointed out by Baveye and Boast (1999), Darcy's experiment can in effect be interpreted as yielding an upscaled, effective saturated hydraulic conductivity. In contrast, downscaling is the disaggregation of scale into smaller scales, for example, as in distributed hydrological modeling. Baveye and Boast (1999) discuss the confusion on concepts of scales in vadose zone hydrology. In contrast to the "perceived" clear hierarchy of spatial and temporal scales, they point out that the differentiation between scales is partly arbitrary, and depends, for example, on the scale of measurement and system scale. Moreover, whatever the spatial scale considered, it has its own characteristic dynamics, and should be treated that way, so that focus should be placed on experimentation and measurement methods that are representative for the different scales. Loosely, one may define the microscopic pore scale, the local scale, and the regional scale such as agricultural fields and watersheds. The macroscopic Darcy equation is considered to be valid for the local scale, with a typical size in the range of centimeters to meters. It is the local scale for which equation (1) is considered to be generally valid. It is also this scale, for which the Darcy equation can be derived from the volume averaging of the Stokes equations at the microscopic scale level. Increasingly, innovative measurements and modeling techniques are becoming available to measure and model pore size scale properties and processes. The regional scale typically applies to agricultural fields and watersheds for which the relevant soil hydrological properties become increasingly nonstationary. Yet, it is at these larger spatial scales that solutions are increasingly sought, putting the validity of equation (1) into question.

When increasing the spatial scale, soil properties typically become nonstationary, as evidenced by the delineation of soil map units by a soil survey. As one moves through a sequence of increasing sampling scales, nonstationarities at smaller spatial scales may be eliminated, and soil properties may change from deterministic to random, with the smaller-scale variations filtered out by the larger scale process or aliasing (Kavvas, 1999). The spatial organization and its evolvement across spatial scales can be viewed as continuous with deterministic patterns evolving as the field-of-view changes. At each field-of-view, the large-scale variation can be regarded as deterministic, whereas the smaller scale variations within each main unit can be treated stochastically. As explained earlier, this hierarchy of spatial scales (Cushman, 1990) can be described by structural and textural elements, as defined by the scaleway approach of Roth *et al.* (1999), with the structural elements describing the dominating soil patterns that affect the hydrological mechanisms operating at the *a priori* defined field-of-view. For the purpose of using soil information towards hydrological modeling, one must be careful on focusing on soil properties only, since spatial patterns of soil properties may be different from the functional organization of soil hydrological processes that may also be determined by landscape position and land use. It may be argued that as different flow processes may be dominant at each scale, different mathematical relationships may be required to describe the underpinning physical process at each spatial scale.

According to the scaleway approach, subsequent aggregation of information and the modeling of flow and transport at one specific scale, provides the required information

at the next, larger scale level. For example, if the scale of interest is an agricultural field, one defines the structural elements based on the dominant soil hydrological mechanism that causes the major differences in soil water regime between structural units. Most recently, Becker and Braun (1999) defined these units as hydrotopes or hydrological response units (HRU's) based on differences between vegetation types, shallow groundwater presence, soil type or hillslope. Likewise, in his review on scale issues in hydrological models, Beven (1995) introduced the simple patch model for scale-dependent modeling, with a patch defined as any area of the landscape that has broadly similar hydrological response in terms of the quantities of interest.

SPATIAL SCALING APPROACHES

In soil hydrological studies, soil map units may define the structural units across the landscape (Ferguson and Hergert, 1999), or soil types may need to be regrouped, classifying soils by their hydrologic functioning (Dunn and Lilly, 2001). By combining GIS with fuzzy logic techniques, Zhu and Scott Mackay (2001) generated spatial continuous soil information as input to a distributed watershed model. This provided a gradual transition between HRU's, depending on soil type, position in the landscape, and land use, instead of the discrete and generally coarse resolution of soil maps. This distribution or disaggregation of a watershed in structural units is deterministic (distributed modeling) and their aggregation to the scale of interest may be possible by simple mass conservation principles. The selection of the main HRU's or hydrotopes with their corresponding effective hydrological parameters is determined by calibration, such as was presented by Eckhardt and Arnold (2001) using parameter optimization. Rather than expecting a unique solution for the distributed hydrologic parameters, nonlinearity and measurement uncertainty, Beven (2001) introduced the equifinality concept, indicating that many solutions may be acceptable. Recent optimization algorithms now allow for multiple objective functions for multiparameter distributed watershed modeling, with effective hydrologic parameter values determined by the choice of the most relevant hydrological variables. Increasingly, efficient global optimization algorithm's are developed such as the shuffled complex evolution (SCE) algorithm (Duan *et al.*, 1993) to calibrate for a large number of parameters for distributed watershed models. Madsen (2003) demonstrated the successful application of SCE using multiple objective functions for calibration of a multiparameter distributed watershed model. He showed that if multiple measurement types of different importance are available, a so-called Pareto set of solutions provides trade offs between the different objectives. The current state-of-the-art in calibration of watershed models is presented in Duan *et al.* (2003), and appears ready to be applied to unsaturated water flow modeling (*see* **Chapter 77, Inverse Modeling of Soil Hydraulic Properties, Volume 2**).

Most of the uncertainty in the assessment of water flow in unsaturated soils at the field scale can be attributed to soil spatial variability caused by soil heterogeneity (*see* **Chapter 79, Assessing Uncertainty Propagation Through Physically based Models of Soil Water Flow and Solute Transport, Volume 2**). The exact nature of the functional dependence of both soil water retention and unsaturated hydraulic conductivity with water content differs among soil types with different particle size compositions, and pore size geometry within a heterogeneous field soil. The scaling approach has been extensively used to characterize soil hydraulic spatial variability, and to develop a standard methodology to assess the variability of soil hydraulic functions and their parameters. The single objective of scaling is to coalesce a set of functional relationships into a single curve using scaling factors that describe the set as a whole (e.g. structural unit). The procedure consists of using scaling factors to relate the hydraulic properties at a given location to the mean properties at an arbitrary reference point. This physically based scaling concept provides for the simultaneous scaling of the soil water retention (Kosugi and Hopmans, 1998) and unsaturated hydraulic conductivity functions (Tuli *et al.*, 2001), leading to scaled mean soil hydraulic functions for each structural unit, to serve as effective soil hydraulic functions (e.g. Mohanty *et al.*, 1997).

Stochastic approaches to upscale soil hydrological processes from the local to the regional scale include Monte-Carlo (MC) analysis and solution of a stochastic form of equation (1). A common assumption in using the stochastic approach is that of ergodicity, that is, the ensemble average is equivalent to the spatial average. Typically, in MC analysis, numerical solutions of equation (1) are repeated using different realizations of spatially variable soil hydrological properties. Realizations are generated using a random number generator from *a priori* knowledge of the statistical distribution of the parameter(s) in questions, including their spatial correlation. Repeated solutions will yield the stochastic information needed for the relevant output variables. An example of this approach was used by Hopmans and Stricker (1989). In this study, scaling factors and soil hydraulic functions were generated for different soil map units and soil horizons to study the soil water regime in a 650-ha watershed, specifically the influence of soil heterogeneity on plant transpiration.

Although MC analysis is conceptually straightforward, it can become computationally very intensive. Another approach is to use a perturbation approximation of equation (1), by representing local soil hydraulic properties as the sum of a deterministic and a stochastic component (Zhang, 2002). The result is that the local Richards equation (1) with deterministic parameter values is replaced by

an upscaled equation with stochastic parameters, that is, the means, variances, and covariances of hydrological parameter values. A disadvantage of this method is that it is mostly restricted to relatively small fluctuations of the stochastic parameters. A third approach assumes that local-scale flow can be simplified so that analytical expressions may be derived that describe the flow statistics at a larger scale. As an example, Chen *et al.* (1994) present a solution for the area-averaged Green and Ampt infiltration model that is applicable for large parameter uncertainties.

The inverse method offers a powerful procedure to estimate flow properties across spatial and temporal scales. As numerical models have become increasingly sophisticated and powerful, inverse methods are applicable to laboratory and field data, no longer limited by the physical dimensions of the soil domain, or type of imposed boundary conditions. Inverse methods might be especially appropriate for estimating regional-scale effective soil hydraulic parameters, from boundary condition measurements. For example, Eching *et al.* (1994) estimated field-representative hydraulic functions using inverse modeling with field drainage flow rate serving as the lower boundary condition for the Richards flow equation applied at the field scale. The application of inverse modeling to estimate soil hydraulic functions for laboratory soil cores has been extensively reviewed by Hopmans *et al.* (2002b). Although the inverse method may suffer from nonuniqueness (e.g. Beven, 2001), the application of inverse methods in general to estimate soil hydraulic functions across spatial scales is very promising, yielding effective hydraulic properties that pertain to the scale of interest.

EXAMPLES OF SOIL WATER FLOW AT DIFFERENT SPATIAL SCALES

The application of the various modeling techniques for unsaturated water flow is presented. First, at the microscale, the measurement of porosity at the pore scale is demonstrated using X-ray computed tomography. Examples are presented for local-scale unsaturated water flow models, whereas the application of using effective soil hydraulic functions is presented at the regional scale for an irrigation water district in California, USA.

Pore Scale

Although equation (1) is not applicable at the pore scale, this example is presented to demonstrate the existence of a Representative Elementary Volume (REV) for porosity, for the first time as it is known (Clausnitzer and Hopmans, 1999), using X-ray computed tomography (CT). Using the three-dimensional spatial distribution of X-ray attenuation as a proxy, porosity measurements for a glass-bead medium were conducted for increasing measurement volumes. X-ray CT measurements were conducted in a random pack of uniform glass beads within a vertical Plexiglas cylinder of 4.76 mm inner diameter. The bead diameter, d_p, was 0.5 mm and the spatial resolution was 18.4 μm, resulting in $(18.4\,\mu m)^3$ voxel volumes (see Figure 1a). In this example, the single structural unit is represented by the glass beads pack, and textural variations are defined by porosity changes at a measurement scale larger than the REV. Starting from the original three-dimensional data set of attenuation values, increasingly larger volumes were extracted, all centered at the same location, beginning with $8 \times 8 \times 8$ voxels and incrementing the cube side length, L, of the averaging volume by 4 voxel lengths (0.0736 mm) in each step. The sequence of porosity calculations with increasing volume size was conducted twice, first with the initial $8 \times 8 \times 8$ averaging volume centered in the air phase, and subsequently with the averaging volume centered in the glass phase. The resulting curves are presented in Figure 1(b), suggesting a REV of about three to five times the bead diameter. Using lattice-Boltzmann modeling, Zhang *et al.* (2000) showed that the REV may depend on the specific soil property measured. In a subsequent study, Clausnitzer and Hopmans (2000) showed that X-ray CT can be used to measure the spatial and temporal distribution of a tracer through this glass-bead medium with a spatial resolution of about 85 microns. Although we have a general good understanding of macroscopic flow and transport, much additional work is needed to describe processes at the scale of pores, thereby improving our understanding of the effects of variations in pore-water velocity and air–water interfaces on flow and transport in unsaturated porous media. Numerical modeling techniques are now becoming available to solve for streamlines and velocities at the pore scale by lattice gas automata (LGA) and the lattice–Boltzmann method.

Local Scale

Most unsaturated water flow and transport models have been developed for applications at the local scale, that is, the laboratory column and field plot scale. Whereas the initial applications were dominantly agricultural, many recent applications are mostly environmental. Also, whereas the earlier models focused on unsaturated water flow only, recent applications require coupling of water flow with models that simulate chemical and biological processes. Although many excellent models are available, we present only a few here as these appear to be applied more often than others. RZWQM (Ahuja *et al.*, 1999) is an integrated physical, biological, and chemical one-dimensional process model, simulating crop growth and movement of water, nutrients, and pesticides over and through the root zone. The model includes a generic crop-growth simulator, estimates soil evaporation and plant transpiration, and links total root water and nutrient extraction to atmospheric demand. The (*see* **Chapter 78, Models**

of Water Flow and Solute Transport in the Unsaturated Zone, Volume 2) SWAP model (Van Dam *et al.*, 1997) combines a one-dimensional water flow and nutrient transport model with a universal crop-growth simulator. Since SWAP has been designed for interactions with surface water and regional drainage, applications are primarily at the field scale. Increased computer capability and development of more efficient computer algorithms has increased the spatial dimension of solutions of equation (1) from one-dimensional to two and three-dimensional. An example of a three-dimensional water flow, coupled with nutrient transport, root water and nutrient uptake, and root growth models was presented by Somma *et al.* (1998).

The application of the aforementioned calibration techniques to a field-scale level was presented in de Vos *et al.* (2002). In this study, four major hydrologic zones with different soil hydraulic functions were identified in a tile-drained field. Soil water matric potential, groundwater level, and piezometric heads, at various locations within the experimental field, field discharge rate and nitrate concentrations were measured during a four-month leaching period. Soil water retention, saturated and unsaturated hydraulic conductivity data for four distinct hydrological soil units were measured from laboratory soil cores. The HYDRUS-2D model (**`http://www.ussl.ars.usda.gov/models/hydrus2d.HTM`**), as presented by Šimunek *et al.* (1999) was used to simulate two-dimensional flow regime and nitrate transport for a 2 by 6 m field plot, matching drainage rates and nitrate concentrations in the drain outlet. Field-effective soil water retention and hydraulic conductivity functions were estimated using an inverse modeling approach, by adjusting the hydraulic parameters that were measured from the laboratory soil cores. The study concluded that effective hydraulic properties were able to describe the average transient soil water behavior for the heterogeneous soil system, as determined from two-dimensional transient water flow modeling. Mohanty *et al.* (1997) demonstrated the application of a two-dimensional local-scale model to describe preferential

flow of a tile-drained field using field-averaged piecewise-continuous hydraulic functions for different soil horizons. Successful applications such as these and the SWAP model demonstrate that local-scale models can be used to spatial scales as large as agricultural fields.

Regional Scale

Soil hydrological information can be fairly easily assigned to local-scale unsaturated water flow models, using small-scale soil properties measurements in the laboratory or field scale. However, in applications at the field to watershed scale, a prohibitively large number of sampling sites are needed to characterize the vadose zone. An alternative approach is to estimate effective values for the hydraulic parameters by inverse modeling. In the presented example study, the inverse approach is applied to the 9700-acres Broadview irrigation district that is located in the San Joaquin Valley, California. The area consists of about 60 tile-drained 160-acre fields. Drains are located at a depth of approximately 2 m with horizontal spacings of 100–200 m. Subsurface drainage flow is measured weekly at 25 sumps, hence each sump collects subsurface drainage from one or more fields. The main crops in the area are cotton, tomatoes, alfalfa, melons, and wheat. Fields are either furrow or sprinkler irrigated. The amount of irrigation water applied to each field is measured every two days from water meters at irrigation turnouts. Rainfall data were obtained from a nearby weather station. A total of 48 shallow groundwater wells are distributed throughout the district from which monthly water table depth readings were available. Topography is nearly flat. The majority of the soils are mapped as vertisols with an average clay content of 50%. The numerical model used in this study was MODHMS (**http://www.modhms.com/modhms.cfm**), which is a MODFLOW-based distributed watershed model. It simulates in an integrated manner evapotranspiration, overland flow, channel flow, and subsurface flow and transport. Three-dimensional variably saturated subsurface flow was simulated with the three-dimensional Richards equation. Input data include spatially distributed crop types, and weekly irrigation and rainfall amounts for each field in the district. Subsurface drains are simulated using a head-dependent function, with drain discharge proportional to head above the drain and the drain conductance, C_d. Separation of crop transpiration and soil evaporation was based on a method developed by Allen *et al.* (1998). Field-specific actual crop transpiration values were determined by a depth-dependent root water uptake distribution, a time-varying crop coefficient, and a water-stress response function. Actual field evaporation was estimated from a wetness function that defines the reduction of soil evaporation with soil surface water content. The Broadview water district was divided into $1\,536\,200 \times 200$ m square cells, using approximately 16 grid cells per field. Vertically, the flow system was divided into four layers with layer thicknesses of 0.9 m, 0.9 m, 1.8 m, and 2.4 m, with a total model thickness of 6 m, resulting in a total of 6144 cells. Adaptive time-stepping was used to solve the variably saturated flow equation. Simulations were done for the 1998-crop year, which started on October 1, 1997, and ended on September 30, 1998. The water flux between the bottom of the model domain at the 6-m depth and the regional aquifer was simulated assuming a linear relation between the head difference of the bottom grid cell and a 10-m deep measured total head in the district, with a proportionality constant defined by the regional conductance, C_b. It was assumed that no lateral flow occurred across the other district boundaries.

Reference soil hydraulic functions $K_{ref}(\theta)$ and $h_{ref}(\theta)$ for clay were estimated based on the neural network analysis (**http://www.ussl.ars.usda.gov/models/rosetta/rosetta.HTM**) of Schaap *et al.* (1998). As part of the calibration, these functions were scaled using a single district-wide scaling factor, α, relating the effective water district hydraulic properties to the reference functions. Calibration parameters included α, C_d, C_b, and the initial head in the unsaturated zone h_{ini}. The latter calibration parameter was added, since it was very sensitive to the initiation of subsurface drainage. These parameters were estimated from weekly district-scale drainage discharge measurements and monthly district-average water table levels using an inverse modeling approach based on the Levenberg–Marquardt algorithm of PEST (**http://www.parameter-estimation.com/html/pest_overview.html**), while minimizing the residuals between simulated and measured drainage discharge and water table levels. Average evapotranspiration (ET), infiltration, drainage rate, and groundwater table levels are presented in Figure 2(a). Optimized district-wide parameter values were: $\alpha = 10.0$, $C_d = 0.08$ m yr^{-1}, $C_b = 3.6 \times 10^{-4}$ m yr^{-1}, and $h_{ini} = -380$ cm. A comparison of measured with optimized drainage rates and groundwater tables is presented in Figure 2(b).

As can be seen in Figure 2(b), the approach of treating the entire district as a homogeneous system in terms of hydraulic properties works surprisingly well, if the interest is only in predicting district-average hydrological conditions. Calibration results were disappointing when comparing drainage data from individual sumps within the district, even though field-specific boundary conditions were used. The optimized district-representative scaling factor was much larger than one, indicating that the district-wide response to irrigation is much faster than that initially estimated from pedotransfer functions on laboratory-scale measurements. This result indicates preferential water flow at this larger scale. However, physical interpretation of the optimized hydraulic functions is difficult since they represent effective properties that are likely not a function

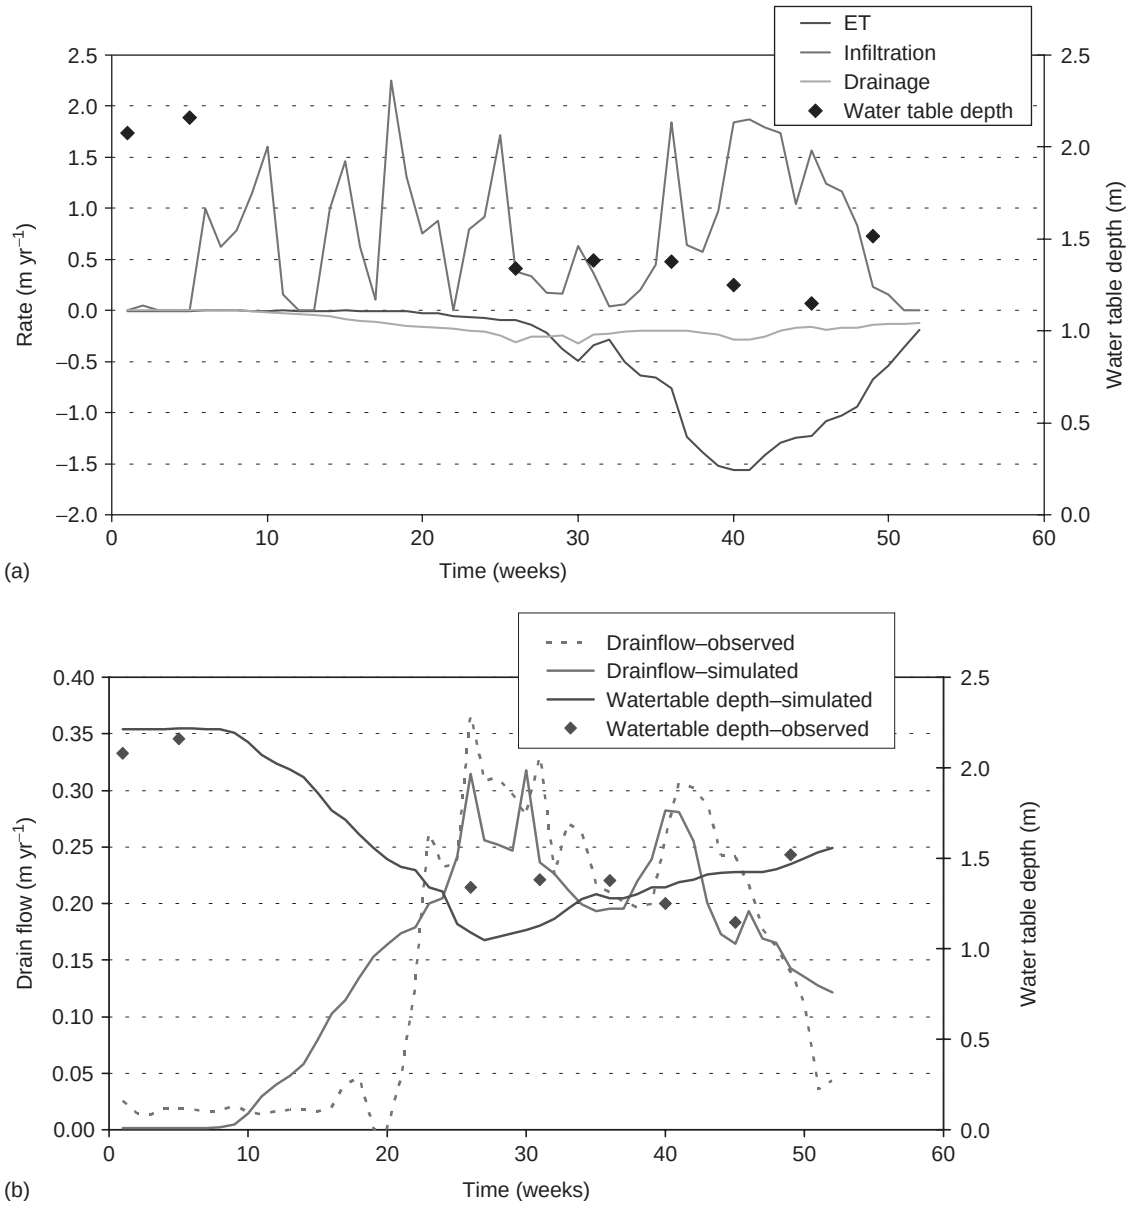

Figure 2 (a) Annual water balance for Broadview Water District, crop year 1998. (b) Comparison of observed and simulated values of district-scale drainage discharge and water table depth after optimization. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

of the porous system only, but also depend on the boundary conditions (Blöschl *et al.*, 1995). Therefore, it may be argued that application of the Richards equation at this scale is conceptual rather than physically based. (Beven, 2001). It is expected that the presented calibration approach may be improved by including spatially distributed scaling factors based on the soil map. The selection of using a single scaling factor for the calibration of the entire water district was based on parameter identifiability limitations of the optimization algorithm. Optimization algorithms that can efficiently optimize larger number of parameters, such as SCE, are likely much more appropriate when calibrating distributed scaling factors.

CONCLUDING REMARKS

It is becoming increasingly obvious that there is a pressing need for unsaturated water flow modeling, monitoring and characterization at the regional scale, such as for an agricultural field or watershed. To date, soil hydrologists are quite comfortable in measuring and modeling flow processes at local scales, since physical characterization methods are applicable at the laboratory or at a small field plot scale.

However, the need for hydrological and associated environmental and ecological solutions is becoming increasingly needed at the regional scale. In response, hydrological scientists mostly apply soil hydrological concepts that are considered valid at the local scale and extend those to the regional scale. Whereas this type of approach requires an enormous amount of experimental observations, one may also question whether this is valid.

The scale problem is extremely complex because of the general presence of large spatial and temporal variability of soil hydrological properties and their highly nonlinear nature. Hence, much more developmental work is needed regarding fundamental concepts and measurement technologies to establish appropriate soil hydrological parameters for the description of unsaturated water flow at the larger spatial scales. Simultaneously, the need arises to develop appropriate scale-dependent measurement techniques that allow for model calibration and the estimation of effective soil hydrological properties. Present theory and applications of remote sensing may potentially improve the understanding of large-scale hydrological processes such as runoff, infiltration, and evapotranspiration, including their spatial distribution and scale-dependency. For example, the monitoring of transient soil moisture changes by remote sensing may provide the essential information to estimate upscaled soil hydrological parameters such as needed for the unsaturated hydraulic functions.

Although it is evident that large-scale measurements and modeling is needed, there is also increasing awareness within the scientific community that vadose zone processes are controlled by mechanisms operating at the pore size scale. Improved understanding of these processes will likely be a function of the development and application of innovative noninvasive measurement techniques that operate at the microscopic level. Examples of such techniques are NMR, CT, and laser technologies. Finally, we note that the required improved integration of vadose science in hydrologic models requires interdisciplinary partnerships with surface and groundwater hydrologists, experts in remote sensing, numerical modeling and parameter optimization, water management and policy, experimentalists, and others.

67: Hydrology of Swelling Clay Soils

DAVID SMILES[1] AND PETER A C RAATS[2]

[1] *CSIRO Land and Water, Canberra, Australia*
[2] *Wageningen University and Research Centre, Wageningen, The Netherlands*

Theory of water flow in nonswelling soils has been used for more than 50 years but liquid flow in porous media that change volume with liquid content is not well established in soil science, although it is considered increasingly in chemical and mining engineering and in soil mechanics. Theory of water flow in swelling systems must satisfy material continuity; it must also account for changes in the gravitational potential energy of the system during swelling and for anisotropic stresses that constrain the soil laterally but permit vertical movement. A macroscopic, phenomenological analysis based on Darcy's law provides a useful first approach to the hydrology of such soils and, if we presume that volume change, in the large, is essentially one-dimensional, material coordinates based on the vertical distribution of the solid phase result in a water flow equation analogous to the Richards equation for nonswelling soils. This framework fully accounts for the vertical strain of the solid phase, and solutions to the flow equation are available for a wide range of practically important initial and boundary conditions. The approach has been well tested in clay suspensions and in saturated systems such as mine tailings and sediments. It is also applied in soil mechanics and, here, we apply it to swelling soils. As with the use of the Richards equation in rigid soils, we recognize that complications arise, but the approach remains the most coherent and profitable to support current needs and serve as a point of departure for future research. The use of material coordinates is simple. We discuss some experimental difficulties in using the approach and also consider extension of the approach to more than one dimension.

INTRODUCTION

Pedologists estimate that there are more than 2.60×10^8 ha of swelling clay soils worldwide. They are among the most fertile of soils and are found mostly in developing countries. At the same time, their hydrology is not well understood, and current approaches are generally based on nonswelling soil theory and rarely account for particle motion and volume change. As a result, significant errors in estimates of local water and solute flux can arise because of the neglect of advection of water with the moving solid. Errors can also occur in water balance calculations because swelling can make volume-based estimates of water content ambiguous.

Four major symposia (Kutilek and Sutor, 1976; McGarity *et al.*, 1984; Bouma and Raats, 1984; Kutilek, 1996) and two reviews (Bronswijk, 1991; Fredlund and Rahardjo, 1993) relating to the hydrology of such soils in the last 40 years present a range of views and much experimental information, but no agreed approach to water movement in these systems emerges. Bronswijk (1991) provides much experimental insight into structural behavior and its consequences in these soils as well as an extensive list of references. A conference focused on the mechanical properties of unsaturated soils (Alonso and Delage, 1995) also provides data and recent theory relating to "engineering" soils, as do Fredlund and Rahardjo (1993).

Two distinct approaches are evident. The first deals with the behavior of individual soil structural elements; it envisages rapid water movement through macropores to these elements, which then swell three-dimensionally to produce one-dimensional, vertical profile swelling. This approach concentrates on the relation between three-dimensional volume change of aggregates or clay pastes and one-dimensional soil profile behavior. The second approach is macroscopic; it argues that, in the large, the detail of the volume change of aggregates is irrelevant, provided that the resulting vertical deformation is well described. It presumes that Darcy's law is valid for these soils and it yields

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

an equation analogous to that of Richards (1931), with focus on one-dimensional flow (Philip, 1968a; Kim *et al.*, 1992a,b). The second approach has been used effectively in civil and chemical engineering, but it is not widely used in soil science, and some of its basic concepts remain misunderstood.

Both approaches have been used, but we focus on the second because we think it provides a more generalizable way to develop theory than does the former one and a more coherent basis for future study. It also results in flow equations whose solutions are well understood. We identify some origins of the approach, discuss basic theory and its test and, following that, discuss the extension of these ideas to multidimensional situations. We focus on one-dimensional flow but pay some attention to application of the approach in two and three dimensions.

HISTORICAL BACKGROUND

Nonswelling Soils

One-dimensional flow of water in nonswelling soils is conventionally described by the Richards (1931) equation, which combines the material balance equation for water,

$$\frac{\partial \theta_w}{\partial t} = -\frac{\partial u}{\partial z} \tag{1}$$

with Darcy's law,

$$u = -k(\theta_w)\frac{\partial \Phi}{\partial z} \tag{2}$$

In these equations, t is time, z is the vertical, positive upward coordinate, θ_w is the water volume fraction, u is volume flux of water, $k(\theta_w)$ is the soil hydraulic conductivity, and Φ is the total potential of the water. In a nonswelling soil,

$$\Phi = z + \psi(\theta_w) = z + p_w \tag{3}$$

If Φ and its components are defined as work per unit weight of water, then they have dimensions L and units m H_2O. The hydraulic conductivity, $k(\theta_w)$, then has dimensions LT^{-1} and units m s^{-1}. Defined this way, Φ is identical to the engineer's hydraulic head with z the gravitational component equal to the elevation of the point of concern in the soil relative to a convenient reference height, and $\psi(\theta_w)$ the capillary component that reflects the interaction of the water with the soil solid surfaces and their geometry. The capillary potential, $\psi(\theta_w)$, equals the manometric pressure, p_w, of the water in unsaturated soil and is negative. Buckingham (1907) first enunciated these concepts and also recognized the water content dependence of $\psi(\theta_w)$ and $k(\theta_w)$.

The implementation of the Richards equation requires that $\psi(\theta_w)$ and $k(\theta_w)$ be known. These macroscopic soil properties represent averages over volumes including many hundreds of pores and pore sequences. They are basically unpredictable although, generally, they can be measured without ambiguity at the scale at which the approach is to be applied. When ψ (θ_w) is single valued, the concept of the soil–water diffusivity, $D(\theta_w) = k(\theta_w)$ $(d\psi/d\theta_w)$, can be invoked (Childs and George, 1948).

This approach underpins current water flow theory (Philip, 1969a, 1980; Jury *et al.*, 1991; Marshall *et al.*, 1996). Where it fails, physically based or empirical modeling follows, but these models still retain the basic elements of continuity and flux of the approach leading to the Richards equation. Its pedagogic and practical utility guides our approach to water flow in swelling soils.

Swelling Soils and Other Porous Media

The theory of one-dimensional flow in swelling soils was conceived by Terzaghi (1923) to describe soil consolidation beneath engineering structures. Terzaghi's insight was that the water initially carries an imposed load in saturated soil and the soil compresses as the water redistributes and the load transfers to the soil matrix. He thus associated consolidation with water flow and his approach, like that of Richards, is based on material continuity and Darcy's law. He also related the soil volume to an effective or interparticle stress, and he conceived a spacelike material coordinate defined in terms of the distribution of the solid. It seems that he assumed the deformation to be so small that it produced no significant geometrical change of the region occupied by the solid phase of the soil, and his material coordinates then reduced to a system attached to the solid phase but moving rigidly in space (see Raats and Klute, 1968a). Terzaghi's analysis envisaged imposed loads that greatly exceeded effects of gravity and the displacement of overburden that contributes to the total potential of the water when soil volume changes. He was aware of the water content dependence of the hydraulic conductivity, but he ignored that also, and he solved the resulting linear analogue of the Richards equation using Fourier series.

Civil engineers were uneasy with Terzaghi's material coordinates and his approach was recast in physical space and specifically identified with small-strain behavior. As a result, his classic text (Terzaghi, 1956) disregards many insights of the 1923 work as does Jaeger's text of 1962, where the small-strain linearized approach is maintained and the effect of gravity and overburden overlooked. Biot (1941, 1955) gave a full three-dimensional treatment of the deformation of the solid phase, but, like Terzaghi, in his early work, he restricted his attention to small deformations. The rudimentary material coordinate of Terzaghi and Biot were not rediscovered until the 1960s (McNabb, 1960),

and Gibson *et al.* (1967) extended the approach to include overburden. There was also substantial experimental study of the water potential in loaded saturated and unsaturated swelling soils by Croney and Coleman in the British Road Research Laboratories (Pore Pressure and Suction in Soil, 1961).

Chemical engineers in the USA (e.g. Tiller and Cooper, 1960; Tiller and Shirato, 1964; Leu, 1986) and in Japan (e.g. Atsumi *et al.*, 1973; Shirato *et al.*, 1970, 1986) also developed filtration and sedimentation theory focused on water flow relative to the solid, although explicit combination of continuity and flux to formulate a flow equation such as that of Terzaghi (1923) or Richards (1931) and the importance of gravity and overburden still await general acceptance.

In soil science, Tempany (1917) identified the earliest measurement of volume change in the work of Schübler in the early nineteenth century. Tempany considered shrinkage of pastes as a basis for describing profile behavior, and Haines (1923) developed the shrinkage curve concept in which the volume change accompanying water content change is used to help characterize structural properties of agricultural soils. Woodruff (1936) used anchored rods to measure profile swelling with water content change and Aitchison and Holmes (1953a,b), Yaalon and Kalmar (1973), Bronswijk (1991), Cabidoche and Ozier-Lafontaine (1995), and Coquet (1998) developed that method. Childs (1936) and Nicholson and Childs (1936) applied a diffusion equation to water flow in heavy clay soils.

Spacelike material coordinates to deal with swelling soils were formulated by Raats and Klute (1968a,b, 1969) and by Smiles and Rosenthal (1968), who also tested the approach using bentonite pastes. Contemporaneously, Philip (1968a) analyzed one-dimensional soil volume change accompanying water content change in physical space. Philip's paper deals well with mechanics of swelling but later he abandoned the approach because the mathematics associated with the material approach was analogous to established one-dimensional nonswelling water flow theory, and his methods of solution of the Richards equation (Philip, 1969a) carried over immediately to one-dimensional swelling materials.

We examine the central elements in one-dimensional flow of water in swelling soils and compare them with the more familiar theory of flow in nonswelling soils, we identify limits to the analysis and some issues yet to be dealt with. The focus is one-dimensional because field volume change, in the large, is constrained to the vertical. The approach accepts three-dimensional volume change of soil structural units, but it asserts that if the area of cross section is large enough and if there is no lateral net transfer of material from the control area, then behavior of structural entities beneath it may be described by a representative average vertical displacement. This approach is analogous to the Darcy scale approach to soil water movement in nonswelling soil, which also deals in volume averages and is agnostic about flow detail in individual pores.

In this one-dimensional domain, analysis is based on the material balance equations for the water as well as the solid, because both may be in motion relative to an observer, and on Darcy's law. Both these elements are critical but material balance must be retained even when the applicability of the Darcy equation is uncertain. As with nonswelling soil water flow theory, material properties and the variables required by the approach are defined in terms of the scale of discourse, and demand unambiguous measurement at that scale (Philip, 1973).

THEORY OF FLOW IN SWELLING SYSTEMS

Material Balance

Equations (4) and (5) define material balance for both the water and the soil solid during one-dimensional flow in a swelling system. Equation (6) recognizes that the flux of water occurs both relative to and with the moving soil solid.

$$\frac{\partial \theta_w}{\partial t} = -\frac{\partial F_w}{\partial z} \tag{4}$$

$$\frac{\partial \theta_s}{\partial t} = -\frac{\partial F_s}{\partial z} \tag{5}$$

$$F_w = u + \frac{\theta_w F_s}{\theta_s} = u + \vartheta F_s \tag{6}$$

In these equations, F_w and F_s are the volume flux densities of the water and of the solid relative to the z-coordinate, the volume fractions θ_w and θ_s of the water and the solid are defined per unit area of horizontal cross section of the soil, and the reference volume includes the cracks; $\theta_w + \theta_s \leq 1$, depending on whether or not the soil is water saturated. It is important to note that, u, the Darcy flux of equation (2), is the flux of water relative to the particles in response to the space gradient of the total potential of the water (Gerzevanov, 1937; Biot, 1955; Zaslavsky, 1964; Raats and Klute, 1968a, 1968b). The second term on the right in equation (6) thus describes transfer of water "advected" with the moving solid. The water ratio, ϑ, is defined as:

$$\vartheta = \frac{\theta_w}{\theta_s} = \theta_g \rho_s \tag{7}$$

with θ_g the gravimetric water content (kg.kg^{-1}) and ρ_s the specific gravity of the soil solid. In saturated soils, $\vartheta = e$, the void ratio.

Equations (4), (5) and (6) give (Smiles, 1986)

$$\frac{\partial \vartheta}{\partial t} = -\frac{\partial u}{\partial m} \tag{8}$$

Equation (8) is a material balance equation for the water, based on a "material" coordinate, $m(z, t)$. The spatial time derivatives in equations (4) and (5) and the material time derivative are related by:

$$\left.\frac{\partial}{\partial t}\right|_{\mathrm{m}} = \left.\frac{\partial}{\partial t}\right|_{\mathrm{z}} + \left(\frac{F_{\mathrm{s}}}{\theta_{\mathrm{s}}}\right)\left.\frac{\partial}{\partial z}\right|_{t} \tag{9}$$

The m-coordinate is determined by the distribution of the soil solid, and it accounts for one-dimensional soil displacement that might accompany water content change.

$$\mathrm{d}m(z,t) = \frac{\partial m}{\partial z}\,\mathrm{d}z + \frac{\partial m}{\partial t}\,\mathrm{d}t = \theta_{\mathrm{s}}\,\mathrm{d}z - F_{\mathrm{s}}\,\mathrm{d}t \tag{10}$$

This definition of m satisfies equation (5) for the solid. Integration of equation (10) is simplified if it is based on a surface, $z = 0$, where $F_{\mathrm{s}} = 0$. The soil surface provides such a datum. Then,

$$m = \int_0^z \theta_{\mathrm{s}}\,\mathrm{d}z - \int_0^{\mathrm{t}} F_{\mathrm{s}_{z=0}}\,\mathrm{d}t = \int_0^z \theta_{\mathrm{s}}\,\mathrm{d}z = \int_0^z \left(\frac{\rho}{\rho_{\mathrm{s}}}\right)\mathrm{d}z \tag{11}$$

so m is the cumulative volume of solid, per unit area of cross section, measured from $z = 0$ to the location z and, thus, the cumulative oven dry mass per unit area is measured away from the soil surface to any depth z, and divided by ρ_{s} (Smiles and Rosenthal, 1968). The final integral in equation (11) shows how m is related to the bulk specific gravity ρ.

This formulation is unaffected by crack volume and is indifferent to three-dimensional volume change of aggregates and cracks provided that the reference area of cross section is large enough to ensure that no horizontal net transfer of material occurs. This is implicit in the Raats and Klute (1969) analysis and it is explicitly stated by Philip and Smiles (1969) and by Philip (1969b,c,d). Water content profiles in this formalism are expressed as $\vartheta(m)$ so the integral, $\int_0^m \vartheta\,\mathrm{d}m$, yields the total volume of water in a profile of material length m regardless of the way its physical length might change with water content change (Smiles, 1997).

The m-coordinate, and equation (8), apply to both swelling and nonswelling porous materials, although their use in the latter case is unusual (but see Smiles and Kirby, 1994).

A three-dimensional generalization of equation (8) was derived by Raats and Klute (1968a). It can be specialized to the one-dimensional formulation described above (Raats and Klute, 1969; Raats, 1987) and can also be used at the meso-scale to describe the deformation of individual aggregates (Raats, 1969, 1984, 2002).

Equilibrium and Flow of Water in Saturated Swelling Systems

It is important to reiterate that Darcy's law in swelling systems describes flow of water *relative to* the solid in response to a space gradient of the water potential with the hydraulic conductivity, $k(\theta_{\mathrm{w}})$, a function of θ_{w}. It is also important to discriminate between measures of potential in nonswelling and swelling soils and then between saturated and unsaturated ones.

The Total Potential of Water in Saturated Swelling Systems

We recall that in a nonswelling soil, Φ has a capillary component that can be measured with a manometer, so $\psi(\theta_{\mathrm{w}}) = p_{\mathrm{w}}$. In a swelling system, however, change of water content displaces the whole profile in the gravity field, so we require an extra component of Φ, the overburden potential, Ω. Philip (1969b, 1970) considered this effect from a mechanistic point of view while Croney and Coleman (1961), Groenevelt and Bolt (1972) and Sposito (1975a) considered it from a thermodynamic perspective. Philip's approach builds on that of Buckingham (1907) for nonswelling, unsaturated soil. He argues that Φ represents the work involved in transferring unit weight of water from a reference flat surface of water at atmospheric pressure to a swelling material at some height, z, above that datum. Thus Φ includes work involved in:

1. elevation of the element of water from the datum to the height z (the gravitational potential, z);
2. interaction between the water and the soil solid surfaces and their geometry (the water content–dependent unloaded matric or capillary potential, ψ); and
3. vertical displacement of the wet soil accompanying unit change in water content at z (the overburden potential, Ω).

In a one-dimensional, saturated system that is laterally constrained but free to move vertically, unit change in water content produces unit change in elevation of the soil. This implies that $\mathrm{d}e/\mathrm{d}\vartheta = 1$ if the volume of the system is parameterized by the void ratio e, and Ω equals the engineer's total normal stress, σ, on a horizontal plane at z. Thus,

$$\Phi = z + \psi + \int_{\mathrm{z}}^{T} \gamma\,\mathrm{d}z = z + \psi + \sigma = z + p_{\mathrm{w}} \tag{12}$$

in which ψ is the *unloaded* capillary potential, that is the potential a tensiometer would measure at the existing moisture ratio in the absence of overburden, γ is the wet specific gravity, and $\sigma = \Omega$. We distinguish between σ and Ω to anticipate the situation in unsaturated soils where $\sigma \neq \Omega$. Civil engineers relate p_{w} to σ, and the effective

or interparticle stress, σ', according to the equation (Pore Pressure and Suction in Soil, 1961)

$$\sigma = \sigma' + p_w \tag{13}$$

Equation (13) was formulated and tested by Terzaghi (1923). Comparison with equations (12) and (13) shows that $\sigma' = -\psi$, and, hence, is related to ϑ through $\psi(\vartheta)$. Additional surface loads will increase the overburden but, if they are constant, we may ignore them here without loss of generality.

Figure 1 illustrates and compares components of the total potential of water in swelling and nonswelling systems.

Equation (12) applies to both swelling and nonswelling soils. Thus, water moves through a swelling soil in response to a measurable hydraulic head gradient just as it does in a nonswelling one. The literature is confused on this point. Jury *et al.* (1991), for example, misinterpret it in their Fig. 2.9b and the Glossary of Soil Science (SSSA, 1997) ignores the energetics of soil volume change altogether.

The Potential Gradient in Saturated Swelling Systems

Equations (12) and (13) have been well tested, and equation (12) may be rearranged and differentiated to obtain

$$\frac{\partial \Phi}{\partial z} = \frac{\partial \psi}{\partial z} + (1 - \gamma) = \theta_s \left(\frac{\partial \psi}{\partial m} + (1 - \rho_s) \right) \tag{14}$$

The second equality in equation (14) arises from the first using the definitions of γ, which in the saturated system equals $(\vartheta + \rho_s)/(\vartheta + 1)$, and of m defined by equation (10). The effect of gravity, including the overburden, is represented by the $(1 - \gamma)$ term in z-space, and the $(1 - \rho_s)$ in m-space. In most mineral soils, $\rho_s \approx 2.65$, so these terms are of different sign to that for nonswelling soils, and this gives rise to what Philip (1991) called the *bouleversement*

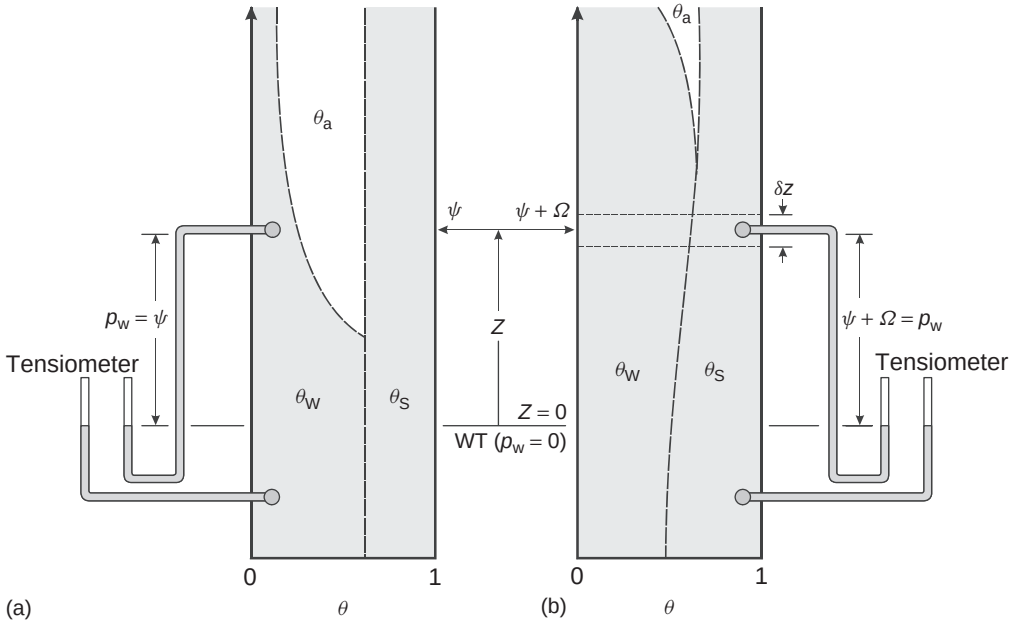

Figure 1 Idealized diagram showing vertical, static equilibrium water content profiles in (a) nonswelling soil and, (b) swelling soil in contact with a free-water surface, WT, at elevation $z = 0$ and at atmospheric pressure and where the manometric pressure $p_w = 0$. The volume fractions of the water, θ_w, of the solid, θ_s, and of the air; θ_a, sum to unity. In swelling soils, θ_s increases with depth towards some maximum density, and θ_w correspondingly decreases. Entry of air above the water table in swelling soil occurs in cracks and then as aggregates desaturate. The diagram also illustrates differences in the components of total potential of the water, Φ, in the two systems. The arrows show the steps in transferring unit amount of water from WT, to the soil at elevation z above it. If the potential is defined per unit weight of water, then z is the gravitational potential of the water relative to WT; ψ is the unloaded ''capillary'' or moisture potential of the water in the soil, and the overburden potential, Ω, arises in swelling soils because of the vertical displacement of the wet profile, δz, that must occur when the element of water is inserted at height z. In the saturated region, unit vertical displacement of the profile above z accompanies insertion of unit amount of water there so Ω is the wet weight of the profile, per unit area above z. In the unsaturated region of the swelling soil, the vertical displacement is less than unity and Ω is reduced by the factor α ($\leq$1), which represents an average value of the shrinking curve in the soil above z. Further detail is presented in the text. The diagram shows that a manometer/tensiometer inserted at elevation z measures $(\psi + \Omega)$ and, at static equilibrium, the manometer/tensiometer water level has the same elevation as the water table, WT, for both swelling and nonswelling soils

in hydrologic behavior of swelling soils. This difference between z- and m-space formulations also gives rise to differences in the flow equations below. It suffices here to note that in physical z-space, if γ is close to unity, the effect of gravity is close to zero. The m-coordinate, because it is tied to the solid distribution, which is also moving in the gravitational field, tends to hide this phenomenon.

Darcy's Law in Saturated Swelling Systems

Substitution of equation (14) in equation (2) gives

$$u = -k(\theta_w)\theta_s\left(\frac{\partial\psi}{\partial m} + (1-\rho_s)\right) = -k_m(\vartheta)\left(\frac{\partial\psi}{\partial m} + (1-\rho_s)\right) \quad (15)$$

and we refer to $k_m(\vartheta)(= k(\theta_w)\theta_s)$ as the "material" hydraulic conductivity.

The Flow Equation in Saturated Swelling Systems

Substitution of equation (15) in equation (8) then yields

$$\frac{\partial\vartheta}{\partial t} = \frac{\partial}{\partial m}\left(k_m(\vartheta)\frac{\partial\psi}{\partial m}\right) + \frac{\partial}{\partial m}(k_m(\vartheta)(1-\rho_s)) \quad (16)$$

Equation (16) is the analogue, in material coordinates, of the Richards equation. It differs only in the definition of k_m and in the modification of the gravity term resulting from the effect of overburden. Its use again requires that $k_m(\vartheta)$ and $\psi(\vartheta)$ be well-defined characteristics of the material. It also requires that $de/d\vartheta = 1$ and ρ_s be known.

Generally, $\psi(\vartheta)$ is hysteretic but, when it is single valued, equation (16) may be written

$$\frac{\partial\vartheta}{\partial t} = \frac{\partial}{\partial m}\left(D_m(\vartheta)\frac{\partial\vartheta}{\partial m}\right) + \frac{\partial}{\partial m}(k_m(\vartheta)(1-\rho_s)) \quad (17)$$

with $D_m(\vartheta)$, the "material" diffusivity or the coefficient of consolidation in soil mechanics (Raats and Klute, 1969; Smiles, 1986) defined by

$$D_m(\vartheta) = k_m(\vartheta)\left(\frac{d\psi}{d\vartheta}\right) \quad (18)$$

The principal differences, which distinguish equilibrium and flow in saturated, swelling systems from equilibrium and flow in nonswelling systems, arise from the overburden effect. Specifically, it

1. reverses (and reduces) the physical effect of gravity in systems where $\rho_s > 1$. Thus, the gravitational potential energy of the wet profile actually increases as water infiltrates (cf equation (14))
2. produces static equilibrium water content profiles that are, in the saturated region, dryer at the bottom than at the top, in contrast to profiles in nonswelling soils (Philip, 1969c; Sposito, 1975a,b) and
3. extends the period of time for which a "gravity free" analysis applies to infiltration in these systems (Smiles, 1974), although the effect is as much due to the relative magnitudes of the average value of $k_m(\vartheta)$ and the square of the sorptivity as it is to the diminution in the effect of gravity (Smiles, 1974).

Equilibrium and Flow of Water in Unsaturated Swelling Systems

The Total Potential of Water in Unsaturated Swelling Systems

In unsaturated swelling systems, unit change in ϑ accompanying addition of water no longer results in unit change in elevation of the wet profile, that is, $de/d\vartheta < 1$. Unit change in the total normal stress, σ, does not then produce unit change in p_w, and a factor $\alpha \leq 1$ is introduced to modify the overburden terms in equations (12) and (13) (cf Croney and Coleman, 1961; Skempton, 1961) so they are written

$$\Phi = z + \psi + \alpha\int_z^T \gamma\, dz = z + \psi + \alpha\sigma = z + p_w \quad (19)$$

and

$$\alpha\sigma = \sigma' + p_w \quad (20)$$

In equation (19), α is the slope of the shrinkage curve (Haines, 1923), and in equation (20) it is the change in p_w with change in σ at constant σ', and, by implication, constant ϑ because $\psi = -\sigma$. In either case, the values of α lie between zero in a nonswelling soil and unity in a saturated swelling one. The "dual" nature of α revealed in equations (19) and (20) is consistent with observations of Croney and Coleman (1961) who suggested that

$$\alpha = \left(\frac{\partial p_w}{\partial\sigma}\right)_\vartheta = \left(\frac{\partial e}{\partial\vartheta}\right)_\sigma \quad (21)$$

Coleman and Croney (1952) and Groenevelt and Bolt (1972) derived the equality between the differentials in equation (21) using thermodynamic arguments (see also Raats, 2002), and Towner (1976) did so using mechanistic ones. However, these differentials are not strictly equal to α, and both Youngs and Towner (1970) and Groenevelt and Bolt (1972) showed that equating of α with the slope of the soil shrinkage curve, as was done by Philip (1969d) following Croney and Coleman, is incorrect. It is now agreed (Philip, 1970) that, while ψ continues to be interpreted as the "unloaded" suction, α in equations (19) and (20) must be an average value of $(\partial e/\partial\vartheta)_\sigma$ or $(\partial p_w/\partial\sigma)_\vartheta$ over the range 0 to P. This perception of α arises from the argument that, while the $\{p_w, \sigma, \vartheta, e\}$ set completely specifies

the state of a swelling system, only three of these variables are independent (Groenevelt and Bolt, 1972; Philip, 1970), so $p_w = p_w(\vartheta, \sigma)$ whence

$$\mathrm{d}p_w = \left(\frac{\partial p_w}{\partial \vartheta}\right)_\sigma \mathrm{d}\vartheta + \left(\frac{\partial p_w}{\partial \sigma}\right)_\vartheta \mathrm{d}\sigma \tag{22}$$

A mathematically practical integration path across the $p_w(\vartheta, \sigma)$ surface up to $\sigma = P$ is

$$\begin{aligned} p_w &= \int_0^\vartheta \left(\frac{\partial p_w}{\partial \vartheta}\right)_{\sigma=0} \mathrm{d}\vartheta + \int_0^P \left(\frac{\partial p_w}{\partial \sigma}\right)_\vartheta \mathrm{d}\sigma \\ &= \psi + \int_0^P \left(\frac{\partial p_w}{\partial \sigma}\right)_\vartheta \mathrm{d}\sigma \end{aligned} \tag{23}$$

Equation (23) can be put in the form (cf equation (19))

$$p_w = \psi + \alpha P \tag{24}$$

with α defined by

$$\begin{aligned} \alpha(\vartheta, P(z)) &= \left(\frac{1}{P(z)}\right) \int_0^P \left(\frac{\partial p_w}{\partial \sigma}\right)_\vartheta \mathrm{d}\sigma \\ &= \left(\frac{1}{P(z)}\right) \int_0^P \left(\frac{\partial e}{\partial \vartheta}\right)_P \mathrm{d}\sigma \end{aligned} \tag{25}$$

where the equality of the differentials in equation (21) has been used. The various definitions of α as a local value and as an average over a defined pressure range have led to ambiguity (see Raats, 2002). Furthermore, substitution of equation (25) in Darcy's law proves impractical, so equation (21) is generally used on the physical grounds (Philip, 1970) that while α is an average of $(\partial e/\partial \vartheta)_P$ over the full range of σ from 0 to P, its variation will be slow. It has, however, been treated as water content–dependent to deal with curvilinearity in the shrinkage curve. We return to this issue later.

The Potential Gradient in Unsaturated Swelling Systems

In this approximation, and if $\vartheta(\psi)$ is single valued, then $\partial\Phi/\partial z$ (from equation (19)) becomes

$$\begin{aligned} \frac{\partial \Phi}{\partial z} &= \frac{\partial}{\partial z}\left(\psi + z + \alpha \int_z^T \gamma \, \mathrm{d}z\right) \\ &= \left(\frac{\mathrm{d}\psi}{\mathrm{d}z}\right) + \left(1 - \gamma\alpha + \left(\frac{\mathrm{d}\alpha}{\mathrm{d}\vartheta}\right) \int_z^T \gamma \, \mathrm{d}z\right) \\ &= \theta_s \left(\frac{\mathrm{d}\psi}{\mathrm{d}\vartheta}\right)\left(\frac{\partial \vartheta}{\partial m}\right) + \left(1 - \gamma\alpha + \frac{1}{\theta_s}\left(\frac{\mathrm{d}\alpha}{\mathrm{d}\vartheta}\right) \int_m^0 \gamma \, \mathrm{d}m\right) \end{aligned} \tag{26}$$

In these equations, the second equality on the right-hand-side is derived by differentiating the first by parts and the third expression uses $\vartheta(\psi)$, and the definition of m, that is, $\partial m/\partial z = \theta_s$ to eliminate z. The leading terms in the second and third equalities are "capillary" terms; the remaining terms represent the effects of gravity and overburden.

Darcy's Law in Unsaturated Swelling Systems

Substitution of the last expression of equations (26) in Darcy's law, in m-space, yields

$$\begin{aligned} u = &-k(\theta_w)\theta_s \left(\frac{\mathrm{d}\psi}{\mathrm{d}\vartheta}\right)\left(\frac{\partial \vartheta}{\partial m}\right) \\ &- k(\theta_w)\left(1 - \gamma\alpha + \frac{1}{\theta_s}\left(\frac{\mathrm{d}\alpha}{\mathrm{d}\vartheta}\right) \int_m^0 \gamma \, \mathrm{d}m\right) \end{aligned} \tag{27}$$

The Flow Equation in Unsaturated Swelling Systems

Substitution of equation (27) in equation (5) then yields the Richards-like equation

$$\frac{\partial \vartheta}{\partial t} = \frac{\partial}{\partial m}\left(D_m(\vartheta)\frac{\partial \vartheta}{\partial m}\right) + \frac{\partial}{\partial m}(k^*(\vartheta)) \tag{28}$$

with $D_m(\vartheta)$ defined by equation (18) and the conductivity-like term $k^*(\vartheta)$ encapsulating the gravity and overburden terms. In many practical cases, α is effectively constant over ranges of water content of concern in the soil. This eliminates the integral term in equations (26) and (27), and $k^*(\vartheta)$ becomes

$$k^*(\vartheta) = \frac{k_m(\vartheta)}{\theta_s}(1 - \gamma\alpha) \tag{29}$$

Further detail of the derivation of equation (28) is illustrated by Philip (1969d) (his equation (32)) and by Kim *et al.* (1992a). Applications of equations (26), (27) and (28) are discussed below. For a saturated system where $\alpha = 1$, equation (28) becomes identical with equation (17).

Extension to Two and Three Dimensions

Three-dimensional Volume Change and Material Properties

One-dimensional volume change accompanying water content change in soil profiles has been measured by Aitchison and Holmes (1953a,b), Bronswijk (1991), Cabidoche and Voltz (1995), Coquet *et al.* (1998), Croney *et al.* (1958), McIntyre *et al.* (1982), Tempany (1917), and Woodruff (1936). These authors focused on the magnitude and significance of profile shrinkage, that is, the value of $(\mathrm{d}e/\mathrm{d}\vartheta)$ averaged over the profile. This profile property has also been related variously to three-dimensional aggregate volume change or to linear shrinkage by some of these authors,

and is supplemented by work such as that of Fox (1964), Berndt and Coughlin (1976), Yule and Ritchie (1980a,b) and Giraldez *et al.* (1983). These studies indicate that three-dimensional volume change of an aggregate is a useful qualitative guide to one-dimensional profile behavior. The coefficient of linear extensibility (COLE), ultimately based on the method of Tempany (1917) also appears useful and the following analysis of multidimensional deformation and one-dimensional flow is relevant.

Multidimensional Deformation and One-dimensional Flow

Drying of a non-rigid soil may start as a combination of purely one-dimensional flow of the aqueous phase and deformation of the solid phase. This changes when cracks appear. Some attempts have been made to cope with such systems by describing them in terms of one-dimensional flow of the aqueous phase and transversely isotropic deformation of the solid phase, that is, a combination of a deformation in the vertical z-direction and an isotropic deformation in the horizontal direction. For one-dimensional deformation (cf equation (10))

$$\frac{\partial m}{\partial z} = \theta_s = \frac{\rho}{\rho_s} \tag{30}$$

and for any transversely isotropic deformation of the soil solid phase, at some point (x, y, z), the deformation in the vertical z-direction is characterized by:

$$\frac{\partial m_z}{\partial z} = \theta_s^n = \left(\frac{\rho}{\rho_s}\right)^n \tag{31}$$

while deformations for any two perpendicular horizontal directions x and y are characterized by:

$$\frac{\partial m_x}{\partial x} = \theta_s^{(1-n)/2} = \left(\frac{\rho}{\rho_s}\right)^{(1-n)/2}$$

$$\text{and} \qquad \frac{\partial m_y}{\partial y} = \theta_s^{(1-n)/2} = \left(\frac{\rho}{\rho_s}\right)^{(1-n)/2} \tag{32}$$

In equation (32), $n = 1$ for purely axial deformation, $n = 1/2$ for balanced axial and lateral deformation, $n = 1/3$ for isotropic deformation, and $n = 0$ for purely lateral deformation.

Furthermore, from equations (31) and (32), it follows that

$$\left(\frac{\partial m_x}{\partial x}\right)\left(\frac{\partial m_y}{\partial y}\right)\left(\frac{\partial m_z}{\partial z}\right) = \theta_s = \frac{\rho}{\rho_s} \tag{33}$$

Disregarding the influence of gravity, so that the gradient of the capillary potential ψ is the only driving force, the flow equation for the water in the vertical z-direction is a nonlinear diffusion equation for the water ratio:

$$\left(\frac{\partial \vartheta}{\partial t}\right)_{m_z} = \frac{\partial}{\partial m_z}\left(\theta_s^{(2n-1)} k(\vartheta) \frac{d\psi}{d\vartheta}\right)\left(\frac{\partial \vartheta}{\partial m_z}\right)_t \tag{34}$$

For purely axial deformation ($n = 1$), equations (31) and (33) reduce to equation (30), equations (32) reduces to $\partial m_x/\partial x = 1$ and $\partial m_y/\partial y = 1$, and the diffusivity in equation (34) reduces to that appearing in equation (28).

The value $n = 1/2$ separates two opposite trends. For $n < 1/2$, swelling causes the factor θ_s^{2n-1} in the diffusivity to increase and shrinking causes it to decrease. For $n > 1/2$, swelling causes the factor θ_s^{2n-1} in the diffusivity to decrease and shrinking causes it to increase.

Raats (1969, 1984, 2002) and also Miller (1975) introduced the expression for the deformation gradient for the class of transversely isotropic deformations in terms of the mass density in an analysis of axial fluid flow in swelling and shrinking rods. The r_s-factor, introduced by Rijniersce (1983, 1984) in a study of physical changes in the sediments of the IJsselmeerpolders, is the reciprocal of the parameter n used above. This r_s-factor has been used extensively to characterize swelling and shrinkage in clay soils (see e.g. Bronswijk, 1991; Bronswijk and Evers-Vermeer, 1990; Garnier *et al.*, 1997a,b; Kim *et al.*, 1999).

DISCUSSION

An approach to water flow in swelling soils that gives rise to theory similar to that of Richards for nonswelling soils has both pedagogic and mathematical benefits (Raats, 2002) and provides access to well-tried technology and to plausible modeling procedures. Measurement problems and difficulties with scale and variability complicate soil measurement and modeling, however.

Scale and Measurement

Fortuitously, space and timescales of laboratory measurement, theory development, and measurement for field application are roughly similar in nonswelling soils. Furthermore, while nonswelling soil structure varies, its range of variability tends to be sufficiently modest that the soil can generally be treated as homogeneous, or at least as systematically heterogeneous at scales of order 0.1 m, and modeling tends to be based on the Richards equation. In swelling soil profiles, however, structural units tend to be much bigger than those in nonswelling soils, and immediate application of laboratory-scale measurement is uncertain except in the case of the finely divided and relatively homogeneous engineering muds and slurries. Characteristically, structural units in self-mulching vertisols vary from a few millimeters at a dry soil surface to units bounded

by slickensides or by tension cracks, which may have characteristic dimensions of order 1 m. Mass movement to produce gilgai features of order 10 m is common. The approach based on Richards equation requires that at some landscape scale, these features may be considered part of a continuum, but the "engineering" required for management will rely on estimates of the material properties of that continuum. These estimates are difficult and conventional devices, in addition to producing uncertain results (e.g. Jarvis and Leeds-Harrison, 1987), reveal heterogeneities, for example, in water content across structural units that are daunting. The increase in scale also increases characteristic equilibration times over and above the effects attributable to the fine particle size that characterizes these soils. For these reasons, values of soil properties averaged over many "point" measurements are required and variation in these averages over extended periods of time would appear to be necessary if systematic field behavior is to emerge. Ultimately, large-scale, remotely sensed data may provide the only practicable way to monitor the behavior of these landscapes. Nevertheless, some effort has been devoted to creating, from detail at one scale, analysis at another. Bronswijk (1991), Garnier *et al.* (1997a) and others, for example, integrate perceptions of three-dimensional behavior of aggregates and cracks to develop an image of one-dimensional profile behavior. The approach remains confined to the beds of relatively small aggregates, and its application to the field is uncertain because, ultimately, focus must remain on formulation of theory at the scale of application (Philip, 1995; Philip and Smiles, 1982). Physical processes at smaller scales are important but rarely permit quantitative prediction of behavior in the large. The "Darcy" field scale has proved most useful in nonswelling soils. It also provides a rational approach to water equilibrium and flow in swelling soils, with the qualification that the material properties that are necessary for the analysis at this scale must exist and be measurable. Common experience suggests that there is often substantial uniformity in the sense that spatially representative water content profiles and their evolution in time can be discerned. The approaches that follow seek to discover and use this uniformity.

The first challenge is to measure representative water contents and their distribution in the landscape so that water balances can be established. Test of generalized theory to deal with equilibrium and flow may then follow.

Material Balance in Swelling Systems

Material balances in one dimension for both the water and the solid are unambiguous if a spacelike coordinate, based on the distribution of the solid, is used to account for the strain of the solid phase (Raats and Klute, 1968a, 1969; Smiles and Rosenthal, 1968; McGarry and Malafant, 1987; Sposito *et al.*, 1976; Smiles, 1997). Such a coordinate is a preferred way to determine the water balance in swelling soils. The fundamental problem is to measure the way the soil volume reflected in the surface elevation is related to the profile water content. Field experiments of Kirby *et al.* (2003) are exemplary, and their data are similar to observations from earlier studies. In these experiments, anchored rods and neutron probes were used to measure volume and water content change in a vertisol with clay (predominantly smectite) content greater than 70%. The soil sequentially supported maize, fallow, and lucerne (alfalfa) over several years. The soil surface rose as much as 200 mm during wetting and fell as much as 140 mm during the lucerne phase, and revealed an average value of $\alpha \leq 0.3$. Errors as great as 20% in the estimation of water storage change arose when swelling was disregarded.

Cabidoche and Ozier-Lafontaine (1995) similarly used a device called *THERESA* to measure the change in thickness during water content change of a mass-based soil layer. It uses a pair of concentric anchored cylinders of small diameter and it revealed behavior similar to that of Kirby *et al.* (2003). Coquet (1998) used a similar device on a less swelling soil.

Both Cabidoche's and Kirby's experimental sets illustrate a very close relationship between the profile water content and the surface elevation, and the use of a profile $\alpha \approx 0.3$ together with surface elevation permitted calculation of the water content within a few percent. These papers also illustrate the difficulty of field work. Data of Kirby *et al.* (2000) are based on averages of five sets of rods; those of Cabidoche and Ozier-Fontaine initially were based on 36 spatially independent stations located according to characteristic spacing of gilgai micro relief under grassland. At another less variable site, only six stations were considered necessary under sugar cane. Coquet (1998) developed his sampling strategy using a geostatistical approach.

Point measurement of water content and bulk density are also difficult. Coquet (1998) illustrated the scale of water content variability when he developed a sampling strategy for his THERESA-like probes. Aitchison and Holmes (1953a) abandoned attempts to measure bulk density in dry profiles while Kirby and Ringrose-Voase (2000) experienced difficulties with very wet rice paddy soils. Jarvis and Leeds-Harrison (1987) discuss some of these difficulties in relation to the neutron probe method and identified particular problems because of cracking about the access tube. Nevertheless, Bavaye (1991) provides an analysis to relate such measurements to the solid-based material coordinate.

These difficulties also affect estimates of solute balance and the consequences carry over to the extreme example of potentially acid sulfate soils. In such soils, with an initial bulk specific gravity as low as 0.75, calculations of water, solute, and organic carbon balance associated with drainage, for example, may err by a factor larger than three if volume change is neglected (Smiles, 1997). Thus, measurement in detail sufficient to fully define the material coordinate in

field soils is critically important. Measured soil bulk density and water content profiles are necessary in mineral soils. If organic matter content is changing or sulfides are oxidized (as may be the case in potentially acid sulfate soils), then the material coordinate may be based on that component of the solid that remains unchanged (Raats, 1998a,b; Smiles, 1997).

Equilibrium and Flow of Water in Swelling Systems

Saturated Systems

For one-dimensional flow in saturated systems, use of the swelling soil analog of the Richards equation is supported by experimental data for filtration and sedimentation of practically important industrial slurries and effluents (Smiles, 1986; Smiles and Kirby, 1992) where the strain is often very large because initial values of ϑ may be as large as 40 and decrease during filtration or centrifugation to values less than five. Smiles (1999) also showed how insights from nonswelling soil water flow theory significantly simplify analysis of centrifugal filtration of particulate suspensions. In addition, Kim *et al.* (1992a) applied the approach to water flow in marine clay and Smiles (1973) used the approach to explain almost 0.5 m of consolidation of estuarine sediment over more than 500 days following construction of a road embankment that was drained at the sediment-embankment interface.

Well-tested methods also permit unambiguous measurements of $k_{\mathrm{m}}(\vartheta)$ (or $D^{*}_{\mathrm{m}}(\vartheta)$) and $\psi(\vartheta)$ in these systems with the qualification that $\psi(\vartheta)$ must be measured in the unloaded state (REFS). Because these systems are saturated, definition of the shrinkage curves $e(\vartheta, \sigma)$ is not needed, although care is required to ensure that sample constraints do not result in experimental artifacts.

Unsaturated Systems

Equilibrium and flow of water in unsaturated swelling soils is more uncertain and it is necessary also to discriminate between laboratory measurements and field studies at a larger scale, but:

1. Philip (1969b) and Sposito (1975a) used equation (19) to explore static equilibrium profiles in these materials and most measured field profiles confirm the Philip and Sposito insights that equilibrium volumetric water contents tend to decrease with depth.
2. Steady vertical flow profiles calculated using equation (27) are also illustrated by Philip (1969d) and Giraldez and Sposito (1978), but neither paper was based on measured material properties.
3. Smiles and Colombera (1975) and Kirby and Smiles (1999) measured transient water content profiles during infiltration from a constant potential water source into beds of natural swelling aggregates that characterize the surface of dry self-mulching clay soils. These tests focused on the extended initial stages of infiltration when the effects of gravity are minimal. Equation (28) was used and transient water content profiles revealed Boltzmann scaling as the approach anticipates.
4. Perroux and Zegelin (1984) described water content profiles associated with constant flux infiltration into self-mulching heavy clay soil at realistic rates, V_0, in both the laboratory and the field. Theory required, and experiments revealed, scaling in terms of $V_0 m$ and $V_0^2 t$. $D(\vartheta)$ was derived in both experimental sets.
5. Kim *et al.* (1992a) and papers identified by Kim *et al.* (1999) use the full equation (28) to analyze behavior of both saturated and unsaturated clays in the laboratory and the field; Giraldez and Sposito (1985) solved it for flux infiltration but did no experiments.
6. The instantaneous profile method for nonswelling soil (Green *et al.*, 1986) was also used by Kirby and Ringrose-Voase (2000) in the field for draining rice soils and the derived material properties were consistent with subsequent predicted behavior.

The instantaneous profile method would appear useful for soil characterization in dryland water management and might be complemented by triaxial and k_o-cell measurement routinely used by civil engineers to measure the coefficient of consolidation. The k_o-cell, in particular, establishes and monitors constraints similar to those in the field during water flow and volume change.

Experimental clarification of a number of issues is still required, however, particularly regarding two- and three-dimensional aspects of flow, although Kim *et al.* (1999), in laboratory studies, marry isotropic behavior of aggregates to essentially one-dimensional behavior of the profile. In the face of the great difficulties involved in field measurement and modeling, a number of other theoretical concerns also remain. Definition of the overburden potential and the assumption of local equilibrium of water potential across aggregates and voids are problems; volume change and definition of material properties necessary to use equations like (28) must also be studied.

The Components of the Total Water Potential

The Overburden Potential

Practically and theoretically, definition of the overburden potential and its components remains a problem. One difficulty is the integration of equation (22) required to define the overburden potential, Ω. This integration requires that we describe work involved in changing the water content of the unloaded soil and then loading it. The "simple, convenient, and useful" path of Philip (1970) that leads to equation (23) requires the soil to dry from saturation water content, under zero load, to some arbitrary

ϑ- value, and then to increase σ from 0 to P at constant ϑ. The first stage in this process involves drainage, the second wetting, because θ_w then increases as e decreases while ϑ remains constant. Groenevelt and Bolt (1972) argued that, from a thermodynamic point of view, hysteresis reflects metastable situations and can be ignored but, within this very robust assertion, it remains difficult experimentally to match the integration path implied in equation (23).

The equality between $(\partial p_w/\partial P)_\vartheta$ and $(\partial e/\partial \vartheta)_P$ expressed in equation (21) also needs investigation. Practically, the former may be easier to measure than the latter, and Miller (1975) suggested that the general theory should be reformulated using the measurable p_w, rather than the more esoteric "unloaded" matric potential, although changes in ϑ would still require measurement of σ as well as p_w. Nevertheless, Croney *et al.* (1958), Talsma and van der Lelij (1976), and Talsma (1977) made successful comparisons of $(\partial p_w/\partial \sigma)_\vartheta$ and $(\partial e/\partial \vartheta)_\sigma$ *in situ*. Such measurements are important but rare and simultaneous measurement of p_w, and the profile $e(\vartheta, \sigma)$ using installations similar to those initiated by Woodruff (1936) are needed if only to establish operationally useful but approximate ways to deal with Ω in unsaturated soils. These issues will be only resolved by laboratory and field experiment as comprehensive and searching as those of Croney *et al.* (1958).

The Unloaded Capillary Potential Characteristic $\psi(\vartheta)$

Within these uncertainties, the unloaded capillary potential characteristic $\psi(\vartheta)$ should be measured on thin samples in exactly the same way as it is in nonswelling soils. The function appears to be hysteretic. In addition, there remain uncertainties about the nature of ψ as a scalar, that have yet to be resolved (Mahony, 1975). This may be of secondary concern practically, compared with continued uncertainty about the relation between $\psi(\vartheta)$ and Ω. As we note above, Miller (1975) discussed the issue and argued that, because only $p_w(= \psi + \Omega)$ permits unambiguous field measurement in relation to hydrostatics and flow, p_w should be the basis for material characterization; his proposition has received little attention.

Capillary Potential Equilibrium Across Aggregates and Voids

Local equilibration of water potential across aggregates and voids is implied in equation (28) but, in flood and furrow irrigated swelling-cracking soils, water often rapidly penetrates the soil profile via cracks, and aggregates may then equilibrate with the "macropore" water quite slowly.

Philip (1968b) extended the Richards equation to absorption into aggregated media where local potential disequilibrium exists, but his approach has not been tested in swelling soils. Bevan and Germann (1981) and Germann and Bevan (1981, 1985) treated flow in the aggregates as Darcian and described flow in the macropores as purely gravitational so the Richards equation was reduced to a kinematic wave equation. Bevan and Germann were not specifically concerned with swelling soils but Ross and Bridge (1984) similarly considered the process in swelling soils as a vertical "infiltration advance" problem with horizontal absorption into aggregates from a rapidly filled crack system. The issues are defined well by Ross and Bridge: they include interaction between precipitation rate and duration and the soil structure associated with the antecedent water content. If absorption of water by aggregates is rapid enough to accept rainfall (or irrigation) and surface cracks close before ponding, then equation (28) will apply. If the soil is dry so cracks are extensive and rainfall or irrigation is intense, then flow down cracks will be rapid and another infiltration model is required. Kim *et al.* (1992b), for example, believed that almost 30% of heavy rainfall moved directly to the water table in a cracked marine sediment; Favre *et al.* (1997) believe that by-pass flow under both rainfall and flood irrigation was only modest; while Kirby and Ringrose-Voase (private communication) working with a rain-fed, self-mulching vertisol, believed that by-pass flow in cracks was relatively minor. Field experiments setting behavioral limits based on rainfall intensity and duration and their interaction with antecedent water content, crack pattern, and the dynamics of surface crack closure are, therefore, desirable.

At the same time, much anecdotal evidence supports the notion that the wetting front, following rainfall on a swelling soil, penetrated about the same distance across an extensive area and, by implication, the water content profiles were fairly uniform. Fawcett (1972), for example, used a penetrometer to show this more detailed sampling of Cabidoche and Ozier-Lafontaine (1995) and Coquet (1998) led to similar expectations, and Wells *et al.* (2003) found that infiltration profiles in cracking soils became increasingly more uniform during successive simulated (heavy) rainfall events separated by drying phases that induced surface cracking.

In recent years, flow of water in structured soils has been incorporated in various comprehensive models such as HYDRUS, MACRO, and SWAP. Discussion of these models is beyond the scope of this article, but the reader is referred to proceedings of two recent symposia for detail (Feyen and Wiyo, 1999; Feddes *et al.*, 2004)

The Hydraulic Conductivity Characteristic $k(\vartheta)$

Focus on α diverted attention from the fact that if we need to concern ourselves with the full family of $e(\vartheta, \sigma)$ curves as illustrated by Groenevelt and Bolt (1972), then $k(\vartheta)$ cannot be unique in an unsaturated soil and should properly be replaced by $k(\vartheta, e)$ (Smiles, 2000). The effect

may be quite important because k scales with the square of a characteristic hydraulic length (Miller and Miller, 1955). This issue had not been identified previously and requires examination (but see Horn *et al.*, 1995). In the interim, it is worth recalling that the k_0-cells routinely used by engineers to measure engineering parameters of consolidating soil cores provide defined lateral constraint but permit free vertical movement (subject to appropriate load) during flow and volume change. These requirements are not always met. Garnier *et al.* (1998), for example, measured infiltration in swelling soil, but their data appear to be vitiated, in part, by artifacts that arose because of inappropriate sample constraints (Kirby and Smiles, 1999).

Subsidiary Issues

There are subsidiary issues, two of which are identified here.

Physical Chemistry of Clays and its Effect on Flow

The structural and flow consequences of the soil physical chemistry are reflected in macroscopically measured $k(\vartheta)$ and $\psi(\vartheta)$ functions (Smiles *et al.*, 1985). In terms of the water flux, the osmotic potential gradient will be important where the reflection coefficient is significant; Barbour *et al.* (1992) provides a recent review.

The Concept of Effective Stress

The effective stress concept is useful in systems that swell, although it leads to debate about the nature of particle–particle interaction in chemical engineering, and it has no meaning in a nonswelling soil. On the other hand, the notions of a measurable capillary potential, ψ, or manometric pressure p_w, permit general analysis of equilibrium and flow of water in and between swelling and nonswelling systems (e.g. Smiles and Kirby, 1994). The capillary potential also permits us to be quite agnostic about detail of microscopic or molecular interactions that are important but are implicit in the macroscopically measured $\psi(\vartheta)$ function.

CONCLUDING REMARKS

Richards' equation provides a well-tested basis for describing water flow in nonswelling soils. It requires that the macroscopic functions $k(\vartheta)$ and $\psi(\vartheta)$ be well-defined. These properties are readily measured using well-established methods at scales that approximate the scale of field application. Use of the Richards equation has been extended to encompass systematic, and to some extent also stochastic, heterogeneity. It can also be used to describe flow in systems where local potential disequilibrium exists.

For one-dimensional water flow in swelling soils, combination of Darcy's law with the continuity equation for water expressed in material coordinates based on the distribution of the soil solid results in an equation of exactly the same form as the Richards equation. This equation also requires that $k_m(\vartheta)$ and $\psi(\vartheta)$ be well-defined and that $e(\vartheta, P)$, which specifies profile swelling behavior, be also known. This approach has been well tested for saturated systems and effectively applied in some unsaturated cases; its general application to swelling soils awaits systematic examination, however, because of the scale and variability of swelling soils and the much greater difficulty in determining representative values of water content, water pressure, and soil density. Nevertheless, examples of successful application of an approach based on the Richards equation are cited.

Finally, we reiterate the importance of the material coordinate in determining material balance of the water, as well as solutes, in soils that change volume with water content change. For most mineral soils, the solid distribution provides such a coordinate. For organic soils or, for example, acid sulfate soils where reaction may destroy part of the matrix, a coordinate based on the distribution of the irreducible mineral fraction is useful. These coordinates are simple to measure and use, and intensive properties, expressed in terms of unit amount of the coordinate, provide an unambiguous basis for profile comparisons in time and physical space.

68: Water Movement in Hydrophobic Soils

DR STEFAN H DOERR[1] AND PROFESSOR COEN J RITSEMA[2]

[1] *Geography Department, University of Wales, Swansea, UK*
[2] *Soil Science Center, Wageningen, The Netherlands*

Hydrophobicity (water repellency) can reduce the affinity for soils to water such that infiltration or wetting may be delayed for periods ranging from as little as a few seconds to in excess of weeks. Soil hydrophobicity is thought to be caused primarily by a coating of long-chained hydrophobic organic molecules on individual soil particles. These substances may be released from a range of plants, decaying organic matter, soil fauna, and microorganisms either naturally or during burning. Hydrophobicity tends to be spatially and temporally highly variable, which makes its effects difficult to observe and predict. It is often most prominent after prolonged dry spells and usually disappears after prolonged contact with water. Owing to the cultivation of certain frequently introduced plant species and the increase in wildfires in some regions, hydrophobicity has developed in previously unaffected areas. Amongst its effects are inhibited plant growth, increased overland flow and soil erosion, uneven spatial and vertical wetting patterns, reduced evaporation, and enhanced risk of groundwater contamination associated with enhanced preferential flow. Recent modeling approaches have been successful in predicting the effects of hydrophobicity on soil water movement at plot or small-field scales, however, approaches to predict in detail its hydrological effects at larger scales are yet to be developed.

INTRODUCTION

Soils are commonly considered to wet readily under rainfall or irrigation. This is, however, not always the case as soils can also behave in a hydrophobic (water repellent) manner. Depending on its degree, hydrophobicity can reduce the affinity of soils to water such that they may resist wetting for seconds, hours, days, or even months (e.g. King, 1981; Dekker and Ritsema, 1994; Doerr and Thomas, 2000). Soil hydrophobicity is typically confined to the organically enriched top centimeters or decimeters of the soil and tends to be both spatially and temporally highly variable. It often disappears after prolonged wet periods, but will usually reemerge during drier periods when soil moisture falls below a critical threshold (Dekker *et al.*, 2001).

Early reports of reduced soil wettability date back to 1837, where Waring (as reviewed by Bayliss, 1911) investigated mycelium growth associated with "fairy rings", a term describing a circular area of vigorous plant growth (i.e. grass or crops) on moist soil, surrounded by withered plants covering dry soil. In many cases the fairy ring phenomena was so abundant locally that it materially affected the yield of crops (DeBano, 2000). In 1910, Schreiner and Schorey (p. 9) reported a Californian soil that "could not be wetted, either by man, by rain, irrigation, or the movement of water from the subsoil". Subsequently, studies by Jamison (1946) showed that soil hydrophobicity affected the productivity of citrus orchards in Florida, and nowadays wetting agents are widely used to increase soil wettability, for example, in horticulture and turf grass industries. During the 1990s and early 2000, it became evident that soil hydrophobicity is not restricted to a few locations with very specific environmental conditions. It has now been reported from all continents except Antarctica, from climates ranging from seasonal tropical to subarctic, from land uses including ploughed cropland, grass and shrubland, and a wide range of forest types, and from soils ranging from coarse- to fine-textured (e.g. Wallis and Horne, 1992; Bauters *et al.*, 2000; DeBano, 2000; Doerr *et al.*, 2000b). Its degree can vary considerably from extremely high as observed under Eucalyptus plantations in Portugal (Doerr *et al.*, 1998) to being detectable only with a purpose built micro-infiltrometer as reported from some agricultural soils in Scotland (Hallett and Young, 1999).

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Most workers in this field agree with the notion of Wallis *et al.* (1991) that hydrophobicity in soils is the norm rather than the exception, with its degree being variable.

Apart from its often costly implications for plant growth (e.g. York, 1993; Blackwell, 2000), soil erodibility (Shakesby *et al.*, 2000) and other effects described elsewhere (DeBano, 2000; Doerr *et al.*, 2000a) soil hydrophobicity has substantial repercussions for water movement in soils. These include reduced infiltration rates leading to enhanced Hortonian overland flow (cf. **Chapter 111, Rainfall Excess Overland Flow, Volume 3** and **Chapter 120, Land Use and Land Cover Effects on Runoff Processes: Fire, Volume 3**), uneven wetting patterns, development of preferential flow (cf. **Chapter 78, Models of Water Flow and Solute Transport in the Unsaturated Zone, Volume 2**), and the accelerated leaching of agrichemicals (e.g. Imeson *et al.*, 1992; Ritsema *et al.*, 1997; Doerr *et al.*, 2003). These soil hydrological effects are discussed in the following sections after a brief introduction to the origin and classification of hydrophobicity. This is then followed by an overview of current approaches to modeling water movement in hydrophobic soils at a range of scales.

ORIGIN AND CLASSIFICATION

The Principles Underlying Hydrophobicity

A wettable (i.e. hydrophilic) surface allows water to spread over it in a continuous film, whereas water on a hydrophobic surface "balls up" into individual droplets. If the surface is a porous medium like sand or soil, water infiltration is inhibited (Figure 1). The affinity or repellency between water and solid surfaces originates from mutual attractive forces (adhesion) and the attraction between the water molecules (cohesion). To understand these forces better, some properties of water are briefly considered here.

A water molecule comprises an oxygen atom with a partial negative charge and two hydrogen atoms with a partial positive charge. The hydrogen and oxygen atom bonds are positioned 105° apart, giving the water molecule a strongly dipolar structure (Parker, 1987). The attraction of these positive and negative ends causes water molecules to form aggregates, held together by hydrogen bonds. Water adheres to most natural surfaces since they consist of positively and negatively charged ions attracting the negative end or the positive ends of a water molecule respectively. The dipole character of water, however, also results in a comparatively strong force counteracting the attraction to charged surfaces. Within a liquid, the net force acting on an individual molecule is zero as it is surrounded by other molecules and their forces. Beyond the surface of a liquid, however, no similar molecules exist to oppose the attraction exerted by the molecules within the liquid. Consequently, the surface molecules experience a net attractive force towards the interior, which promotes the reduction of the surface area of water. Thus, if opposing forces are minimal, liquids will assume a spherical shape (i.e. that of a droplet). To enlarge the surface of a liquid, work is necessary. This work is related to the surface tension (γ) or surface-free energy of the liquid. Most liquids have a surface tension of $20-40\,\mathrm{N\,m^{-1}} \times 10^{-3}$ at 20 °C, but that of water is exceptionally high at $72.75\,\mathrm{N\,m^{-1}} \times 10^{-3}$ (Parker, 1987).

Figure 1 Water droplets resisting infiltration into a sandy dune soil sample from the Netherlands because of extreme hydrophobicity. (photo: E. van den Elsen)

The same principle applies to solid surfaces, although their nature inhibits deformation into a spherical shape. The surface tension of solids therefore leads to lateral forces at the surface. Values for hard solids such as soil minerals range from $500-5000\,\mathrm{N\,m^{-1}} \times 10^{-3}$, increasing with hardness and at its melting point (Zisman, 1964). For water to spread on a solid, the adhesive forces between them must exceed the cohesive forces within the body of water. Thus, surfaces with a surface-free energy $>72.75\,\mathrm{N\,m^{-1}} \times 10^{-3}$ attract water and are therefore hydrophilic. The higher the surface tension of the solid, the stronger is the attraction. All principal soil minerals have a much higher surface-free energy than water and are therefore hydrophilic (Tschapek, 1984), whereas soft organic solids, such as waxes or organic polymers can exhibit γ values below $72.75\,\mathrm{N\,m^{-1}} \times 10^{-3}$ and are thus hydrophobic (Zisman, 1964).

Origin of Hydrophobicity in Soils

In theory, a single layer of hydrophobic molecules can render a hydrophilic mineral surface hydrophobic (Zisman, 1964), although in practice hydrophobic compounds may not be absorbed as uniform monolayers, but as small globules. Thus, an amount equivalent to that of several

monolayers may be required to result in a complete cover on a mineral grain (Ma'shum *et al.*, 1988). This amount is still relatively small. For example, Ma'shum *et al.* (1988) induced severe hydrophobicity in 1000 g of medium-sized sand using only 0.35 g of the hydrophobic compound. Soil hydrophobicity can also be caused by the presence of hydrophobic interstitial matter. If hydrophobic particles are present in the pore spaces of a hydrophilic matrix, the wettability of the composite material is reduced. For example, severe hydrophobicity has been induced by intermixing as little as 2–5% by weight of solid organic matter to hydrophilic sand (McGhie and Posner, 1981). For naturally hydrophobic sand, it has been suggested that slight to moderate levels can be caused by the presence of hydrophobic particles in a soil matrix, but that more extreme hydrophobicity results from a coating on individual soil particles (Bisdom *et al.*, 1993).The biological origin of hydrophobic compounds in soils is undisputed, however, the exact source(s) and chemical nature of these compounds have to date not been fully established. Organic compounds with hydrophobic properties are naturally abundant in the biosphere and may be gradually released into the soil, for example, as roots exudates (Dekker and Ritsema, 1996; Doerr *et al.*, 1998), from soil fauna (Wienhold and Gish, 1991), fungi (Savage *et al.*, 1969) or microbes (Hallett and Young, 1999), or directly from decomposing organic matter (McGhie and Posner, 1981). Depending on vegetation cover present and soil temperatures reached, a rapid release or redistribution of hydrophobic compounds often accompanies the burning of vegetation, leading to a distinct hydrophobic layer at the soil surface or at some depth in the soil profile (DeBano *et al.*, 1976; Doerr *et al.*, 2004) (cf. **Chapter 120, Land Use and Land Cover Effects on Runoff Processes: Fire, Volume 3**).

The specific types of compounds suggested to be a cause of hydrophobicity include alkanes (Ma'shum *et al.*, 1988; Roy *et al.*, 1999; Horne and McIntosh, 2000) fatty acids and their salts, and esters (Ma'shum *et al.*, 1988; Franco *et al.*, 2000; Roy *et al.*, 1999) and other related compounds such as phytanes, phytols, and sterols (Franco *et al.*, 2000; Morley *et al.*, 2005). The presence of these compounds, however, does not necessarily lead to the expression of hydrophobicity in soils. It has been demonstrated that comparable amounts of such compounds occur also in wettable soils (Doerr *et al.*, 2005; Morley *et al.*, 2005) and it has been suggested that these compounds only cause hydrophobicity when they form a specific molecular arrangement (Roy and McGill, 2000; Morley *et al.*, 2005).

Classification of Soil Hydrophobicity

Most techniques for measuring and classifying soil hydrophobicity are described in Wallis and Horne (1992), Hallett and Young (1999), Bachmann *et al.* (2000), Letey *et al.* (2000), Wang *et al.* (2000), and Roy and McGill (2002). One of the most common methods, the "Water Drop Penetration Time" (WDPT) test (Van't Woudt, 1959) is referred to later and is therefore briefly described here. It involves placing droplets of distilled water onto a sample surface and recording the time for their complete infiltration. This test broadly determines how long hydrophobicity persists in the contact area of a water droplet. This *persistence* or stability of hydrophobicity is usually somewhat, but not always well, related to the apparent surface tension (i.e. the *severity* of hydrophobicity) of a soil (Dekker and Ritsema, 1994; Doerr, 1998). Hydrophobicity *severity* will determine how strongly a droplet initially balls up when in contact with the soil and can be determined by contact angle measurements (see Letey *et al.*, 2000). Contact angles can, however, change rapidly if the *persistence* of hydrophobicity is low. Perception of what constitutes a high or low degree of hydrophobicity varies widely. To distinguish between hydrophilic and hydrophobic soils, an arbitrary WDPT threshold of 5 s (Bisdom *et al.*, 1993) has been used widely, although considerable effects on water movement at the centimeter-scale have been shown to be caused by lower levels of repellency (Hallett *et al.*, 2004). WDPT values found in the literature are generally presented in categories rather than distinct values and are not always directly comparable because, for practical reasons, this test is often terminated before droplet penetration occurs. In many studies to date, WDPTs exceeding one h have been recorded (= classed as extreme persistence, Bisdom *et al.*, 1993), but *persistence* can in some cases reach levels such that even ponded water may not infiltrate for periods exceeding one month (Doerr and Thomas, 2000). Although the aforementioned laboratory tests allow a general classification of soils according to hydrophobicity *persistence* and *severity*, these measurements do not always relate well to the actual wetting behavior of field soils (Doerr and Thomas, 2000). Thus, Dekker *et al.* (1999) and Doerr *et al.* (2003) recommended the wider use of wetting rate measurements and rainfall simulations.

HYDROPHOBICITY EFFECTS ON SOIL WATER MOVEMENT

The main hydrological impacts of hydrophobicity are: (i) reduced infiltration; (ii) increased overland flow; (iii) spatially localized infiltration and/or percolation, often with fingered flow development; (iv) modifications of the three-dimensional distribution and dynamics of soil moisture; (v) enhanced streamflow responses to rainstorms; and (vi) enhanced total streamflow. Because of enhanced overland flow on, and increased erodibility of, hydrophobic soil, slopewash, and sometimes the formation of rills and gullies may be promoted (see review by Shakesby *et al.*, 2000).

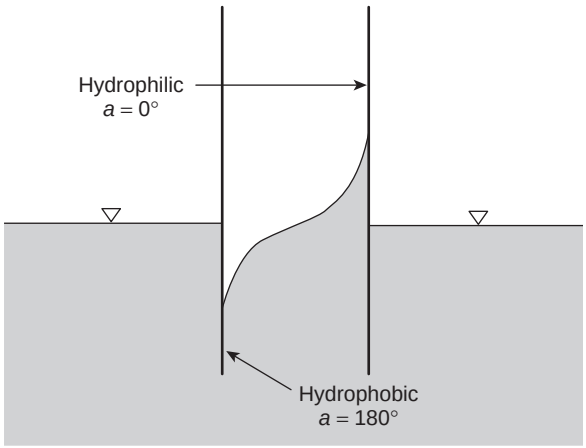

Figure 2 Shape of the meniscus of water between a hydrophilic and a hydrophobic plate with liquid–solid contact angles of 0° and 180° respectively (adapted from Bauters *et al.,* 2000)

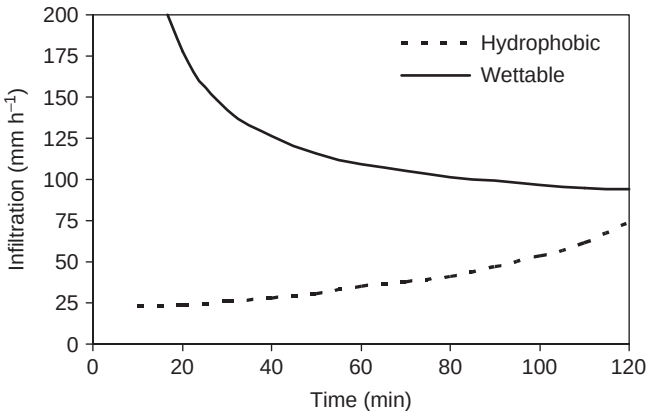

Figure 3 Infiltration rates into hydrophilic and hydrophobic soils (adapted from Letey *et al.,* 1962)

Infiltration and Overland Flow

The most frequently reported impacts of hydrophobicity are those of reduced infiltration into soil (e.g. Van Dam *et al.*, 1990; Imeson *et al.*, 1992; Doerr *et al.*, 2003) and thus increased overland flow (e.g. McGhie and Posner, 1980; Witter *et al.*, 1991; Crockford *et al.*, 1991). For example, the infiltration capacity of a hydrophobic soil was found to be 25 times higher than for a similar soil rendered hydrophilic by heating (DeBano, 1971) and for the first 5 min of measurement a hydrophobic soil was found to exhibit only 1% of the potential infiltration capacity when hydrophilic. Owing to the reduced surface tension of the soil pore walls, a hydrophobic soil matrix will have a *positive* soil water potential. This effectively leads to a capillary depression effect illustrated in Figure 2. Infiltration into a relatively dry hydrophobic soil matrix will therefore only occur if a ponding depth (hydraulic head; entry pressure) sufficient to exceed the positive soil water potential is reached. The necessary ponding depth may decrease with time if hydrophobicity decays during water contact. These factors acting in combination usually result in infiltration rates to *increase* during rainfall, although an initial decrease followed by an increase has also been observed (Clothier *et al.*, 2000). Infiltration theory for wettable soils, however, ascribes infiltration rates to *decrease* over time (Figure 3; Letey *et al.*, 1962; Kirkham and Clothier, 2000). Infiltration behavior of hydrophobic soils has been investigated in detail in a range of laboratory-based studies (Bauters *et al.*, 1998; Carrillo *et al.*, 2000; Wang *et al.*, 2000; Feng *et al.*, 2001). Observed behavior, however, may not always be relevant to field conditions, since some workers (e.g. Bauters *et al.*, 1998; Carrillo *et al.*, 2000; Feng *et al.*, 2001) have used porous media with a permanent (nondecaying) hydrophobicity to avoid the confounding effects of unstable hydrophobicity, although these effects typically do occur under field conditions.

On a hydrophobic soil surface in the field, rainwater will pond and, if rainfall is sufficient and surface detention is exceeded, Hortonian (infiltration-excess) overland flow will occur. The frequency of "gaps" through this layer (such as structural or drying cracks, root holes and burrows, and patches of hydrophilic or less hydrophobic soil) will then determine whether overland flow is widespread or only local (Figure 4a). Under some conditions, for example, where intense soil heating during a wildfire has destroyed hydrophobicity in the top few centimeters of the soil (see DeBano, 1971), a distinct hydrophobic layer underlies a hydrophilic and often highly permeable topsoil or ash layer. Rainfall infiltrating such a topsoil may pond above the hydrophobic layer (Figure 4b) and can subsequently:

1. be stored in the hydrophilic layer and later evaporated or used in transpiration;
2. run off as saturation overland flow when the hydrophilic layer becomes saturated;
3. spread out as "distribution flow" and move vertically downwards as "preferential flow" either through structural or other gaps in the water-hydrophobic layer or as "fingered flow" through vertical cylinders of hydrophilic or less hydrophobic soil as discussed in more detail later;
4. move laterally downslope as throughflow above the hydrophobic layer;
5. enter the matrix of the hydrophobic layer (if ponding depth is sufficient, or hydrophobicity undergoes a phase-change to a hydrophilic condition).

Where overland flow is considered the key effect of hydrophobicity, it is often not clear whether Hortonian or saturation overland flow, or a combination of the two, is involved, particularly if the hydrophilic layer is thin,

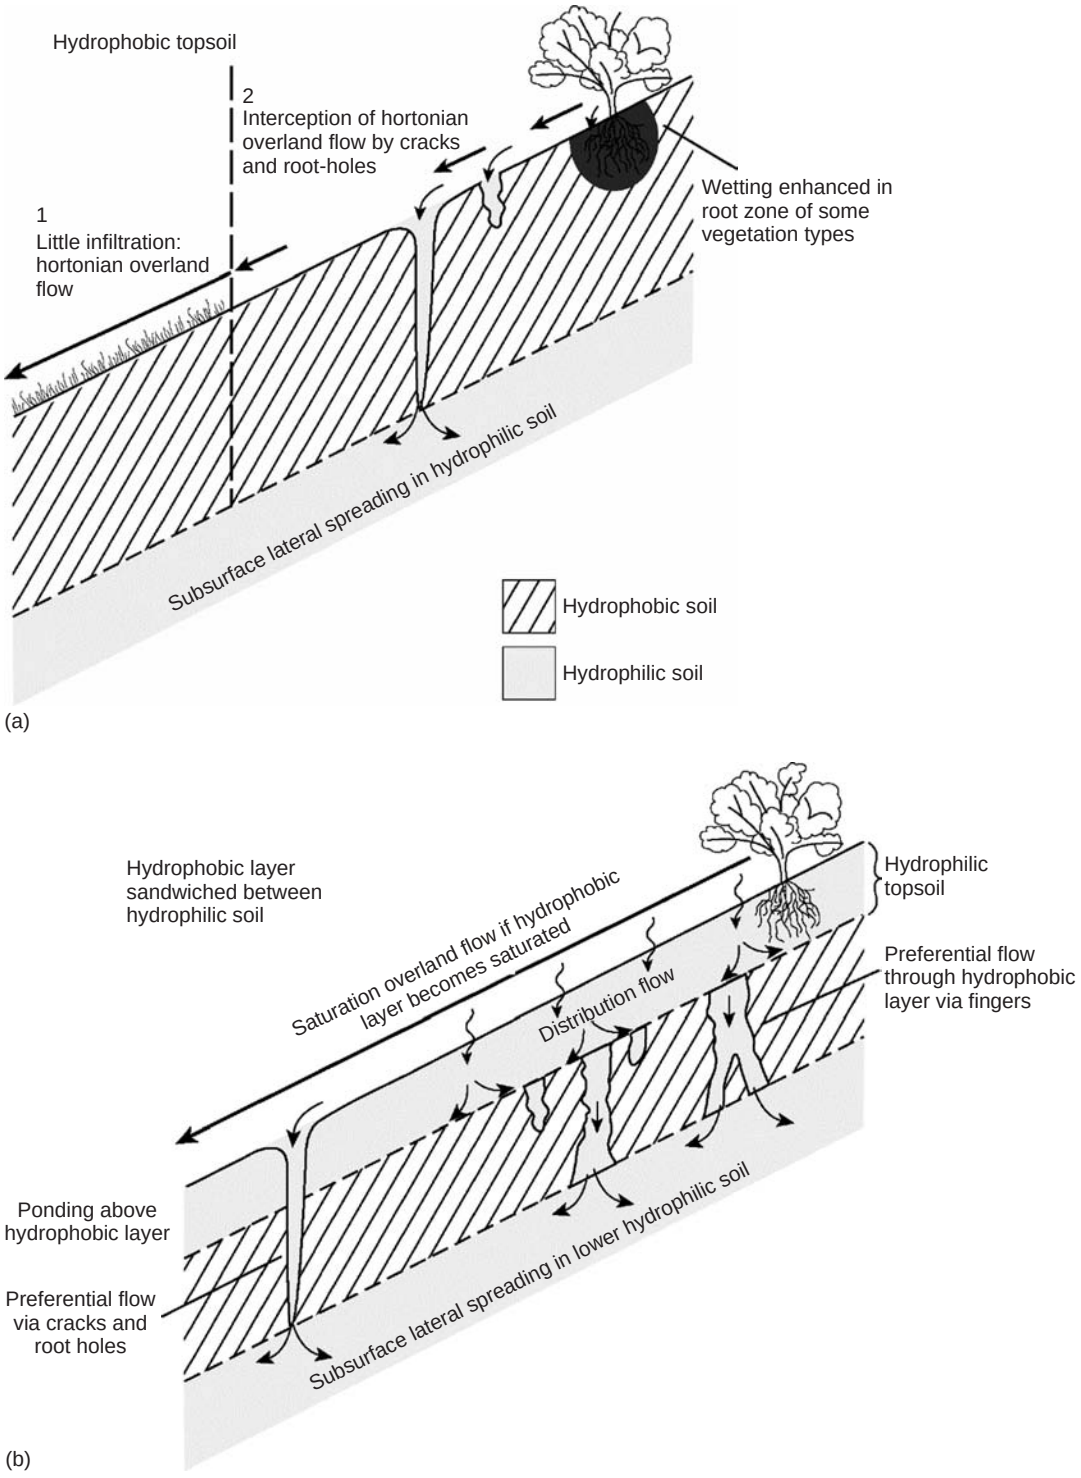

Figure 4 Schematic illustration of possible hydrological responses of soil with (a) a hydrophobic layer located on the surface and (b) a hydrophobic layer sandwiched between hydrophilic soil (adapted from Doerr *et al.,* 2000a)

below the surface, or discontinuous. Thus, in an Australian eucalyptus forest, Burch *et al.* (1989) reported that the development of soil hydrophobicity following drought conditions led to a threefold increase in the rainfall to runoff conversion from an initial 5 to 15%. In a burnt pine forest in South Africa, saturation overland flow promoted by a subsurface hydrophobic layer led to an increase in the stormflow response of 7.5% compared to just 2.2% on

unburnt terrain (Scott and Van Wyk, 1990), and Jungerius and De Jong (1989) attributed the lack of any simple relationship between rainfall and overland flow in Dutch sand dunes to spatial variations in hydrophobicity.

Some studies, particularly those investigating burnt terrain, highlight hydrophobicity as one of several factors enhancing overland flow responses (cf. **Chapter 120, Land Use and Land Cover Effects on Runoff Processes: Fire, Volume 3**). Thus, Dyrness (1976) reported a threefold increase in overland flow after a fire in a pine forest in Oregon and Walsh *et al.* (1994) found a 5–25% higher overland flow response on a burnt Portuguese eucalyptus and pine forest compared with the unburnt forest. Rather than invoking only hydrophobicity, postfire increases in overland flow are also attributed to removal of a protective vegetation cover (with resulting increases in rainbeat compaction, inwash of fines into cracks, and rootholes and reduction in infiltration capacity), reduction in soil particle size, erosion of permeable topsoil (cf. **Chapter 26, Weather Patterns and Weather Types, Volume 1**), stone lag development, and organic matter losses (White and Wells, 1982; Imeson *et al.*, 1992; Shakesby *et al.*, 1996). Such increases were demonstrated using rainfall simulation plot experiments carried out in Portugal during dry conditions on unburnt Pinus pinaster slopes and a nearby area that was burnt two years earlier (Walsh *et al.*, 1998). In both areas, most surface soil remained dry and intensely hydrophobic throughout the 1-h 40–46 mm artificial rainstorms. However, whereas in the unburnt soil, overland flow was modest (4%) and most water infiltrated through cracks and rootholes, on the burnt soil overland flow was more substantial (8–20%).

Thus, depending on prefire conditions, postfire increases in overland flow can be associated with:

1. fire inducing or significantly increasing hydrophobicity, thus enhancing overland flow responses until soil hydrophobicity reaches prefire levels;
2. increased effectiveness of preexisting hydrophobicity, where a return to prefire conditions of a prevailing, but less effective soil hydrophobicity would await revegetation and the reformation of a litter mulch;
3. soils that are hydrophilic before and after the fire, but the loss of interception capacity amongst other fire-related changes also enhances overland flow (Zierholz *et al.*, 1995).

Hortonian overland flow (cf. **Chapter 111, Rainfall Excess Overland Flow, Volume 3**) tends to be most pronounced where soils have an uninterrupted hydrophobic layer. Figure 4(a/1) provides an explanation for the contrasts in overland flow response on hydrophobic terrain reported in the literature. Several studies have pointed towards the localization of overland flow on hydrophobic soils. For example, only 25% of the land surface following a fire in southwest Oregon was hydrophobic, resulting in a low impact on infiltration and overland flow (McNabb *et al.*, 1989). Also, Meeuwig (1971) and Imeson *et al.* (1992), working in pine forests in North America and northeast Spain respectively, found that Hortonian overland flow generated on hydrophobic soil around trees tended to infiltrate on adjacent hydrophilic soil around shrubs (Figure 4(a/2)). This pattern was also found using simulated rainstorms in southwest Spain (Cerdà *et al.*, 1998).

The commonly observed temporal variability of hydrophobicity also needs to be considered here. Thus, reductions in infiltration capacity and increases in overland flow can be expected to be most pronounced following prolonged dry periods, when hydrophobicity tends to become most severe. For example, Burch *et al.* (1989) recorded infiltration capacities in an Australian eucalyptus forest of $0.75–1.9\,\mathrm{mm\,h^{-1}}$ when dry, but $7.9–14.0\,\mathrm{mm\,h^{-1}}$ when wet. In many areas, hydrophobicity-linked overland flow can therefore be confined to storm events following dry weather (Sevink *et al.*, 1989; Walsh *et al.*, 1994). Hortonian overland flow responses following dry weather when the soils tend to be most hydrophobic contrast sharply with the muted overland flow following prolonged wet weather when soils are generally hydrophilic (Jungerius and DeJong, 1989; Ferreira *et al.*, 2000). Since few studies address this issue and the understanding of the processes involved in the breakdown of hydrophobicity is poor, it is often not known how long reduced infiltration associated with hydrophobicity persists during wet conditions. For example, in the eucalypt forest in Australia, Crockford *et al.* (1991) found that several weeks of consistently wet weather were required for hydrophobicity to break down and nine hot days were sufficient for its reestablishment. For Portuguese eucalypt stands, Ferreira *et al.* (2000) found that some hydrophobicity still remained after a week of wet weather with 200 mm rainfall, whilst it took up to two months for surface hydrophobicity to become completely reestablished from a wettable soil status (Leighton-Boyce *et al.*, 2005).

Finally, the effects of hydrophobicity on overland flow generation should also be seen in relation to the spatial scale of measurements. Imeson *et al.* (1992) argued that although hydrophobic soils can produce high overland flow rates locally, the effects at slope or catchment scales can more subdued because of the high spatial variations in infiltration. Similar findings were reported by Roberts and Carbon (1971), Pradas *et al.* (1994), and Doerr *et al.* (2003).

Preferential Flow (Including Fingered Flow)

Preferential flow is the concentrated vertical movement of water via preferred pathways through the soil. It may originate for a variety of reasons such as cracks and biopores, textural discontinuities, and unstable wetting fronts, which may result from soil layering, air entrapment, and so on (Ritsema *et al.*, 1993). Although not restricted to

hydrophobic soils (Kung, 1990; Ritsema and Dekker, 1994a), hydrophobicity can be particularly effective at preventing or hindering downward water movement, directing it into structural or textural preferential flow paths (Figure 4 (a/2) and 4 (b)), and creating an unstable irregular wetting front (Figure 5). Consequently, soils may not wet completely with the passage of a wetting front (DeBano, 1971), and water may be channeled via biopores, cracks, and pipes, thereby bypassing the soil matrix (Burch *et al.*, 1989). Root channels and rodent burrows are thought to represent particularly effective bypass routeways through hydrophobic soil (Meeuwig, 1971; Garkaklis *et al.*, 1998). Walsh *et al.* (1995) considered that such bypass routes explained why even large storms produced little overland flow for highly hydrophobic mature pine and eucalyptus forest soils in Portugal.

Where a hydrophobic layer is overlain by hydrophilic soil, infiltrating water tends to pond above the former, which is then directed via lateral flow to preferential flow routeways, leading it through the underlying hydrophobic layer (Figure 4b). This phenomenon has been described for many burnt soils (see review by DeBano, 1981) and has been investigated further by Ritsema *et al.* (1993) and Ritsema and Dekker (1995), who have termed the process *distribution flow*. On a grass-covered sandy dune in Holland, Ritsema *et al.* (1993) used tracers to record distribution flow within a thin (<2.5 cm) hydrophilic, relatively moist humose topsoil, which supplied water via columns of less hydrophobic soil (preferential flow paths) in an otherwise extremely hydrophobic layer to a second hydrophilic zone below 45-cm depth, where the water spread laterally. This has been termed *fingered flow* (Ritsema and Dekker, 1994a,b). The fingers formed only after dry weather when soil moisture levels in the sandy, hydrophobicity-prone layer were below a "critical" value of 4.75% (vol.) (Figure 6). The fingers ranged from 10–50 cm in width (expanding in wetter weather), being the sole means of water transport for several hours during sustained rainfalls. Such fingers have been shown to recur at the same places in successive storms following intervening dry weather, possibly aided by preferential leaching of hydrophobic substances from the finger pathways (Ritsema *et al.*, 1998). In contrast, instead of any fingered flow, a uniform wetting front may develop in a hydrophobic layer if the overlying hydrophilic top-layer is very thick (Van den Bosch *et al.*, 1999). Preferential flow in general is thought to be reinforced by soil water hysteresis between wetting and drying phases, a feature of most hydrophilic soils, but more pronounced in hydrophobic ones (Ritsema *et al.*, 1998).

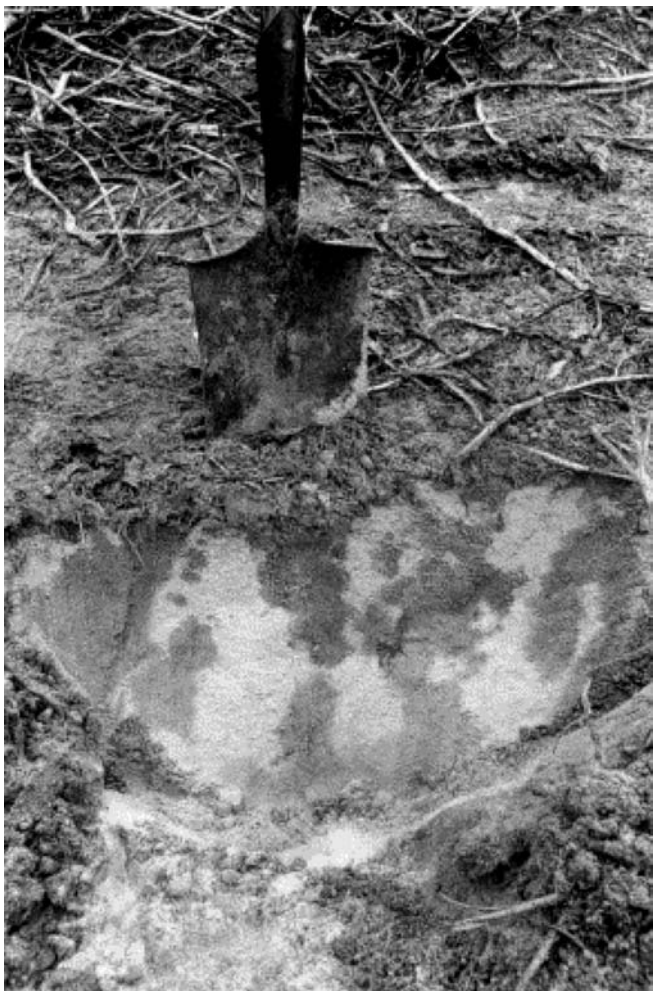

Figure 5 Unstable irregular wetting front and preferential flow pathways in a hydrophobic sandy agricultural soil in Western Australia (photo: S. Doerr)

Effects on the Three-dimensional Distribution and Dynamics of Soil Moisture

As is evident from the previous sections, hydrophobicity influences the three-dimensional distribution and dynamics of soil moisture. Effects will vary with the vertical position of the hydrophobic zone, the frequency of preferential flow routeways through this zone, and the *severity* and *persistence* of its hydrophobicity. For example, a strongly hydrophobic surface layer with preferential flow routeways can lead to dry surface soil and higher soil moisture in the subsoil (e.g. Meeuwig, 1971; Burch *et al.*, 1989; Imeson *et al.*, 1992). In a study in northeast Spain, Imeson *et al.* (1992) described how a hydrophobic surface layer not only trapped water in the B/C horizon, but also prevented evaporation and upward capillary movement of water. It is possible that exudation of hydrophobic compounds is a strategy employed by some plants, fungi, or microorganisms to reduce evaporation, to reduce nutrient leaching in parts of the soil profile, or to suppress the germination and growth of competing vegetation.

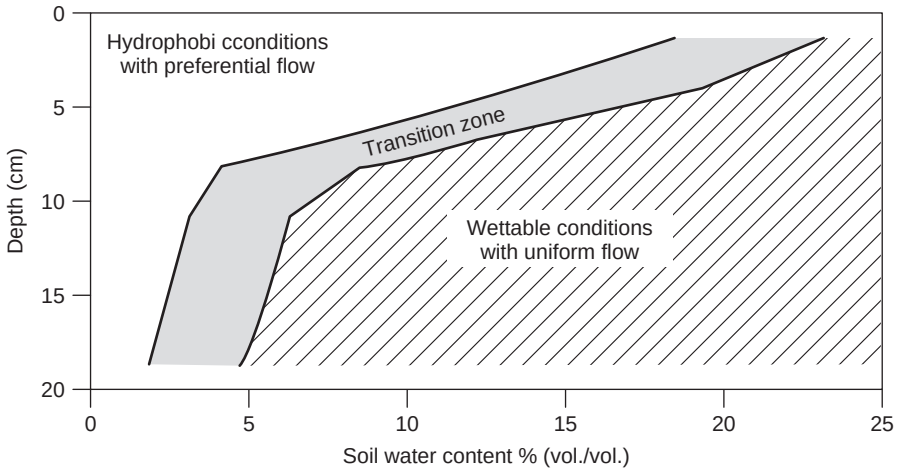

Figure 6 Schematic example of the critical soil moisture threshold changing with depth derived from a sandy soil under permanent grass cover in the Netherlands. Above and to the left of the critical soil water content line, the soil is hydrophobic, which results in the formation of preferential flow paths during infiltration events. At higher soil water contents (below and right of the lower line), the soil is wettable with predominantly uniform flow behavior (modified from Dekker *et al.*, 2001)

Hydrophobicity-induced fingered flow can lead to considerable variations in water content in an initially hydrophobic soil such that zones of very dry soil can be directly adjacent to zones of wet soil. For example, Dekker and Ritsema (1996) found differences in soil moisture of up to 28% (vol.) between closely spaced samples in both clay and sandy soils (see also Figure 5). Such differences not only result in the widely reported poor seed germination and plant growth. Any type of preferential flow path formation can also lead to accelerated leaching of surface-applied agrichemicals and an increased risk of surface and groundwater contamination (Hendrickx *et al.*, 1993; Ritsema *et al.*, 1993).

Effects on Streamflow Generation and Patterns (cf. Chapter 122, Rainfall-runoff Modeling: Introduction, Volume 3)

The tendency for fire-induced or enhanced hydrophobicity, combined with vegetation removal, to increase both total streamflow and the magnitude of storm peaks, as well as reducing peakflow response times has been well established (White and Wells, 1982). For example, increases of 800% for streamflow and 450% for catchment runoff efficiency during the first postfire wet season compared to prefire values were attributed in large part to hydrophobicity-enhanced overland flow in a pine forest catchment in Arizona (Campbell *et al.*, 1977). More recent studies have suggested that impacts may be more complex. Scott and Lesch (1997) attributed the lack of streamflow nine years after the afforestation of grassland catchments with *Eucalyptus grandis* and *Pinus patula* in South Africa to an enhanced deep drainage through the hydrophobic soil via preferential flow along the eucalyptus root channels. Instead of promoting overland flow, hydrophobicity associated with afforestation-enhanced water storage at greater depths in the soil, subsequently used in transpiration. Investigating hydrological responses at a range of spatial scales in a catchment dominated by *E. globulus*, Doerr *et al.* (2003) found that the highly hydrophobic soil status associated with dry antecedent conditions enhanced overland flow responses at plot scales (0.12 and 16 m^2) but did not result in greater storm runoff at the catchment scale (0.33 km^2) than was generated by storms with similar rainfall totals and intensities following moist and more wettable soil conditions. Streamflow peak response time, however, was considerably shorter for hydrophobic, compared to more wettable conditions. It was argued that an increased capture of overland flow generated locally under hydrophobic conditions with increasing scale of investigation may be one of the reasons for the limited effects on streamflow magnitude.

Variations in hydrophobicity, its response to fire, and its interaction with other factors were thought by Scott (1993) to be responsible for differences in catchment response to fire between Fynbos vegetation, *Pinus radiata*, and *Eucalyptus festigata* in mountain catchments in South Africa. In the native Fynbos catchments, only a modest increase in total discharge (16%) and no increase in stormflow occurred following both prescribed fire and wildfire. This low response was attributed to only a minor and spatially patchy increase in hydrophobicity, causing little overland flow to reach the base of slopes. The increase in total flow was thought to be due to reduced evapotranspiration. In contrast, in the *E. festigata* and *P. radiata* catchments, the stormflow component increased by 92% and 201% respectively, the latter being attributed to

fire-induced hydrophobicity. For the former, hydrophobicity had been a prefire feature, which became more effective in promoting overland flow following fire.

EVALUATION AND MODELING HYDROLOGICAL EFFECTS OF SOIL HYDROPHOBICITY

Clearly, hydrophobicity can affect soil water movement in a fundamental way such that conventional principles of infiltration and vadose zone water transport may not be applicable. In contrast to wettable soils, which are often dominated by more or less uniform flow conditions, hydrophobic soils exhibit more pronounced preferential flow conditions as outlined earlier. Fundamentally, hydrophobicity induces an extreme form of hysteresis in the water retention characteristic of soils, which during infiltration events might result in wetting front instabilities and the formation of preferential flow paths. These preferential flow paths typically protrude through the entire hydrophobic zone of a soil, which may extend to depths exceeding of 50 cm (Ritsema *et al.*, 2000), but vanish in underlying, more wettable subsoil layers (Figure 4b). Also, preferential flow paths might disappear in case of rising water tables or after an abundance of rainfall. This indicates that soils might shift from a wettable to a hydrophobic state and *vice versa*, causing flow and transport to be either predominately uniform or preferential. The so-called "critical soil water content" as introduced by Dekker and Ritsema (1994) and Ritsema and Dekker (1994b), and modified by Dekker *et al.* (2001), demarcates the soil moisture content range, in which the transition between these two hydrological states of a soil may occur (Figure 6). The critical soil moisture content appears to vary with, for example, soil organic matter content (Dekker *et al.*, 2001) or soil texture (Doerr *et al.*, 2000b). As the complex and dynamically changing state of soils from wettable to hydrophobic and *vice versa* is strongly influenced by the sequence of weather conditions, soil characteristics, and antecedent soil moisture distributions, it is particularly challenging to model and simulate.

The first modeling attempts to simulate flow and transport through hydrophobic porous media were performed by Van Dam *et al.* (1990), using a static two-domain approach in which the area between the fingers behaved inert, and a calibration factor was used to match computed results of flow and transport properties with observed field data. A slightly more advanced model was developed by Steenhuis *et al.* (1994), in which it was assumed that fingers could only form after saturation of the so-called distribution zone. This zone is located at the top of the soil profile and is generally only a few centimeters thick. In case of fingers, solutes move at a velocity corresponding to saturated unit gradient flow, and the fraction of soil participating in fingered flow was made dependent on changes in precipitation.

On the basis of the field observations by Ritsema *et al.* (1993), De Rooij (1995) used a three-region concept in modeling flow and transport in hydrophobic soils. In this approach, the soil is divided into a distribution zone overlying a hydrophobic layer, with a wettable subsoil underneath. The model, which is basically analytical in character, showed that arrival times of solutes at the underlying groundwater level are shorter when the hydrophobic layer increases in thickness.

The initial formation of preferential pathways in hydrophobic soils and their recurrence during subsequent infiltration events have been modeled by Nieber (1996) and Ritsema *et al.* (1998), using two-dimensional numerical modeling approaches and particle tracking routines. Results showed that wetting front instabilities might occur for extremely hydrophobic conditions and that they are characterized by highly hysteretic water retention functions.

The most detailed approach in modeling water movement in hydrophobic soils to date has been made recently by adapting the established SWAP (Soil-Water-Atmosphere-Plant) model (Van Dam *et al.*, 1997; Kroes *et al.*, 1999) to the specific conditions occurring in hydrophobic soils (Ritsema *et al.*, 2005). The SWAP model calculates evapotranspiration, groundwater level, crop growth, storage and transport of water, solute, and heat in soils. Within SWAP, soil water flow is calculated using the Darcy and Richards equations (*see* **Chapter 5, Fundamental Hydrologic Equations, Volume 1**). These equations are numerically solved using the finite difference method. Solute flow is computed using a numerical solution of the convection–dispersion equation. The traditional version of SWAP calculates uniform flow and transport in soils, and thus cannot be applied to hydrophobic soils.

The schematic representation of the preferential flow process as incorporated within the adapted semi-two-dimensional SWAP model by Ritsema *et al.* (2005) is shown in Figure 7. Basic assumptions and rules, which had to be used to make SWAP applicable also to hydrophobic soil conditions, are:

1. Flow switches dynamically from uniform to preferential flow in cases where an intermittent drying event reduces the water content in a layer of the soil profile to below the "critical soil water content". As a consequence, this layer will become hydrophobic, imposing a zero-flux condition at its upper boundary. This allows for the formation of a perched water table above the dry hydrophobic zone.
2. Saturated conditions above the hydrophobic zone may result in lateral flow (depending on layer anisotropy etc.) towards locations where vertical preferential flow paths might form.

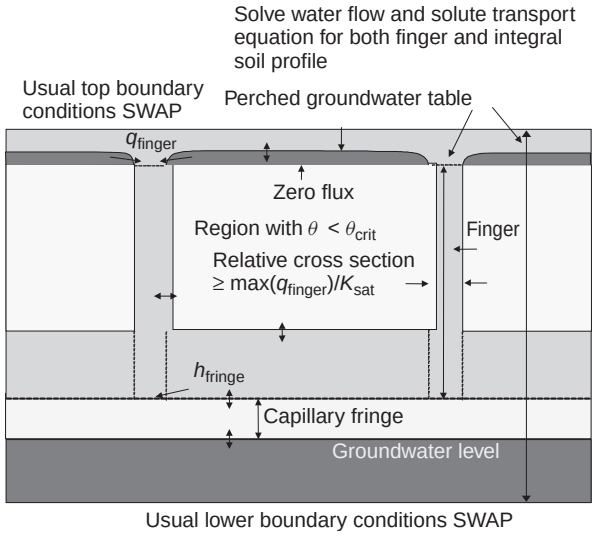

Figure 7 Schematic representation of the preferential flow concept occurring in hydrophobic soils and as incorporated in the modified SWAP model code adapted to hydrophobic conditions

3. The diameters of the preferential flow paths are calculated according to the relationship provided by Selker *et al.* (1996), showing a relationship between the texture of a soil and the flux towards the fingers divided by the saturated soil moisture content of a soil. The number of fingers will depend on the amount and duration of the rainfall. Simulated lateral flow quantities are added dynamically to the fingered flow zone.
4. With sufficiently high fluxes, soil water contents in the preferential flow paths will be near saturation.
5. Lateral diffusion from preferential flow paths towards surrounding dry soil will be slow, due to the extreme hysteresis in the soil water retention characteristic of the hydrophobic material. Hysteresis is accounted for in the adapted SWAP model according to the formulations proposed by Kool *et al.* (1987).
6. Preferential flow paths disappear dynamically either as a consequence of prolonged drying of the soil profile (soil water contents within the fingers drop below the critical level), after extremely wet periods causing many fingers to be formed in the profile, or after a considerable rise of the groundwater table.

Additional model input consists of, amongst others, values of critical soil water contents per layer and anisotropy characteristics of the surface layer. Model output consists of soil water content, pressure head, and solute concentration profiles for both the preferential flow domain and the surrounding immobile matrix.

When tested for a hydrophobic sandy field soil in the Netherlands, computed averages of the water contents within and outside the fingered flow regions obtained with the adapted SWAP code were found to be in much closer agreement with the observed field data than the results generated by the traditional model code. The traditional SWAP model overestimates average soil water contents for the summer period, that is, the period during which hydrophobicity occurred in the experimental field site. In reality, large parts of the soil are then bypassed by infiltrating water as a result of the occurrence of preferential flow paths, resulting in lower average soil water contents per depth, which is predicted by the adapted SWAP model. As a result of the preferential flow process within the experimental field, solutes move more rapidly in the downward direction compared with a situation without hydrophobicity and occurrence of preferential flow paths. This is illustrated in Figure 8, which indicates that arrival times of a conservative tracer (bromide) at 100-cm depth is not only much faster, but total solute loads are also higher compared with a comparable soil without occurrence of water repellency and preferential flow in the respective summer period. The modified SWAP model code has been further tested and applied for untreated and clay-amended hydrophobic soils in southwestern Australia, whereby also effects upon crop productivity have been investigated (Kramers *et al.*, 2005).

So far, the traditional and adapted SWAP model codes have been developed for application on plot and small-field scales, and approaches for modeling hydrophobicity effects at larger scales are yet to be developed. As the spatial and temporal variations in the occurrence, severity, and persistence of hydrophobicity become more difficult to establish with increasing spatial and temporal scales, the uncertainty

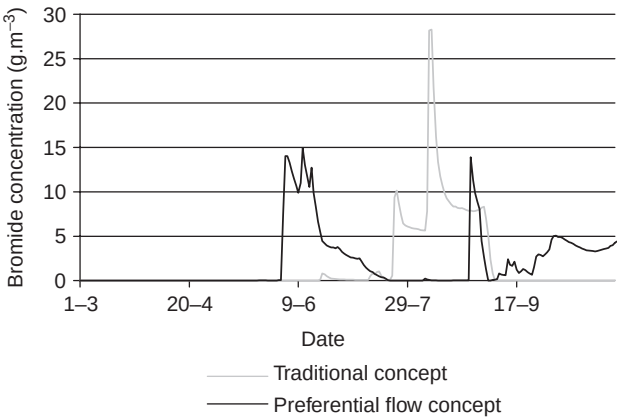

Figure 8 Simulated tracer (bromide) arrival at 100-cm depth for a sandy soil with three different layers after 50 mm of rainfall using the traditional (no preferential flow) and modified (including hydrophobicity-induced preferential flow) SWAP model codes with identical boundary conditions. Accounting for the occurrence of hydrophobicity and preferential flow (modified SWAP code) results in earlier arrival times of a conservative tracer and higher leaching totals

regarding the net-effects of hydrophobicity on soil water movement increases accordingly (Doerr and Moody, 2004). In addition, other hydrologically important factors such as the presence and spatial distribution of macropores (e.g. root channels, animal burrows) become increasingly important, affecting infiltration and water movement in the hydrophobic terrain (Burch *et al.*, 1989), and the variations in the storage capacity of the canopy, litter, and duff layers over larger scales will determine how much water will be delivered to the soil surface during a rainfall event, which in itself is likely to be spatially variable. These spatial and temporal uncertainties pose a considerable problem in evaluating and modeling the effects of hydrophobicity on soil water movement at larger scales (Doerr and Moody, 2004), but need to be tackled in order to upscale existing modeling approaches. Modeling at larger scales would then allow, for example, establishing to what degree hydrophobicity actually contributes to, what are perceived by many as "unusual" hydrological events such as the runoff and erosion events following the 2001 fires in the United States and Australia, or the 2000 and 2002 river floods in Europe.

Acknowledgments

We wish to thank all our colleagues in the field of soil hydrophobicity, whose work or personal communications have helped the preparation of this article. In particular, thanks go to Louis W. Dekker, John A. Moody, Klaas Oostindie, Richard A. Shakesby, and Rory P.D. Walsh for coauthorship on previous work relevant to this article. The preparation of this article was facilitated by a NERC Advanced Fellowship (NER/J/S/2002/00662; SHD).

69: Solute Transport in Soil at the Core and Field Scale

MARNIK VANCLOOSTER,[1] MATHIEU JAVAUX[1,2] AND J VANDERBORGHT[2]

[1]Department of Environmental Sciences and Land Use Planning, Université Catholique de Louvain, Louvain-la-Neuve, Belgium
[2]Agrosphere Institute, (ICG-IV), Forschungszentrum Jülich GmbH, Jülich, Germany

A detailed understanding of the flow and transport processes of chemicals in soils is needed to implement effective and efficient soil and water management strategies and to meet the current challenges of sustainable development. The solute transport process is a key process determining the mass flow of chemical substances once they are released in the soil solution. The transport process is a highly nonlinear and space-time dynamic process for which models are still poorly validated at the larger scale. In this article, we review some recent advances in describing solute transport in soil at the macroscopic core scale, corresponding to the scale of most soil measurement devices, and the pedon scale, corresponding to the scale of a small field. After introducing basic concepts, major problems using the classical Convection Dispersion Equation (CDE) model for describing field-scale solute transport is presented and alternative modeling concepts are introduced.

INTRODUCTION

Soil and groundwater are important natural resources that should be protected from human-induced pollution, requiring a thorough understanding of the fate and transport mechanisms of solutes in soils. Dissolved substances entering the soil from diffuse and point pollution sources, further referred to as solutes, are carried with the water phase through the soil zone, where it is subjected to a range of phase exchange (e.g. sorption) and transformation processes. Along with the boundary conditions at the soil surface, these transport, phase exchange, and transformation processes will determine the ultimate concentrations and fluxes of dissolved substances in soil and groundwater. The modeling and characterization of solute fate and transport are essential for efficient soil and groundwater management and engineering.

The modeling and characterization of solute fate and transport in soils is complicated by the space-time variability of the underlying processes. In addition, any experimental technique is operational at a certain scale, which is not necessarily the scale at which the process can reasonably be described, neither the scale at which a prediction is needed. The expressions of the solute fate and transport are therefore often considered as scale-dependent, and scaling is needed to model and characterize the solute transport processes at the larger spatial scale. The scaling is of utmost importance given the fact that most environmental problems occur at the larger spatiotemporal scales, while most characterization techniques and well-validated modeling concepts are only operational at the lower scale.

This article gives a summary of the processes affecting solute transport at the local core and field-scale and introduces approaches for modeling. The local scale is considered as the laboratory scale, pertaining to the scale where most classical experimental techniques are operational. It is typically the scale of the soil core or the soil lysimeter (Dagan, 1989). The field-scale considered here is the one defined from a pedological point of view, that is, a three-dimensional soil body large enough to permit the study of solute transport for practical purposes. It often corresponds to a poly-pedon and is considered as a homogeneous soil unit in soil maps. After reviewing the basic transport processes that are embedded in classical transport theory, shortcomings of classical modeling approaches for modeling solute transport at the field-scale are illustrated. In

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

the last section, alternative approaches are presented which allow a more comprehensive modeling of solute transport in heterogeneous soil.

SOLUTE TRANSPORT: DEFINITIONS, CONCEPTS, AND CLASSICAL MODELLING APPROACHES

Solute, Concentration

Chemical substances can be present in different phases of the soil. The resident chemical concentration [$M L^{-3}$] is defined as the mass storage of the chemical substance per unit volume. The volume averaged total resident concentration C_t^r is the volume-weighed sum of the resident concentrations in the separate phases:

$$C_t^r = \theta C_l^r + C_a^r + \alpha C_g^r + \eta C_n^r \quad (1)$$

where θ [L^3 L^{-3}] is the volume average water content, η is the nonaqueous liquid volume fraction [L^3 L^{-3}], α is the volumetric air content, the subscripts l, a, g, and n define the dissolved, adsorbed, gaseous, and nonaqueous phases respectively. Usually, C_a^r is defined as the product of the soil dry bulk density by the mass density of adsorbed chemicals (mass of chemicals by mass of soil). For inert nonvolatile substances in a nonsaturated soil, composed of only one single liquid phase (i.e. the soil water), the resident fluid concentration of the chemical substance will therefore be $C_l^r = C_t^r/\theta$.

We consider a solute, a chemical substance that dissolves in the liquid soil water phase. The substances may be more or less ionized according to their ionic charge, but may also be present as electrically neutral molecules or complexes of different molecules or ions (de Marsily, 1986). The fate and transport processes of solutes will be influenced by interface phenomena between the soil liquid, solid, and gaseous phases, and the transport phenomena in these phases. However, in this paper, we will focus on "inert" solutes that do not partition between different phases but remain in the water phase. For mobile solutes, flux averaged concentrations are defined as the ratio of solute flux to soil liquid flux through a given area, that is,

$$C_l^f = \frac{J_s}{J_w} \quad (2)$$

where J_s is the area-averaged solute flux vector [$M L^{-2}$ T^{-1}], and J_w is the area-averaged soil water flux vector [$L T^{-1}$]. When water flow in the unsaturated zone is predominantly in the vertical direction and when solutes are applied uniformly over a wide area, the horizontal components of the water flow and solute flux vectors can be neglected. Since this often applies to leaching experiments and to practical applications dealing with diffuse pollution, transport in soils is often treated as a one-dimensional problem. Using a 1-D mass balance equation, both concentration definitions are related through:

$$\frac{\partial C_t^r}{\partial t} + \frac{\partial J_w C_l^f}{\partial z} = 0 \quad (3)$$

Liquid-phase Transport Processes

Convection/Advection

This is the phenomenon where the solutes move with the water. The convective solute flux, $J_{s,c}$ [$M L^{-2}$ T^{-1}] is given by:

$$J_{s,c} = J_w C_l^r \quad (4)$$

where J_w is the area-averaged Darcian water flux vector.

The advance of a solute plume through a soil is characterized by an average velocity, which, in case of inert solute, equals the averaged pore water velocity $\overline{v}$:

$$\overline{v} = \frac{J_w}{\theta_{eff}} \quad (5)$$

where θ_{eff} [L^3 L^{-3}] the effective transport volume. When all the water is accessible for the solutes, θ_{eff} equals the soil volumetric moisture content θ. However, because of the electric repulsion of ions by an oppositely charged solid phase, very slow diffusive mixing between mobile and stagnant pore water, and exclusion of larger molecules from small pores, θ_{eff} may be much smaller than θ.

Diffusion and Dispersion

When solute plume migrates in a soil, it will disperse essentially because of two mechanisms: molecular diffusion and hydrodynamic dispersion. Molecular diffusion is a microscopic process, induced by thermal agitation and molecular collisions, referred to as *Brownian motion*. Brownian particle displacement of a solute added to a stagnant liquid phase leads to a Gaussian distribution of particle locations that results from a large number of independent and zero mean particle displacements (Einstein, 1905). Because of the independence of the particle displacements, the variance of the particle location distribution is proportional to the time: $\sigma_x^2 = 2.D_0.t$, where t [T] is the time and D_0 [L^2 T^{-1}] is the Brownian diffusion coefficient. For sufficiently low concentrations, Brownian motion in a stagnant liquid leads to a diffusive flux J_{dif} [$M L^{-2}$ T^{-1}] that dissipates concentration gradients and can be modeled by Fick's law:

$$J_{dif} = -D_0.\frac{\partial C_l^r}{\partial z} \quad (6)$$

A similar process will occur in a static fluid in a porous medium. The diffusion process in this case will be hindered

by the presence of the solid phase. The cross-sectional area across which diffusion can take place is reduced by a factor that is equal to the volumetric water content, θ. The tortuosity of the pores increases the microscopic distance across which diffusive transport must take place to dissipate macroscopic concentration gradients and reduces the diffusive flux by a tortuosity factor ξ:

$$J_{\text{dif}} = -D_0.\xi.\theta.\frac{\partial C_l^r}{\partial z} \tag{7}$$

Because the tortuosity of the water-filled pore space increases with decreasing soil water content, ξ is a decreasing function of θ.

When water flows through the porous medium, the deviation of the local-scale advection velocities around the mean advection velocity $\overline{v}$ induces hydrodynamic dispersion. At the pore scale, streamline density increases from the pore wall to the pore center. For real and irregularly shaped soil pores, however, this within-pore variability will be more pronounced, as streamline densities change between pore bodies and pore necks. The heterogeneous pore-size distribution with larger flow velocities in larger pores leads to an important additional variability of velocities.

The advection velocity variability generates additional "advective particle displacements", relative to the mean particle displacement $\overline{v}$. Analogous to Brownian motion, the effect of a large number of independent "advective particle displacements" on solute transport can be described for the 1-D case as a Fickian dispersive process:

$$J_{\text{disp}} = -\theta D.\frac{\partial C_l^r}{\partial z} \tag{8}$$

where D [L^2 T^{-1}] is the hydrodynamic dispersion coefficient. Crucial for applying equation (8) is the independence of advective particle displacements. This implies that a solute particle samples a representative set of the advection velocity distribution on its trajectory. The time needed for a particle to sample a representative set of velocities at the macroscopic scale is the characteristic mixing time τ^*. Although the hydrodynamic dispersion has an analogous effect on solute transport as diffusion, that is, it tends to spread out the concentration differences, hydrodynamic dispersion is strongly influenced by the advective velocity $\overline{v}$. The exact relationships between D and $\overline{v}$ can only be obtained from theoretical considerations for simple or hypothetical geometrical pore systems. For small values of $\overline{v}$, chemical diffusion is the dominant process, and D is independent of $\overline{v}$ and reaches a value slightly lower than D_0 (because of matrix tortuosity effects on the diffusion process). In Taylor's dispersion theory for solutes in a cylindrical tube with a laminar flow field, $D = r^2.\overline{v}^2/48.D_0$ (Taylor, 1953), where r [L] is the radius of the tube. In this case, mixing is caused by lateral diffusion so that τ^* does not change with $\overline{v}$. According to the Hagen–Poiseuille relationship, the variance of velocities in a capillar with laminar flow increases quadratically with $\overline{v}$, and so does D. This regime applies for lower flow rates when the mixing caused by local diffusion is faster than the mixing caused by advection of particles into regions with a different particle velocity. For sufficiently high $\overline{v}$, advective mixing due to divergence and convergence of streamlines becomes the dominant mixing process. When the geometry of the water-filled pore space remains constant with $\overline{v}$, that is, in saturated media, and mixing is dominated by advection, the mixing time τ^* is inverse proportional to $\overline{v}$, whereas the variance of velocities increases quadratically with $\overline{v}$. As a consequence, D increases linearly with $\overline{v}$: $D = \lambda.\overline{v}$, with λ [L] being a soil characteristic parameter called hydrodynamic dispersivity. Saffman (1959) derived the theoretical relationship between D and $\overline{v}$ for saturated networks of pores. At the larger scale, for example, the scale of an aquifer, the variance of advection velocities is determined by the spatial variability of the hydraulic conductivity. The relation between D and $\overline{v}$ at the larger scale depends, similarly to the relation at the pore scale, on the dominant mixing process: diffusion or advection.

Formalisms for Modeling Solute Transport

Differential Description of Solute Transport

Averaging the pore-scale transport process over a given soil volume, and assigning the average properties to the centroid of the voxel, results in continuous functions in space of the hydrodynamic properties and state variables. In this continuum approach, differential calculus can be applied to establish mass and momentum balance equations for infinitesimal small soil volume and time increments. For the case of inert solute transport in a macroscopic homogeneous soil, the general continuity equation applies:

$$\frac{\partial C_t^r}{\partial t} = -\frac{\partial Js}{\partial z} \tag{9}$$

Considering in this case that the solutes only resides in the liquid phase (i.e. $C_t^r = \theta.C_l^r$) and decomposing the total solute flux in a convective and dispersive component yields the classical CDE:

$$\theta\frac{\partial C_l^r}{\partial t} + \overline{v}.\frac{\partial C_l^r}{\partial z} - \frac{\partial}{\partial z}\left(\theta D\frac{\partial C_l^r}{\partial z}\right) = 0 \tag{10}$$

This linear partial differential equation is a complete mathematical description of the dynamics of the inert solute transport process over an infinitesimal small space and time increment. The differential equation needs to be integrated over space and time to describe the transport process at integral soil and time scale. Numerous analytical and numerical techniques have been developed to integrate

equation (10) for variable boundary conditions. For an overview, the reader is referred to **Chapter 78, Models of Water Flow and Solute Transport in the Unsaturated Zone, Volume 2**.

The classical CDE equation has been intensively used to model solute transport in saturated porous media (Dagan, 1989). In partially saturated soils, the CDE model is usually considered to be more appropriate to describe transport in repacked or nonstructured soil (Radcliffe *et al.*, 1998; Wilson *et al.*, 1998), but has also successfully been used to describe transport in real structured soils (Bejat *et al.*, 2000; Comegna *et al.*, 1999).

Integral Description of Solute Transport: Transfer Function Theory

In contrast to the differential approach, linear transfer function theory can be used to formulate mathematically the transport process at the integral scale of the considered soil using an integral property: the impulse response function (Jury, 1982; Jury and Roth, 1990). The transfer function formalism is attractive because it allows the convenient description of transport experiments, in particular, column breakthrough experiments. In addition, any linear transport process can be expressed as a transfer function and is a physically equivalent mathematical formalism of the same process. Finally, applying the transfer function directly to integral soil problems often results in effective integral parameterizations, avoiding thereby the parameterization problems often associated with differential continuum modeling approaches.

Using the transfer function theory, the output solute flux leaching from a given integral soil volume with a given transport distance is calculated using a convolution between a soil characteristic impulse response function $f^f(t;z)$ and the time series of the input solute flux:

$$J_s(z,t) = \int_0^t J_s(0,\tau) f^f(t-\tau;z)\,d\tau \qquad (11)$$

where $J_s(z,t)$ is the output solute flux, $J_s(0,\tau)$ the input solute flux, and τ the solute input time. This equation is submitted to three important assumptions (i) the transfer function f^f is measurable, (ii) the transport process is linear and, (iii) the system is stationary, that is, f^f does not depend on the time of the input pulse. For a steady-state water flux, and considering the definition of the solute flux concentration, equations (2) and (11) yield:

$$C_1^f(z,t) = \int_0^t C_1^f(0,\tau) f^f(t-\tau;z)\,d\tau \qquad (12)$$

For steady-state flow, the pulse input response function, $f^f(t;z)$ can be interpreted as a travel time distribution of solute particles that are added at the soil surface to a given depth z in the soil profile.

In equations (11) and (12), a temporal pulse input response function is defined, which links the temporal reaction of the system, that is, the solute flux at a certain depth, to a temporal input function, that is, the solute flux at the soil surface. In analogy, a spatial pulse input response function which links an initial solute mass distribution in the soil profile to the solute mass distribution at a later time can be defined. For steady-state flow and a soil profile with uniform water content, the concentration distribution can be calculated from:

$$C_1^r(z,t) = \int_0^\infty C_1^r(z',0) f^r(z;z';t)\,dz' \qquad (13)$$

where $f^r(z;z';t)$ is the spatial pulse input response function at time t for a concentration Dirac pulse at a depth z' in the soil profile. It should be noted that unlike the temporal pulse input function, the spatial pulse input response function is not a stationary function with depth when the boundary condition at the soil surface influences transport within the soil profile. Nonstationarity in this context refers to the dependence of the spatial pulse input response function on the depth z' where the Dirac pulse is applied.

The drawback of the transfer function model (TFM) representation is that it is not easy to apply to transient flow conditions (Butters and Jury, 1989; Roth *et al.*, 1991). In addition, to reduce errors in the convolution, a good temporal (or spatial) resolution is needed.

LIMITATIONS OF THE CONVECTIVE DISPERSIVE TRANSPORT MODEL

The CDE process model is probably the most popular solute transport model that has been used in soil hydrological research so far. The model considers the soil as a homogeneous matrix in which the pores are well connected, and in which solutes mix perfectly laterally when traveling through the soil. The differential description of the process is given in equation (10) and simplifies for a homogeneous soil profile and steady-state conditions to:

$$\frac{\partial C_1^r}{\partial t} + \bar{v}\frac{\partial C_1^r}{\partial z} - D\frac{\partial^2 C_1^r}{\partial z^2} = 0 \qquad (14)$$

Using transfer function theory, the CDE process in a semiinfinite soil column can be captured as follows:

$$f^f(t;z) = \frac{z}{2\sqrt{\pi . D . t^3}} \exp\left(-\frac{(z-\bar{v}t)^2}{4\,Dt}\right) \qquad (15)$$

A characteristic of the CDE travel time distribution is that the variance of the travel times grows linearly with travel distance z. This is equivalent to the particle location

distribution, which grows linearly with time for a Brownian motion process.

Essential in the derivation of equations(14) and (15) is the consideration that the hydrodynamic dispersion can be described as a diffusion process, that is, on average, all solute particles are subjected to the same forces and the transport time is sufficiently large so that the incremental microscopic particle displacements are no longer statistically correlated. As a corollary, the CDE process cannot be valid for small soil volumes where the travel times are too small as compared to the mixing time, or to describe transport close to interfaces. A comparison between the particle travel time and the mixing time during a transport experiment forms the basis for discrimination between different "transport processes" or "mixing regimes" (Simmons, 1982). If the "mixing" time τ^* is much smaller than the solute travel time, the dispersion of a solute plume can be described as a Fickian concentration gradient-driven process (Dagan, 1989).

Limitations of the CDE in Unsaturated Soils

For stationary flow conditions, D and $\overline{v}$ are independent parameters describing the transport process. In transient conditions, however, the relationship between D and $\overline{v}$ must be taken into account. Experimental evidences show that for transport in homogeneous saturated porous media, D is a monotonous function of $\overline{v}$. In unsaturated media, this relation becomes extremely complicated since the transport volume θ_{eff} changes with the water flux. Therefore, the structure of the water-filled pore space and, hence, the flow field depends on the saturation degree (Flury *et al.*, 1994) so that the variance of local velocities and the mixing time cannot be simply related to the mean advection velocity. As a consequence, no validated theoretical models exist to calculate the relationship between D and $\overline{v}$ for unsaturated soils and the dispersivity λ cannot be considered to be a material constant, that is, independent of θ.

It has been observed that the variance of local advection velocities increase dramatically with increasing flow rate, especially when macropores are activated (e.g. White, 1985; Dyson and White, 1989; Bouma, 1991). On the other hand, a decrease in water saturation may result in larger tortuosity of the solute trajectories, a disconnection of continuous flow paths and a physical nonequilibrium due to a slow diffusive exchange of solutes between mobile and immobile pore regions. Therefore, in some experimental studies (e.g. Corey *et al.*, 1963; De Smedt *et al.*, 1986; Maraqa *et al.*, 1997; Padilla *et al.*, 1999), a higher solute dispersion was found for unsaturated than for saturated flow conditions.

Limitations of the CDE in Structured Media

Flow processes affected by the heterogeneous structural properties of real soils prevailing at different spatial scales contribute to an incomplete mixing of the solutes during the transport in real soils. At the microscopic scale, structural heterogeneity of the pore liquid system is characterized by the complex geometry of the pore liquid phase and irregular distribution of the carrying liquid water phase in the soil. The heterogeneity of the soil pore systems is expressed by the presence of microaggregates, aggregates, and pedons in real soil horizons. Therefore, under such conditions, CDE fails to describe the observed dispersion (e.g. Butters and Jury, 1989; Khan and Jury, 1990). Evidence of non-CDE behavior is obtained when the variance of the solute travel time does not grow linearly with depth, or, similarly when the variance of the solute travel distance does not grow linearly with time.

Scale-variable dispersivity was observed in saturated porous media at the laboratory and the field-scale, as well in homogeneous as in heterogeneous formations (Pickens and Grisak, 1981; Huang *et al.*, 1995; Vanclooster *et al.*, 1995; Pang and Hunt, 2001). Studying solute transport through two undisturbed Spodosols monolithes (0.8 m i.d., 1 m deep), Seuntjens *et al.* (2001) obtained opposite depth scaling behaviors of the dispersivity and related this to the different morphological characteristics of the two pedons.

In the context of transport, the presence of macropores plays a particular role. Macropores are large pores, which form at the macroscopic level an obviously distinguished pore system from the soil matrix pore system. Macropores constitute sometimes a separate and/or a continuous network in which particle velocities may deviate systematically from those in the soil matrix. As a result, the solutes released in the macropore network will be subjected to a preferential flow as compared to flow in the matrix system and will not completely mix with the total pore water volume at short time intervals. Preferential flow through macropores is considered here as a macroscopic process since concentrations in the macropores cannot be easily determined separately from the concentrations in the micropore system.

Besides preferential flow through macropores, preferential flow may as well occur through certain parts of the soil matrix. Fingered flow, for example, will be caused by wetting front instability (De Rooij, 2000) by air entrapment in the matrix (Peck, 1964), by water repellency of the solid phase (Ritsema and Dekker, 1995; Ritsema *et al.*, 1998), or by the increase of the soil hydraulic conductivity with depth (Raats, 1973). Funneled flow will typically develop along the inclined bottom of a fine layer overlaying a coarse sublayer (Kung, 1990; Poletika and Jury, 1994; Quisenberry *et al.*, 1994).

At the field-scale, the soil hydraulic properties such as the soil hydraulic conductivity and water retention curve are variable in space (Jury, 1985; Mallants *et al.*, 1996a). The macroscopic variability of the flow and transport properties at the field-scale will be expressed in a variable flow field,

thereby deviating locally the direction of the macroscopic particle velocity vectors. The mixing of solutes from, for example, low to high conductive zones at these larger scales will only be fully established if again the process is evaluated at sufficiently large transport volumes or transport times (Flühler *et al.*, 1996). A full characterization of the dispersion process at the field-scale would therefore need a full description of the variability of the flow properties. This, however, remains a complicated task, which for the time being is only realizable in a research oriented context.

Van Wesenbeeck and Kachanoski (1995), Kasteel (1997), and Vanderborght *et al.* (1997b) predicted solute dispersion observed in field-scale leaching experiments from the spatial variability of measured soil hydraulic properties. Vanderborght *et al.* (1997b) concluded that the mixing regime could be fairly well reproduced for smaller flow rates if small correlation scales of the hydraulic properties were assumed. For higher flow rates, the dispersion was largely underestimated owing to a large variability of particle velocities at the pore scale when macropores were activated. On the basis of a summary of leaching experiments that were carried out in a range of soils at different scales and for different leaching rates (Vanclooster *et al.*, 1995; Vanderborght *et al.*, 1997a; Jacques *et al.*, 1998, Seuntjens *et al.*, 2001, Vanderborght *et al.*, 2000), Vanderborght *et al.* (2001) linked the solute transport regime to morphological and hydraulic properties. The change of dispersivity with leaching rate was linked to the unsaturated hydraulic conductivity using a multidomain conceptualization of the pore space as was introduced by Steenhuis *et al.* (1990). The mixing regime was further related to soil morphological features, such as vertical tongues, stratification, macropores, and a water repellent layer. In all investigated soils, the hydrodynamic dispersion increased more than linearly with increasing leaching rate confirming that the dispersivity is not an intrinsic soil characteristic for unsaturated flow conditions at this scale of observation.

TRANSPORT MODELS IN HETEROGENEOUS SOILS

Modeling Approach Versus Structural Variability

Given the limitation of the CDE flow concept, alternative transport models have been developed for describing solute transport in real field soils. These alternative models consider the variability of the process due to structural variation in the flow domain. The models can be ranked depending on the degree of explicitness with which the structural variability is considered in the model (see Figure 1).

In the first class of models, the structural variability is embedded in a completely implicit way in the transport models. As a consequence, the parameters of these models need to be derived from model fits to experimental data from tracer experiments. In this class, two asymptotic transport models, which cover the end-points of mixing in the soil, that is, the complete mixing versus no-mixing model, can be grouped (Sposito and Jury, 1988; Flühler *et al.*, 1996). The complete mixing model, that is, the CDE model, implicitly assumes that the spatial scale of the velocity variability or the mixing scale is much smaller than the scale of the transport process. In the opposite no-mixing model, that is, the stream-tube model, it is assumed that the mixing scale is much larger than the transport scale. Also, "generalized" stream-tube models (STM) (e.g., Zhang (2000)), which were introduced to describe intermediate mixing regimes, fall in this class of implicit transport models. In the generalized STMs, the intermediate mixing regime is accounted for by an additional fitting parameter.

In the second class of models, multidomain models, the structure of the flow field is embedded in the model by dividing the porous medium in two (e.g. van Genuchten and Wierenga, 1976; Jarvis *et al.*, 1991a; Chen and Wagenet, 1992; Gerke and van Genuchten, 1993) or more (Steenhuis *et al.*, 1990; Skopp and Gardner, 1992; Gwo *et al.*, 1995;

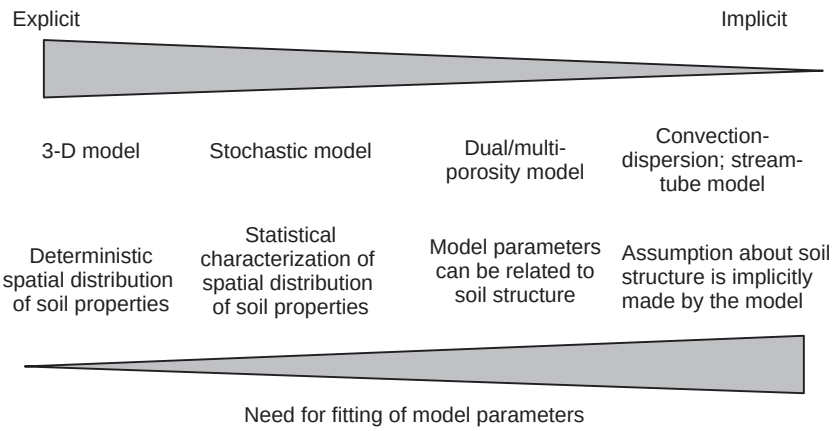

Figure 1 Implementation of structure/heterogeneity in transport models. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Durner and Flühler, 1996) subdomains in which solutes move at different velocities. Between the subdomains solutes are exchanged by diffusion and/or advection. The exchange rate is a fitting parameter that can be related to some extent to the structure and spatial scale of the different flow domains.

In the third class, the structure of the porous medium is characterized in a geostatistical sense. By solving the stochastic-continuum flow and transport equations, the lateral solute mixing and the mixing time are derived from the spatial distribution of macroscopic hydraulic properties (e.g. Russo, 1995a,b).

In the fourth class of models, the structure of the porous medium is explicitly considered and 3-D flow and transport processes, be it at the pore or the macroscopic scale, are solved in a medium with a known structure. When the structure of the medium is identified, the flow and transport processes may be predicted without any fitting of flow and transport parameters (Vogel and Roth, 2003). Kasteel *et al.* (2000) successfully applied this concept at the scale of a small column.

Stream Tube Models (STM)

In a STM, the transport in a 3-D heterogeneous flow field is represented by a set or ensemble of one-dimensional flow lines or "stream tubes" along which a one-dimensional transport process takes place. STMs ignore the lateral exchange of mass between the stream tubes during the transport process, which is characterized in a stream tube by a set of constant local transport parameters (e.g. Jury and Roth, 1990). Flow concentrations at the outlet of the flow domain are obtained by integrating the stream-tube scale local concentration over the set of available stream tubes in the total flow domain, considering the probability function of the local-scale velocities as weighing functions. The effective dispersion generated in this model will be completely determined by the distribution functions of the flow field describing the variability of the advection velocities in the ensemble of stream tubes (Simmons, 1982). STMs have been used for basically two different purposes. In the first type of application, STMs were used just to parameterize the heterogeneity of the flow field between an injection and observation surface. This parameterization was subsequently used to describe the behavior of reactive substances in heterogeneous flow fields using either analytical solutions (e.g. Simmons *et al.*, 1995; Dagan and Cvetkovic, 1996; Cvetkovic and Dagan, 1996) or numerical solutions of the local 1-D transport and reaction equations (e.g. Ginn, 2001; Malmström *et al.*, 2004). The parameterization of the STM is adapted depending on the distance between the injection and observation surface to represent the effect of changing velocities along the stream lines due to local stream line convergence and divergence in a 3-D flow field as well as due to mixing and solute exchange between stream lines (e.g. Cirpka and Kitanidis, 2000). Therefore, this type of application does not make a certain assumption about the 3-D flow field.

In the second application, the STM is assumed to represent the 3-D flow field in the subsurface and is used to predict the solute breakthrough at other depths than the depth at which it is parameterized. The most simple STM considers only piston flow to occur in each stream tube so that the velocity of a particle remains constant along its trajectory. For steady-state flow, this implies the following relation between pulse input response functions or travel time distributions at two different depths (Jury, 1982):

$$\mathrm{f}^{\mathrm{f}}(t;z) = \frac{l}{z}\mathrm{f}^{\mathrm{f}}\left(\frac{tl}{z};l\right) \tag{16}$$

Considering a lognormal distribution for describing the pdf of the local velocity field results in the convective lognormal transport (CLT) model (Jury, 1982). Using transfer function representations, it can be shown that the effective dispersivity in this case will grow linearly with travel depth and travel time. The variance of the solute travel time grows quadratically with depth. The CLT model was successfully used to characterize the solute dispersion in structured soils at the scale of soil columns (Persson and Berndtsson, 1998), undisturbed soil monoliths (Vanclooster *et al.*, 1995; Vanderborght *et al.*, 1997a; Javaux and Vanclooster, 2003b), or at the field-scale (Butters and Jury, 1989; Jacques *et al.*, 1998). Parameters of the STM are obtained by interpretation of transport experiments. The description of the flow process in the stream tubes was improved by considering local-scale variability and dispersion (Bresler and Dagan, 1981; Destouni and Cvetkovic, 1991; Toride and Leij, 1996; Mallants *et al.*, 1996c) and transient conditions (Bresler and Dagan, 1983; Dagan and Bresler, 1983).

However, solute transport in a natural soil cannot always be conceptualized using the two asymptotic models: convective dispersive and stream-tube model. Structural heterogeneity may generate heterogeneous flow, modifying the mixing process when solutes migrate through the soil (White *et al.*, 1986; Snow *et al.*, 1994; Nissen *et al.*, 2000; Seuntjens *et al.*, 2001). In these cases, the solute dispersion process and the variance of the solute travel time with depth, or the variance of the travel depth with time will be an irregular function.

Recently, Zhang (2000) presented a flexible generalized transfer function model (GTF) that encompasses as well the convective stochastic STM as the convective dispersive transport process. In addition, the GTF model can also be used to characterize solute transport processes in heterogeneous soils such as those in which the mean travel time increases nonlinearly with depth and those in which the dispersivity is a scale-dependent function of the travel distance with any power value. The GTF is thereby a comprehensive TFM allowing a formalization of the solute

transport process in heterogeneous soils in a synoptic way. The additional flexibility of the GTF model is at the expense of increasing the number of fitting parameters. However, using the robust estimation techniques developed by Vanderborght *et al.* (1996), Javaux and Vanclooster (2003a) showed that the GTF transport parameters can be estimated in a robust way from classical solute transport experiments.

Multidomain Models

Multidomain models have been developed to describe variability in real soils, in particular, as a result of observed solute transport in soil column studies. In the most simple case, the flow domain is separated in two regions. Examples of these models are the mobile–immobile transport model (MIM; e.g.Coats and Smith, 1964; van Genuchten and Wierenga, 1976) where flow in the immobile region is considered to be negligible and the macropore/micropore flow models (Jarvis *et al.*, 1991a; Chen and Wagenet, 1992; Gerke and van Genuchten, 1993) where advective transport in the micropores is considered. In case of two-region models, the solutes are divided in a mobile and an immobile soil region. Thus:

$$\theta C_{\mathrm{l}}^{\mathrm{r}} = \theta_{\mathrm{m}} C_{\mathrm{m}}^{\mathrm{r}} + \theta_{\mathrm{im}} C_{\mathrm{im}}^{\mathrm{r}} \qquad (17)$$

with θ_{m} is the mobile and $\theta_{\mathrm{im}} = \theta - \theta_{\mathrm{m}}$ the immobile volumetric soil water content, and $C_{\mathrm{m}}^{\mathrm{r}}$ and $C_{\mathrm{im}}^{\mathrm{r}}$ are the mobile and immobile resident concentrations respectively. Lateral mixing of the solutes can be diffusion limited and modeled by a kinetic first-order rate constant, in which the first-order rate constant depends on the effective diffusion and the size of the aggregates in the immobile region. The two-region MIM models were successfully used to describe solute transport in real soils (Nkedi-Kizza *et al.*, 1983; Vanclooster *et al.*, 1992; Mallants *et al.*, 1996b). Other common macroporous models have been successfully used in other studies (Jarvis *et al.*, 1991b).

In contrast to the CDE model, more parameters are needed to apply the two-region model for describing the solute transport process in soil. The increase of parameters definitely increases the flexibility with which the solute transport process can be described. However, this increased flexibility should be carefully balanced with the well-posedness of the identification problem. Vanderborght *et al.* (1997c) for instance, clearly illustrated the uncertainty associated with the identification of MIM parameters from classical breakthrough experiments.

Stochastic-continuum Models

Within a stochastic-continuum approach, the spatial variability and structure of flow properties of the heterogeneous soil are represented by spatial random functions. Similar to a random variable, a spatial random function is characterized by probability density functions. In order to simplify the characterization of the random space function, the second-order stationarity criterion is invoked. Second-order stationarity implies that the mean and variance of the variable are constant in space and that the spatial covariance only depends on the distance between the observations. The stochastic-flow and transport equations, of which the parameters are random space functions, can be solved in an approximate way using a first-order perturbation approach (e.g. Gelhar and Axness, 1983; Yeh *et al.*, 1985; Dagan, 1989; Russo, 1993; Zhang, 2002). The outcome of these first-order solutions is a closed-form relation between the spatial statistics of the flow and transport parameters and those of the flow and transport variables. For transport modeling, the expected concentration or the average concentration at a certain depth in the soil profile is the principal variable of interest. First-order approximate solutions of the stochastic-flow and transport equations revealed that the average concentration may be described by an "effective" convective–dispersive model for transport distances that are much larger than the correlation scale of the hydraulic conductivity. The "effective" or "macrodispersion" coefficient is derived from the spatial variability of the flow parameters. For small travel distances, the macrodispersion was shown to scale linearly with travel distance or time similar to a stream-tube model. However, owing to mixing at larger travel distances, the increase of the macrodispersion with distance flattens of at intermediate travel distances until it reaches a constant value. Another important result of first-order approximate solutions of the stochastic-flow and transport equation is the flow rate dependence of the "macrodispersivity" (Russo, 1995b). Flow rate changes induce different macroscopic velocity fields influencing the mixing process and thus the hydrodynamic dispersivity (e.g. Roth and Hammel, 1996). The change of the macrodispersivity with flow rate or degree of saturation depends on the correlation between the saturated hydraulic and a parameter that quantifies the distance over which capillary forces influence the flow, that is, the capillary length scale (Raats, 1976). For a negative correlation between the capillary length scale and the hydraulic conductivity, the macrodispersivity changes nonmonotonically with degree of saturation and a critical water content exists for which the macrodispersivity is minimal. The flow heterogeneity and macrodispersivity increase when the soil becomes drier or wetter than this critical water content. For a positive correlation, the macrodispersivity increases with decreasing soil water content.

In addition to spatial variability, temporal variability also affects greatly the transport in heterogeneous flow field. However, the solution of the stochastic-flow and transport equations for transient flow conditions is far more complex. Russo *et al.* (1994) carried out numerical experiments of solute transport in generated Gaussian heterogeneous

conductivity fields for transient boundary conditions and conclude to a decrease of the dispersion compared to steady-state conditions. However, these results depend on the parameter cross-correlations. Therefore, the conclusion that transient flow conditions lead to a lower vertical solute spreading or effective dispersivity than in steady-state flow conditions can at present not be generalized. The more so as experimental data that could confirm this conclusion are missing or even contradicting this conclusion (e.g. Vanderborght *et al.*, 2000). Transient boundary conditions may lead additionally to temporal changes of soil physical and physico-chemical properties, such as a change in soil structure and the occurrence of water repellency due to soil drying, which enhance solute spreading. These effects are not considered in modeling approaches that are based on a concept of spatially variable but temporally constant soil properties.

Foussereau *et al.* (2000, 2001) also included the uncertainty of the boundary fluxes in the velocity two-point covariance function on the prediction of expected concentration breakthrough curves at a certain depth. For the cases they considered, that is, an inert tracer and a humid climate without evapotranspiration, they found that the uncertainty of the boundary fluxes dominates the travel time variance of a solute from the surface to a certain observation. However, the importance of the climatic boundary condition uncertainty relative to that of the soil properties depends also on the absolute solute travel time from the surface to a certain depth. The larger this time period, the larger is the time averaging window and the smaller the variability or uncertainty of the averaged rainfall. Therefore, the conclusion that uncertainty of the climatic boundary conditions dominates the prediction of ensemble-averaged concentrations must be questioned for substances that are retarded due to sorption and need a considerably longer time to leach.

Stochastic-continuum approaches were also developed for studying the influence of chemical heterogeneity of the medium on the transport process. For linear reactions (linear adsorption isotherms), the field-scale averaged concentrations can, similarly to the transport of inert tracers, be described using an "effective" convection-dispersive model. But, an important outcome of these studies is that the macrodispersion coefficient for reactive substances depends on the variance and spatial covariance of the local-scale sorption coefficients and their spatial correlation with the hydraulic soil properties (e.g. Bellin *et al.*, 1993; Burr *et al.*, 1994). As a consequence, the macroscale dispersion coefficient that should be used to describe the leaching of a sorbing substance is different from that of an inert tracer. Hence, the use of a model that describes large-scale reactive transport, using a macrodispersion inferred from inert solute transport studies and effective retardation inferred from local-scale batch experiments will fail to describe effective reactive transport. Examples of the failure of the latter approach are illustrated by Kasteel *et al.* (2002) and Javaux (2004).

Although stochastic-continuum models have contributed a lot to our understanding on the effect of heterogeneity on transport and the scale-dependency of effective transport parameters, there are some additional drawbacks that limit their application for real soils. First, the first-order perturbation approach only yields reliable results when the variability of the flow and transport parameters is not too large. This assumption is not always guaranteed in real soils, especially not under unsaturated conditions when the hydraulic conductivity may vary by several orders of magnitude. Second, the stationarity criterion is clearly violated in layered media, such as soils. But, even in a stationary conductivity field, flow may be highly nonstationary as for instance, in case of an infiltration in an initially dry soil. Finally, a reliable characterization of the spatial variability remains a difficult task, which is jeopardized by the limited observations of flow and transport properties in the subsoil.

CONCLUSIONS

For the last decade, solute transport in soil has been studied to be able to cope with the soil management and engineering problem at the larger scale. Understanding the influence of the porous medium heterogeneity and velocity field variability on the plume dispersion is a key issue in this research area. Several modeling approaches (described in Section "Transport models in heterogeneous soils") have been developed to account for an increasing complexity in the description of the medium heterogeneity. In addition, parameter identification approaches have been developed to infer larger-scale solute transport properties from local measurements. Research has also demonstrated the weaknesses of some of the classical modeling approaches, in particular, the convection dispersion model for describing larger-scale solute transport.

However, despite the well-established limitations of the classical modeling approaches and the broad range of alternatives which are presently developed in geosciences, the simple CDE model is still the most popular model used in an engineering context (Vanclooster *et al.*, 2004). The gap between science and engineering in this area can partially be explained by the reductionistic research approach that is often followed when studying soil solute transport processes. Indeed, to understand the effect of flow field variability on transport, geoscientists often built their models on the interpretation of inert solute transport experiments. However, to implement such understanding in engineering models a more holistic approach is needed where the interaction(s) between flow field heterogeneity, local chemical reactivity, and plant uptake are considered.

Recent research on transport of nonlinear reactive substances has shown that such a holistic approach may be

extremely cumbersome, since traditional upscaling procedure may no longer be valid. The integration of plant processes is another point of concern. Although plants are almost always considered in practical problems, the effect of root water uptake on the heterogeneous flow field and the solute transport is essentially unknown. Through numerical-simulations, Russo *et al.* (1998) suggested that crop water uptake intensifies lateral water redistribution in the root zone even more and therefore further reduces the vertical solute spreading as compared with the steady-state flow condition. However, to date, more research is necessary to experimentally characterize and to model the impact of plant water and nutrient uptake on solute transport.

To conclude, the use of the classical CDE model to describe the fate and transport of substances in the subsurface for practical applications should be coupled with the conscience that the dispersion coefficient which is used in this equation and which may have a large impact on the predicted environmental concentrations (e.g. Boesten, 2004) is a parameter that lumps different processes. It depends on static soil properties such as soil heterogeneity and structure, and also on problem specific conditions, such as the scale of the transport process, the boundary conditions, substance properties, and plant root activity. Therefore, the classical representation in textbooks of the hydrodynamic dispersivity being a static soil property is a naïve and incorrect representation of reality.

70: Transpiration and Root Water Uptake

PETER DE WILLIGEN[1], MARIUS HEINEN[1] AND MARY BETH KIRKHAM[2]

[1]*Alterra, Wageningen, The Netherlands*
[2]*Department of Agronomy, Kansas State University, Manhattan, KS, US*

Root water uptake is one of the major components of the water balance of a soil. In this article, both the physical as well as the physiological aspects of root water uptake and transpiration are dealt with. The regulation of transpiration by different mechanisms on different levels (e.g. through hormones, adaptation of vessel diameter, root radius, and vertical extension of the root system) is discussed. Attention is paid to the modeling of water uptake by single roots and root systems. The last section deals with the different techniques used to measure root water uptake, for example, lysimeter, sap flow, inverse modeling, and discusses the advantages and disadvantages of the different methods.

INTRODUCTION

Transpiration is defined as the loss of water in the form of vapor through the surface of leaves and other aerial parts of plants (*see also* the definition given in **Chapter 42, Transpiration, Volume 1**). It is due to the evaporative demand of the atmosphere. Plant roots take up all the water needed for transpiration; only a very small part is used for the increase of fresh plant material. Water uptake is one of the major components in the water balance of a soil. On a global scale, precipitation is estimated to amount to 99–115 $Tm^3\ y^{-1}$, evapotranspiration (the sum of evaporation from soil surfaces and open water and transpiration) to 62–75 $Tm^3\ y^{-1}$, and runoff to 37–40 $Tm^3\ y^{-1}$ (Oki, 1999; WW2010, 1999). Transpiration comprises about half of the evapotranspiration, which in the data shown above includes evaporation from bare soil surfaces, lakes, and streams.

Transpiration depends on the type of vegetation and is usually higher than bare soil evaporation. In the experiments of Aase *et al.* (1996) for instance, a lysimeter covered by a lentil crop lost in about 100 days approximately 250 mm more water than a fallow lysimeter. One of the reasons of enhanced water loss by transpiration compared to the bare soil evaporation is that in the latter case a dry surface layer of soil with low water conductivity develops, which protects the soil of any further desiccation. The root system of a plant, however, forms a system of interconnected vessels, which takes up and transports water also from the deeper layers in the root zone.

Transpiration and root water uptake have both physical (see Section "Root water uptake as a physical process") as well as physiological aspects (see Section "Physiological aspects"). The maximum value of transpiration depends on meteorological conditions, which determine the energy balance of the wet leaf surface. Whether or not the leaf surface continues to be wet depends on plant physiological mechanisms, which in their turn depends on the plant–water status and ultimately on root distribution with respect to distribution of soil reserves of water.

ROOT WATER UPTAKE AS A PHYSICAL PROCESS

Water Uptake as a Passive Process

Though regulated by the plant (see Section "Physiological aspects"), the uptake of water is mainly passive. It is often described as a purely physical process, a consequence of gradients in water potential in the path: bulk soil – soil/root interface – root – leaf – atmosphere. To quote Steudle and Peterson (1998): "Under conditions of transpiration, roots do not 'take up water' so much as they allow it to pass through them. In other words water ... moves passively

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

through the roots in response to a water potential gradient set up by transpiration".

Water potential is expressed in units energy per volume ($J\,m^{-3}$), which is equivalent to force per area ($N\,m^{-2}$) (*see also* **Chapter 73, Soil Water Potential Measurement, Volume 2**, and Bolt *et al.*, 1976). In soil physics, it is frequently expressed in the so-called *head equivalent* expressed in m water pressure (*see* **Chapter 67, Hydrology of Swelling Clay Soils, Volume 2**). In the following, we shall use head terminology and units. The total head (H) is the sum of different components; for our purposes the relevant components are the pressure head (h_p), the osmotic head (h_o), and the gravitational head (h_g). Water flow along the path soil – atmosphere has often been described using the attractive analogue of an electrical current flowing through a series of resistances, as was already done in the first half of the last century (Gradmann, 1928; Van den Honert, 1948). So the flow in the path bulk soil – soil/root interface – root xylem can be given as:

$$Q = \frac{H_s - H_{R0}}{\omega_s} = \frac{H_{R0} - H_x}{\omega_{R0}} \qquad (1)$$

where Q is the flow ($m^3\,s^{-1}$), H_S the total head in the bulk soil (m), H_{R0} is the total head at the interface of soil and root (m), H_x the total head in the root xylem (m), ω_S the resistance against flow of the soil ($s\,m^{-2}$), and ω_{R0} the radial resistance against flow of the region between root wall and root xylem ($s\,m^{-2}$). For a given transpiration rate the highest resistance in the path bulk soil – soil/root interface – root is usually that of the (radial) root resistance, provided that the water content of the soil is not too low. The soil resistance increases strongly with decreasing water content. However, up to levels of the pressure head of -10 to -300 m the soil resistance is about one order of magnitude less than the root resistance (see Figure 5, and Section "Modeling").

For transport from the bulk soil to the soil/root interface the osmotic and gravitational head can be ignored: the former because semipermeable membranes are assumed to be absent in the soil, the latter because in this analysis the flow path is taken to be horizontal. However, in the path from the soil/root interface to root xylem, water has to pass through several semipermeable membranes and differences in osmotic head have to be taken into account.

Water Uptake in Relation to Hydraulic and Osmotic Properties

Many studies have shown a nonlinear relation between the flow of water through a plant and the difference in pressure outside and inside the root. This suggests a variable radial root resistance (see Dalton *et al.*, 1975, for references). Gardner (1970) pointed out that the nonlinearity could be explained on the basis of coupled transport of water and ions across root membranes. Dalton *et al.* (1975) and Fiscus (1975) explained the nonlinearity on the basis of data from literature (e.g. Mees and Weatherley, 1957). These and similar data from literature showed that the relation between pressure head difference, Δh_p, and flow, Q, is nonlinear at low flow rates but linear at high flow rates. The relation between Q and Δh_p can be explained taking into account the existence of a semipermeable membrane in the flow path (Dalton *et al.*, 1975; Fiscus, 1975). Later, the description has been extended to two membranes in series (Dainty, 1985; Miller, 1985; Newman, 1976). Recently, Raats (2005) discussed transport through a single membrane and series arrays of membranes.

The nonlinearity at low flow rates, according to the description where the presence of membranes in the flow path is taken into account, arises from the active transport of solutes into the xylem where they manifest themselves osmotically and generate transport of water through the root even when Δh_p is zero. When Δh_p is large, however, the resulting high flow rates dilute these solutes and their effect on Q becomes negligible. A linear relation between Q and Δh_p then results with slope α, the hydraulic conductance of the root system and, when extrapolated, with an intercept on the pressure axis of almost zero. However, the intercept on the pressure axis as found in experiments is considerably larger than what follows from the theory. This still is a matter of much debate. According to Passioura (1988), there is no alternative but to accept the large value of the intercept without explanation and to use the next equation as the most economical way of summarizing the available data:

$$Q = \alpha(\Delta h_p - h_0 - \sigma\,\Delta h_o) \qquad (2)$$

where α is the conductance ($m^2 s^{-1}$) Δh_p (m) is the difference in hydrostatic pressure, h_0 is a parameter, σ is an effective reflection coefficient for weighting any osmotically induced flow, and Δh_o is the difference in osmotic pressure across the roots. In this article *conductivity* (k) is the proportionality coefficient between flux of water and gradient of water potential:

$$q = -k\nabla H$$

In radial coordinates the volume flow for a root of length Δz at any distance from the root midpoint is:

$$Q = -2\pi r k \Delta z \frac{\mathrm{d}H}{\mathrm{d}r}$$

In the case of steady state Q is a constant, so integrating over a finite distance, say from r_x to r_0, yields:

$$Q = -\frac{2\pi k \Delta z (H_0 - H_x)}{\ln r_0 - \ln r_x} = -\alpha(H_0 - H_x), \text{ or}$$
$$\alpha = \frac{2\pi k \Delta z}{\ln r_0 - \ln r_x}$$

Conductance (α) is thus the proportionality coefficient between the flow of water and the difference of water potential at two points of the flow path. Conductance accordingly applies to a larger scale than conductivity. The reciprocal of conductivity and conductance are called *resistivity and resistance respectively*. The reflection coefficient is a unitless number and varies between 0 and 1. If $\sigma = 1$, all solutes are reflected from the membrane and no solute gets across it. If $\sigma = 0$, all solutes can cross the membrane (Kirkham, 2005, p. 221).

It is common to define the "hydraulic resistance", ω, of a root system as $\Delta H/Q$, where ΔH is the difference in total head across the root system. ω equals the reciprocal of α in equation (2) only if $\sigma = 1$ and $h_o = 0$ (with $\Delta H = \Delta h_p - \Delta h_o$). If these conditions are not true, and if we take the true hydraulic resistance to be $1/\alpha$, then ω is only an apparent hydraulic resistance; and variation in it, through time or with Q, need not imply that α varies (Passioura, 1988, p. 255).

Aquaporins

The hydrophobic nature of the lipid bilayer of a membrane presents a considerable barrier to the free movement of water into the cell and between intracellular compartments. However, plasma membranes (around the cell) and tonoplasts (around vacuoles) can be rendered more permeable to water by proteinaceous transmembrane water channels, called *aquaporins*. Aquaporins are a class of water-channel proteins that have been found in nearly all living organisms (Maurel and Chrispeels, 2001). They are highly expressed in plant membranes. They are members of a family of transmembrane channels known as the *major intrinsic protein* (MIP) family (Maurel, 1997).

Water movement through aquaporins can be modulated rapidly. Evidence suggests that these channels may facilitate water movement in drought-stressed tissues and promote the rapid recovery of turgor on watering (Buchanan *et al.*, 2000, p. 1170–1171).

Over the last 12 years, advances at the cellular level have occurred in the understanding of water movement across plant membranes (Tyerman *et al.*, 1999). It has been found that aquaporins can mediate bidirectional water flow. It is generally accepted that they function as narrow pores or channels through which water flows passively down a free energy gradient. Aquaporins consequently enhance the conductivity of the membrane considerably. They can appear in any membrane. But their presence in root membranes is of particular significance in water uptake. Changes in the nature of the potential energy driving water across a tissue may cause changes in the transport pathway, from apoplastic (cell-wall pathway) to cell-to-cell (water-channel pathway), and changes in hydraulic conductivities.

Figure 1 shows the pathways for passive movement of water and solutes across a root cylinder (Steudle and Frensch, 1996). Two parallel pathways (A) and (B) are considered. (A) represents the cell-to-cell path and (B) the

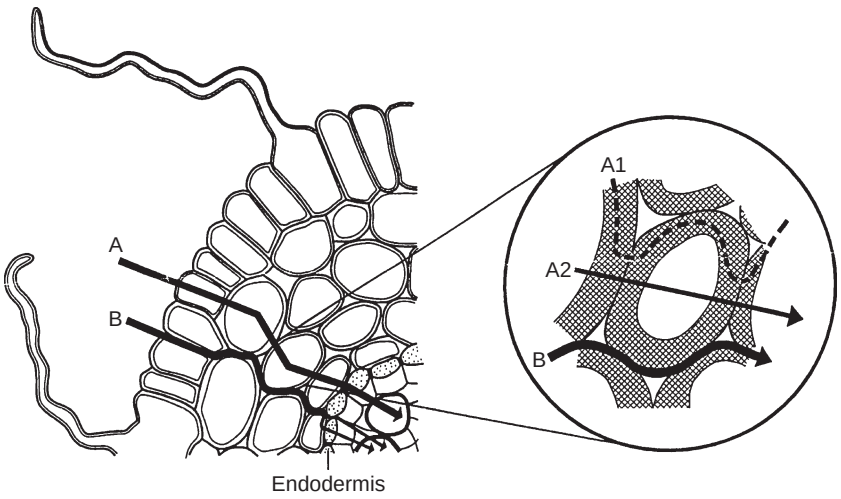

Figure 1 Pathways for passive movement of water and solutes across a root cylinder. Two parallel pathways (A) and (B) are considered. (A) represents the cell-to-cell (protoplastic) path and (B) the apoplastic path. Path (A) is split into symplastic (A1) and transcellular (A2) components. In the symplastic path, flow is restricted to the symplast, that is, water and solutes move from one cell to the next via plasmodesmata. The transcellular path denotes flow across cell membranes. Because components (A1) and (A2) cannot be separated experimentally, the two pathways are summarized as the cell-to-cell path (A). The parallel apoplastic route (B) refers to flow around the protoplasts. Across the endodermis, apoplastic transport is usually considered to be completely blocked by the Casparian band. (From Steudle and Frensch, 1996 by permission of Kluwer Academic Publishers B.V)

apoplastic path. Path (A) is split into symplastic (A1) and transcellular (A2) components. In the symplastic path, flow is restricted to the symplast, that is, water and solutes move from one cell to the next via plasmodesmata. The transcellular path denotes flow across cell membranes where the aquaporins are situated. Because components (A1) and (A2) cannot be separated experimentally, the two pathways are summarized as the cell-to-cell path (A). The parallel apoplastic route (B) refers to flow around protoplasts. Across the endodermis, apoplastic transport (water, solutes) is considered blocked by the Casparian strip. Future work needs to determine how both apoplastic and membrane-bound water flow contribute to the overall water uptake by plant roots.

Hydraulic Redistribution

Roots are movers of water in the soil (Clothier and Green, 1997). One method of movement is through hydraulic redistribution, which occurs when plant roots extract water from a moist soil layer and release it in another part of the root system into a dry soil layer. When transport is upwards the phenomenon is termed *'hydraulic lift'*, whereas the reverse process is called *'downward siphoning'* (see Smith *et al.*, 2004, and the references given there). Kirkham (1983a) presents a physical model based on Darcy's law, which explains the occurrence of hydraulic lift. Hydraulic lift is felt to be important for the survival of plants in arid and semiarid conditions. At night, when stomata are closed and the water potential of the shoot is high because transpiration is much reduced, water at depth can be brought near the soil surface by roots, where it is released into the dry soil, so water is brought to layers where roots are most abundant. Another favorable effect of hydraulic lift is increasing the availability of nutrients in the drier zones. Nutrients are usually most plentiful in the upper layers and their mobility can be considerably enhanced by increased moisture content (Caldwell *et al.*, 1998). The amount of water released during reverse flow is small (Song *et al.*, 2000), but may increase water in soil from the permanent wilting point to the available range.

PHYSIOLOGICAL ASPECTS

Two organs regulate a plant's water status, the leaves and the roots. Here, we consider physiological processes that control transpirational water loss from the leaves and root water uptake. Regulation takes place at different levels, that is, at the level of cells, organs, and assemblages of organs, for example, root systems.

Stomata

Water can be lost through the cuticle or through the stomata. The resistance of movement of water vapor through the cuticle is extremely high, and most water is lost through the stomata when they are open (Waggoner, 1966). The stomata are the main controllers of transpirational water loss and control exchange of carbon dioxide (CO_2) with the atmosphere as well.

A stoma is an opening in the epidermis of leaves and stems, bordered by two guard cells. Figure 2 shows a cross section of a leaf with guard cells and the other cell types in a leaf. The outstanding feature of stomata, the unevenly thickened walls of the guard cells, is related to their changes in shape and the concomitant changes in the size of the stomatal aperture (Esau, 1965, p. 159–160). When turgor increases, the aperture increases in size. Reversed changes occur under decreased turgor. Stomatal guard cells are able to sense environmental signals such as light, carbon dioxide (CO_2) concentration, and humidity, as well as endogenous signals such as plant hormones (Assmann, 1993). Guard cells integrate environmental and endogenous signals, so that the stomatal aperture is neither too small, which would inhibit CO_2 uptake for photosynthesis, nor too large, which would cause excessive water loss.

Environmental Signals

In addition to water availability, light, CO_2, and humidity are the main environmental signals that affect stomatal aperture. Red and blue light stimulate stomatal openings.

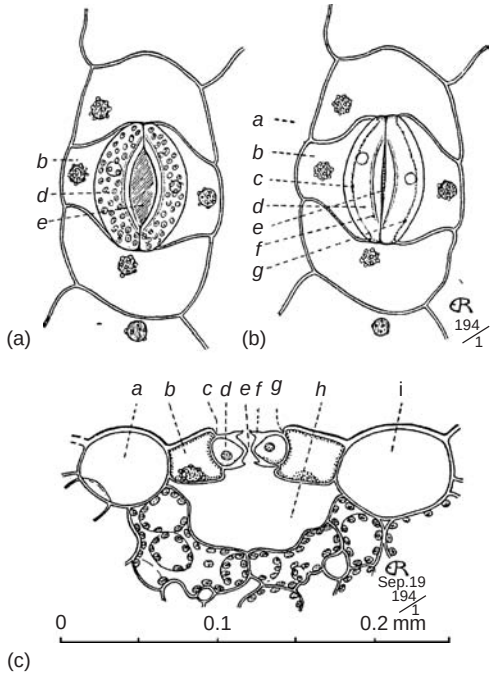

Figure 2 Stoma of *Tradescantia virginiana*. (a) Open stoma viewed from above (b) Closed stoma viewed from above (c) Cross section. *a*, epidermis cell; *b*, subsidiary cell; *c*, joint; *d*, guard cell; *e*, pore; *f*, cuticle; *g* = c; *h*, substomatal cavity (From Reinders, 1957)

Elevated CO_2 typically stimulates stomatal closure, while lowered CO_2 concentrations have the opposite effect. It is the intercellular concentration of CO_2, and not the external concentration, or the concentration within the pore, to which the guard cells are responding. The mechanism of the CO_2 response is unknown.

Reduction in ambient humidity causes stomatal closure, but the reason for the closure is poorly understood. Experiments suggest that transpiration water loss is the important signal. Guard cells respond metabolically to humidity, for example, by losing K^+. Guard cells also may be responding to regulatory metabolites such as abscisic acid (ABA) (see Section "Internal signals"), which are carried in the transpiration stream.

Stomatal closure requires membrane depolarization, which can be driven by anion efflux, and decreases in organic osmotica. Alterations of any of these processes can affect stomatal aperture; such changes are triggered by alterations in the level of activity of two so-called *'second messengers'*, Ca^{2+} and H^+ (pH).

Calcium is an important second messenger. Exogenously applied Ca^{2+} is potent in reducing stomatal aperture (Assmann, 1993). However, there are also data suggesting that Ca^{2+} may play a role in stomatal opening. Also, pH acts as an extracellular signal. As extracellular pH becomes more alkaline, water stress increases, which results in stomatal closure.

Internal Signals

Messengers that are produced within the leaf, or are translocated from a distant site of synthesis include the plant hormones. A hormone, by definition, is a naturally occurring chemical substance formed in some organ of the plant and is carried to another organ or tissue, where it has a specific effect; it operates in small amounts. For 40 years, it has been known that hormones produced in the roots affect shoot–water relations. There are five plant hormones: cytokinins, ethylene, gibberellins, auxins, and abscisic acid. The following paragraphs explain in general terms how hormones affect plant-water relations. For more detailed information, the interested reader can read the reviews for cytokinins, Mok and Mok (2001); for ethylene, Kieber (1997); for gibberellins, Richards *et al.* (2001); for auxins, Leyser (2002); and for abscisic acid, Leung and Giraudat (1998).

Cytokinins are produced in roots and travel to leaves where they promote stomatal opening. Experiments have shown that stomata open more widely than they are under normal conditions when cytokinins are sprayed on plant leaves (Kirkham *et al.*, 1974). The rate of transpiration has been used as a bioassay for cytokinin activity (Luke and Freeman, 1967). Reduced cytokinin production in stressed roots results in increased stomatal resistance (Tal *et al.*, 1970).

Ethylene, the only gaseous hormone, is the simplest organic compound that affects plants. It is active in trace amounts, which makes its detection under nonstressed conditions difficult (Rose, 1985). The effects of ethylene on stomata are contradictory (Kirkham, 1983b). Some experiments show no response of stomata to ethylene, while others have found that ethylene increases stomatal resistance. Essentially, no papers report that ethylene decreases stomatal resistance.

Little information exists concerning the effect of gibberellins on transpiration. Gibberellic acid seems to stimulate transpiration rate (Livnè and Vaadia, 1965) and decrease stomatal resistance (O'Leary and Tarquinio Prisco, 1970).

Depending on the type of auxin and the auxin concentration, either stomatal opening or stomatal closure may occur. Indole-3-acetic acid (IAA) is a natural auxin, and it stimulates stomatal opening at concentrations from 10 μM to 1 μM. With the synthetic auxin 1-NAA (1-napthylacetic acid), maximal stimulation of opening occurs at 5 μM and inhibition of opening occurs at 0.5 μM (Assmann, 1993).

The hormone that has been most widely studied in relation to stomata is abscisic acid because it strongly promotes stomatal closure. ABA is produced in the roots in response to stress, particularly drought stress. It is thought that ABA which is synthesized in roots exposed to dry soil is transported to shoots, where it leads to a reduction in guard cell turgor and stomatal closure (Fry and Huang, 2004, p. 68). Actual measurements of the rate of ABA movement to the shoot, as it is produced under drought stress, are not known.

Even though ABA is important in controlling stomatal aperture, it is probably the balance of hormones that determines the opening of the stomata (Tal and Imber, 1971). Cytokinins decrease stomatal resistance and increase the resistance of the root to absorption of water. The general effect of cytokinins, therefore, is to reduce plant turgor, and their concentration decreases in stressed plants. In contrast, ABA increases stomatal resistance and decreases the resistance of the root to water flow. This hormone increases the plant turgor and its concentration increases in stressed plants. Rapid changes in concentrations of both cytokinins and ABA have been demonstrated in water-stressed plants. The plant undergoes alternating periods of low turgidity during the day, when absorption lags behind water loss by transpiration, and high turgidity at night, when transpiration lags behind water absorption. The periodic changes of water status may induce periodic fluctuations of hormonal concentrations, which influence stomatal and root resistances. The balance of hormones in water-stressed plants may cause the "aftereffect" that is observed in stomata (Fischer *et al.*, 1970). Stomata commonly fail to resume regular opening after a period of wilting of leaves despite rapid recovery of leaf water content. The aftereffect

may be due to an accumulation of an inhibitor like ABA (Livnè and Vaadia, 1972) or a deficiency of a substance that promotes stomatal opening like a cytokinin.

Regulation at the Level of the Root and Roots Systems

Vessel Diameter

The *axial* resistance of a root, that is, the resistance to vertical flow from the root upward through the xylem vessels to the stem, is a function of the vessel diameter. Poiseuille (1799–1869), a French physiologist, discovered the law on velocity of flow of a liquid through a capillary tube. He found that the volume of fluid moving in unit time along a cylinder is proportional to the fourth power of its radius and that the movement depends on the drop in pressure (Kirkham, 2005, p. 216). One of the first important agronomic uses of Poiseuille's law was in a pioneering paper by Passioura (1972) in Australia, where wheat plants face terminal drought. He suggested that when wheat is growing predominantly on stored water, it is an advantage for the plants to have root systems of high axial resistance, so that they will conserve water during early growth and thus have more water available while filling their grain. The xylem of the seminal roots in wheat is dominated by one large metaxylem element (vessel member), the diameter of which (about 50 μm in diameter on average) probably determines the amount of water flowing through the wheat plant, and, thus, indirectly its hydraulic resistance. He suggested that the resistance to flow in the wheat root could be increased in one of two ways: (i) by decreasing the size of the central metaxylem element, or (ii) by reducing the number of seminal roots. He chose to reduce the number of seminal roots. The plants with one seminal root had a larger pressure gradient than the plants with three seminal roots. The single-rooted plants had double the available water at anthesis and produced double the grain yield. Passioura (1972) concluded that it might be possible to conserve water by growing wheat plants with a single seminal root, and it may be possible to breed high root axial resistance into existing cultivars by breeding for smaller vessels. Passioura's classic paper showed that Poiseuille's law can be used to calculate the pressure drop in crops and that this value can be used to breed drought-resistant varieties.

The phloem tissue develops before the xylem tissue (Kirkham, 2005, p. 208). Until the metaxylem elements form, Poiseuille's law cannot be applied and longitudinal (axial) resistance (movement of water in the vertical direction in plants) is large. Taylor and Klepper (1978) discuss axial resistances. Another factor that limits the use of Poiseuille's law is the formation of embolisms in vessels. Air bubbles cause cavitation of the continuous water channels in the vessels. Kirkham (2005, p. 321–327) discusses this problem and how plants maintain water-filled conducting cells.

Richards and Passioura (1981), following the earlier work of Passioura (1972) on the significance of vessel diameter, screened the world's wheat collection (over 1000 accessions) for two factors that control resistance to water movement in the wheat root: number of axes (number of seminal roots) and central metaxylem-vessel diameter. Because there was greater variability in the vessel diameter than in the number of axes, they concluded that the diameter was more important in determining resistance than the number of axes. Accordingly, one should rather breed for change of diameter than for change of number of axes.

Root Radius

Both experimental (Burch, 1979) and theoretical (Gardner, 1960; De Willigen and Van Noordwijk, 1987) studies show that root radius has but a minor influence on root radial resistance and required head gradients in the soil.

Root Growth at Different Soil Depths

A well-developed root system often shows an exponential decrease in root length density with depth (Gerwitz and Page, 1974; Jackson *et al.*, 1996). When soil water is more or less evenly spread over the root zone, distribution of water uptake is determined by distribution of root length density (Sharp and Davies, 1985). In that case most of the extraction of water is from the topsoil. When data from many different experiments were plotted together, it was determined that 40% of the extraction of water is from the first 20% of the root depth, then 33, 20, and 7% from successive depths. This is similar to the rule of thumb that 40% of the water is extracted from the first 30 cm (1 ft), then 30, 20, and 10% from successive 30-cm increments (Gardner, 1983). The percentages are a generalization, and root growth among species and cultivars varies widely. For example, drought-resistant cultivars of wheat have been shown to have more highly branched root systems than drought-sensitive cultivars of wheat (Kirkham and Kanemasu, 1983, p. 490–492).

When there are large differences in water content in the root zone, these patterns mainly determine the distribution of water uptake. Data of Sharp and Davies (1985) depicted in Figure 3 show the distribution of water uptake, root length density, and water content with depth for a well-watered and nonwatered plant. It is clear from this figure that in moist conditions, root length density determines the distribution of water uptake, whereas under dry conditions the distribution of water is more important. Under rain-fed conditions in semiarid regions it is important to have crops that exploit water at all depths in the soil, not just the surface, to make maximum use of water. Two drought-resistant row crops in semiarid areas are grain sorghum and sunflower. A study in Kansas (Rachidi *et al.*, 1993)

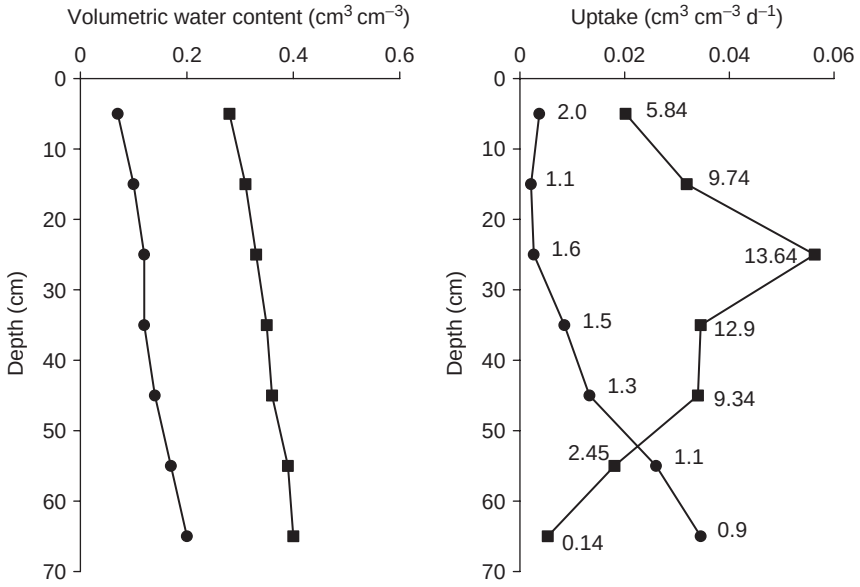

Figure 3 Distribution of water content and water uptake for a maize plant after 18 days, well-watered (■) and unwatered (•). (a) Water content (b) water uptake, the figures at the points give the root length density in cm cm^{-3}. (Data of Sharp and Davies, 1985)

showed that the two crops use water from different depths. Sunflower depleted water to 1 m more depth than sorghum. These results suggest that deep-rooted crops like sunflower might be planted in rotations with shallow-rooted crops to take advantage of water depth.

A split-root experiment with a kiwifruit vine documents the dominant role of surface roots in extracting water under irrigated conditions and demonstrates how irrigation can influence the spatial pattern of root water uptake (Clothier and Green, 1994). Initially, soil water content and water uptake rate were uniformly distributed across the root zone. Next, only one-half of the root zone was irrigated. Following this differential irrigation of the root zone, the sap flow in the "wet" root increased, while the flow in the "dry" root was about halved. Thus, the vine quickly switched its pattern of uptake away from the drier parts of the root zone. Even of greater interest was the vertical pattern of root uptake observed on the wet side. There was a preference of near-surface water uptake. The vine continued to extract water in the densely rooted region surrounding its base, but the shift in uptake to the surface roots on the wet southern side was remarkable. The results showed that greater efficiency in irrigation water use could be obtained by applying small amounts of water more frequently, instead of large, infrequent irrigation. Water from low irrigation would be used rapidly by the active, near-surface roots. This would eliminate the movement of irrigation water into lower regions of the root zone, where draining water passes by inactive roots and is unavailable for plant uptake.

MODELING

Single Root Models

A model by definition is a simplified representation of part of reality; this of course also applies to models on root water uptake. In order to make the problem of transport to and uptake by plant roots manageable, many assumptions and simplifications have to be employed. An obvious and widely used assumption is that of the cylindrical root confined in a soil cylinder, the radius of which is a function of root length density. This leads to the choice of expressing the transport equation in cylindrical coordinates. When tangential and vertical gradients are assumed negligible, it assumes the form:

$$\frac{\partial \theta}{\partial T} = \frac{1}{R}\frac{\partial}{\partial R} D_w R \frac{\partial \theta}{\partial R} \tag{3}$$

where θ is the volumetric water content of the soil (−), T is time (s), and R the radial distance from the center of the root(m). The water diffusivity $D_w(\theta)$ (m^2 s^{-1}) is defined as:

$$D_w = K \frac{\mathrm{d}h_p}{\mathrm{d}\theta} \tag{4}$$

where h_p is the pressure head (m), and K the hydraulic conductivity of the soil (m s^{-1}).

The boundary condition at the outer boundary of the soil cylinder is that of vanishing flux:

$$R = R_1, \;\; D_w \frac{\partial \theta}{\partial R} = 0 \tag{5}$$

where R_1 is the radius of the soil cylinder exploited by a root given by:

$$R_1 = \frac{1}{\sqrt{\pi L_{rv}}} \tag{6}$$

where L_{rv} is the root length density ($m\,m^{-3}$). At the inner boundary – the root surface – the boundary condition is of the form:

$$R = R_0, \;\; D_w \frac{\partial \theta}{\partial R} = \frac{F_1}{2\pi R_0 \Delta z} \tag{7}$$

where R_0 is the root radius (m), Δz the root length (m) and F_1 the uptake rate ($m^3\ s^{-1}$). On the one hand, the uptake rate is linearly related to the difference in hydrostatic and osmotic pressure in analogy to equation (2):

$$F_1 = \alpha\{h_{p,R0} - h_{p,P}\} - \sigma(h_{o,P} - h_{o,R0}) \tag{8}$$

where h_{p,R_0} is the pressure head of the rhizosphere (m), $h_{p,P}$ is the pressure head in the root (m), α is the conductance of the root ($m^2\ s^{-1}$), $h_{o,P}$ is the osmotic head in the root and $h_{o,R0}$ is the osmotic head in the rhizosphere. On the other hand, F_1 is also equal to the transpiration rate per root:

$$F_1 = \pi R_1^2 E = \frac{E}{L_{rv}} \tag{9}$$

where E is the actual transpiration rate ($m\,s^{-1}$), and L_{rv} the root length density ($m\,m^{-3}$).

Both the hydraulic conductivity as well as the pressure head and thus D_w are nonlinear functions of water content, making equation (3), a nonlinear partial differential equation, difficult to solve in general terms. However, approximate solutions can be obtained when assumptions on steady state or steady-rate conditions are applied with or without a linear relation between water content and diffusivity. Though applicable only in a limited range, these have considerably contributed to a better understanding of water transport to plant roots (Gardner, 1960; Passioura, 1980; De Willigen and Van Noordwijk, 1987). A particularly useful partial linearization of (3) is obtained by employing the matrix flux potential Φ ($m^2\ s^{-1}$) (Raats, 1970) defined as:

$$\Phi = \int_{\theta_{ref}}^{\theta} D_w \, d\theta \tag{10}$$

The steady-rate assumption then leads to the next equation giving the distribution of matrix flux potential as a function of radial distance:

$$\Phi = \Phi_{R0} + \frac{F_1}{2\pi \Delta z}\left(\frac{\rho^2}{\rho^2 - 1}\ln r - \frac{r^2 - 1}{2(\rho^2 - 1)}\right) \tag{11}$$

where $\rho = R_1/R_0$ and the dimensionless distance $r = R/R_0$.The distribution of water content around a root can now be calculated relatively simply with equation (11). Figure 4 shows the good agreement between the water content distribution calculated with the steady-rate approximation and with the numerical solution of equation (3).

The single root uptake model can be used to assess the relative importance of the soil resistance with respect to the root resistance. Figure 5 shows the plant and soil resistance as a function of the average pressure head for a root length density of $10^4\ m\,m^{-3}$, and a transpiration of $5 \times 10^{-3}\ m\,d^{-1}$ for a clay, sand, and peat soil in the Netherlands (hydraulic characteristics from Wösten, 1987), and a root conductance of $2.3 \times 10^{-7}\ m.d^{-1}$, the highest value found in literature (De Willigen and Van Noordwijk, 1987). Clearly, even with

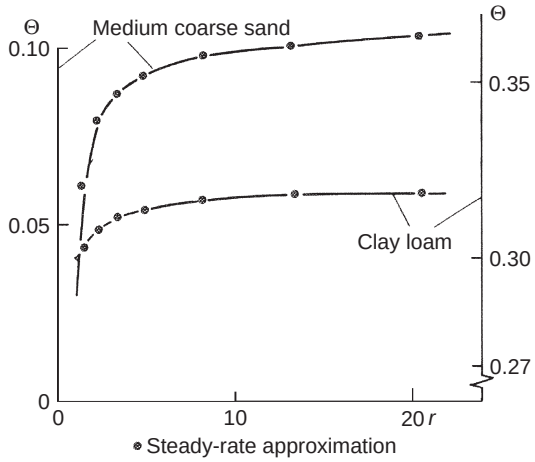

Figure 4 Distribution of the water content around a root taking when the pressure head at the root equals 5 Mpa, calculated with a numerical model (line) and with the steady-rate approximation (points) (equation (11) in the text)

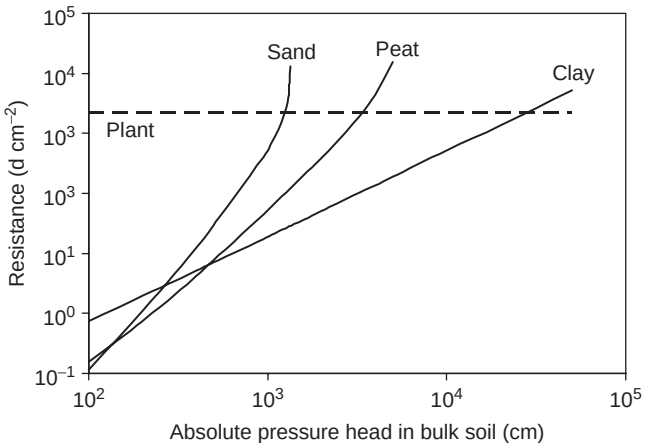

Figure 5 Soil and plant resistance as a function of average pressure head of the soil. Parameters: root radius 0.01 cm, root length 20 cm, root length density 1 cm cm^{-3}, root conductance 23×10^{-6} cm d^{-1}, transpiration 0.5 cm d^{-1}

this high value of the root conductance, the root resistance exceeds the soil resistance for h_p values up to -1000 cm (sand) or even $-30\,000$ cm (clay).

The model can also be used to examine the influence of root length. From a water uptake point of view it appears that doubling the total root length within a layer, for example, increasing the root length density with a factor two, is much less favorable than maintaining the same average root length density and doubling the root length (De Willigen *et al.*, 2000).

Root System Models

One can distinguish two types of uptake models. In the first group where root length density and root water potential do not play a role, uptake is determined by the depth of the root zone and the pressure head or water content of the soil layers (e.g. Feddes *et al.*, 1978; Van Genuchten, 1986; van Keulen and Seligman, 1987). The other is based upon steady state or steady-rate approximations of the single root model (e.g. Nimah and Hanks, 1973; Hillel *et al.*, 1976; De Willigen and Van Noordwijk, 1995).

An example of the first group is the water uptake module as used in the SWATRE model (Feddes *et al.*, 1978). First, a potential water uptake rate is calculated, which is reduced for unfavorable pressure heads in the soil. In its simplest form the potential water extraction rate ($S_{\max}$) is assumed to be equally distributed over the root zone (Z_r):

$$S_{\max} = \frac{E}{Z_r} \tag{12}$$

Later (Bouten, 1992), the potential uptake was distributed according to the relative distribution of the root length density and corrected for the water content distribution. For the ith layer in the soil profile the equation reads:

$$S_{\max,i} = \left[\frac{\frac{\theta_i}{\theta_{s,i}} L_{rv,i} \Delta z_i}{\sum \frac{\theta_i}{\theta_{s,i}} L_{rv,i} \Delta z_i} \right] \frac{E}{\Delta z_i} \tag{13}$$

where $\theta_{s,i}$ is the saturated water content of the layer. The term $\theta_i/\theta_{s,i}$ ensures that water is preferentially taken up from wetter layers. The actual uptake rate (S) in a certain layer is then reduced in the case of nonoptimal pressure head of that layer:

$$S_i = a(h_{p,i}) S_{\max,i} \tag{14}$$

De Willigen and Van Noordwijk (1995) used a water uptake model (WATUP) based on an extension of the single root model treated earlier. Again, for a root system distributed over several soil layers (or compartments), they assumed that within each layer (compartment) the roots are regularly distributed and that the flow of water from the bulk soil to the rhizosphere in each layer equals that from the rhizosphere into the root:

$$[\bar{\Phi}_i - \Phi_{R_0,i}] \frac{\pi \Delta z_i (\rho_i^2 - 1)}{G(\rho_i)} = \alpha (h_{p,R_0,i} - h_{p,P}) \tag{15}$$

where the subscript i denotes the number of the layer and the function $G(\rho_i)$ is given by:

$$G(\rho_i) = \frac{1 - 3\rho_i^2}{4} + \frac{\rho_i^4}{\rho_i^2 - 1} \ln(\rho_i) \tag{16}$$

Also the total uptake should equal the transpiration:

$$\sum_i^N L_{rv,i} \alpha (h_{p,R_0,i} - h_{p,P}) = E_{act} = f(h_{p,P}) E_{pot} \tag{17}$$

This yields $N + 1$ equations with $N + 1$ unknowns: the N values for $h_{p,R0,i}$ and the root pressure head $h_{p,P}$. The equations have to be solved by iteration because of the nonlinear relation between matrix flux potential and pressure head, and the nonlinear nature of $f(h_{p,P})$. For a relative wet soil the major resistance is found in the root (Figure 5), the gradients in the soil are accordingly very small, and $h_{p,P}$ is much smaller (more negative) than $h_{p,R0,i}$. Equation (17) for a given layer can then be approximated as:

$$L_{rv,i} \alpha (h_{p,R_0,i} - h_{p,P}) \approx -L_{rv,i} \alpha h_{p,P} \tag{18}$$

The uptake from a certain layer is thus proportional to the relative root length density in that layer. So for relatively wet conditions, both models yield the same distribution of uptake. Greater differences can be expected for dry conditions. The second model is able to simulate hydraulic redistribution.

Which type of model should be used depends on the conditions. If these are not too extreme the first type is to be preferred, it is simpler and requires fewer parameters. The second type is more flexible and seems therefore a better fit for more extreme circumstances.

MEASURING ROOT WATER UPTAKE

Weighing Lysimeter

Possibly, the most robust way to determine root water uptake is by means of a weighing lysimeter (Howell *et al.*, 1991). The change in weight of a well-defined volume of rooting medium is attributed to transpiration. The measurement can be very precise, say $0.05\,\mathrm{kg\,m^{-2}}$. The volume of rooted medium can range from say, one

liter up to several cubic meters. Instead of weighing the lysimeter, the mass balance method can be used (see Section "Water balance"). A special technique of weighing can be done by the so-called *hanging 'load cells' or hanging weighing scales* (e.g. Ehret *et al.*, 2001). Corrections may be needed for increase in plant fresh weight during the measurement interval. When combined with measurements of changes in water content in the rooting zone (see Section "Water balance") at several depths, differentiation of water uptake with depth can be achieved. For detailed studies, one can consider leaving out a porous rooting medium and letting the plant grow in water on a balance (e.g. the potometric water-budget meter of Flach *et al.*, 1995). The weighing methods are direct, robust, and very precise. However, the conditions in the rooting zone may differ from the surrounding crop, and large weighing lysimeters are expensive and sensitive to wind.

Water Balance

Root water uptake can be determined from a mass balance approach: root water uptake is equal to water input in the system minus water output from the system minus the increase in water storage in the system (e.g. Evett, 2002). This does not require a lysimeter (see Section "Weighing lysimeter"). The changes in water storage in the rooted medium can be followed by means of water content measurements, for example, dielectric methods such as time or frequency domain reflectometry (TDR, FDR), neutron scattering, and ground-penetrating radar (GPR) (*see* **Chapter 72, Measuring Soil Water Content, Volume 2**), or by means of pressure head measurements, for example, tensiometers, electrical resistance blocks, psychrometers. These techniques require calibration and knowledge of the water retention characteristic, which exhibits hysteresis. The water balance method is simple, and differentiation of water uptake with depth can be achieved when sensors are installed at different depths. The disadvantages of this method are that the water output may be difficult to measure (if no lysimeter is used), and that errors (including heterogeneity) in the determination of input, output, and change in storage accumulate in estimate of root water uptake.

Sap Flow

There are techniques to determine the sap flow rate through the stems (or even through individual roots) of plants. Three thermal tracer techniques are known: the heat-pulse method, the heat probe, and the heat balance technique. Smith and Allen (1996) reviewed principles and application of both the heat-pulse and the heat-balance techniques. Another method is the nuclear magnetic resonance (NMR) technique (Van As and Schaafsma, 1984). The advantages of measuring sap flow are: they give a direct indication of water flow through an individual plant; the measurement is rather precise compared to the weighing lysimeter technique (Weibel and De Vos, 1994 give a review of published accuracy tests); the required equipment is commercially available; and the method is nondestructive. However, not all stem diameters can be measured, possible heat-damage of the stem (heat flow) may occur, it requires calibration against another exact method (heat flow), and the sophisticated NMR equipment is heavy, voluminous, and expensive (except, maybe, for proton-NMR).

Inverse Modeling

Simulation models that describe water movement in porous media including a sink term can be used to estimate root water uptake for given conditions. Such an approach can be used when detailed information on root uptake is lacking and other detailed information is available for the other processes described by the model. Using inverse modeling techniques, the sink term (= root water uptake) in the model can be calibrated (e.g. Vogeler *et al.*, 2001; Vrugt *et al.*, 2001; Zuo and Zhang, 2002). The advantage of the inverse modeling technique is that root water uptake can be determined for situations where it is not directly measured. The disadvantages of this method are that it is a very indirect way of determining root water uptake, errors will propagate through errors in model input and model assumptions, and independent calibration is needed of the chosen root water uptake model.

Root Uptake Ability and Plant-water Status

The ability of roots to take up water is expressed by the root hydraulic conductance, and it can be measured by several techniques that have in common the ability to determine the volume of water flowing through a root that is exposed to a known gradient in water potential (e.g. Huang and Nobel, 1994; Fernández *et al.*, 2000).

The plant-water status can be measured by the following techniques: linear variable differential transducer (LVDT) that measures the changes in stem diameter (more flow results in thicker stems); porometer (transient or steady state) that measures stomatal resistance (or conductance) which indicates if stomata are fully open or not; psychrometer technique for measuring the plant (e.g. leaf, stem, root) water potential; and the pressure chamber, an alternative technique to measure plant-water potential. Advantages of the psychrometer technique are that it has a sound theoretical basis, it can be applied to small portions of plant tissue, and it can measure −40 bars or lower. However, this technique requires careful temperature control, and it has relatively long equilibrium times. The advantages of the pressure chamber are that the method is easy (but should be applied with some care) and quick, but it is not suitable

for small plant parts. A disadvantage of the LVDT technique is that it cannot be applied for small stem diameters. A disadvantage of the porometer is that it cannot be used for small leaves. Some general problems associated with measuring plant-water status have been described by, for example, Bennett (1990).

Additional Techniques

Computer assisted tomography applied to x-ray or γ-ray attenuation measurements can be used to show the spatial distribution of water contents in the soil surrounding a single root (e.g. Hamza and Aylmore, 1992; contributions in Anderson and Hopmans, 1994). Another technique to measure water content in the vicinity of roots (e.g. as close as 6 mm) is the dual-probe heat-pulse (DPHP) technique (e.g. Philip and Kluitenberg, 1999; Song *et al.*, 2000). Stable isotopes can be used to determine water uptake and to discriminate water taken up from different depths (Fernández *et al.*, 2000; Bingham *et al.*, 2000).

Split-root techniques can be used to study water movement within root systems or to study the reaction of the plant to highly variable conditions in the rooting zone. For example, such techniques can be used to demonstrate the existence of hydraulic redistribution or to study the effect of osmotic pressure on root water uptake.

Acknowledgment

Thanks are due to Dr. P.A.C. Raats for useful discussions on conductivity, conductance, and effects of build up of osmotic pressure in roots.

71: Freezing and Thawing Phenomena in Soils

MANFRED STÄHLI

Swiss Federal Research Institute WSL; Water, Soil, and Rock Movements, Birmensdorf, Switzerland

More than one-third of the Earth's land surface is subjected to seasonal or permanent soil frost. The freezing and thawing of the soil may generate severe geotechnical, hydrological, and environmental problems, such as frost heaving, restricted infiltration, and enhanced overland flow. Each soil has its own specific freezing characteristic, primarily depending on texture and the prevailing solute concentration. Fine-textured soils tend to form ice lenses at freezingthat causes the soil to heave. In coarse-textured soil, on the other hand, the ice is more regularly distributed within the matrix. The behavior of the soil is always strongly linked to the prevailing meteorological conditions. The hydraulic conductivity of frozen soils is reduced, similar to very dry soils. Locally, this leads to reduced infiltration and delayed recharge to groundwater during snowmelt. For larger areas, for example, watersheds, the effect of frozen ground on infiltration and runoff is ambiguous, as a number of recent studies showed.

This article summarizes current theories and recent investigations on soil freezing and thawing phenomena with a major emphasis on implications for hydrology.

INTRODUCTION

When temperature in a soil drops below 0 °C, water starts to transform to ice. This phase change is termed as *soil freezing*, resulting in a state of *soil frost.* Approximately 35% of the Earth's land surface is significantly affected by soil freezing and its opposing process, the *thawing* of the soil (Williams and Smith, 1989). This area is referred to as the *periglacial* environment. Whereas in many places of the world the soil freezes seasonally only a few centimeters at the surface or down to 1 or 2 m in the soil, about 20–25% of the land surface (Péwé, 1991) – especially at northern latitudes and high altitudes – remains partially frozen year-round. Here we talk about *permafrost areas* (*see* **Chapter 172, Permafrost Hydrology, Volume 4**).

Substantial environmental, hydrological, and geotechnical problems are related to soil freezing and thawing. Roads and buildings can be damaged by the fact that some soils heave at freezing and collapse during thawing. Precipitation or snowmelt water may pond on a frozen soil surface causing lateral surface runoff and possible enhanced erosion. Water uptake by vegetation may be considerably delayed and reduced because of the presence of soil frost.

This article summarizes current theories and recent investigations on soil freezing and thawing phenomena with a major emphasis on implications for hydrology. Geotechnical aspects related to soil freezing, which have had a key role in soil frost research since the early 1930s, are only superficially considered.

SOIL FREEZING AND THAWING

In a soil the transition from water to ice does not take place at a specific temperature, but over a range of several degrees. This means that below 0 °C, heat loss simultaneously decreases the soil temperature (change in sensible heat) and transforms liquid water to ice (change in latent heat). We can formalize that in the general heat flow equation stating that for a given soil layer of thickness z, all changes in total heat storage during a time period t are balanced by the change in latent heat caused by freezing/thawing and the heat losses/inputs (q_h) to/from the adjacent soil:

$$\frac{\partial(CT)}{\partial t} = L_f \rho_{soil} \frac{\partial \theta_{ice}}{\partial t} + \frac{\partial}{\partial z}(-q_h) \qquad (1)$$

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

where C is the heat capacity, T is the temperature of the soil layer, L_f is the latent heat of freezing ($3.338\ 10^5\ \mathrm{J\,kg^{-1}}$), ρ_{soil} is the soil bulk density and θ_{ice} is the volumetric ice content. This general heat flow equation is complicated by the fact that the ratio between latent and sensible heat loss is not constant, but decreases with decreasing soil temperature. Soil texture and solute concentration determine this partitioning between sensible and latent heat. It is usual to express this soil specific property with the so-called *freezing characteristic curve*, that is, the decrease of the liquid water content below 0 °C (Figure 1). From various laboratory and field experiments it is well known that for clay soils the liquid water content decreases at lower temperatures than for sandy soils, and that even at temperatures below −5 °C a fraction of the total soil water remains unfrozen. Capillary and adsorptive forces of the soil particles that act on the water by reducing its pressure are largely responsible. From thermodynamic principles, we know that in order to maintain equilibrium a change in soil temperature must lead to a corresponding change in the pressure of all water phases (liquid water, vapor, and ice). Thus, there is a unique relationship between a decrease in temperature, $\mathrm{d}T$, and a change in soil-water pressure, $\mathrm{d}p_w$, according to the well-known Clausius–Clapeyron equation:

$$\frac{\mathrm{d}p_w}{\rho_w} - \frac{\mathrm{d}p_{ice}}{\rho_{ice}} = \int_{T_0}^{T} \frac{L_f}{T}\,\mathrm{d}T \qquad (2)$$

where p is pressure (relative to atmospheric pressure), ρ is density and the subscripts w and ice denote liquid water and soil ice. This implies that, as a rough approximation, a decrease in soil temperature by 1 °C lowers the soil-water potential by 1.22 MPa. (Note that equation (2) is strictly valid only if no additional forces act on the ice.) If we now assume that the water retention curve (i.e. the relationship between water pressure and liquid water content; *see* **Chapter 75, Determining Soil Hydraulic Properties,** **Volume 2**) is similar in an unfrozen and a frozen soil, we can explain the differences in freezing characteristic curves of different soil types. Spaans and Baker (1996) demonstrated experimentally that this similarity between freezing/thawing and drying/wetting is justified (Figure 2).

In addition to the soil mineral surfaces, solutes in the soil-water phase also contribute to the freezing point depression through the osmotic potential. In most natural soils, the concentration of dissolved salts is rather weak, lowering the freezing point by less than 0.1 °C. But for ion-rich soils it might be important to account for their concentration and mobility at freezing. Although it is generally known that solutes are excluded from the ice grid, there has been speculation whether they are excluded locally (e.g. in small pockets) or ejected ahead of the ice front. Recent measurements by Spaans and Baker (1997) and Overduin and Young (1997) tend to support local exclusion.

An interesting question to address is where exactly the liquid water, the ice, and the air is located in a partially frozen soil. For sand it is appropriate to adopt the capillary model for explaining the distribution of liquid water, ice, and air in an unsaturated frozen soil. Combining the Laplace surface tension equation, which relates pressures in two phases that meet at a curved interface (*see* **Chapter 73,**

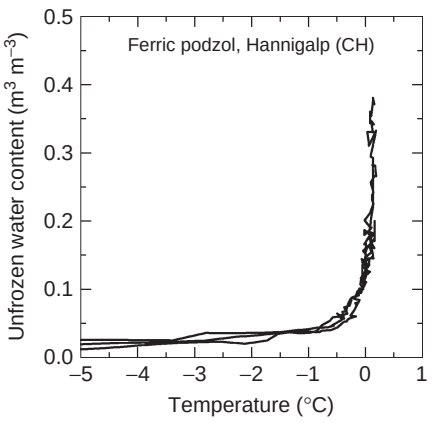

Figure 1 Freezing characteristic curve of a sandy loam (Data provided by M Stähli, WSL)

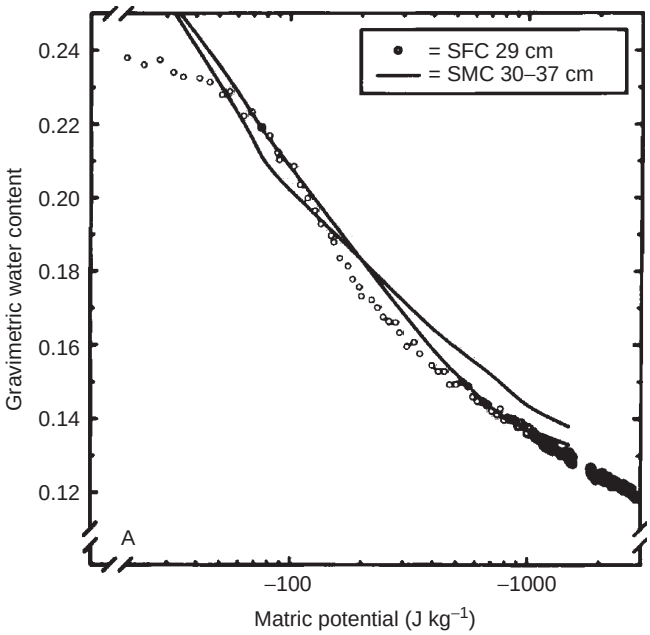

Figure 2 Similarity between freezing/thawing and drying/wetting. Nice agreement of the water retention curve gravimetrically measured in the lab on unfrozen silty loam samples (solid line) and calculated from its freezing characteristic curve (open circles) (Reproduced from Spaans and Baker, 1996; The solid freezing characteristic: its measurement and similarity to the soil moisture characteristic. Soil Science Society of America Journal, 60, page 17 by permission of Soil Science Society of America)

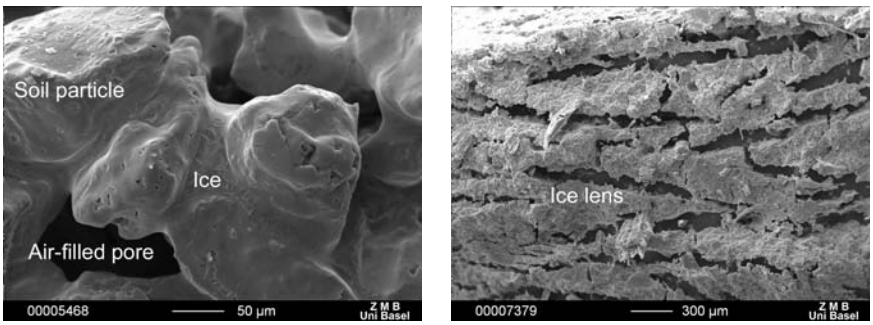

(a) (b)

Figure 3 Low-temperature SEM micrographs of a frozen unsaturated sand (a) and a frozen clay soil (b) (Images provided by D. Mathys, Center of Microscopy, University of Basel)

Soil Water Potential Measurement, Volume 2) with equation (2), provides the pore radius, r_{wi}, at the boundary between unfrozen water and ice:

$$r_{wi} = -\frac{2\sigma_{wi}T_f}{gL_f(T - T_f)} \tag{3}$$

where T_f is the freezing temperature of free water, σ is the surface tension, and g is the gravitational constant. Pores with a radius $< r_{wi}$ are filled with liquid water, whereas pores having a radius $> r_{wi}$ are occupied by ice. The boundary pore radius between ice and air, r_{ia}, can be given by the following expression:

$$r_{ia} = \frac{2\sigma_{ia}}{\rho_w g p_w(\theta_i)} \tag{4}$$

where σ_{ia} is the surface tension between ice and air ($\sim$100 mN m^{-1}; Miller, 1980) and θ_i is the initial water content at freezing. A low-temperature Scanning Electronic Microscope image (Figure 3) illustrates these theoretical considerations.

In a clay soil, unfrozen water surrounds the clay particles as an adsorbed layer, whereas the frozen water accumulates in horizontal bands of pure ice, the so-called *ice lenses* (Figure 3). The mechanisms behind the formation of such ice lenses have probably been the most investigated in frozen soil research during the last century. The theory of Miller (1980) defining the mechanisms for the development of an ice lens and the associated volume expansion, referred to as *frost heave*, is generally accepted as the most plausible model for freezing of clay soils. Air-filled voids in a frozen clay soil are restricted to macropores, such as cracks and root channels.

WATER MOVEMENT IN FROZEN SOILS

As demonstrated above, unfrozen water occupies the smallest pores because it is strongly adsorbed by the soil particles. If we transfer the assumption of similarity between freezing and drying to the hydraulic conductivity (k_w) - water content relationship (*see* **Chapter 76, Models for Indirect Estimation of Soil Hydraulic Properties, Volume 2**), a sharp decrease of k_w has to be expected as freezing sets in and progresses, resulting in a nearly immobile state at some degrees below 0 °C. Burt and Williams (1976) confirmed the validity of this assumption in an ingenious lab experiment. They measured the permeability of different frozen saturated soils at different temperatures closely below 0 °C using a permeameter in which water in two reservoirs was prevented from freezing by dissolved sugar. Their results suggest a decrease in hydraulic conductivity by 3–5 orders of magnitude from an unfrozen to a fully frozen state.

These results (from saturated frozen soils) conflict with a number of field studies and cold-chamber sprinkling experiments clearly demonstrating that under nonsaturated conditions liquid water very well may infiltrate into a frozen soil. There is strong evidence that for this "faster" water flow, the initially air-filled pores play a key role. Similar to low-permeable unfrozen soils, the largest pores, that is, cracks and macropores, become the dominant flow paths for infiltrating water unless they are blocked by ice (Seyfried and Murdock, 1997). The concept of water transfer through frozen unsaturated soil, assuming nearly immobile liquid water film in the smallest pores, and a faster water conducting flow domain in the largest (air-filled) pores, was implemented into a numerical model of soil water and heat transport by Stähli *et al.* (1996).

Whereas for saturated sandy soil it is plausible that water flow dominantly occurs through the liquid water film, it has become clear that for frozen clay soils with segregated ice lenses, additional water transport mechanisms have to be involved. In a classic lab experiment, Miller (1970) demonstrated that ice lenses are not impermeable to water redistribution, but allow water molecules to migrate through the ice, a process referred to *regelation*. The push for this redistribution of H_2O molecules through the ice arises from

pressure differences at both sides of the ice layer. A detailed discussion of this mechanism can be found in Miller (1980).

When describing water movement in frozen soils, what happens at the boundary between frozen and underlying unfrozen soil also needs to be considered. This transition zone is termed the *frozen fringe*. The steep gradient in water pressure difference between the frozen and the unfrozen soil layer induces upwards-directed water redistribution from the subsoil – especially when a shallow groundwater table is present. This uplift of water to the frozen fringe favors the formation of ice lenses and, thereby, forces the soil to heave. *Frost heaving* was earlier believed to be solely a consequence of volume expansion when water transforms to ice ($+9\%_{vol}$). Taber (1930) and Beskow (1935) were the first to show that more important for the initiation of frost heave was the redistribution of water towards the freezing front. Later, Miller (1978) postulated an additional mechanism responsible for the formation of new ice lenses and therefore further promoting frost heave, the so-called *rigid ice model*: Under a temperature gradient, segregated ice may move within the frozen fringe from warmer to colder regions. Soil particles are pushed apart when the ice pressure rises sufficiently, leading to a particle-free zone filled by ice, which is the newly developed ice lens.

INFILTRATION INTO FROZEN SOIL AND ITS SIGNIFICANCE FOR CATCHMENT RUNOFF

At the end of the winter season when the accumulated snow pack melts and releases a large amount of water to the soil surface, it is of particular concern to know whether this water may infiltrate or not. From the previous section, it can be expected that a frozen soil surface markedly reduces or even impedes water infiltration. This has been confirmed in numerous experiments of *local* infiltration into soil columns, plots, or fields. The effect of frozen ground on runoff from larger areas, however, is ambiguous, as a number of recent studies showed.

Local Infiltration into Frozen Soil

The infiltration behavior of frozen agricultural, forest, or alpine soils has been investigated extensively during the last 30 years in the field as well as in cold chambers. Several factors have been demonstrated to influence – directly or indirectly – the infiltration capacity of a frozen soil: soil texture, ice content, initial water content, soil surface management, soil temperature, the presence of a basal ice layer, the overlaying snowpack, and its melt rate, and so on. Many studies have shown concurrently that the total soil-water content at freezing is one of the key-factors governing the infiltration capacity of frozen soils. A dry soil in early winter clearly allows for considerable water infiltration, whereas nearly saturated frozen soils tend to build up a massive ice body and become nearly impermeable. This has been shown in field studies by Granger *et al.* (1984), who made direct *in situ* infiltration measurements at 90 sites in the Canadian Prairies, and Kane and Stein (1983) who used double-ring infiltrometers to determine infiltration rates into variable wet soils on a permafrost-free slope in Alaska. Also, a column study carried out by Stadler *et al.* (2000) in a cold chamber supported this hypothesis: two frozen sandy soil columns having different initial water contents were irrigated with two different dye tracer solutions during two successive 5-h periods. The columns were then sectioned vertically, and the distribution of the dye tracers analyzed. The depth profiles of the dye tracer concentration distribution in the two columns clearly confirmed the effect of the different initial water content.

For agricultural soils the treatment of the soil surface has a significant effect on the frozen soil infiltration, as many experimental studies have shown. Not only might furrows and cracks from tillage or ripping increase the macroporosity and improve water infiltration (Pikul *et al.*, 1990) but the presence of residue and stubble can also reduce the frost depth and thereby indirectly favor infiltration.

On sloped locations, inhibited soil infiltration may produce lateral surface or near-surface runoff associated with the risk for erosion. The partitioning between vertical soil percolation and lateral runoff in relation to the soil frost conditions and snowmelt release has recently been investigated on a boreal transect in northern Sweden (Stähli *et al.*, 2001), as well as in two studies in the Swiss Alps (Stadler *et al.*, 1996; Bayard *et al.*, 2005). The latter two studies nicely demonstrated the increase of lateral near-surface runoff with the presence of soil frost compared to unfrozen situations. The mechanisms for this enhanced lateral runoff appeared conspicuously in a dye tracer experiment by Stähli *et al.* (2004): An examination of vertical profiles, excavated in an early stage of the snowmelt, showed that the stained meltwater was concentrated in the uppermost 20 cm, demonstrating the impeding effect of the frozen zone (Figure 4). In addition, and probably even more important, was a basal ice layer that built up on the soil surface.

Large-scale Effects of Frozen Soil on the Hydrology

While the local influence of frozen soil on water infiltration is undisputed, it is much more difficult to prove its impact for catchment runoff or groundwater recharge at a larger scale. Most probably, this arises from the large spatial heterogeneity in frost occurrence and depth, as well as from reinfiltration of laterally displaced meltwater at lower areas. The heterogeneity of the frost distribution already becomes significant for water fluxes when we look at the runoff from single agricultural fields. Baker and Spaans (1997) provided an illustrative example on the Rosemont experimental field

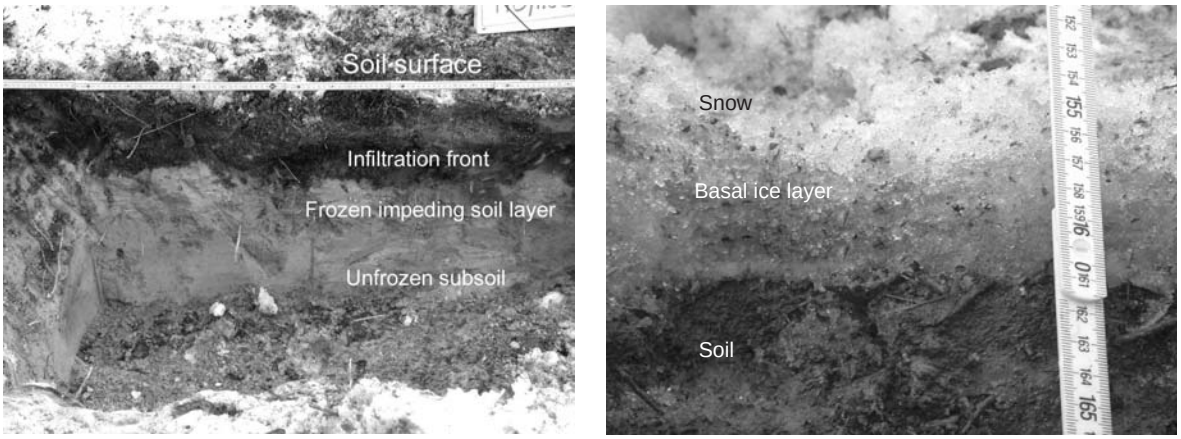

Figure 4 (a) Excavated vertical profile showing inhibited snowmelt infiltration into a frozen sandy alpine soil visualized with a dye tracer (dark color). The frost depth at this stage was approximately 45 cm. (b) Basal ice layer of a few centimeters built up at the base of the snowpack above frozen soil generating considerable lateral surface runoff (Images provided by D. Bayard, EPF Lausanne, and M. Stähli, WSL)

in Minnesota. During the spring melt, they first observed ponds of meltwater in local depressions of the field that suddenly drained in a short time although the soil was still considerably frozen. In a spatial examination of the frost distribution across the field, they found some single unfrozen locations in the depressions where the water obviously had bypassed the frozen soil layer. A closer analysis of the spatial distribution of soil frost across this relatively flat arable field (Cherkauer *et al.*, 2004) suggested that land use, soil moisture content, and soil properties were more important for the spatial pattern of soil frost than the thickness of the snowcover.

However, at a larger scale (e.g. watersheds) and especially in alpine areas with a more pronounced topography, the variation of the snowcover with its insulating effect becomes more dominant for the formation of soil frost. Unfortunately, studies on frost-depth distribution at the landscape scale are scarce.

Analysis of long-term records of frost depth and runoff from small forested catchments in Vermont (Shanley and Chalmers, 1999) and northern Sweden (Lindström *et al.*, 2002) did not support the hypotheses of faster runoff or increased peak flow with increasing frost depth. Also, Lindström *et al.* (2002) found that their hydrological runoff model, which did not account for soil freezing processes, did not simulate a systematic bias compared with runoff measurements in springs with deep soil frost. And finally, a study by Cherkauer and Lettenmaier (1999) demonstrated that runoff predictions for two subcatchments in the upper Mississippi River basin were not significantly improved by introducing a frozen soil algorithm that realistically simulated the frost-depth development.

All these published studies tend to imply that – in contrast to general belief, probably arising from local scale observations – catchment runoff is not significantly altered by the presence of a frozen soil.

FROST EFFECT ON OTHER SURFACE PROCESSES

Apart from soil infiltration and heaving, other important land surface processes are also affected by soil frost. It appears that during recent years, these processes – in the context of a changing climate – rather than the soil freezing and thawing mechanism itself have been addressed with more emphasis by the research community.

It has been recognized that water uptake by trees can be severely reduced by the presence of soil frost. This is of special concern for permafrost regions and boreal forest. Mellander *et al.* (2004) showed in a field experiment in northern Sweden that transpiration (*see* **Chapter 70, Transpiration and Root Water Uptake, Volume 2**) of 70-year old Scots pine trees on a deeply frozen soil plot was delayed by more than 1 month compared with a nonfrozen soil plot. The primary reason for inhibited water transport was not the lack of water availability, but rather the low soil temperature. In a similar study in New Hampshire in the United States, Tierney *et al.* (2001) observed larger fine root mortality on plots with deep soil frost, presumably because of mechanical damage from the pore ice, which is probably an additional reason for reduced water uptake.

Gas emission from the soil to the atmosphere seems to be strongly affected by frozen ground. Recent nitrous oxide emission measurements by Teepe *et al.* (2001) and van Bochove *et al.* (2001) have shown that accumulating gas is trapped below a frozen soil layer. As soon as the frozen layer melts, the trapped gases may escape to the atmosphere resulting in a considerable peak of nitrous oxide emission.

Thawing soils above a frozen subsoil have been shown to be most susceptible to surface erosion and rill or gully development (e.g. Oygarden, 2003). The high-surface saturation due to the low permeability of the frozen subsoil may temporally reduce the strength, increasing the potential for surface erosion. Surface residue cover seems to have a great impact in reducing frozen soil erosion (Cruse *et al.*, 2001).

NUMERICAL MODELS OF SOIL FREEZING AND FROZEN SOIL INFILTRATION

During the last 20 years, quite a large number of mesoscale meteorological models (*see* **Chapter 32, Models of Global and Regional Climate, Volume 1**), watershed runoff models (*see* **Chapter 132, Rainfall-runoff Modeling for Assessing Impacts of Climate and Land Use Change, Volume 3**), and erosion models (*see* **Chapter 82, Erosion Prediction and Modeling, Volume 2**) have been extended to mimic the presence of soil frost and its effect on surface processes (e.g. Bathurst and Cooley, 1996; Flanagan *et al.*, 2001; Mölders *et al.*, 2003).

But only a few numerical models have been developed with the principle goal of providing a detailed description of the combined water, heat, and solute fluxes in a freezing soil. The two models that probably have gained widest recognition are the Simultaneous Heat and Water (SHAW) Model (Flerchinger and Saxton, 1989) from the USDA Agricultural Research Service, and the Coupled heat and mass transfer (COUP) model for soil-plant-atmosphere system (former name: the SOIL-model; Jansson and Halldin, 1979; Jansson and Karlberg, 2001) developed at the Swedish University of Agricultural Sciences and KTH Stockholm. Both models simulate vertical water and heat fluxes in a layered (frozen or unfrozen) soil profile following the basic concept of the hydrodynamic model originally suggested by Harlan (1973). Boundary conditions, such as surface energy balance, snowpack, evapotranspiration, groundwater, or deep percolation are treated in detail by both models using standard meteorological data as the driving inputs. The models have been used for agricultural applications, as well as for studying the effect of winter conditions (possibly changing with a warming climate) on runoff and solute transport. The SHAW model and its user manual can be downloaded from **http://www.nwrc.ars.usda.gov/Models/SHAW/.**

The COUPModel includes a user-friendly interface and a comprehensive help manual. It can be downloaded from **http://www.lwr.kth.se/Coup.htm.**

For hydrological applications at the landscape scale, Cherkauer and Lettenmaier (2003) introduced a snow and frozen soil algorithm into the Variable Infiltration Capacity (VIC) macroscale hydrologic model (Liang *et al.*, 1994), allowing spatial variation in soil ice content. The code of the modified VIC macroscale hydrologic model is available at **http://danpatch.ecn.purdue.edu/~cherkaue/software.htm.**

Other numerical models of water and heat transport in a partly frozen soil have been developed by Zhao *et al.* (1997) in Canada, Gusev and Nasonova (2002) in Russia, and Ippisch (2002) in Germany. However, to the author's knowledge these models are not available for public use.

Acknowledgments

I would like to gratefully acknowledge the comments of Per–Erik Jansson, KTH Stockholm and John Baker, University of Minnesota, as well as the assistance of Melissa Swartz and Brian Mc Ardell in proofreading the manuscript. Financial support was provided by Swiss Federal Research Institute WSL.

72: Measuring Soil Water Content

G CLARKE TOPP[1] AND TY PA FERRÉ[2]

[1] *Agriculture and Agri-Food Canada, Ottawa, ON, Canada*
[2] *University of Arizona, Tucson, AZ, US*

Major advances in the measurement of soil water content have arisen from electromagnetic (EM) methods that have developed rapidly in the last 20 years. Estimates of water content from EM measurements make use of the large relative permittivity of water compared to other soil components. Time domain reflectometry (TDR) and capacitance approaches use "probes" that convey signal into the soil and thus can measure principally the upper one-meter depth. Ground penetrating radar (GPR) using noninvasive, transmitting, and receiving antennae possesses the capability to measure to even greater depths without causing soil disturbance. Remote radar and passive microwave methods, operating generally above 1 GHz, derive their information from within a few centimeters of the ground surface. Thermogravimetric and neutron moderation continue as viable long-standing methods but are being used less as these methods are not amenable to data-logging. The variety of instruments has increased the surface and near-surface soil water measurement capabilities. Now it is possible for hydrologists to make informed choices among methods, and it is important to do so to optimize their study results.

INTRODUCTION

The measurement of soil water content has undergone revolutionary advancements in the last 20 years. From having gravimetric sampling and neutron moderation as the primary field methods in the early 1980s, we now have numerous options, such as time domain reflectometry (TDR), capacitance (and impedance) devices, ground penetrating radar (GPR), airborne/satellite active radar, and passive microwave methods. These five newer methods are all based on electromagnetic (EM) measurements. The development of improved understanding of microwave interaction in soil was part of the basis for these advances, but could only be brought into practice with the accompanying development of instrumental capability for effective measurement at frequencies above 10 MHz and improved data handling capabilities for large data sets. All of the EM methods make use of the high relative permittivity (dielectric constant) of the water (80) in soil compared with the permittivities of the other soil components, which range from one for air to three to five for typical soil solids. Owing to this contrast, methods that measure the bulk dielectric permittivity of soil are effective for the measurement of volumetric water content.

The diversity of EM methods provides a great range of measurement opportunities at or near the soil surface. Capacitance and TDR methods allow for alteration of the configuration of their embedded probes to meet specific measurement requirements within the soil. GPR methods generate a signal whose interaction with the soil is detected with a dedicated receiving antenna and interpreted for estimation of water content. GPR, especially when used within boreholes, can be used to profile the volumetric water content to tens of meters depth. Remote radar from airborne or satellite platforms uses transmitter and receiver to obtain a reflection from the soil surface giving an estimation of water content. Passive microwave utilizes radiation emanating from the soil as a measure of the water content of the top few centimeters. Standard non-EM methods complement these EM methods. Neutron moderation techniques operate primarily below 20 cm depth, and the gravimetric method may be used from wherever appropriate samples can be removed for later laboratory analysis. In total, the hydrologist has available a variety of water content measurement possibilities from which to choose for specific applications. This article reviews the basis and capability of each method with a view to offering assistance when making choices among these water content measurement methods.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Several detailed procedural reviews of these methods are available for further reference (e.g. Noborio, 2001; Topp and Ferré, 2001; Hendrickx *et al.*, 2002; Huisman *et al.*, 2003a; Jackson *et al.*, 1996; Gardiner *et al.*, 2001; Topp and Ferré, 2002; Robinson *et al.*, 2003; Jones *et al.*, 2002; Wraith, 2003).

THE WAVE EQUATION FRAMEWORK FOR EM METHODS IN SOIL

As the majority of current water content measurement methods rely on the measurement of EM properties, a brief review of EM wave propagation follows as a framework for comparing these methods. Specifically, for in-field use, there are five well-developed EM techniques operating between frequencies of 10 MHz and 10 GHz. These rapidly developing methods for measurement of soil water content have their bases in an understanding of the propagation of EM waves in space or on a transmission line. The equation describing the transmission of an EM wave along a transmission line has the following form in the general case of a conductive medium (Kraus, 1984):

$$V(z) = V_1 e^{\alpha z} e^{j(\omega t + \beta z)} + V_2 e^{-\alpha z} e^{j(\omega t - \beta z)} \qquad (1)$$

where V is the voltage between the transmission line conductors, z is the propagation direction, V_1 and V_2 are constants, t is time, ω is the angular frequency, α is the attenuation coefficient, and β is the phase constant. In soils, the quantities α and β are dependent upon the water content and electrical conductivity of the soil and, therefore, serve as a useful indirect measurement of these properties. Other useful parameters for characterizing soil physical properties can be derived from equation (1), such as phase velocity, v, characteristic impedance, Z_0, and voltage reflection coefficient, ρ. Incorporating the electromagnetic properties of soils gives the following equations that form the basis of the EM methods presented here. The velocity of propagation of an EM wave is defined as (Von Hippel, 1954):

$$v = \frac{c}{\sqrt{\frac{\varepsilon_r'}{2}\left[1 + \sqrt{1 + \left(\frac{\varepsilon_r'' + \sigma_0/\omega\varepsilon_0}{\varepsilon_r'}\right)^2}\right]}} \approx \frac{c}{\sqrt{\varepsilon_{ra}}} \qquad (2)$$

where c is the velocity of propagation of light in free space, ε_r' and ε_r'' are the real and imaginary components of the relative permittivity or dielectric constant, respectively, σ_0 is the dc electrical conductivity, ε_0 is the permittivity of free space, and ε_{ra} is the apparent relative permittivity.

Although the soil electrical conductivity has offered some complication for EM methods, it can also be estimated from some measurements, such as TDR. This provides an extra characterization of the hydrological regime, which can be useful in monitoring processes such as soluble salt transport. The right-most approximation in equation (2) recognizes that conductivity is present in soil, but in the methods to be presented in the following section, the effects of conductivity are generally assumed negligible. The characteristic impedance and reflection coefficient are defined as:

$$Z_0 = 120\pi \sqrt{\frac{1}{\varepsilon_r' - j\left(\varepsilon_r'' + \frac{\sigma_0}{\omega\varepsilon_0}\right)}} \approx \frac{120\pi}{\sqrt{\varepsilon_{ra}}} \qquad (3)$$

where $j = \sqrt{-1}$, and

$$\rho = \frac{Z_L - Z_0}{Z_L + Z_0} \qquad (4)$$

where Z_L is the load impedance (of the soil, in our case). Although the reflection coefficient is presented here for a transmission line, it applies equally to reflections from boundaries in media for the radar backscatter and ground penetrating radar methods.

The Electrical Properties of Water – Pure and in Soil

The unique electrical properties of water, both pure and in soil, form the basis of indirect electromagnetic water content measurements in soil. The relative dielectric permittivity of water is generally more than an order of magnitude larger than that of other soil components. As a result, the bulk dielectric permittivity of a soil was found to be a function of the volumetric water content, with only a slight dependence on the volume fraction of solids and electrical conductivity (Topp *et al.*, 1980). In each of the five EM methods presented here, a measurement of the relative permittivity of the soil is used to infer the volumetric water content. In Figure 1, the frequency bands of these instruments have been superimposed on the relative permittivity of pure water as a function of frequency. The figure shows that for those methods that operate at frequencies below 1 GHz, ε_r' of pure water is constant over their entire operating range. The operating assumption underlying the inference of water content from dielectric measurements on soils is that the majority of the water in soil retains a relative permittivity very similar to that of pure water. The figure also shows that those methods that operate at lower frequencies also avoid the frequency band at which ε_r'' increases to a maximum. This imaginary part of the dielectric permittivity describes the dielectric loss that arises due to mechanisms of absorption such as molecular rotations, molecular vibrations, or electronic transitions. The dc electrical conductivity, σ_0, (see equation 2) adds to dielectric losses to

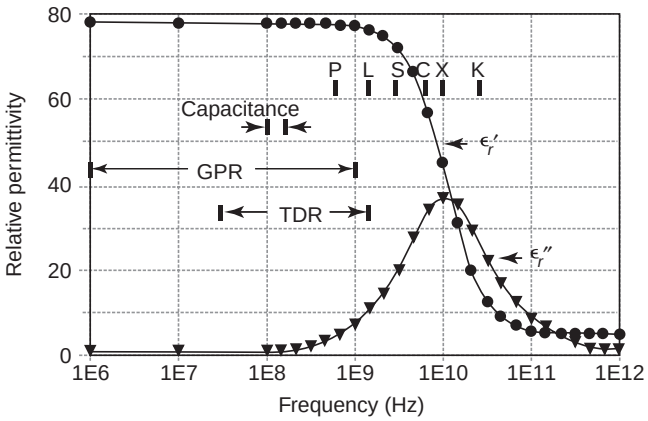

Figure 1 The real, ε_r', and imaginary, ε_r'', components of relative permittivity of water at 25 °C as a function of frequency. The operating frequencies of microwave sensors are designated by the letter band identifiers. Frequency range of other methods are also given (Reproduced from Topp and Ferré (2002) by permission of Soil Science Society of America)

produce greater attenuation of an EM signal travelling in a soil. For most nonclay, nonsalinized soils, these conductivity and dielectric loss effects are negligible, allowing for accurate measurement of the volumetric water content with EM methods operating between 30 MHz and 1 GHz.

There have been numerous attempts to establish the nature of the relationship between ε_r' and the volumetric water content to use as a basis for calibrations. Later improvements or refinements to the earlier empirical relationships have used dielectric mixing formulae that require more prior knowledge of the soil, such as density, texture, and/or organic content. The dielectric mixing formulae and related experimental work have shown a robust linear relationship between the volumetric water content, θ_v, and $\sqrt{\varepsilon_r'}$ is applicable for a wide range of soils (Topp and Reynolds, 1998):

$$\theta_v = 0.115\sqrt{\varepsilon_r'} - 0.176 \qquad (5)$$

This relationship deviates by less than 0.01 $m^3\,m^{-3}$ from the polynomial equation introduced by Topp *et al.* (1980) over the range 0.05–0.45 $m^3\,m^{-3}$. Equation (5) may be used for methods that measure relative permittivity (dielectric constant) as an approximation of ε_r'. We prefer to use ε_{ra} rather than ε_r' in equation (5), because it indicates clearly that there is an implicit assumption that electrical conductivity and/or dielectric loss influences are ignored.

TWO INTRUSIVE METHODS

The TDR and capacitance (and impedance) methods depend on probes to guide the signal through the soil being measured. Both methods have made use of parallel rods inserted into the soil from the surface to serve as the waveguide. Capacitance devices are also configured where both capacitor electrodes are on a single rod. In this case, the electrodes are as a sequence of parallel circumferential rings spaced along plastic pipes in pairs. The pipes are installed in the soil, usually inside another concentric plastic pipe. The EM fields fringing through the plastic interact with the soil. Similarly, TDR probes have been designed to measure through plastic sheaths.

TDR

Over the past 30 years, TDR has been used to measure water content at many scales and under a broad range of conditions (Topp and Reynolds, 1998; Robinson *et al.*, 2003) and has become a standard method of water content measurement second only to the thermogravimetric method. Most TDR instruments launch a fast rise voltage step (rise time < 200 ps) along a transmission line buried in the soil or medium of interest. The voltage pulse propagates as a planar EM wave, travelling in the soil and guided by the conductors. This waveguide is generally referred to as the TDR probe (Figure 2). As discussed below, these probes may have a variety of configurations. The properties of the soil that govern the propagation of the TDR pulse are described collectively by the propagation constant of the soil from which velocity of propagation (v) is derived (Ferré and Topp, 2002). The velocity, v, is entered into equations (2) and (5) to give the volumetric water content of the soil through which the EM wave has propagated.

The configuration of the waveguide or probe determines the extent and shape of the measured soil sample (Robinson *et al.*, 2003). The basic elements are conductive components, often parallel metallic rods, which act as waveguides and the soil material in which the wave or signal propagates. Currently, the most common soil probes are of the parallel rod type. The balanced pair transmission line, consisting of two parallel rods, rapidly became the probe of choice for use in field measurements (Figure 2). These usually varied in length, depending on the measurement requirement, from 0.1 to 1.0 m, and with rod separations from 0.01 to 0.1 m. In multipronged probes, one prong or wire is centrally located and variable numbers of prongs are located circumferentially around the central wire. These configurations, even with only two outer prongs, emulate a coaxial transmission line and result in a marginally improved TDR reflection over those from the balanced pair configuration. The extra rod(s), however, make for greater installation difficulty and associated soil disturbance compared with a parallel rod-pair. An important design parameter for accurate water content determination is the probe length. The minimum practical probe length for standard equipment is 10 cm. The upper limit on length of probe is largely determined by electrical conductivity, clay content, and maximum water content expected. The cross-sectional dimensions of TDR

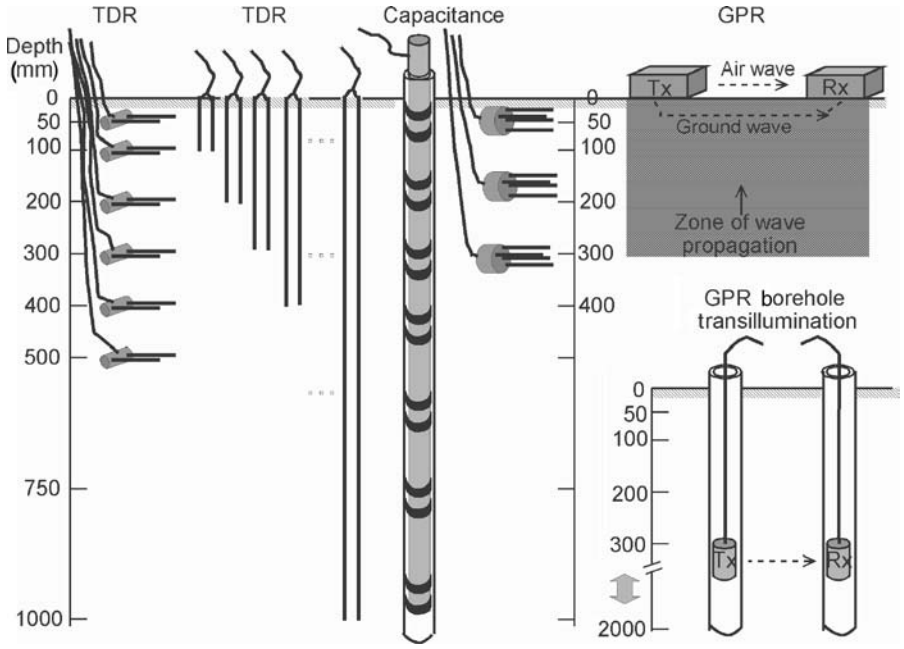

Figure 2 Schematic representations of two configurations each of TDR, capacitance, and GPR methods

probes, that is, the rod diameters and their separation, are at least as important as length considerations. Ideally, the EM energy should propagate in the soil well away from the regions that may be disturbed by inserting the rods. Ferré and Topp (2002) and Robinson *et al.* (2003) have provided more specific criteria affecting probe performance and the selection of probes. Detailed procedures for TDR measurement have been given by Ferré and Topp (2002).

An important application of TDR relates to the measurement of soil water content profiles or the vertical distributions to 1.5 m depth. Three general approaches for water content profiling are now available. Each offers certain advantages along with some limitations. Probes of sequentially increasing depths, inserted from the surface and near to each other, provide the total water to each depth (Figure 2). From these, one compares adjacent depths to get the water content in each depth interval. Secondly, individual TDR probes can be inserted into the sidewall of an excavation (Figure 2). Measurements from probes at a variety of depths give an estimate of the water content distribution with depth. Thirdly, the MoisturePoint TDR instrument (Environmental Sensors, Inc.) uses electronic segmentation of a single probe to isolate each depth increment for TDR measurement. Thus, selected depth intervals can be isolated during the TDR measurement giving the water content of each interval along the probe. Which method is best is dependent on the purpose for which data will be applied and the amount of allowable site disturbance. Excavation for horizontal installations causes the most disturbance.

The measurement and monitoring of soil water content have been advanced significantly by data acquisition and signal multiplexing capability. Although the Tektronix model 1502 B or C cable tester coupled with custom software and a PC have been foundational TDR instruments, numerous other instruments that have been designed specifically for soil measurement are now available (Ferré and Topp, 2002). Most commercial instruments perform analyses of the TDR traces internally and display or record the interpreted water contents only.

Capacitance Measurements

As the name implies, capacitance devices determine the apparent capacitance of a probe placed in or near a soil (Gardiner *et al.*, 1998; Paltineanu and Starr, 1997; Robinson *et al.*, 1998; Starr and Paltineanu, 1998). The capacitance probe (along with the soil) forms part of an inductance-capacitance (LC) resonant circuit with a specific frequency that depends upon the water content of the soil near the probe. The probe capacitance, C, is expressed as (Starr and Paltineanu, 2002):

$$C = g\varepsilon_{ra} \tag{6}$$

where g is the geometrical constant for the electrode configuration. With appropriate choice of inductance, L, it is possible to establish the resonant frequency for soil probes in the frequency range of 100 to 150 MHz (Figure 1) where salt and other conductivity factors are minimized. The oscillation frequency, F, is an inverse square root function of capacitance and a function of water content:

$$F = \left(2\pi\sqrt{LC}\right)^{-1} = f(\theta_v) \tag{7}$$

In principle, inserting equation (6) into equation (7) leads directly to a calibration equation for capacitance probes having a similar basis as equation (5). In practice, however, such a calibration approach has not proven robust and empirical calibrations are recommended for each soil. There are some instruments that operate on a very similar basis, although the manufacturers may claim to measure impedance or some other parameter. In effect, these are capacitance instruments since the capacitance contribution to impedance is the quantity most affected by water content.

Capacitance instruments can be adapted to use different electrode configurations (Figure 2). They generally fall into two categories, two or more parallel rods constructed to be pushed into, or buried in, the soil, or one or more pairs of cylindrical metal rings separated by a nonconducting plastic ring and mounted on a cylindrical support that is inserted into a previously installed PVC access pipe. The zone of influence or sensor sampling volume for rod-type capacitance probes is similar to that of a TDR probe using the same rods as a probe. That is, it is integrated along the length of the rods, and largely contained between the electrode rods. These probes are best suited for surface or burying near surface, provided soil disturbance by installation is minimized. Capacitance probes configured as one or more pairs of cylindrical metal rings are well suited for discrete depth interval measurements in the soil profile. The zone of influence of the electromagnetic field in the metal ring probes includes the plastic separating the rings, the PVC access pipe, and the surrounding soil that is in a fringe field of the capacitor. As a result, the sample area is limited to the region immediately adjacent to the access tubes.

Semipermanently installed capacitance probes placed in access tubes can be automated for real-time measurements over large areas, with probe readings essentially unaffected by cable lengths up to 500 m. The access pipe must be carefully installed so as not to introduce air-gaps along the pipe or disrupt soil structure near the pipe. Capacitance probes configured with multiple capacitance sensors are reported to be highly sensitive and robust for field-scale research. Starr and Paltineanu (2002) have given specific procedures for calibration and use of capacitance probes.

THREE NONINTRUSIVE METHODS

Three methods operating at frequencies >10 MHz, such as GPR, active microwave, and passive microwave methods, measure EM waves after they have propagated through and/or reflected from the soil. In each case, the detected wave contains the desired water content information. An electromagnetic induction technique, primarily aimed at measuring electrical conductivity, has been used to infer water content from electrical conductivity.

GPR

GPR is a geophysical method that uses electromagnetic signals that propagate as waves to map subsurface structure. GPR instruments are quite simple in concept, consisting of a transmitter, a receiver, and a data recording and display device. The details of making such devices in reliable, easy-to-use form are complex, and the instrumentation side of GPR has only recently come of age for effective application in soil. Even a few years ago, measurements discussed here were not practical because of instrumentation limitations. Electromagnetic fields are strongly absorbed by soils and rocks. In some situations, the fields are absorbed so rapidly that penetration into the ground can be very limited. Wave penetration is required to provide information at depths other than at the surface. GPR penetration is determined by the electrical conductivity of the soil, water content antenna frequency, and the presence of strong reflectors. Typical wave penetration would be 1 to 3 m in silty sands and nonsaline clays while low frequency GPR waves can penetrate tens of meters in dry, nonsaline sandy soil. As a result, GPR response is highly site-specific and testing at a specific location before use of GPR is highly recommended if substantial depth penetration is required. GPR is used for estimation of soil water content in several ways (Davis and Annan, 2002; Huisman and Bouten, 2003; Huisman *et al.*, 2003a), as discussed below.

For surface-launched and subsurface reflections and scattering, a GPR transmitter and receiver are placed on the ground surface to obtain good energy coupling into the subsurface and to minimize any effects of above-ground features. As the transmitter and receiver are moved over the ground surface, a GPR section is collected that images reflections from interfaces in the soil or scattering from localized objects. As with TDR, the primary information used for water content estimates is the velocity of the signal. Equations (2) and (5) can be used to relate this velocity to the volumetric water content. Unlike TDR, the EM wave transmitted from a GPR signal travels unguided through the medium. Therefore, the traversed path length must be defined in order to translate the recorded pulse travel times to velocities. Either discreet buried targets, such as buried pipes, or flat surfaces, such as a water table, can be used if their depth is known independently. The resulting water content from this method is a linear weighted average of the water contents along the travel path of the wave (Huisman *et al.*, 2003a).

Surface-launched direct wave arrivals make use of the fact that there are radar signals that travel both through the air and through the ground between the transmitter and the receiver (Figure 2), where travel path equals antenna separation (Huisman and Bouten, 2003). The physical process underlying the signal transmission requires that both the transmitter and the receiver be placed close to the ground surface. The signals travel through the air and

through the ground with the intrinsic velocities of the two materials. The ground signal will always arrive later in time. Measuring the differential travel time yields an estimate of the ground wave velocity since the source-receiver separation and the velocity in air are known. Using the ground wave velocity and combining equations (2) and (5), one can then infer the volumetric water content. Requiring only one transmitter and one receiver makes this method conceptually straightforward and offers the possibility for a system to be towed over the ground and make continuous recordings of the air-wave and ground-wave arrivals. In practice, however, the direct ground wave may not be always readily visible on the record, particularly in more electrically conductive soils. Although the transmitter and receiver must be in close contact with the soil, they must also be separated sufficiently from each other to give separation of air and ground wave arrivals (Huisman *et al.*, 2003b). The depth of the ground-wave measurement is a complex function of wavelength, soil properties, and antenna separation. The depth of wave propagation uncertainty gives ambiguity to the water content and requires more research investigation.

Air-launched surface reflection methods place the transmitter and the receiver at some distance above the ground using a wheeled vehicle or a low-flying air platform (Figure 3) (Redman *et al.*, 2002; Huisman *et al.*, 2003a). In these methods, the air-soil reflection coefficient is measured remotely, requiring no physical contact with the ground. The lack of physical contact leads to the attractive possibility of moving the GPR system rapidly over large areas to generate large-scale maps of soil water content conditions. The reflection coefficient from the air-ground boundary is represented by equation (4). To measure the reflection coefficient to the required high degree of accuracy, one must be able to measure the amplitude of the return signal. Usually, the system is calibrated by measuring the reflected signal from a "perfect" reflector such as a metal plate of sufficient areal extent to cover the measurement footprint. Extracting water content information involves substitution of equation (3) into equation (4) for the air-soil interface to obtain ε_{ra} of the soil. Equation (5) is then used to infer the volumetric water content. The operating frequency must be high enough, typically greater than 10 MHz, to eliminate σ_0 as a dominant factor in equation (3). The resulting water content measurement represents a nonlinear averaging over a depth that is dependent on the operating frequency and the water content, but heavily weighted to the near-surface conditions.

Surface-launched multioffset subsurface reflections use one or more transmitters and/or multiple receivers to measure the GPR response from a ground-based system. The array of units is moved over the ground and measures the signals as they travel over a multiplicity of travel paths at every measurement point. Essentially, this is equivalent to common midpoint, CMP, or wide-angle reflection and refraction, WARR, soundings commonly used in seismic geophysical sounding. The advantage of this approach is that it does not require any controlled information about the subsurface to be available to extract a radar velocity versus depth; it only requires the presence of reflecting

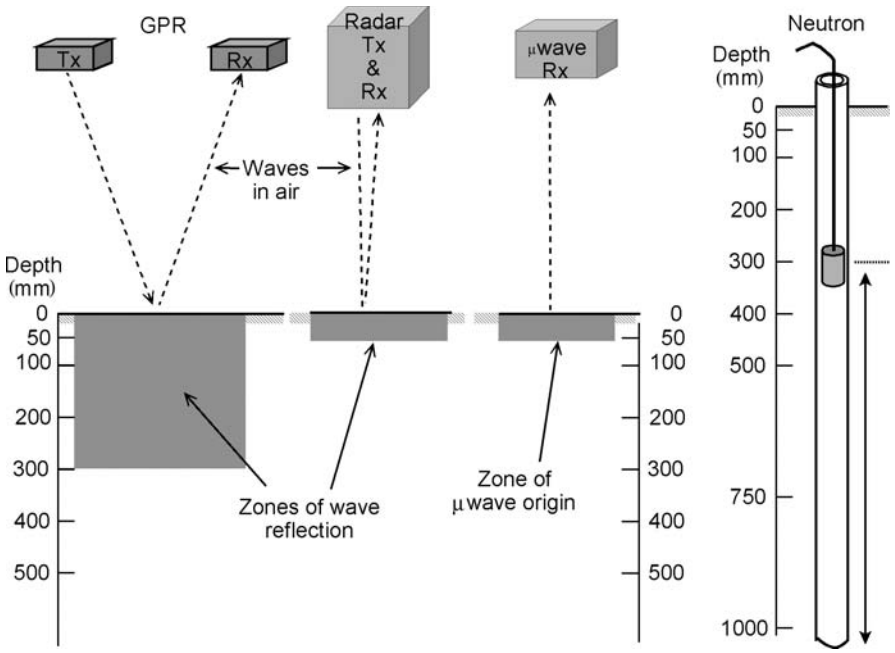

Figure 3 Schematic representations of air launched surface reflection GPR, active microwave remote sensing, passive microwave remote sensing, and neutron themalization methods

horizons or objects. The multiplicity of travel paths down and back from the reflecting horizon can be used to estimate both velocity and depth of the horizon. Measurement accuracies of better than 5 to 10% in volumetric soil water content are practical. This method is attractive and has been used in experimental groundwater investigations on a larger scale. The limitations of this method are that one must have detectable stratigraphy and adequate GPR signal penetration. In addition, multitransmitter and/or multireceiver GPR systems are not usually in standard commercial existence. The complexity and costs are factors that will likely preclude rapid advance of this technique except for research investigations. Use of a single channel instrument at successive separations is an inexpensive way to develop the technique before moving to the added cost of the multiple receiver system. The penalty is the time required to carry out each CMP sounding in the field. The advantage of this method is that it gives both reflecting horizon depth and water content as independent measurements from the data. One can envisage that a system like this could be towed over the ground to map water content versus depth over large areas in a fairly efficient manner. This approach to measuring soil water content is attractive, but the technological cost of the system will be high and the practicality of automated data reduction still needs to be demonstrated.

Borehole transillumination is a means whereby a transmitter or a receiver or both are placed into the ground and, thus, is, in reality, an intrusive measurement (Figure 2) (Parkin *et al.*, 2000; Ferré *et al.*, 2003). The physical measurement being made is the transit time for the signal between the transmitter and the receiver. Access pipes for transmitter/receiver may be vertical or horizontal. The method is fairly simple in concept in that one has known geometrical path lengths and one only has to measure the travel time to infer a velocity that can be associated with the particular path travelled. By making measurements over multiple paths and using tomographic reconstruction techniques, one can generate images of velocity in the subsurface. From this velocity image, one can then infer the water content distribution over the same area, using equations (2) and (5). The signal amplitude can also be measured and then the signal attenuation in the soil can be determined. This, combined with the velocity, permits the electrical conductivity to be determined. This technique has been demonstrated to work well and can be very reliable for making water content measurements (Ferré *et al.*, 2003).

The requirement for semipermanent access pipe(s) makes this technique much more of a site-specific investigation tool and may be used as a calibration or a reference point for area reconnaissance techniques. The minimum allowable separation of boreholes for ground penetrating radar transillumination is defined by the need to achieve far field EM transmission conditions. As a rule of thumb, this distance is approximately equal to the length of the dipole antennae used (e.g. 1 m for 100 MHz antennae). The maximum separation is limited by signal attenuation. As with surface ground penetrating radar applications, signal attenuation increases with increasing bulk electrical conductivity, increasing antennae frequency, and increased effects of dielectric relaxation. Unlike surface-based radar reflection techniques, borehole transillumination only makes use of the first arriving energy and only requires a one-way travel path through the medium. As a result, achievable borehole separations are typically at least twice the maximum depth of investigation using surface-based radar approaches. As an illustrative example, a 100 MHz signal can be propagated at least 2–3 m in most nonclay soils. However, it is recommended to estimate or measure the dielectric and electrical properties of site soils before installing borehole radar access tubes.

A number of commercial companies manufacture GPR instruments, primarily focused on geological, geotechnical, and engineering applications. All of the instruments are primarily designed for use in the reflection-sounding mode where the transmitter and receiver are placed in a single package. These are satisfactory for the air-launched surface reflection and the surface-launched reflection and scattering methods. The remaining GPR methods given here require separation of transmitter and receiver antennas, which is only offered by three commercial vendors (Davis and Annan, 2002).

Active Microwave Remote Sensing

Active microwave remote sensing (radar) is similar in principle to air-launched surface reflection GPR that can be mounted on either airborne or space-borne platforms. Synthetic Aperture Radars (SARs) in the 1 to 10 GHz frequency range are most commonly used for soil water content estimation (Boisvert *et al.*, 1996; Jackson, 2004). A microwave pulse is generated by a transmitter, and this signal is directed towards the ground target via a transmitting antenna (Figure 3). The polarization (generally horizontal (H) or vertical (V)) of the transmitted wave can be chosen by employing different antennae. The backscattered signal travels back to the radar's receiving antenna. A receiver then amplifies the signal, which is processed electronically to provide the transmission time, signal amplitude, and signal phase. The transmission time to and from the target is used to determine the range or distance to the target. The relative permittivity of the soil surface is the primary factor determining the strength of the signal returned to the sensor from the target. The frequencies used for soil water content estimation correspond to wavelengths in air of 3 to 30 cm. In wet soil, the wavelengths are reduced by a factor of approximately 5. At 5.3 GHz (C-Band and 6 cm wavelength in air), plants, plant residue, and surface roughness become major factors causing scattering of the

transmitted wave and, thus, obscuring a pure reflection and preventing the direct application of a reflection coefficient, equation (3), for determining the volumetric water content (Jackson *et al.*, 1997; McNairn *et al.*, 1996). Hence, empirical calibrations are most often used. Some semiempirical calibrations have been developed that make use of polarization data to estimate crop and roughness contributions and to refine estimates of soil permittivity. More research must be undertaken to develop models to account for vegetation effects, but using current approaches, soil water measurements from SAR are limited to surfaces without significant vegetation cover.

An important factor is the depth of soil sensed by the radar reflection. An approximate depth estimate is the wavelength in soil, which varies inversely with the water content. The 1 to 10 cm range is that which is measured by current radar systems. A high proportion of the reflection originates within the upper few centimeters, regardless of the water content. The lateral resolution of radar is at best 30 m and the lateral resolution of most methods used for calibrating radar has been of the 2 to 5 cm range. Hence, reference data for calibrating radar remains a challenge in that reference methods, usually TDR and gravimetric sampling, do not offer adequately fine vertical resolution and or sufficient lateral coverage. Nevertheless, successful correlation models for water content have been developed offering promise for further development and use of radar imagery for soil water mapping (McNairn *et al.*, 2002). In the context of soil water detection, airborne SAR images are currently used in research to simulate imagery of future space-borne systems.

Passive Microwave Remote Sensing

In the passive microwave method, the ground surface is the source of the EM signal. This signal is detected and interpreted for estimation of water content. This method measures the natural thermal emission of the land surface using very sensitive detectors that are tuned to specific frequency bands in the microwave region (0.3 to 30 GHz, Figure 1) (Jackson, 1993, 2002, 2004). Owing to the uncontrolled source strength, it is more complicated to infer the soil water content from these measurements than from active radar. Interpretations are made as follows: (i) normalize brightness temperature to emissivity; (ii) remove effects of vegetation; (iii) account for surface roughness effects; (iv) relate emissivity to relative permittivity; and, finally, (v) convert relative permittivity to water content using an equation similar to equation (5). The relationship between relative permittivity and water content was developed for passive microwaves by assuming that the emitting surface is a planar. This permitted the use of Fresnel reflection equations that predict the surface microwave reflectivity as a function of relative permittivity and the viewing angle. Invoking the relationship between reflectivity and emissivity, and assuming that effects of conductivity are negligible, one gets a relationship between relative permittivity and the measured emissivity. The presence of vegetation reduces the sensitivity to soil water content by attenuating the signal originating from the soil and by adding extraneous microwave emissions to the microwave signal. Because this attenuation increases as frequency increases, lower frequencies are commonly used. Semiempirical approaches have been used to correct emissivity for both vegetation and surface roughness.

The EM methods presented to this point have used gravimetric water content measurement as their primary reference for calibration. But, over the past decade, TDR has become an alternative reference because TDR is easier to use and provides equal or better quality data compared with gravimetric methods. This has not been the case for passive microwave measurements, where the development of calibrations followed the empirical path and developed separate equations for different frequencies and different soil textures based solely on gravimetric measurements. Curves for several combinations of these parameters as given by Jackson (2002) are shown in Figure 4. For comparison, equation (5) for TDR is also given (Figure 4). These passive microwave calibrations show close agreement with equation (5), particularly at lower frequency and for loamy textured soils. As shown by other researchers, there is increasing deviation from equation (5) with increasing clay content (Wraith and Or, 1999). As suggested above and in Figure 1, there is also a systematic difference between the TDR-measured dielectric permittivity and that measured by passive microwave methods as the frequency of operation increases beyond the TDR bandwidth.

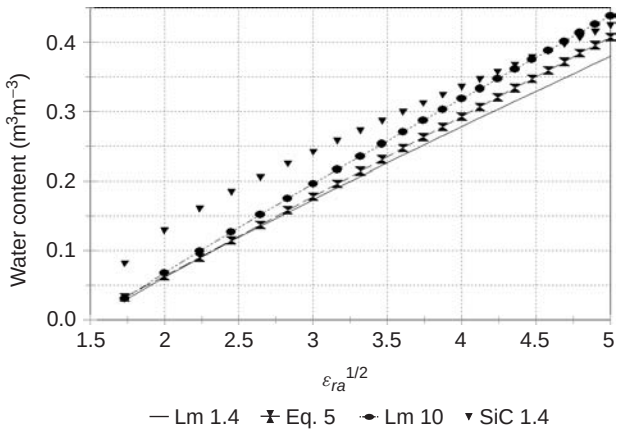

Figure 4 Water content to relative permittivity relationship from TDR (equation 5) and from passive microwave at 1.4 and 10 GHz for loam (Lm) and silty clay (SiC) soils (Reproduced from Topp and Ferré (2001) by permission of MFPA Weimar)

To date, passive microwave systems for soil water content have only been employed on aircraft platforms as prototypes of future space-borne instruments. Depth resolution limits for passive microwave satellites are similar to active radar but the lateral resolution is broader than for active radar, at greater than 50 km from current and future satellites systems.

Electromagnetic Induction

The bulk electrical conductivity (EC) of a medium is also strongly dependent on the volumetric water content. Because this property is relatively simple to measure, EC-based methods have long been used to infer water content. However, the EC is also sensitive to other soil properties, including the temperature, the clay content, and the salinity. As a result, EC-based water content measurements are best viewed as qualitative measures of water content. Electromagnetic induction (EMI) uses two antennae to transmit and receive electromagnetic signals through the subsurface. EMI instruments are not designed to measure the velocity of propagation of these signals as described above. Rather, they employ lower frequency signals and primarily measure the signal loss to determine the electrical conductivity of the medium and to measure different properties. The volumetric water content can then be inferred through relationships with the measured bulk electrical conductivity of the soil, but the calibration process is not straightforward and is both site- and temperature-restrictive. EMI has been used with success for intraseasonal comparisons in quite different geological and hydrological settings (Kachanoski *et al.*, 1988; Sheets and Hendrickx, 1995).

TWO LONG-STANDING METHODS, OPERATING ON NON-EM BASES

The thermogravimetric method has often been considered the only direct measure of water content as it determines the actual amount of water in a soil sample through evaporative drying of the sample. This method has long been considered the standard against which all other methods have been evaluated and against which procedures have been calibrated.

Thermogravimetric Water Content

In the gravimetric method, the water initially present in a sample is determined by recording the loss of mass in response to heating of the sample. Samples can be heated in a variety of ways including: incandescent heating to a controlled temperature to achieve a constant mass; microwave heating to a constant mass, and vacuum distillation of water to a desired vapor pressure level. Ovens using incandescent heaters and convective heat transfer are most common and a standard for mineral soils is based on heating at 105 °C until the mass of soil is constant (Topp and Ferré, 2002). Samples must be removed from the site of measurement for the gravimetric method. This method may be used for laboratory experiments and in field situations. The sample removal requirement makes this a method that is destructive of the site and not amenable to repetitive measurement or data-logging.

Although thermogravimetry is considered a standard method, it has a significant accuracy limitation that is often not recognized. The gravimetric method results in water content on a mass basis, which can be estimated to a high degree of accuracy. All other methods here included make estimates of water content on a volume basis. Conversion from mass to volume basis requires an estimate of soil bulk density, which can seldom be estimated to better than 5% accuracy. Hence, using the gravimetric method as a standard has at least this level of uncertainty associated with comparisons to other methods measuring on a volume basis.

Neutron Thermalization or Neutron Moderation

These instruments include a radioactive source of high-energy, (fast) neutrons. When these epithermal neutrons collide with atoms in the soil, they lose energy, becoming thermalized. Given that hydrogen nuclei are similar in size and mass to neutrons, they serve particularly well in thermalizing fast neutrons. Thus, a measure of the quantity of thermalized neutrons returning to a detector on the probe within a given time period gives a good measure of the saturation of hydrogen atoms in the soil. That is, the measured concentration of thermal neutrons changes mainly with changes in the hydrogen content of the surrounding material. On the timescales of normal interest in water management, changes in H content occur mainly due to changes in soil water content. Therefore, the concentration of thermal neutrons surrounding a neutron source can be precisely related to soil volumetric water content at the time. The source and detector are commonly placed together in a cylindrical probe that is lowered into the soil via a preinstalled access pipe (Figure 3). The volume of measurement is approximately a sphere with radius of about 0.15 m in a wet soil and up to 0.5 m at 0.02 m^3 m^{-3}, limiting measurements to 0.3 m depth and below.

In addition to hydrogen, atoms of oxygen, carbon, and nitrogen, as well as other soil components, are somewhat effective in the neutron thermalization. This requires that neutron probes be calibrated for each soil. There are well-documented calibration and use procedures (Hignett and Evett, 2002) from which it is possible to achieve accurate water content profiles to depths not easily attained with most other methods. As a result of the large and variable measurement volume, the method is inappropriate where detailed vertical definition is required or where sharp water

content gradients exist. Due to regulations concerning the use of radioactive sources, the method is not suitable for automatic, unattended measurement and is, therefore, labor intensive.

ON CHOOSING SOIL WATER INSTRUMENTATION

A number of methods of measuring soil water content have been described. While the wide variety of methods available is a benefit to hydrologists, it also embodies a responsibility to choose appropriately the instrumentation that will "do the job" most efficaciously. The variety of hydrological research and applications requiring soil water content is vast and precludes a prescriptive evaluation of the methods for all uses. We offer, instead, some considerations that should be included when initiating projects involving soil water measurement.

Accuracy and Precision Requirements

Although very important, accuracy is often not considered when choosing instrumentation but, instead, one adopts the assumption that more accuracy is always better. In addressing questions of accuracy, it is important to identify what will limit the accuracy of the final data to be used. For example, in environments where spatial variability contributes large uncertainties, more useful data may result from more replications in space using less accurate, more rapid methods. Furthermore, it is imperative to evaluate whether it is important to have absolute accuracy or relative accuracy. That is, most instruments provide better measures of the magnitude of change of water content than absolute water content. This is especially true of methods that require calibration for soil and vegetation factors such as capacitance probes, neutron moderation, active remote radar, and passive microwave. For GPR, there have not been enough studies to document its relative performance. TDR shows the least difference between relative and absolute accuracy, unless clay content is high and temperatures change dramatically (Wraith and Or, 1999). Relative accuracy is often limited by precision or repeatability of measurement. Improved precision results from those methods where fewer factors change between repeat measurements. Included here would be TDR using semipermanently installed probes, capacitance at installed sites, and neutron moderation.

The limit for accuracy for any method is determined by the accuracy of the reference method used to form the calibration equation. Traditionally, the thermogravimetric method has been the reference standard that has a practical accuracy of about 5% of the range (i.e., $\sim\pm 0.02\,m^3\,m^{-3}$), being limited by the accuracy of the bulk density as already stated. TDR has been shown to have a similar level of accuracy and has become widely used as a reference method for calibration of other methods, in particular GPR and active remote radar.

Sample Geometry

Each of the methods presented performs measurements over vastly different geometries of samples, making choices between instruments on this basis impractical. Sample geometry, however, can be an important consideration in at least two situations. Where two methods are to be used in complementary working relationship, it is important to optimize the complementarity by choosing appropriate sample arrangements. For example, TDR probes can be designed with a variety of configurations. Often, TDR is increasingly used to spot-check or monitor within transects of GPR and remote radar. In both cases, it is imperative that the TDR used for ground truthing measures throughout the same increment of soil, that is, tens of millimeters deep for remote radar and 100 s of millimeters for the GPR equivalent.

The geometry of the sampled soil should be representative of the hydrological process under study. In the case of intrusive devices (capacitance and TDR), the installation of probes and/or access pipes causes disturbance to the soil. Probe size and configuration must optimize the measurement in soil not affected by the installation and the installation must not affect the flow of water. This is particularly important for capacitance approaches where only the fringing EM field is used, which lies within the zone disturbed by the access pipes.

One of the most difficult regions of the soil to measure is at the soil surface, a most important hydrological interface. The factors affecting soil water content are usually variable in time and space as a result of vegetation, rainfall, traffic, and evaporation, all interacting to change the soil and water properties at the soil surface. TDR offers the best capability for accurate measurement in the 10s of mm depth, but one must choose the probe location and orientation carefully to assure that the EM field remains within the soil for measurement. Most existing TDR probes cannot be left in place at the surface as they would interfere with infiltration and evaporation. From 50 mm and deeper, horizontally oriented probes inserted from a small soil pit have worked successfully (Topp *et al.*, 2000). Improved measurements at the soil surface would be possible from TDR probes specifically designed for that measurement requirement. At the larger scale, surface-launched direct wave GPR may become an important method for monitoring near-surface water contents.

Site Replication

When it comes to field measurement in heterogeneous media, more is generally better. But, diminishing returns

and cost usually limit the number of replicates that can be collected. The nature and scale of variability generally determine the acceptable degree of replication. A number of geostatistical guides and handbooks are available to assist this choice (e.g. Warrick and Van Es, 2002). One will either need to characterize the site variability or to rely on previously obtained characterizations of the site variability to design optimal sampling protocols. For example, to have representative measure of the root zone soil water dynamics in a maize crop with 0.75 m row spacing, one would ideally choose cross-row lateral replication spacing and number in relation to the 0.75 m dimension. Many factors are not as conveniently periodic but should be recognized in developing a sampling strategy. Oftentimes, the number of measurement sites and the spatial replication at a site are restricted by instrumental or operational factors, such as allowable lengths of cables or land use traffic. Such restrictions cause the measurement site to be a surrogate sample and increase the requirement that such sites are adequately representative of the overall landscape and hydrological processes. All available site information becomes very helpful in the site selection process.

CONCLUDING REMARKS

The advancements in electromagnetic methods provide the hydrological sciences with a variety of choices for measurement of soil water content. These EM methods allow greater emphasis on soil water measurement at and near the soil surface, which is one of the most dynamic interfaces in the hydrological cycle. Capacitance, GPR, and TDR methods offer data-logging options to enable the recording of both spatial and temporal dynamics of the changes in soil water content. As these methods advance, it will be increasingly important that hydrologists make informed decisions regarding the most appropriate water content measurement method(s) for specific applications.

73: Soil Water Potential Measurement

WOLFGANG DURNER[1] AND DANI OR[2]

[1]Institute of Geoecology, Department of Soil Physics, Braunschweig Technical University, Braunschweig, Germany
[2]Department of Civil and Environmental Engineering, University of Connecticut, Storrs, CT, US

Soil water potential controls the dynamics of water in soils. This article describes methods to measure soil water potential. Available methods differ with respect to the moisture range where they are applicable. In the moist range, the pore water pressure of the soil is directly measured with tensiometers. In the intermediate moisture range, reference porous media are suitable, where the water saturation changes with water potential. Gypsum blocks, granular matrix sensors, heat dissipation matric potential sensors, and filter paper are used. If embedded in the soil and in hydraulic equilibrium with it, soil water potential is obtained by a calibration relationship from a water content dependent measurement in the reference porous medium. In relatively dry soils, water potential is derived from vapor pressure measurements by thermocouple psychrometry. This article presents the theoretical background of the various measurement techniques and illustrates the construction principles of measuring instruments. Problems and pitfalls of water potential measurements, in particular with tensiometers, are discussed. A list of manufacturers of water potential measurement instruments is given at the end of the article and a reference list provides material for further background information.

INTRODUCTION

Soil water potential reflects the energy state of water in porous media and thus drives movement of water. Its proper measurement is fundamental for the analysis of water dynamics in the vadose zone. The energy state of soil water can be expressed as energy per mass of water ($J\,kg^{-1}$), as energy per volume of water ($J\,m^{-3}$), which is equivalent to pressure (Pa), or as energy per unit weight of water ($J\ (9810\,kg\,m\,s^{-2})^{-1}$). The latter leads to the expression of the water potential as pressure head, with units of water column length (m), and is commonly used in vadose zone hydrology.

The lack of single measurement technology covering the entire energy range of interest, from moist to dry conditions present a challenge to the measurement of soil water potential. Tensiometry, which is an accurate and widely used technique to determine soil water (matric) potential, requires extensive maintenance and is restricted to relatively wet conditions. Instruments for water potential measurement measure beyond the tensiometric measurement range are heat dissipation sensors (HDS), gypsum blocks, granular matrix sensors, or filter paper. They all depend on equilibration of a reference porous medium with the surrounding soil and require individual calibration to infer soil water potential. At the dry end of the moisture range, thermocouple psychrometers, which use equilibrium water vapor pressure (relative humidity) in soil air, are often used to infer soil water potential.

Measurement range, accuracy, repeatability, response time, and spatial resolution of specific sensors are important considerations to their potential applications and in the analysis of soil water measurements (Or and Wraith, 2002). Our discussion in this contribution focuses on principles and applications of tensiometry, because this technology is the most widely used water potential measurement technology in practice. The techniques which extend the measurement range toward drier conditions will be presented subsequently, focusing first on the more classic reference porous media such as gypsum blocks and granular porous media, and then discussing the recent developments in HDSs. Finally, the principles of vapor pressure–based methods and thermocouple psychrometry along with available instruments will be described.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

GENERAL MEASUREMENT PRINCIPLES

The measurement of soil water potential requires hydraulic equilibrium between soil water in the porous medium around an instrument and the measurement device. For thermocouple psychrometers, this contact is provided by the vapor phase, and for all other instruments by the fluid phase. The tensiometer porous cup is placed in contact with the soil at the location of interest. The pore water outside the cup and the liquid in the interior of the tensiometer are bridged through water-filled fine pores of the cup. Following pressure equilibration, the liquid pressure in the tensiometer is directly measured by a manometer. This measurement technique is straightforward, but the pressure range is limited by the air entry pressure of the porous cup material. It is further restricted to pressures where the fluid is able to exert a pressure force, which in practice is stable only at positive absolute fluid pressures.

Measurement of water potential at drier conditions rely on reference porous media such as gypsum blocks, granular blocks of filter paper brought into close contact with the surrounding soil. With varying matric potential of the soil, the water saturation of these reference porous media vary in a characteristic manner, dependent on the particular pore-size distribution of the reference porous material. The sensor's water content is measured and related to matric potential by an individual calibration relationship. Indirect measurement methods are accordingly based on water content sensor technology, as described in Topp and Ferré (2005), and use weight, electrical, thermal, or dielectric properties of the reference porous medium to infer matric potential. Hysteresis and slow response introduce difficulties as discussed in the following sections.

Finally, the measurement of soil water potential in very dry conditions is based on equilibrium between liquid soil water and water vapor in the ambient soil atmosphere. The drier the soil the fewer water molecules escape into the ambient atmosphere, resulting in a lower relative humidity. The thermocouple psychrometer measures the dew-point temperature in a headspace of a closed chamber with gas-permeable walls, the value is related to relative humidity and soil water potential at the same ambient conditions.

Total water potential is composed of gravitational, matric, pneumatic, overburden, thermal, and osmotic components. For a fixed measurement point, we often disregard thermal and gravitational components (Durner and Lipsius, 2005). In a rigid porous medium, the solid phase does not contribute to the pressure of the water phase, and the overburden potential component can be disregarded. In the absence of semipermeable membrane, that is, when dissolved ions are free to move between the surrounding soil and the measurement cell, the osmotic component of the total potential will not affect the measurement (this is typical for all instruments referred to in this paper, except the psychrometer where vapor–gas interface represents an osmotic barrier). Therefore, psychrometers provide a combined measurement of osmotic and matric potentials. Tensiometers measure the sum of the pneumatic and matric potential, because tensiometer cups are impermeable for the gas phase. Reference porous media (HDSs, gypsum blocks, granular matrix sensors, filter paper) measure the matric potential only, because they are permeable for the gas phase in their operation range and the pneumatic potential does not contribute to the signal.

Any of the measuring instruments referred to thereafter influence the state of the signal to be measured. The measurement characteristic of an instrument is determined by the relation between the sensitivity and the conductance of the instrument. The sensitivity expresses the ratio between the change of the signal (pressure change Δp) with respect to the amount of water ΔV that is required to flow from the surrounding soil to (or from) the instrument (Richards, 1949),

$$S = \frac{\Delta p}{\Delta V} \tag{1}$$

The conductance is dependent on the area of exchange between instrument and soil, and on the flow resistance of the instrument. In the case of tensiometers, this resistance is determined by the thickness and the saturated conductivity of the porous membrane. In the case of equivalence porous media, it is dependent on the volume and porosity of the sensor and its unsaturated conductivity. In general terms, the measurement characteristic of modern advanced tensiometers is very good and almost constant across the measurement range due to the high sensitivity of the pressure transducers and sufficient conductance of the porous cups. The sensitivity of equivalent porous media (EPM) is lower, since by principle the water content of the sensor must change. Furthermore, the conductance varies with suction, since the flow rate is determined by the unsaturated conductivity of the EPM.

TENSIOMETRY

Tensiometers for matric potential determination along with TDR for water content measurement (Topp and Ferré, 2002; Topp and Ferré, 2005) are the most widely used measurement technologies for soil hydraulic properties in the field. Tensiometers are particularly suited for the measurement of soil water energy status at high water contents where transport processes are relatively rapid (e.g., solute transport from the vadose zone down to groundwater). Owing to their limited measurement range, tensiometers are unsuited for drier conditions where soil water becomes limiting for plant growth. Under relatively moist soil conditions, tensiometric measurements are robust, reliable, and accurate, with a considerable body of theoretical and practical knowledge gained by soil physicists,

hydrologists, and other practitioners. However, tensiometers require maintenance and their use at frozen conditions is problematic.

In the following, we discuss principles of tensiometric measurements, tensiometer design, and measurement range, and show recent developments. A treatise on all aspects of practical applicability of tensiometers, including a recent list of vendors of tensiometer systems and components (limited to US market) was provided by Young and Sisson (2002).

Measurement Principle

A tensiometer is used to measure the soil water energy state, which in unsaturated soils is dominated by the matric component of the potential (resulting from combined effect of capillary and adsorptive forces exerted by the soil matrix). A water-filled reservoir, connected to a pressure-sensing element (pressure gauge or transducer), is brought into contact to the soil through a rigid porous membrane, which is permeable for water and impermeable for air. The membrane is in most cases made of a porous ceramic cup, which is brought into contact with the soil by inserting the tensiometer into a predrilled access hole with a diameter at the position of the cup slightly smaller than the porous cup. Alternatively, the tensiometer can be inserted to a larger predrilled hole, where a slurry of nonswelling fine material or sieved local soil is filled in, which is used to provide hydraulic contact between the cup's surface and the soil. When the matric potential of the soil is lower (more negative) than in the tensiometer, water from the tensiometer is attracted by the surrounding porous media, thereby creating suction sensed by the pressure gauge. Water flows until equilibrium is reached and the suction inside the tensiometer equals the soil matric potential. When the soil is wetted, flow may occur in the reverse direction.

Partial contact between the cup and the surrounding material is in principle sufficient, since contact area does not affect the equilibrium pressure, but rather it affects the rate at which equilibrium is attained. Similarly, if material properties near the cup are altered by slight compression of the surrounding soil or by difference of hydraulic properties of the contact material, it does not affect the measured soil water potential value, as energy status is continuous across different porous materials in hydraulic equilibrium.

The porous cup consists of a rigid, fully wettable material with pores of radius r_{max}, through which the spatially discrete arrangement of the water phase of the porous medium (outside the membrane) is connected with the continuous water phase inside the membrane. The fluid pressure outside and inside the membrane equilibrates, and is measured by a pressure sensor. In most cases, the membrane has the form of a porous ring or a porous cup at the scale of few centimeters, and pure water is used as a pressure transducing fluid. To operate properly, the pores of the membrane must remain impermeable for the nonwetting fluid (soil, air), that is, fully water saturated. Pore openings of the membranes are in the range of micrometers, which is about 6000-fold larger than the size of a hydrated Na molecule (Young and Sisson, 2002), thus making them permeable to dissolved ions. Hence, the pressure measured inside the porous cup is not affected by the osmotic potential component.

In most hydrological applications, it is not the absolute pressure of soil water that is of interest, but rather the capillary pressure, which is defined as pressure difference between the water and the gas phase in the soil

$$p_w - p_a = p_c + \frac{1}{L}\frac{\partial \theta}{\partial t} \tag{2}$$

where p_w is the macroscopic pressure in the water phase, p_a is the pressure in the air phase, p_c is the capillary pressure, L is a nonnegative material coefficient, and t indicates the time. Under hydrostatic conditions, the capillary pressure is equal to the matric potential (Hassanizadeh *et al.*, 2002). This equality is implicit in most vadose zone hydrology applications, even at transient conditions. Pressure sensors used for tensiometers, therefore, typically are differential, measuring the difference between the pressure in the tensiometer cell and ambient air pressure, which is negative in unsaturated soils. The absolute value of this pressure difference is called *suction* or *tension*. For isothermal conditions and negligible effect of soil overburden pressure, this suction represents the matric and pneumatic potentials.

For most practical purposes, the contribution of the pneumatic potential in the unsaturated zone is zero, that is, gas pressure in the vicinity of a tensiometer cup is equal to ambient atmospheric pressure. However, there are cases where during rainfall, a layer of air may become sandwiched between a sharp wetting front and the groundwater, and air pressure will increase substantially. Also, in soils that are very wet, the local pressure of enclosed air is not identical to ambient air pressure as long as the gas-phase continuity is restricted. If the tensiometric pressure in such cases is interpreted as matric potential, it will be a misconception and this contributes to a class of phenomena called *dynamic effects* (Schultze *et al.*, 1999; Durner and Lipsius, 2005).

Measurement Range

The measurement range of tensiometers is restricted by the air entry pressure of the porous membrane, p_e. The capillary rise equation relates this pressure difference to a pore size

$$r = \frac{(2\sigma \cos \varphi)}{p_e} \tag{3}$$

where r is the effective pore radius (L), σ is the surface tension between fluid and gas phase (MT^{-2}), φ is the contact angle between the fluid and the cup material, and p_e is the air entry pressure ($ML^{-1}T^{-2}$). To remain fully water saturated up to a pressure difference of 1 bar, membranes of perfectly wettable material ($\gamma = 0°$) must have pore diameters smaller than 3 μm. Young and Sisson (2002) list the properties of various materials used in practice. Mostly, porous ceramic materials are used as membranes, with maximum pore diameters of about 2 μm.

A second constraint to tensiometric measurement range is imposed by the spontaneous boiling or cavitation of water inside the tensiometer at subatmospheric pressures. As the energy state of water in the porous medium becomes more negative and the liquid water pressure inside the tensiometer approaches the vapor pressure $p_v(T)$ at ambient temperature, T, spontaneous evaporation (boiling) of water occurs. However, thermodynamic equilibrium can be inhibited for considerable periods. This metastable state associated with the delay in boiling (defervescence) enables considerable extension of tensiometric measurement range. The theoretical limit of suction is given by the energy needed for cavitation in a pure water phase, which needs a calculated tensile strength of 140 MPa (Fisher, 1948; Zheng *et al.*, 1991). Practical limits of 140 kPa (microtensiometer model #4, Nardeux, St. Avertin, France; Tamari *et al.*, 1993) and −400 kPa (microtensiometer model T5, UMS, Munich; G. von Unold, UMS Corp. Munich, personal communication), and −1400 kPa (tensiometer prototype; A.A. Diene, *Development For High Suction Tensiometers Analyzed in Laboratory Lysimeters in the Study of Drainage*. MSc. Thesis, COPPE/UFRJ, Rio de Janeiro, Brasil) have been reported. If the stress on water surpasses the boiling inhibition, a sudden pressure jump occurs in the tensiometer cell to the pressure of the water boiling point. Requirements for a stable defervescence are the absence of boiling germs, absence of air bubbles or dissolved gases, a strongly hydrophilic ceramic surface, a low-enough air entry value of the porous ceramic, and surfaces that are all hydrophilic and polished, even pressure transducer and ceramic. To reach this, a clean and precise manufacturing is necessary. As a further technique, microorganisms are applied, which apparently "bind" water by adhesive forces to all surfaces, and take up the rest of dissolved gases (G. von Unold, UMS Corp., personal communication). In such a system, the defervescence is reversible and reproducible.

Tensiometer Designs

Historically, the concept of soil water potential in unsaturated soil was introduced by Buckingham (1907) from a theoretical perspective. The most widely cited first descriptions of tensiometers are attributed to Gardner *et al.* (1922) and Richards (1928), but recently Or (2001) has shown that already Livingston (1908, 1918) had proposed the use of a tensiometer, consisting of a porous water-filled cup and a pressure manometer. In these early descriptions, a liquid-filled porous cup is connected to a U-manometer, filled with water or mercury (Figure 1).

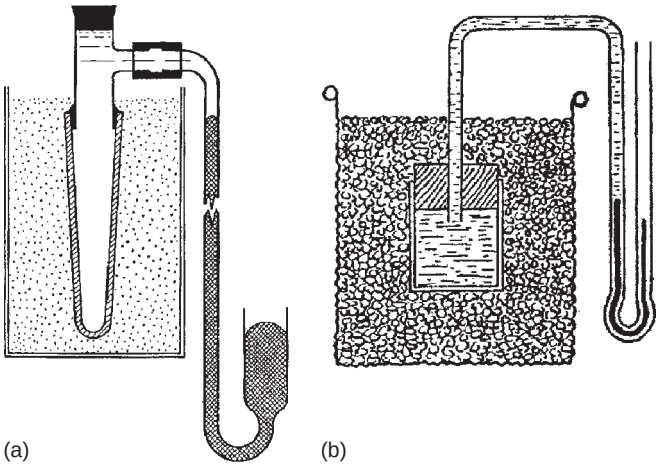

Figure 1 (a) Richards (1928) *tensiometer design*. (b) Haines (1927) *design attributed to* Livingston (1918). (Reprinted from Or (2001) with permission of Soil Science Society of America)

Up to the 1980s, tensiometers were constructed on the basis of the design shown in Figure 1, using mercury manometers. These instruments have advantages with respect to the accuracy of the readings, but suffer from inherently sluggish response times owing to their low sensitivity.

Mechanical Tensiometer

Owing to environmental concerns and their low sensitivity, mercury manometers were replaced by mechanical pressure gauges and pressure transducer tensiometers in laboratory experiments (Vachaud and Thony, 1971) and field investigations (Bianchi, 1962; Watson, 1967). Problems are manometer hysteresis, temperature effects, and costs.

Tensiometers Without a Permanent Manometer (Septum Tensiometers)

In an attempt to reduce costs, Marthaler *et al.* (1983) proposed a mobile pressure transducer system. This type of tensiometers is in wide use nowadays. Tensiometer tubes without a manometer are installed in the soil, filled with deaerated water, and plugged with septum stoppers. A mobile electronic pressure transducer manometer is connected to a syringe needle, which is stitched through the septum to measure the pressure in the tensiometer. Insertion of the syringe needle into a completely water-filled system exerts a positive pressure and can significantly alter interior pressure, which in turn drives a small amount of water out of the ceramic cup. To avoid this, Marthaler *et al.* (1983) recommend leaving a 2-cm high air bubble

at the upper end of the tensiometer. Inserting the needle into the air pocket below the septum leads to a moderate increase in pressure, which again leads to a leakage of water into the soil, resulting in a new equilibrium pressure. Marthaler *et al.* (1983) estimated complete reequilibration to take from 2 to 10 min. In practice, this type of tensiometer needs careful and skilled operators. Otherwise, problems with clogged needles, air leakage while boring through the septum, air leakage by perforation of septums, and temperature effects (Warrick *et al.*, 1998) make readings unreliable. Furthermore, the existence of an air bubble leads to a dramatic worsening of the instrument's sensitivity at high suctions, as will be shown later.

Generally, these tensiometers may not be suitable for precise measurements.

Pressure Transducer Tensiometers

In pressure transducer tensiometers, a metal membrane of a permanently connected pressure transducer is deformed by a pressure change. The electrical response can, for example, be caused by a silicon crystal, onto which a piezoresistive circuit is fused (Tandeske, 1991). Pressure transducer tensiometers have a far higher sensitivity than U-manometer tensiometer, and are nowadays widely used. Further, they allow automated logging of the tensiometer signal in almost arbitrary temporal resolution, which enables us to measure the fast changes of the pressure signals in soils during transient flow processes, thus enhancing our process understanding of water flow in soils. Following traditional tensiometer designs, the early pressure transducer tensiometers had the manometer installed at the soil surface as the tensiometer tip is transmitted by a water column to a manometer located at the soil surface. This makes them very sensitive to temperature fluctuations, as will be discussed below. Furthermore, their use at larger depths is impractical.

Advanced Tensiometers

The most advanced way to measure pressures in tensiometer cells is by electronic pressure transducers that are embedded in the instrument directly at the ceramic cup. Advanced pressure transducer-equipped tensiometers have features that enhance measurement stability and control (Sisson *et al.*, 2002) such as: (1) integrated amplifier and signal conditioning for the electric output, (2) temperature-compensation and proximity to the porous cup, (3) filling status indicator, (4) external *in situ* refilling, and (5) an integrated temperature sensor in the porous cup for additional control of temperature effects. Figure 2 shows the design drawing of such tensiometers. Figure 3 shows two examples of commercially available modern tensiometers.

Self-filling Tensiometers

Recently, a self-filling tensiometer has become commercially available (TS1, UMS, Munich, Germany). After drying periods, when the soil is rewetted by rain, an integrated

micropump, controlled by an onboard controller, starts to suck the water from the soil into the tensiometer until the whole interior is water filled again. The rate of water intake can be concurrently used to estimate the unsaturated conductivity of the surrounding soil.

Osmotic Tensiometers

Various designs attempt to extend the range of tensiometers by filling the tensiometer with solutions made up of large molecules (see Figure 4). Peck and Rabbidge (1969) used polyethylene glycol with a molecular weight of 20 000 to extend the measurement range to −15 bar. They stressed the importance of temperature correction in this system, since thermal transients give rise to expansion of both

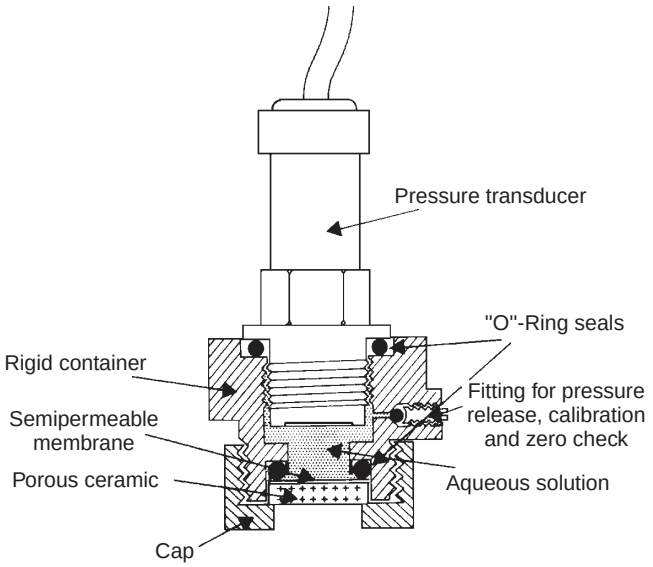

Figure 4 Schematic of an osmotic tensiometer. (Adapted from Peck and Rabbidge (1969) with permission of Soil Science Society of America)

the solution and the tensiometer cell, giving "spurious" readings. Bocking and Fredlund (1979) investigated the practicability of the osmotic tensiometer and concluded that many difficulties stand in the way of a routine application, amongst them leaking and drifting, slow response time, and temperature dependence. Biesheuvel *et al.* (1999) simulated the response of the osmotic tensiometer, incorporating membrane permeability, instrumental sensitivity, differential temperature change, and osmotic pressure – temperature dependency. They found reasonable accuracy when comparing their model with results obtained from a prototype that was exposed in a climatic chamber in pure water. However, Gee and Ward (1999) conclude that despite recent attempts with improved membrane materials and sensor configurations, to date the problems of sensor drift and leakages of the osmotic solutions remain unsolved, and no commercially osmotic tensiometers are presently available.

Measurement Practice

Good measurement practice with tensiometers requires knowledge on proper installation and maintenance, and interpretation of the signals. The specific measurement characteristic and the practical functioning of a tensiometer will depend on a variety of factors. Among those is the type of pressure sensor, the size and type of the porous cup material, the amount of water and air inside the tensiometer, and the contact between the tensiometer and the surrounding soil.

Soil-tensiometer Contact

For any instruments for soil water potential measurement, the hydraulic contact between the tensiometer cup and the soil is essential for a proper operation. If the tensiometer cup is pressed in a predrilled hole that is slightly narrower than the diameter of the cup itself, this contact is generally sufficient. In stony soils, this practice might, however, not be feasible. In these cases, either a slurry of local sieved fine soil or else a silty contact material can be used to provide contact in a predrilled access hole of larger diameter. Sand cannot be used as contact material, since the hydraulic contact at lower potentials gets essentially lost owing to the steep decrease of sand's unsaturated conductivity. Clay and loam material is also not recommended, since it hampers the fast equilibration at high potentials because of its low saturated conductivity, and, further, is likely to shrink when the soil is drying, thus creating an isolating crevice between the soil and the tensiometer cup.

Response Times

The response time of a tensiometer is determined by the sensitivity S of the reading and the resistance R of the cup/soil system against water flow (Flühler and Roth, 2004)

$$t_r = \frac{R}{S} \tag{4}$$

where the sensitivity S is defined by equation (1), and the resistance of the cup is given by

$$R = \frac{1}{k_{cup}} = \frac{d_{membrane}}{A_{cup} \cdot k_{membrane}} \tag{5}$$

In (4) and (5), t_r is the response time (T), S is the sensitivity of the reading with respect to volumetric water exchange between soil and instrument ($M L^{-4} T^{-2}$), R is the hydraulic resistance of the porous cup ($L^4 T M^{-1}$), V is the volume of Water (L^3), k_{cup} is the hydraulic conductance of the cup, $d_{membrane}$ (L) is the thickness of the cup, A_{cup} (L^2) is surface the of the cup, and $k_{membrane}$ ($L^2 T M^{-1}$) is the hydraulic conductivity of the cup material. In the early water tensiometers and mercury tensiometers, the response times were slow, even in wet soil, because the sensitivity S was low. Advanced tensiometers, which have very small water reservoirs and highly sensitive pressure transducers nowadays have response times in the range of seconds, if measurements are done at wet soil conditions. A further improvement in the response characteristic of tensiometers results from minimizing the flow resistance of the porous cups. This is achieved by "high flow" material, where the bulk of the porous cup is made of a material with large pores, and just a skin on the outside of the tensiometer has pore sizes in the required range of small pores. In relatively dry soil, however, the response time of the instrument is primarily affected by the resistance of the

soil to unsaturated water flow around the tensiometer cup. This leads to response times in the range of minutes in the intermediate moisture range, up to days at the dry range.

Temperature Influence on Readings

Temperature changes and the formation of gas bubbles pose particular problems for tensiometric measurements. Temperature changes may cause spurious readings, because they affect the calibration of the pressure sensor, the expansion of the tensiometer shaft and the cup material, and the expansion of water. The combined effect is not easy to correct. Air-temperature fluctuations in the exposed head space of the tensiometer can cause large air-pressure changes, leading to misinterpretation of the soil water potential (Butters and Cardon, 1998). Warrick *et al.* (1998) showed in the limiting case of zero conductivity around the tensiometer cup that a cyclical variation of temperature of $35 \pm 15\,^{\circ}\mathrm{C}$ leads to variations in water pressure inside the cup of $\pm$70-cm water head. While cup impedance was found to be a negligible factor, their analysis suggested that conductivity of the soil immediately around the cup is the main factor governing temperature-induced pressure fluctuations inside the cup.

Frost

Measuring matric potentials at temperatures below $0\,^{\circ}\mathrm{C}$ is a challenge, since water in the tensiometer, which acts as pressure-transmitting agent freezes and the tensiometer fails. In some instances, the use of a glycol-water mixture or the combination of water in the measurement cell with oil above it toward the surface has been proposed. Finally, for larger depths ahead of the freezing front, it would be possible to obtain measurements with an advanced tensiometer (no continuous water column to the surface).

Formation of Gas Bubbles

If a tensiometer reading approaches its minimum pressure, gas bubbles (air or water vapor) may come into play, which reduce the sensitivity of the system. A large gas bubble in the system essentially deactivates the reaction. Gas entry can be caused by (i) exceeding the air entry value of the membrane, (ii) aggregation of small air bubbles, which result from dissolved air in the water that has been filled into the tensiometer, (iii) air that diffuses through the porous membrane, in particular over long measurement times, and (iv) by reaching the boiling pressure of the soil water. To reduce the effects of gas bubble formation within the tensiometer during a long-term operation, air stripper tensiometers have been introduced using a stripper tube in the porous cup to continually remove air (Miller and Salehzadeh, 1993). The tube contains droplets of water ("wet vacuum") to minimize net diffusion of water molecules into and out of the tube.

Tensiometer Performance in Drying Soils

When a soil is drying, the response times of tensiometers can become much longer, in particular, if their sensitivity is not high. In general, the decrease in performance is not caused by the conductance of the porous cup, but rather by the decreasing conductance of the surrounding soil, which becomes the limiting factor. The deterioration of the response characteristic in drying soils is, in particular, dramatic in cases where there is an air bubble in the head space of a tensiometer, as recommended for stitch tensiometers, since the expansion of the air bubble causes the sensitivity of the instrument to continuously decrease with increasing tension.

This is illustrated in Figure 5, where the interplay between the matric potential and the tensiometer response in a drying soil is modeled. The simulated domain is 2-D in cylindrical coordinates, with a depth of 100 cm and a radius of 75 cm. The tensiometer has a length of 30 cm and is placed 25 cm in the soil, with a porous cup of 50 mm length and 12.5 mm radius at its end. The tensiometer is originally filled with air-free water, but has an air bubble of 1-cm length at the top. The soil is a silty loam with a homogeneous initial capillary pressure of -10 kPa. Drying takes place with a transpiration rate of 5 mm day^{-1} through root water uptake, with roots being equally distributed along the upper 50 cm. Figure 5(b) shows how the tensiometer cup short-circuits pressure differences along the drying front in the surrounding soil matrix. With ongoing drying of the soil, the expansion of the air bubble in the tensiometer causes water to leave the tensiometer, but this effect is negligible up to a pressure of -50 kPa at about 12 days. After that, the unsaturated water flow in the soil surrounding the tensiometer is no longer high enough to keep the tensiometer reading in equilibrium with matric potential at some distance from the instrument. From then on, the tensiometer acts more and more as a local irrigation device, and the true pressure deviates far from the measured pressure. This analysis confirms experimental results by Reece (1996) who compared HDS measurements with tensiometric measurements and found tensiometers to be less responsive and measuring less negative potentials in the range from -70 to -90 kPa.

The important point is that there is no indication from the tensiometer reading itself about this deviation, except from the observation of an increasing length of the air bubble. The extent of these kinds of deviations in a specific practical situation depends on factors such as soil type (in particular, unsaturated conductivity), rate of transpiration, and root distribution.

The systematic deviation between true soil state and tensiometer reading can be amended to a large extent by the use of advanced tensiometers. This is illustrated in Figure 6, which shows typical tensiometer readings during

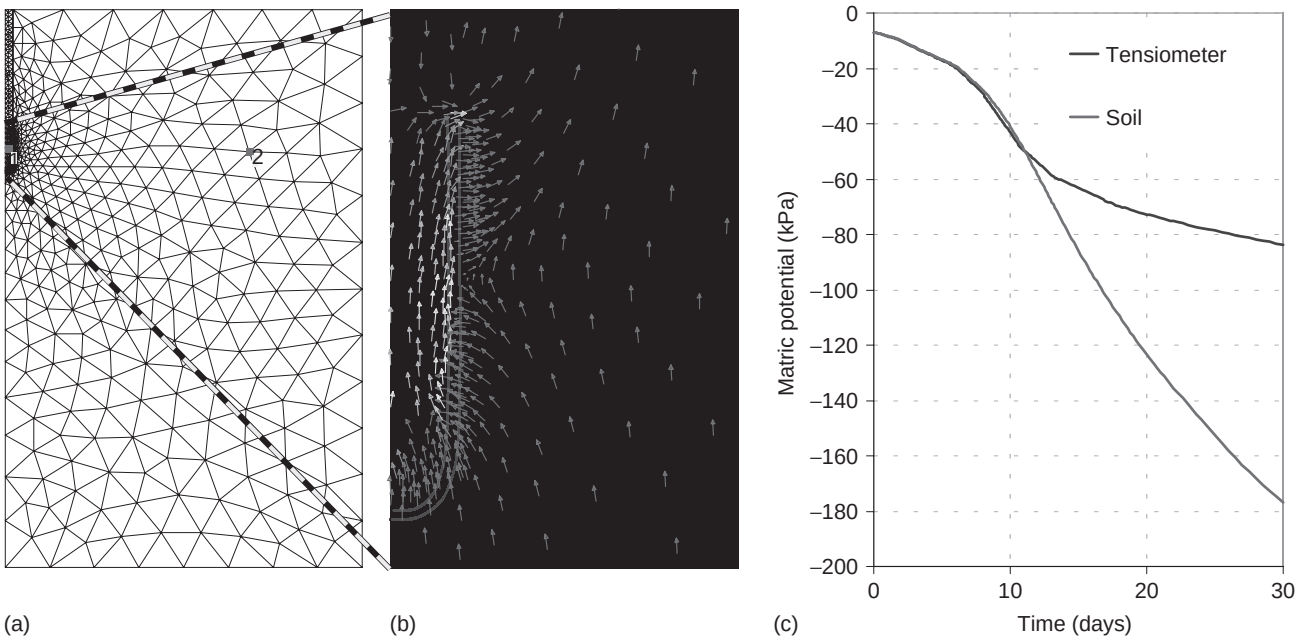

Figure 5 Hydraulic functioning of a vertical tensiometer with a small gas bubble. (a) Simulated domain. (b) Flow through the porous cup at $t = 30$ days. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

a vegetation period. The accordance of the readings of the instruments that are placed in parallel at 20 cm and 40 cm depth is excellent. Second, we see the influence of root water extraction in the form of daily oscillations. In the early period, when the roots are just in the upper soil, only the tensiometers at 20-cm depth show this influence. At later time, the roots' influence can be seen at the depths of 40, 60, and finally also at 80 cm. Upon close inspection, one sees that the two tensiometers at 40-cm depth are not equally affected by the roots, which indicates local differences in root activity in the direct vicinity of the two tensiometers.

Since defervescence cannot be avoided on the long range, boiling occurs in the tensiometer once its measurement range is reached. For the uppermost tensiometers, this is the case around May 27. Then, the build up of the vapor phase inside the membrane leads to water flowing out of the tensiometer, wetting the surrounding soil. The pressure inside the tensiometer will remain at the level of the temperature-dependent vapor pressure until all water inside the cup has evaporated. The pores of the membrane remain water filled (Figure 6).

When all water inside the porous cup has been absorbed by the soil, the water release from the porous membrane to the surrounding soil ceases and water potential starts to drop quickly. Soon the air entry point of the largest pores in the membrane is reached and some pores become conductive to air. This leads to ventilation of the cup, and the pressure inside the tensiometer cup rises steeply until it reaches atmospheric pressure. For the depicted tensiometers at 20-cm depth, this is the case on June 7. After that, the instrument can only be used if the cup is again filled with degassed water.

GYPSUM BLOCKS AND OTHER REFERENCE POROUS MEDIA

Measurement of soil matric potential in the intermediate pressure range between tensiometric (0 to −90 kPa) and field psychrometers (500 to 50 000 kPa) poses experimental challenge. Limitations in obtaining direct measurements resulted in reliance on alternative methods based on measuring water content or water content–related properties in well-characterized reference porous media that are in hydrostatic equilibrium with the surrounding soil. Typically, these methods require calibration to infer matric potential from the sensor response. Wettable porous media with pore-size distribution that leads to continuous and repeatable desaturation of water in the matric potential range of interest may be used for this purpose. The requirements for the porous materials to equilibrate with soil is a major obstacle for using these sensors in processes with high temporal dynamics. In particular, a mismatch between the pore-size distributions of the sensor and the soil can lead to hydraulic decoupling of the sensors, which is mostly relevant to coarse-textured soils (Wraith and Or, 2001).

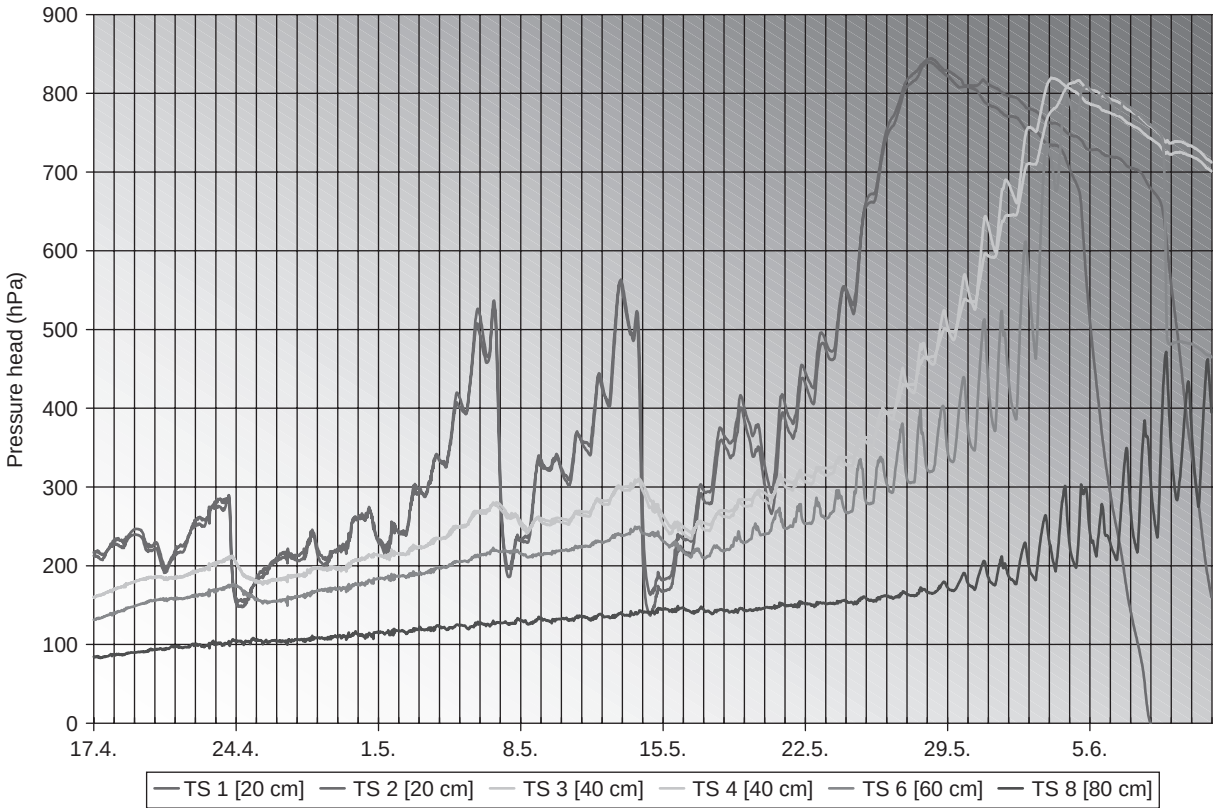

Figure 6 Typical tensiometer readings from a barley field during a growing period, interrupted by irrigation events (May 6, May 13) and some rain events (e.g., April 23, May 20). Two replicate tensiometers were installed at 20-cm depth (TS1, TS2) and 40-cm depth (TS3, TS4); further tensiometers were installed at depths of 60 and 80 cm (TS6 and TS8, resp.). The measurements show daily oscillations, caused by root water uptake. Roots extend in the early period to the upper tensiometers only, but then grow continuously deeper. TS1 and TS2 reach their measurement range limit on May 27. Then, water inside the tensiometer cup starts boiling and passes through the porous cup of the tensiometer, irrigating the surrounding soil. The decrease of the depicted head, which is the difference between atmospheric pressure p_a and the vapor pressure p_v inside the tensiometer, is due to an increase of p_v, caused by an increase in soil temperature (data not shown). From June 4 onwards, the tensiometer cup of TS1 starts leaking and the pressure difference drops to zero within a few days. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Classic porous reference materials are blocks of gypsum, fiberglass, or nylon. Recently, granular matrix sensors have become available, which consist of gypsum wafers embedded in granular matrix (Scanlon *et al.*, 2002). Measurements of water content are obtained either by electrical resistance, heat dissipation (see next section), or by measuring the electromagnetic properties of the reference porous medium. Gypsum blocks with embedded electrodes to measure the electric resistance have been used for more than 60 years in agricultural applications (Buoyoucos and Mick, 1940). The electrical conductivity in these blocks is buffered by the ion strength of the saturated gypsum solution ($\sim$0.2 S m^{-1}). This is contrary to nylon and fiberglass blocks, where the electrical conductivity is dependent also on the ionic strength of the soil solution. The problems of these sensors are a limited temporal stability, a long response time, appreciable hysteresis, and the need for individual calibration. Furthermore, the measurements are temperature dependent and must be corrected accordingly. Handling and disadvantages of these probes are well known and documented (Scanlon *et al.*, 2002), and it appears that not much development has taken place during the last decade.

More recently, activities have been directed toward methods where the water content of the reference porous medium is obtained from its dielectric permittivity (Or and Wraith, 1999; Wraith and Or, 2001). In 1996, Delta-T Devices introduced the so-called "equitensiometer", where a capacitance probe is embedded in a porous matrix. Noborio *et al.* (1999) embedded a portion of a TDR probe in porous gypsum, with the remainder of the electrode rods surrounded by soil. The signal travel times through the two sequential media were separately analyzed to obtain their respective apparent dielectric constant. The electric permittivity of the porous gypsum was calibrated against water content in the pressure plate apparatus. Or and Wraith (1999) introduced a TDR-based sensor, where disks of

porous ceramic and plastic, having a variety of pore sizes from 120 to 0.6 μm, were stacked within a coaxial cage. The pack was brought in in hydraulic equilibrium with the surrounding soil and its water content measured by TDR. The relationship between integral water content and water potential of the sensor's porous matrix was initially calibrated and subsequently used to infer the matric head of the surrounding soil. Both the studies of Or and Wraith (1999) and Noborio *et al.* (1999) identified a need for porous materials having a wide range of pore sizes. Or and Wraith (1999) reported a trade-off between the sensor's matric potential range and its sensitivity to changes in the surrounding soil. To provide a flexible alternative to probes constructed using porous disks, Wraith and Or (2001) proposed that previously characterized porous media having similar particle and/or pore-size distributions as those of soils or other media under investigation, may be used as the porous matrix for TDR-based water potential sensors.

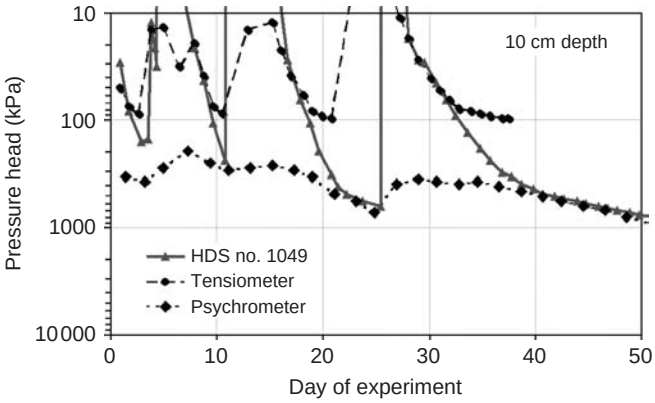

Figure 7 Changes in water potential measured by heat dissipation sensor, tensiometer, and psychrometer during a laboratory experiment [Redrawn from C.F. Reece, *Soil Sci. Soc. Am. J.*, **60**, 1022–1028 (1996)]. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

HEAT DISSIPATION MATRIC POTENTIAL SENSORS

Similar to gypsum blocks and granular matrix sensors, HDSs infer water potential by measuring a water content–dependent property in a porous medium, which is in hydraulic equilibrium with the surrounding soil. Fredlund (1992) compiled a brief historical review of HDSs showing that already 75 years ago Shaw and Baver (1939) demonstrated that soil water potential could be inferred from the rate of head dissipating into the soil. A HDS consists of a heating element and thermocouple embedded within a porous ceramic matrix (Phene *et al.*, 1971). The measurement is based on the rate of temperature rise from a line heat source, embedded in the cylindrical porous ceramic. The rate of heat dissipation in a porous medium is dependent on specific heat capacity, thermal conductivity, and density. Since these properties are greatly affected by the water content, heat dissipation can be related by a calibration relation to water potential.

Reece (1996) presented a thorough analysis of HDSs and concluded that the range of measurable matric potentials lies between −10 and −1000 kPa. In a comparison with tensiometers and psychrometers, he found that at no time did HDS response appear to lag tensiometer or psychrometer measurements under wetting or drying cycles (Figure 7). A significant advantage of HDSs is their insensitivity to solution salt content, in contrast to electric conductivity–based sensors. Additionally, sensors are relatively inexpensive (<$100 per sensor, Flint *et al.*, 2002). Often, variations in heat transfer properties between heater and ceramic of different sensors necessitates individual calibration. Flint *et al.* (2002) developed a normalization procedure that simplified calibration and presented temperature correction, using sensors from three sources and different calibration methods.

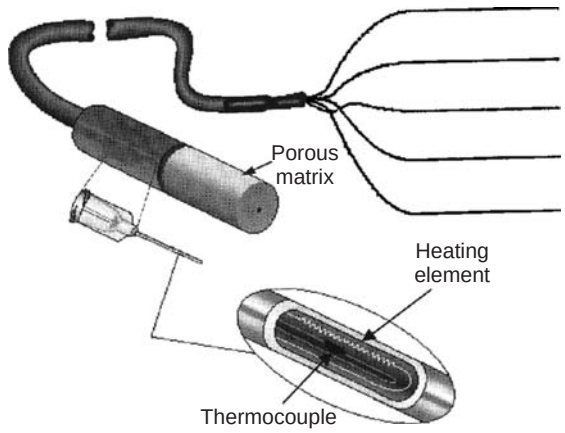

Figure 8 Schematic of heat dissipation sensor CSI 229 (Reproduced with courtesy of Campbell Scientific Inc., Logan, UT, USA)

The normalized calibration resulted in a mean absolute error of 23% over a matric potential range of −0.01 to −35 MPa.

Commercial availability of sensors is listed in Flint *et al.* (2002) and Scanlon *et al.* (2002). Sensors available from Campbell Scientific, Inc. (CSI, Logan, UT) measure matric potential in the range of approximately −0.01 to −100 MPa with sensitivity proportional to matric potential value. Resolution is approximately 1 kPa at matric potentials greater than −0.1 MPa and is capable of responding to changes in the matric potential of dry soils (see Figure 8).

VAPOR PRESSURE–BASED METHODS AND THERMOCOUPLE PSYCHROMETRY

Psychrometric measurements are based on equilibrium between liquid soil water and water vapor in the ambient

soil atmosphere. Water potential in the air phase is related to relative humidity, *RH*, through the Kelvin equation (Or and Wraith, 2002)

$$RH = \frac{e}{e_0} = \exp\left(\frac{M_w g h}{RT}\right) \quad (6)$$

where e is water vapor pressure, e_0 is saturated vapor pressure at the same temperature, M_w is the molecular weight of water ($0.0018\,\mathrm{kg\,mol^{-1}}$), g is the gravitational acceleration ($9.81\,\mathrm{m\,s^{-2}}$), h is the water potential per unit weight (m), R is the ideal gas constant ($8.31\,\mathrm{J\,K^{-1}\,mol^{-1}}$), and T is the absolute temperature (K). The relative humidity of the air can be determined from the dew-point temperature, using a chilled mirror. In water activity measurement devices (Decagon Inc., Pullman), water potential is measured by equilibrating the liquid-phase water of a sample with the vapor-phase water in the headspace of a closed chamber. A thermoelectric (Peltier) cooler controls the mirror temperature. A beam of infrared light is directed onto the mirror and reflected back to a photodetector, which detects the change in reflectance when condensation occurs on the mirror. A thermocouple attached to the mirror accurately measures the dew-point temperature.

Psychrometers measure the difference between a dry bulb and wet-bulb temperature. The dry bulb is at the temperature of the surrounding soils, the wet bulb at the temperature of an evaporating surface. The lower the humidity, the higher will be the rate of evaporation from the wet bulb, and thus the temperature depression below ambient. Since air is an effective diffusion barrier for most solutes, the corresponding water potential includes the osmotic and the matric potential. Rearranging (6) and taking a log-transformation leads to

$$h = \frac{RT}{M_w g} ln\left(\frac{e}{e_0}\right) \quad (7)$$

For the range of e/e_0 near 1, which is usually encountered in soils in humid climates, equation (7) can be simplified to

$$h = \frac{RT}{M_w g}\left(\frac{e}{e_0} - 1\right) = 0.471 \cdot 10^6\ T\left(\frac{e}{e_0} - 1\right) \quad (8)$$

for h in m.

A thermocouple psychrometer consists of a fine-wire chromel-constantan or other bimetallic thermocouple. A thermocouple is a double junction of two dissimilar metals. When the two junctions are subject to different temperatures, they generate a voltage difference (Seebeck effect). Conversely, when an electrical current is applied, the junction is heated or cooled, depending on the direction of the current (Peltier effect). For typical soil use, one junction of the thermocouple is suspended in a thin-walled porous ceramic or stainless screen cup buried in the soil, while another is embedded in an insulated plug to measure the ambient temperature at the same location (Figure 9). By an electrical current, the suspended thermocouple is cooled below the dew point until water condenses on the junction. The cooling current then stops, and as water evaporates, it draws heat from the junction, depressing it below the temperature of the surrounding air until it attains wet-bulb temperature. The difference in temperatures between the wet and dry bulb is related to the relative humidity by the psychrometer equation

$$\frac{e}{e_0} = 1 - \left(\frac{s + \gamma}{e_0}\right)\Delta T \quad (9)$$

where s is the slope of the saturation water vapor pressure curve ($s = \mathrm{d}e_0/\mathrm{d}T$), γ is the psychrometric constant ($\sim 0.067\,\mathrm{kPa\,K^{-1}}$ at 20°C), and ΔT is the temperature difference (K) between the dry and wet bulb.

An accurate determination of the temperature difference plays a critical role in psychrometric water potential determination. For water potential measurements to be accurate to $\sim 10^5$ kPa, temperature difference measurements need to be accurate to 0.005 °C. Psychrometers are therefore highly susceptible to thermal gradient effects and do not perform well at shallow soil depths. The necessity of equilibrium of different phases further causes a relatively slow response time. When the osmotic potential is negligible, the soil water potential measured by a psychrometer is nearly equal to the soil matric potential. In principle, soil psychrometers may be buried in a soil and left for long periods, although corrosion is a problem in some environments.

PotentiaMeter (model WP4, Decagon, WA) is a new device for rapid measurement of water potential using the chilled-mirror dew-point technique (described above) (see Figure 10). The vapor pressure in the headspace above a thermally equilibrated soil sample is computed as the saturation vapor pressure at dew-point temperature; with known sample temperature the water potential in the sample is determined as discussed in psychrometric measurements. Since both dew-point and sample surface temperatures are simultaneously measured, the need for complete thermal equilibrium is eliminated, and measurement time is reduced to less than five minutes. Readings are provided directly in MPa with accuracy for water potential range of 0 to -10 ± 0.1 MPa, and from 0 to -60 MPa $\pm 1\%$.

CONCLUDING REMARKS

In contrast with soil water content sensors, no single matric potential sensor is currently capable of covering the entire range of interest (10^{-1}–10^2 kPa tensiometers; 10^1–10^5 kPa reference porous media; and 10^5–10^8 kPa thermocouple psychrometers). The gap in measurement capabilities of these two important soil attributes is accentuated

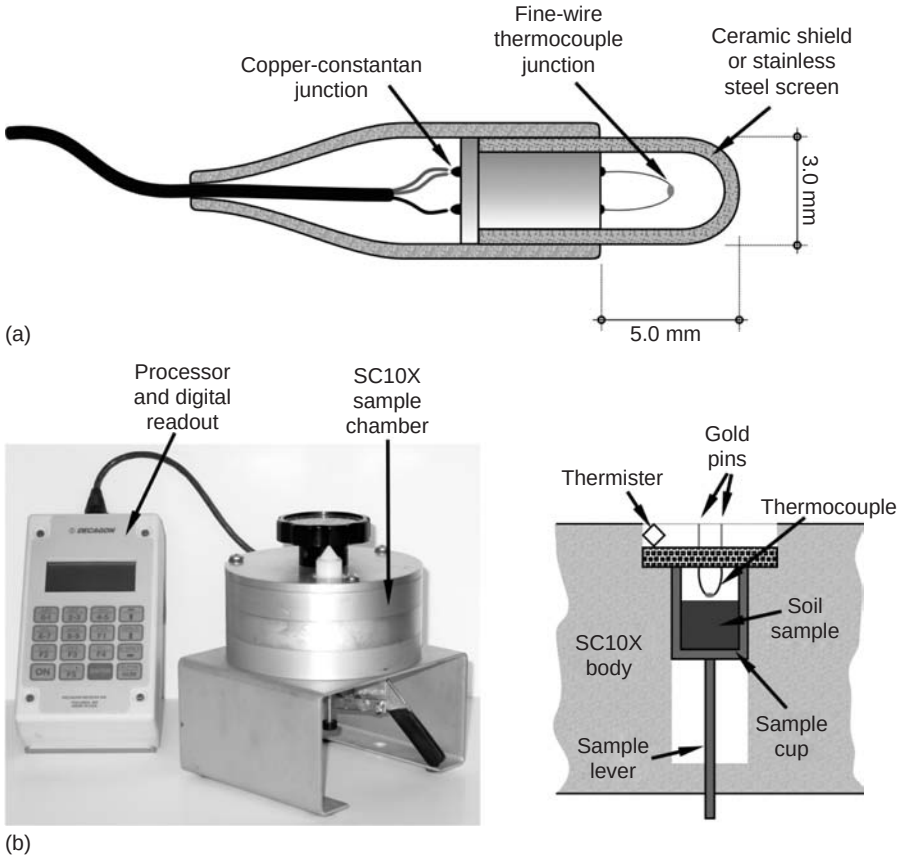

Figure 9 Field thermocouple psychrometer with porous ceramic 229 (Reproduced with courtesy of Wescor Inc., Logan, UT, USA). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

by rapid developments in water content detection using electromagnetic methods (TDR and other noninvasive microwave methods). Some progress has been made in the reliability and ease of use of tensiometers, which have evolved and are now considered among the most accurate and reliable soil hydration status measurements. Their limited measurement range, however, remains a severe limitation for field and laboratory studies.

Indirect methods, especially those based on hydraulic equilibration with reference porous media remain limited by technical challenges. It is to be expected that the combination of different porous materials in EPM, and the use of TDR or the use of HDSs to determine their composite water content, will bring certain progress. If the problem of a fully reproducible packing technique can be solved, the method proposed by Wraith and Or (2001) appears to be very promising. For the present, we concur with Smiles (2001), who claims that it "remains a challenge that there are still no good methods to measure suction in the field over any length of time, and comments on the osmotic tensiometer remain pertinent".

Finally, while water content measurements methods are rapidly evolving toward noninvasive estimation of water contents over large areas and large soil volumes (ground-penetrating radar, electrical tomography, passive microwave radiation), the methods for soil water energy state remain restricted to point measurements.

MANUFACTURERS

A broad overview over suppliers of soil water content sensing is given by the SOWACS web page (**http://www.sowacs.com/suppliers/index.html**). Instrumentation for water potential measurement can be found at

- **Adcon's Electrotensiometer** (**http://www.adcon.com/**) has a standard ceramic cup, but the signal from the vacuum sensor above the water-filled tube is conditioned to be compatible with Adcon's data acquisition units.
- **Campbell Scientific Inc**. manufactures dataloggers, data acquisition systems, and measurement and control products, and the heat dissipation matric water potential sensor.
- **Decagon Devices Inc**. (**http://www.decagon.com/**) produces and sells water activity meters.
- **Delta-T Devices Ltd** (**http://www.delta-t.co.uk/**) offer a range of electronic, pressure transducer tensiometers, including miniature and rugged-use models. Typical usage is in multiple arrays, automatically recorded by a field data logger.
- **Earth Systems Solutions** (**http://www.earthsystemssolutions.com/**) are the American distributors for various SDEC (French) tensiometers including accessories and electronic transducers for continuous logging.
- **Irrometer** (**http://www.irrometer.com/**). Original American Suppliers since 1951. They also produce the Watermark sensor.
- **SDEC's Tensionics** (**http://www.sdec-france.com/us/index.html**). A French company that also makes a capacitance sensor. They also have a "Tensiometer" (electronic readout unit), which is designed for use as a portable gauge for use with tensiometers.
- **SoilMoisture Equipment Corporation** (**http://www.soilmoisture.com/**) supply tensiometers as well as many other devices for monitoring soil and plant water potential Suppliers index.
- **UMS Inc. Munic**, Germany, (**http://www.ums-muc.de/**), produce a variety of high-quality tensiometers, including the new self-filling type TS1.

The accurate knowledge of hydraulic properties for unsaturated soils is critical in addressing problems in a variety of disciplines such as hydrology, ecology, environmental sciences, soil science, and agriculture. The purpose of this paper is to review the characterization of unsaturated soil hydraulic properties for their applicability in models simulating unsaturated water transport. In a theoretical section, we present the fundamentals for the definitions of the hydraulic properties in the framework of the continuum theory as well as provide the common parameterizations of the hydraulic functions. The characterization and parameterization of hysteresis and the phenomenon of dynamic effects in hydraulic properties are addressed in subsequent sections. Finally we discuss issues related to the handling of spatial and temporal variability, including geostatistical characterization, upscaling, and scale dependency of effective properties. The review closes with a summary on limits and opportunities for modeling water transport with Richards' equation.

INTRODUCTION

The accurate characterization of the hydraulic properties for unsaturated soils is critical in addressing many problems in hydrology, ecology, environmental sciences, soil science, agriculture, and other disciplines. Knowledge of the hydraulic properties is required in nearly all basic and applied aspects of soil, water, nutrient, and salinity management research (van Genuchten *et al.*, 1999). This chapter describes how hydraulic functions are defined in the framework of the continuum theory by averaging the microscopic phase properties (see Section "What are soil hydraulic properties?"). The hydraulic properties must be parameterized in closed-form expressions for their later application in simulation models. In Section "Parameterization of hydraulic functions", we discuss common parameterizations and illustrate in particular some problems and pitfalls associated with the widely used van Genuchten/Mualem model (van Genuchten, 1980). It is common knowledge that the hydraulic properties of soils are hysteretic in nature, which is especially significant with regard to transient water and solute transport. Nevertheless, there still exists very little standard representation of hysteresis in numerical models and it continues to remain a poorly modeled phenomenon. Section "Hysteresis" briefly reviews the current state of knowledge with respect to the parameterization and incorporation of hysteresis into numerical models.

Frequent observations on water flow phenomena in unsaturated soils under transient conditions show that the concept of uniquely occurring soil hydraulic properties must be questioned, since the relationship between matric potential and water content may depend on boundary conditions. Section "Dynamic effects" reviews the history of empirical evidence for these so-called *dynamic effects* and presents approaches on how to deal with them in numerical modeling. The final part of the paper, Section "Variability", discusses the impact of soil variability on the definition and measurement of effective hydraulic properties for large-scale applications. We show how geostatistical methods in combination with the concept of "scaling" are used to handle the variability of unsaturated hydraulic properties and we further illustrate the difference between mean and effective hydraulic conductivity in an example.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

WHAT ARE SOIL HYDRAULIC PROPERTIES?

Unsaturated soils contain two fluid phases, namely, soil water and soil air, and an immobile phase, the soil matrix. In an universal sense, "soil hydraulic properties" describe macroscopic relations between the chemical potential, the phase concentration, and the transmission behavior of water and gases in soil. These relations depend on a multitude of factors, including temperature, pore space geometry, surface properties of the soil matrix, chemical composition of the soil solution, and properties of the wetting and nonwetting fluids that occupy the complementary parts of the pore space. Two-phase flow systems have historically been described using fluid pressures and volumetric saturations as primary variables. The capillary pressure, defined as the difference between fluid phase pressures under equilibrium conditions, is related algebraically to the saturation by a nonlinear relationship, which is usually highly hysteretic. Fluxes of water and air are related to the potential gradients of the respective phases. The coefficient of proportionality between flux and gradient involves the relative permeability, which is a nonlinear function of saturation. Macroscopic mass balance equations, augmented by these constitutive relationships, represent the state of the art in mathematical descriptions of two-phase flow in porous media (Held and Celia, 2001).

Representative Elementary Volume and Measurement Window

On a microscopic scale, water content is either one (in the water phase) or zero (else). To come to a reasonable definition of water content, we must average the phase density over a certain soil volume. A practical choice is to choose the smallest volume that contains all structural elements of the pore system in sufficient abundance. We call this minimum volume *representative elementary volume*, REV (Hubbert, 1956; Bear, 1972). In fine-textured nonstructured soils, such as fine sands or loess, volumes of $1\,cm^3$ or less might be sufficiently large to yield a reliable average for soil porosity. Buchter *et al.* (1994) estimated the REV of the porosity of a Rendzina with >50% stones to be $1.5\,dm^3$. In soils with shrinkage cracks, such as vertisols, the REV is as large as the whole soil profile. Since large structures will often extend preferentially into one spatial direction, it follows that the size of the REV will vary in different spatial directions. In general, the REV for repacked samples, which contain the soil fraction with particle diameters less than 2 mm, will be much smaller than the REV of undisturbed samples, since stones, worm channels, roots, cracks, and lenses are large structures and must be contained in an REV in sufficient numbers. The question as to how well and accurate we can measure hydraulic properties will depend on the relation of the REV scale to the size of the measuring window.

If we extend the REV concept to characterize structural properties of natural soil, we see that no single REV exists. Enlarging the averaging volume will lead again and again to the inclusion of new structural elements of larger size (Figure 1). If, on the other hand, we extend the sampling region keeping the sample volume constant, we would observe that the average variability increases continually. This shows that observed variability of a measured soil hydraulic property will depend on the size of the measuring window, on the size of structural elements of the system, and on the extent of the region of sampling. In other words: the question whether a property is "homogeneous" or "heterogeneous" depends on one hand on the extent and the structure of the system under consideration, and on the other hand, on the averaging volume. This implies that an adequate sampling volume must be adapted to the state property to be measured, and also to the system to be described.

Continuum Approach, Darcy's Law, Richards' Equation

Averaging the local phase fractions or phase properties in an REV, and mapping the resulting value to the central

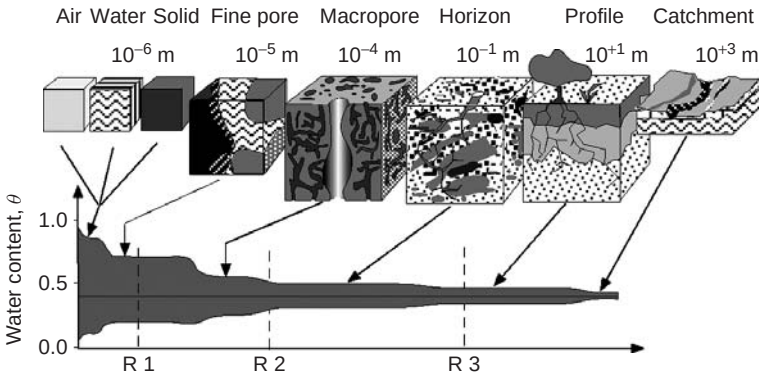

Figure 1 Scale dependence of water content variability (Courtesy of H. Flühler and K. Roth). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

point of the averaging volume leads to the definition of spatially continuous variables such as water content, air content, soil density, porosity, or water potential. The state variable "water content" thus represents the hydraulic condition of the soil at any given time and location as a result of hydraulic processes, which in turn are governed by soil hydraulic properties. This "continuum approach" (Cushman, 1984) enables us to relate in a mass balance the temporal changes of water content at a point to spatial gradients of the water flux, here noted in a one-dimensional form

$$\frac{\partial \theta}{\partial t} = -\frac{\partial q}{\partial z} + s \tag{1}$$

where θ is volumetric water content [$L^3\,L^{-3}$], q is volumetric water flux [$L^3\,L^{-2}\,T^{-1}$], t is time [T], z is a spatial coordinate [L], and s is a source/sink term [T^{-1}]. The water flux is driven by a gradient of the water pressure, p_w,

$$q = -K^*(\theta)\frac{\partial (p_w - \rho g)}{\partial z} \tag{2}$$

where K^* is the hydraulic conductivity [$L^3\,T\,M^{-2}$] and p_w is water pressure [$M\,L^{-1}\,T^{-2}$], ρ is the density of water [$M\,L^{-3}$], g is the gravitational acceleration [$L\,T^{-2}$]. Water pressure is an expression of water potential in units of energy per volume (Durner and Or, 2005; *see* **Chapter 73, Soil Water Potential Measurement, Volume 2**). The total water potential, ψ_{tot}, is affected by the position in the gravity field (gravitational potential, ψ_g), by forces due to water sorption on soil particle surfaces and capillary forces in the soil pore system (matric potential, ψ_m), by dissolved substances in the soil solution (osmotic potential, ψ_o), by forces due to soil swelling and overburden (overburden potential, ψ_Ω), and by forces that result from air pressure acting on water–air interfaces (pneumatic potential ψ_p). If a pore system is rigid, nonswelling, isotropic, and osmotic gradients and flow resistance of the nonwetting fluid are negligible, isothermal soil water movement is governed just by gradients in the matric, and the gravitational potential (Jury *et al.*, 1991; Kutilek and Nielsen, 1994).

In soil physics, it is customary to express the water potentials in units of energy per weight, that is, as heads [L]. Neglecting the pneumatic, osmotic, and overburden components of the water potential, and considering that the gradient of the gravitational potential is equal to -1 (the direction of the spatial coordinate taken positive downward) leads to

$$q = -K(\theta)\left(\frac{\partial h}{\partial z} - 1\right) \tag{3}$$

where h is the pressure head [L] and $K(\theta)$ is the hydraulic conductivity [$L\,T^{-1}$]. Equation (3) expresses the Darcy–Buckingham law (Darcy, 1856; Buckingham, 1907) and defines the saturated/unsaturated hydraulic conductivity. It implies that the hydraulic conductivity is a system property that can be determined only by an inverse approach, that is, by matching its value to be consistent with an observed dynamic system behavior (Durner and Lipsius, 2005; *see* **Chapter 75, Determining Soil Hydraulic Properties, Volume 2**). For saturated water flow, K will not depend on h, and equation (3) is linear. This is contrary to the unsaturated case, and makes it simple to invert the equation analytically by simple rearrangement.

Inserting equation (3) in equation (1), and replacing the dependency of K on θ by h leads to the pressure-form of the one-dimensional Richards' equation

$$C(h)\frac{\partial h}{\partial t} = \frac{\partial}{\partial z}\left[K(h)\left(\frac{\partial h}{\partial z} - 1\right)\right] + s \tag{4}$$

where *C(h)* is the specific water capacity [L^{-1}], defined by the change of water content with pressure head, $C = \partial\theta/\partial h$. Equation (4) was first derived by Richards (1931) and is the fundamental model for describing water flow in the unsaturated zone on the macroscopic scale (i.e. the scale where we usually measure soil hydraulic properties). The model is completed by appropriate initial and boundary conditions, and knowledge of the coefficients *C(h)* and *K(h)*. Since C and K are nonlinearly dependent on h, solution of equation (4) requires generally numerical methods. The neglecting of the pneumatic potential implies that equation (4) is valid only if gradients in the pressure of the nonwetting fluid are negligible, or – in other words – if air is free to move in the soil at any system state. This is not always the case, neither in nature nor in measurement experiments. Equation (4) is frequently used as a process model for water transport at much larger scales. The coefficients C and K are then used as *effective* properties, which have the same names as for the local scale. However, their values are no longer consistent with the local, REV-based definition, as shown in Section "Variability".

In analogy to a diffusion process, water transport can also be described by

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial z}\left[D(\theta)\left(\frac{\partial \theta}{\partial z}\right)\right] - \frac{\partial K(\theta)}{\partial z} + s \tag{5}$$

where D is the water diffusivity [$L^2\,T^{-1}$]. For horizontal water transport and without sinks or sources, equation (5) is formally equal to Fick's second law of diffusion. Comparison of equation (4) and (5) shows that the water diffusivity is given by the ratio of conductivity and specific water capacity,

$$D(\theta) = \frac{K(\theta)}{C(\theta)} \tag{6}$$

The coefficient D is highly water content-dependent and expresses a propagation velocity for water content changes.

It is highest for low damping (low capacity) and high hydraulic conductivity, which is the case for conditions near water saturation. Equation (5) is less frequently applied than the pressure head form of Richards' equation, (4), because its use is restricted to purely unsaturated soils, and, for vertical transport, the knowledge of the hydraulic conductivity function is also required. Therefore, our discussion will be restricted to the water retention curve (WRC) and the conductivity curve.

Retention Curve and Hydraulic Conductivity Curve

In the remainder of this chapter, we will use the term "soil hydraulic properties" for the constitutive relationships $\theta(h)$ and $K(\theta)$, or $K(h)$, as defined by equations (3) and (4) in the framework of the continuum approach. The relationship $\theta(h)$ is called *water retention curve, WRC* (Also, "water retention characteristic", "soil moisture characterisitic", "capillary pressure – saturation relationship", "water characterisitic curve", "water content – matric potential curve", "pF curve"). In principle, it can be determined by monitoring simultaneously the state variables h and θ at an identical point in space during a hydraulic process that changes the systems state. The dependence of the hydraulic conductivity, K, on water content is called *hydraulic conductivity curve*. It can be determined from simultaneous flux and head gradient measurements by inverting equation (4), or more simply, equation (3).

A multitude of empirical investigations lead to general expectations about the shapes of the relationships $\theta(h)$, $K(h)$ and $K(\theta)$ for different soils (Carsel and Parrish, 1988; Schaap, 2005; *see* **Chapter 76, Models for Indirect Estimation of Soil Hydraulic Properties, Volume 2**). Figure 2 shows examples of hydraulic properties for a sand, a silt, and a clay. The depicted functions have been derived by a neural network prediction with the program Rosetta (Schaap *et al.*, 2001). They are based on many measurements documented in the UNSODA soil properties database (Nemes *et al.*, 2001) and follow the parameterization of van Genuchten/Mualem (see Section "Parameterization of hydraulic functions"). It is important to note that these "typical" shapes of hydraulic properties are largely based on measurements on sieved, repacked samples. Compared to undisturbed soils, significant differences must be expected, in particular in the range near saturation, because of the structural pore system (Durner, 1994). For an illustration, see Figure 1 in Durner and Lipsius (2005); *see* **Chapter 75, Determining Soil Hydraulic Properties, Volume 2**.

PARAMETERIZATION OF HYDRAULIC FUNCTIONS

Water Retention Functions

For use in simulation models of unsaturated water transport, the constitutive relationships must be expressed in a continuous way over the whole moisture range, from dryness to saturation. This requires interpolation and smoothing of measured data, and it is common to express these interpolations by parametric functions. Numerous expressions have been proposed to describe the water retention characteristic (Brooks and Corey, 1964; King, 1965; Brutsaert, 1967; Visser, 1968; Taylor and Luthin, 1969; Laliberte, 1969; Farrel and Larson, 1972; Ahuja and Swarzendruber, 1972; Rogowski, 1972; Campbell, 1974; Su and Brooks, 1975; D'Hollander, 1979; Simmons *et al.*, 1979; van Genuchten, 1980; Kovacs, 1981; Russo, 1988; Kosugi, 1996; Assouline *et al.*, 1998). All these curves describe a continuous change of water content from a maximum value, θ_s, which is called *saturated water content*, toward a minimum value, θ_r, which

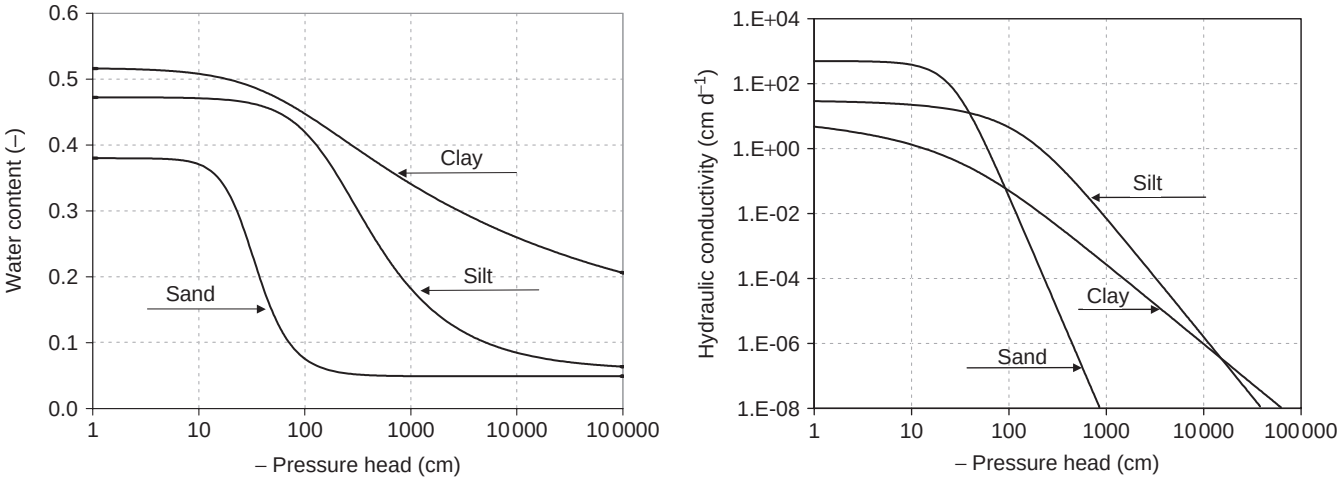

Figure 2 Typical hydraulic properties of differently textured soils (a) Water retention curves. (b) Unsaturated conductivity curves

is called *residual water content*. The transition from full to partial saturation takes place at some characteristic pressure head (often called *bubbling pressure* or *air entry pressure*) that is related to a characteristic width of the largest pores in the porous medium, and thereby depends on soil texture and structure. The slope of the WRC at pressures lower than the air entry pressure depends on the width of the pore-size distribution. Thus, all parametric expressions need, in general, at least four adjustable parameters, and differences in their ability to describe observed data are generally small (Buchan and Grewal, 1990).

Empirical studies (van Genuchten and Nielsen, 1985) showed that out of the functions listed above, the expression proposed by van Genuchten (1980) is particularly suited,

$$S_e = (1 + (\alpha|h|)^n)^{-m} \tag{7}$$

where $S_e = (\theta - \theta_r)/(\theta_s - \theta_r)$ is a scaled water content, called *effective saturation*, and $\alpha > 0$ [L^{-1}], $n > 1$ [$-$] and $m > 0$ [$-$] are empirical curve shape parameters. The inverse of α is related to the air entry pressure head, n is related to the width of the pore-size distribution between saturation and air entry pressure, and the product nm is related to the width of the pore-size distribution between air entry pressure and dryness. In practical use, the van Genuchten equation (7) is mostly applied with the constraint $m + 1/n = i$ $(i = 1, 2, \ldots)$. This reduces the flexibility of the function, but has the advantage that it yields closed-form expressions for the hydraulic conductivity functions when inserted into the conductivity prediction models of Mualem (1976), Burdine (1953), or Childs and Collis-George (1950). This makes it particularly easy to use the hydraulic relationships in numerical models (Luckner *et al.*, 1989), and thus the constrained van Genuchten/Mualem model has become *de facto* a standard in numerical modeling of water transport in unsaturated porous media.

When hydraulic properties are expressed by parametric functions, the process of measuring hydraulic properties is reduced to the process of estimating function parameters. In doing this, it is of crucial importance to be aware that there is no *a priori* evidence that the selected empirical relationship is indeed suited for a given soil. In particular, any extension beyond the moisture range covered by the actual measurement method is (sometimes reasonable) speculation. Accordingly, the determination of optimal model parameters should be combined with a measure that tests the adequacy of the chosen functional model approach (Finsterle, 1999). Unfortunately, this is rather seldom done in practice, because it requires sufficient measurements over the range of interest to be statistically significant.

The approximate nature of the van Genuchten function and other low-parameterized functions as models for the effective pore-size distribution becomes evident in the asymptotic behavior toward saturation and dryness. From physical reasoning, finite values for both the water capacity function and the slope of the conductivity function are to be expected over the whole moisture range, but for values of $n < 2$, the slope of the van Genuchten/Mualem conductivity function becomes infinity close to saturation. Constraining the n parameter to values greater than 2 is impractical since empirical investigations for all textural soil groups, except for sands, yield optimal fits for $n < 2$ (Carsel and Parrish, 1988). Also, toward dryness, the residual water content must be regarded as a pure empirical fitting parameter, and analyses of both, water retention data (Rossi and Nimmo, 1994) and conductivity data, (Tuller and Or, 2001) show that the usual functions are not capable in describing the measured values in the dry range appropriately. On the basis of thermodynamic reasoning, the true equilibrium water contents at pressure head ranges beyond -10^5 cm are clearly smaller than those given by the usual parameterizations, approaching oven dryness at pressure heads of $h = -10^7$ cm. For the practice of simulating water transport in the liquid phase, however, the use of residual water concept appears to yield reasonable results.

The above-cited parametric expressions for WRCs describe measured retention data well if the soils do not exhibit a distinct secondary pore system. To describe naturally structured soils, more flexible expressions have been introduced. These are either constructed by superposition of basic shape functions (Othmer *et al.*, 1991; Durner, 1992; Rossi and Nimmo, 1994) or by piecewise combinations of local shape functions, such as splines or Hermitian basis functions (Erh, 1972; Rossi and Nimmo, 1994; Mohanty *et al.*, 1997; Kastanek and Nielsen, 2001; Prunty and Casey, 2002; Bitterlich *et al.*, 2004). To determine these types of functions accurately, the demand on the precision and range of measurement methods is high (Zurmühl and Durner, 1998).

The consequences of using oversimplified hydraulic functions in practical applications depends on the extent and nature of the deviations between true and parameterized curves, on the range and type of applied boundary conditions, and on the purpose of the measurements. In general, even small changes in hydraulic descriptions can cause significant changes in hydraulic behavior, which is a prerequisite for the identification of hydraulic properties from transient-flow experiments (Vogel *et al.*, 2001; Lambot *et al.*, 2004). But for soil classification purposes, such as the estimate of plant available water, simplified descriptions may perfectly serve its purpose. For use in models of water and solute transport, spatial variability of soil hydraulic functions may be so large that seemingly small errors in the representation of the properties at a point scale appear irrelevant. Deviations of systematic nature, however, can have systematic and significant consequences for the predicted hydraulic conductivity curves

(Durner, 1994) and thus lead to a different effective system behavior, regardless of the superposed local variability. For very demanding applications, for example, tests of conductivity prediction models, investigations on dynamic flow behavior, or derivations of pedotransfer functions (Schaap, 2005; *see* **Chapter 76, Models for Indirect Estimation of Soil Hydraulic Properties, Volume 2**), systematic biases induced by oversimplified functions are intolerable since they lead to misinterpretations of comparisons between observations and models.

Hydraulic Conductivity Functions

Similar to the water retention characteristic, the dependence of the hydraulic conductivity on water content, water saturation, or pressure head, is generally expressed by a simple parametric expression. Common to all expressions is the scaling of a shape function, the so-called *relative conductivity function* $K_r(\theta)$, to the saturated conductivity, K_s

$$K(\theta) = K_s \cdot K_r(\theta) \tag{8}$$

Parametric expressions for the relative conductivity function are less manifold, as compared to the water retention function, because the conductivities are often coupled to the retention model. Simple empirical expressions for the $K(\theta)$ and $K(h)$ relation have been proposed, amongst others, by Gardner (1958), Brooks and Corey (1964), King (1965), and Rijtema (1965). Most frequently used are the exponential model (Gardner, 1958)

$$K(\theta) = K_s \cdot \mathrm{e}^{\alpha h} \tag{9}$$

and the power function (e.g. Averjanov, 1950; Irmay, 1954, Brooks and Corey, 1964; Ahuja and Swarzendruber, 1972),

$$K(\theta) = K_s \cdot S_e^{\beta} \tag{10}$$

where α and β are empirical coefficients. The combination of statistical pore-bundle conductivity models, for example, of Burdine (1953) or Mualem (1976), with the retention function of van Genuchten (1980) leads to closed-form expressions, which are sometimes used as empirical "stand-alone" expressions of the conductivity curve. The van Genuchten/Mualem model (van Genuchten, 1980) is most frequently used,

$$K_r(S_e) = S_e^l \left[1 - \left(1 - S_e^{1/m}\right)^m\right]^2 \tag{11}$$

where the parameter l [−] is called *tortuosity factor*, and m is related to the retention curve parameter n in equation (7) by $m = 1 - 1/n$. When applying the van Genuchten/Mualem conductivity model (11), the user should be aware of a model artifact. For small values of the parameter n, an unrealistic steep decrease of the predicted conductivity near saturation occurs, because the function considers no finite air entry pressure. Modifications of the van Genuchten/Mualem conductivity function have been proposed that avoid this artifact (Vogel and Cislerova, 1988; Vogel *et al.*, 1999, 2001).

In analogy to the WRC, piecewise combined functions are used to express the conductivity function with enhanced flexibility (e.g. Poulsen *et al.*, 2002; Schwartz and Evett, 2002; Bitterlich *et al.*, 2004). Recently, analytical expressions for retention and conductivity functions have been proposed which are not fully empirical, but depend on hydrodynamic considerations about the topology of the pore space of porous media. Notable are the functions of Assouline *et al.* (1998), Assouline (2001), Tuller and Or (Tuller *et al.*, 1999; Or and Tuller, 1999; Tuller and Or, 2001), and Zhu and Mohanty (2003).

HYSTERESIS

The dependencies of θ and K on the pressure head h are hysteretic. This implies that the relationships, as shown in Figure 2, are valid only for a certain history of wetting and drying, and for one particular saturation or desaturation path. Most measurement experiments therefore rely on a uniquely defined initial hydraulic state, from which the system is changed continually in one direction. Drainage experiments in the laboratory start usually from a maximum achievable saturation. Rewetting the soil from complete dryness will yield different relationships. Further, drying and wetting cycles from intermediate states between full saturation and oven dryness will again give different relationships. Hysteresis of the water retention characteristic is schematized as shown in Figure 3. Drainage of a full

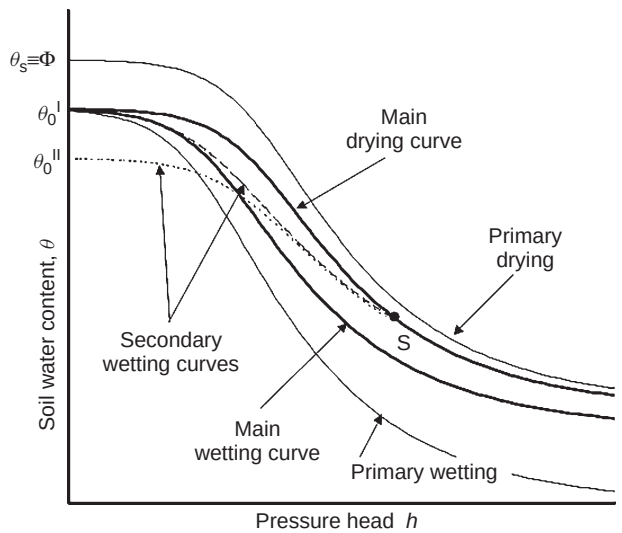

Figure 3 Schematization of hysteresis of the water retention characteristic

saturated medium yields the *primary drying curve*, imbibition from oven dryness yields the *primary wetting curve*, drainage from satiation yields the *main drying curve*, imbibition from the residual water content yields the *main wetting curve*, and any changes between imbibition and drainage at intermediate pressure values yield *secondary scanning curves*.

Hysteresis has been recognized as an important component of soil water redistribution since the early work of Haines (1930). The maximum water saturation of soils in the unsaturated zone under natural conditions is always significantly lower than the porosity, due to air entrapment, with typical saturation values of 80 to 90% of pore space (Klute, 1986; Dane and Hopmans, 2002). Full saturation of the pore space can be obtained only by specific experimental manipulations (slow wetting from the bottom, flushing with carbon dioxide, flushing with de-aired water, and application of vacuum). To distinguish the "saturated water content" from the typical maximum saturation in the field, Hillel (1980) proposed the term "satiation" for the latter.

The hysteresis of $\theta(h)$ leads to hysteresis of $K(h)$, since conductivity is controlled by the water-filled pore space. The hysteresis of the $K(\theta)$ relation of soils is generally regarded as negligible (Mualem, 1986; Kool and Parker, 1987). Ignoring hysteresis in the K-θ-h relations may be partly based on an assumption that its effects are negligible, partly on the absence of a well-validated hysteretic model that is easy to calibrate (Lenhard *et al.*, 1991), and partly on the difficulties of performing measurement experiments that are suitable to identify parameters of hysteresis models. Neglecting hysteresis leads to significant errors in the water redistribution under transient boundary conditions (Dane and Wierenga, 1975; Gillham *et al.*, 1979, Hoa *et al.*, 1977; Viaene *et al.*, 1994; Lehmann *et al.*, 1999; Si and Kachanoski, 2000). Russo *et al.* (1989) and Mitchell and Mayer (1998) investigated the influence of hysteresis on solute transport and found that the magnitude of the deviations between hysteretic and nonhysteretic simulations was not a simple function of single parameters, but rather depended on the combined values of many or all of the hydraulic parameters. Hysteresis is also seen as one of the major obstacles for comparing different measurement methods for the $K(\theta)$ (Stolte *et al.*, 1994; Basile *et al.*, 2003).

Hysteresis has been incorporated into simulations of unsaturated flow since Rubin (1965). Jaynes (1992) showed that soil water redistribution is retarded by hysteresis, and its magnitude depends on the rate at which the soil-water content varies. This supports the consensus that highly transient soil water conditions enhance hysteresis effects (Topp *et al.*, 1967). Hysteresis is typically assumed to be caused by the inkbottle effect, but other processes such as contact angle hysteresis, shrink-swell effects, or entrapped air play a significant role (Hillel, 1980). Contact angle hysteresis is affected by numerous factors, like surface roughness, chemical heterogeneity, fluid dynamics, particle shape, and gas adsorption, and all these relations depend on the composition of the soil solution (Dury *et al.*, 1998; Henry *et al.*, 2001). Therefore, hysteresis effects on soil-water redistribution may result from a single process, or interactions between different processes, and *a treatise on the role of individual factors controlling hysteresis is rather speculative* (Kutilek and Nielsen, 1994, p. 73).

Considerable effort has been put into the analysis and description of hysteretic soil hydraulic properties. This has led to numerous models for describing hysteresis in $\theta(h)$. Both, empirical models (Scott *et al.*, 1983; Hogarth *et al.*, 1988) and physically based models (Poulovassilis and Childs, 1971; Parlange, 1976; Mualem, 1974, 1984; Poulovassilis and Kargas, 2000) have been proposed. Kool and Parker (1987) combined the Scott hysteresis model with the retention function of van Genuchten (1980), which leads to an easily usable and consistent set of constitutive relationships (Luckner *et al.*, 1989). These models provide a simple means for determining scanning curves from a limited amount of data, such as the main wetting and drying hysteresis curves. The models of Parlange (1976) and Mualem (1984) need only one branch of the loop to predict all scanning curves. However, when comparing different models of hysteresis using 10 measured scanning curves, Viaene *et al.* (1994) concluded that the best models were the conceptual models needing two branches for calibration. Jaynes (1992) showed with simulation studies that none of the models were consistently better than the others. Other investigations found the empirical model of Kool and Parker (1987) to be only approximately valid (Schultze *et al.*, 1999; Basile *et al.*, 2003). Incorporating a physically based hysteresis model in numerical codes is demanding, since bookkeeping of the wetting and drying history at any point in the soil must be provided.

DYNAMIC EFFECTS

Hydraulic properties of porous media are commonly assumed to be of "static" nature, that is, to depend only on the size distribution and geometrical arrangement of pores in the porous medium and on the wetting/drying history (hysteresis), provided the solid matrix is rigid, fluid properties are constant, and external conditions do not change with time. This implies that the relationship between water content and pressure head during monotonous draining or imbibition processes is not affected by the dynamics of the water flow. As a consequence, $\theta(h)$ can be expressed by a unique characteristic, which can be determined by any available measuring technique (Durner and Lipsius, 2005; *see* **Chapter 75, Determining Soil Hydraulic Properties, Volume 2**). However, investigations by various authors

indicate that hydraulic properties may depend not only on the wetting and drying history, but also on the dynamics of water flow. This implies that hydraulic functions, which are measured under static equilibrium conditions, are not applicable to simulate water flow under transient conditions.

Davidson *et al.* (1966) found in imbibition and drainage studies that equilibrium water contents were affected by the dynamics of the wetting history. More water was removed from samples by one single large pressure decrease than by a sequence of small decreases. In contrast, more water was sorbed by the soils when a series of small pressure steps was applied in the imbibition process. Topp *et al.* (1967) compared water retention characteristics of vertical sand columns under static equilibrium conditions, under steady state flow, and under transient-flow conditions. They found that for transient experiments, at a given potential, water contents at drainage were significantly higher than water contents determined under static equilibrium or steady state conditions. Smiles *et al.* (1971) performed experiments where a series of imbibition/drainage cycles were applied to horizontal sand columns by imposing stepwise changes in the water pressure at one column end. They found that the retention characteristic depended on the size of the imposed pressure. Vachaud *et al.* (1972) confirmed these results for vertical soil columns. Stauffer (1977) investigated drainage in vertical columns packed with sand. Under dynamic flow conditions, he measured higher water contents at a given pressure as compared to the static $\theta(h)$ relationship. Similar to Smiles *et al.* (1971), gas phase pressure was additionally measured and no deviation from atmospheric air pressure was observed. Plagge (1991) and Plagge *et al.* (1999) confirmed these findings with evaporation experiments on silty soils. Tensiometric pressures and water contents were measured with microtensiometers and TDR (time domain reflector) probes, which were installed at multiple depth levels in soil columns. Dependent on the distance from the boundary of the soil column, the locally measured retention curves differed considerably. The differences were systematic and reproducible, and could not be attributed to faults in packing technique or to measurement errors. Lennartz (1992) investigated dynamic nonequilibrium systematically by performing evaporation experiments on repacked soil samples of four different substrates. He found significant differences between static and dynamic $\theta(h)$ characteristics, but could not identify a unique and simple tendency.

Wildenschild *et al.* (2001) investigated the flow-rate dependence of unsaturated hydraulic properties for disturbed soils in short laboratory columns by performing one-step and multistep outflow experiments. Retention characteristics were obtained from measured tensiometric pressures in the soil column and the average water content. For a sandy soil, they found pressure head differences of 10 to 15 cm (for a given saturation) and water content differences of up to 7% (for a given potential) between the slowest and the fastest outflow experiments. At a given pressure head, more water was retained with greater applied pressure steps. Conversely, Constantz (1993) reported higher water contents in slow multistep drainage experiments as compared to fast one-step drainage experiments. He attributes this to variations in pore water salt concentrations that induce differences in the pore water surface tension. Simunek *et al.* (2001) performed upward infiltration experiments and observed ongoing infiltration despite apparent equilibrium in the pressure heads. Also, during a 5-day redistribution phase where no flux across the boundaries occurred, they found an increase in tension in the whole soil sample by $\Delta h = 50\,\text{cm}$. All the above-mentioned experiments indicate that the dynamic effect depends on the size of the pressure changes, being larger for big changes. Further, there is some indication that dynamic effects are larger for soils with a wide pore-size distribution. Without relating the observed phenomena to specific processes, we may categorize them in a general way as "dynamic nonequilibrium" (Schultze *et al.*, 1999). According to Klute (1986, p. 660), *the reasons for and implication of this observation continue to be a subject of investigation*.

On the basis of a theoretical framework for multiphase flow in porous media, Hassanizadeh and Gray (1993) and Hassanizadeh *et al.* (2002) postulated the existence of a dynamic component in unsaturated water flow. Their analysis yields an approximate capillary pressure equation with a dynamic term, which depends linearly on the rate of change in water saturation

$$p_a - p_w = p_c - \frac{1}{L}\frac{\partial S}{\partial t} \qquad (12)$$

where p_w [$\mathrm{M\,L^{-1}\,T^{-2}}$] is the macroscopic pressure in the water phase, p_a [$\mathrm{M\,L^{-1}\,T^{-2}}$] is the pressure in the air phase, p_c [$\mathrm{M\,L^{-1}\,T^{-2}}$] is the capillary pressure, L [$\mathrm{T\,L\,M^{-1}}$] is a nonnegative material coefficient, $S = \theta/\theta_s$ [$-$] expresses the soil water saturation, and t [T] indicates the time. Equation 12 states that the pressure difference between air and water pressure is larger than the (equilibrium) capillary pressure under drainage conditions, and smaller when imbibition occurs.

Macroscopic simulation of water transport including dynamic effects is still in its infancy. Stauffer (1977) simulated the dynamic process with Richard's equation by using a dynamic retention characteristic, where the difference to the static characteristic depended on the rate of change of the local water content with time. Schultze *et al.* (1999) showed that a two-phase model explains much of the observed dynamic flow behavior in a soil column. Simunek *et al.* (2001) simulated water transport with a dual-continuum model (Gerke and van Genuchten, 1993), and found good agreement with measurements, when

interpreting measured tensiometric measurements as being representative for the interaggregate pore space.

Summarizing, evaluations of transient-flow experiments, thermodynamic reasoning, pore-network modeling (Held and Celia, 2001), and continuum percolation theory (Hunt, 2004) all lead to the conclusion that hydraulic relations are not only dependent on the wetting/drying history and the actual system state, but also on the rate of change of the system state. This is a problem, because hydraulic functions are primarily used in model applications under transient conditions, whereas most measurement experiments are based on equilibrium conditions (Durner and Lipsius, 2005; *see* **Chapter 75, Determining Soil Hydraulic Properties, Volume 2**). However, it is currently not clear as to what degree dynamic effects will affect water flow on time and spatial scales that are relevant for most applications. Despite its early notion, the problem of dynamic nonequilibrium during water flow in soils has not been adequately treated yet. Reasons for this are the high requirements with respect to the measurement, and even more the historic inability to tackle the theoretical problem. Without the availability of fast computers and fast measurement techniques, quantitative comparisons of observed transient-flow process variables with simulation results obtained by models of increasing complexity, such as Richards' equation, the coupled two-phase flow model, and the pore-network models, were not possible. Since dynamic nonequilibrium in water flow is closely related to hysteresis, a satisfying solution of the hysteresis problem also depends on the progress of this issue. In part, the distinction between hysteresis and dynamic nonequilibrium in water flow can be seen as a matter of the time scale, since a true equilibrium distribution of the water phase (which actually may require enormous time) will cause much of the apparently "static" hysteresis to disappear.

VARIABILITY

Soils are heterogeneous from the pore to the geologic scale. We have already noted that homogeneity in soils does not exist unless we refer to the concept of the REV. If the scale of observation is less than the REV, the soil is heterogeneous (Figure 1). Spatial variability of soils critically affects the effective capacity and transmission properties of water, solutes and gases, and controls by the formation of micro-niches and gradients of intensive soil properties during flow processes and the ecological functioning of the vadose zone. Reviews by Warrick and Nielsen (1980), Peck (1983) and Jury (1985) have shown that in soils, water flow and transport properties are the most variable. Jury *et al.* (1991), Kutilek and Nielsen (1994), Warrick (1998), Mulla and McBratney (2002), and van Es (2002) have reviewed techniques to handle spatial variability and soil heterogeneity.

Solute transport in soils is critically dependent on the variability of soil water fluxes. Increased travel time variance results in increased probability of short travel times, that is, preferential flow and transport. Soil water flux variability depends on the soil moisture status (Roth, 1995), and can be enhanced as compared to the variability of the soil moisture or hydraulic conductivity parameters. Owing to the nonlinearity of unsaturated water transport, spatial variability leads to scale dependence of hydraulic properties. Investigation of these questions is amongst the most critical topics in contemporary soil physical and hydrologic research (Sposito, 1998; Roth *et al.*, 1999). Scale issues are treated in this Encyclopedia in **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2** (Hopmans and Schoups, 2005, this issue).

Basically, there are two ways to tackle properties of heterogeneous soils. One way lies in the investigation of frequency distributions of local properties and in the characterization of their spatial structure. The other way is to search for effective transport processes and parameters, allowing for the application of overall initial and boundary conditions for a quasi-homogeneous system. Unfortunately, there is no general upscaling rule for hydraulic properties of unsaturated soils, and even the question about the existence of appropriate process descriptions with effective hydraulic properties at larger scales is not resolved yet. This is of fundamental importance when comparing the results of laboratory and field experiments.

Spatial and Temporal Variability

Since measurement scales are often smaller than the REV scale, soil hydraulic properties are often extremely variable in space and do not conform to conventional statistical assumptions. The structure of variability may be random, correlated, periodic, or in any combination, and may also be scale dependent (van Es, 2002). Spatial variability of hydraulic properties has been documented in many articles (e.g. Nielsen *et al.*, 1973; Simmons *et al.*, 1979, Russo and Bouton, 1992; Istok *et al.*, 1994; Jarvis and Messing, 1995; Mohanty *et al.*, 1994; Shouse *et al.*, 1995; Russo *et al.*, 1997; Shouse and Mohanty, 1998). Water contents in the field are mostly found to be normally distributed with medium variation (coefficient of variation, $0.15 < cv < 0.5$; Jury *et al.*, 1991; Warrick, 1998), with increasing variability when the soils dry out (Shouse *et al.*, 1995). Field investigations of hydraulic conductivities yield in most cases lognormal distributions, with variances of $\log(K)$ in the order of 1 (Dagan, 1984; Butters *et al.*, 1989; Heuvelman and McInnes, 1997; Holt *et al.*, 2002).

Spatial variability is overlaid by temporal variability. The soil pore system is affected by seasonal changes, by diurnal cycles of temperature and corresponding energy gradients, by plant and root growth, by irrigation cycles, and by freezing and thawing. Water transport in soil is

generally driven by weather-related processes or irrigation, which have high short-term dynamics. Soil properties that affect hydraulic behavior, aeration, erosion and runoff, and aggregation are strongly affected by processes such as soil wetting and drying, freezing and thawing, and weather-related behavior of soil organisms (van Es, 2002).

Cultural influences cause spatial and temporal extrinsic variability. Drainage, tillage, vehicle traffic, overburden pressure, plant cover, and soil amendments may dramatically alter mean behavior and variability patterns. For example, tillage tends to homogenize soils spatially, but may cause greater temporal variability from loosening and subsequent settling and recompaction (Mapa *et al.*, 1986; Starr, 1990, van Es *et al.*, 1999).

Geostatistical Characterization of Random Variability

Variations of soil properties are not completely disordered over the field and contain systematic and random components. To describe spatial correlation structures, tools of geostatistics, based on the theory of regionalized variables, have been developed (Matheron, 1963; Journel and Huijbregts, 1978) and successfully applied in soil science (e.g. Warrick and Nielsen, 1980). On the basis of proper statistical information, stochastic random fields can be created and the effective behavior of these "virtual realities" can be investigated.

In stochastic models, it is often assumed that the correlation lengths of different unsaturated parameters are the same (Holt *et al.*, 2002). Horizontal correlation scales for hydraulic properties were reported to be in the order of 6 m to 20–30 m (Ciollaro and Romano, 1995; Shouse *et al.*, 1995), whereas vertical correlation scales are in the order of 0.1 to 0.3 m (Robin *et al.*, 1991; Wierenga *et al.*, 1991). Heuvelman and McInnes (1997) investigated spatial variability of water fluxes on a scale of centimeters and found water flux densities to be normally distributed in a sandy topsoil, becoming lognormally distributed in a loamy subsoil. Jury (1985) and Shouse *et al.* (1995) noted that the range of spatial influence may be related to the scale of the sampled area, and that the commonly observed high nugget variance of soil hydraulic properties may be more closely related to measurement error than to high frequency, small-scale variations.

A particular problem of vadose zone spatial variability results from the fact that the typical travel distance is small compared with the distance required for a solute plume to reach asymptotic, Fickian behavior (Jury and Flühler, 1992). This means that hydraulic properties on the scale of interest are not randomly distributed. Hence, application of geostatistical concepts to derive asymptotic large-scale behavior is of limited value. This is further aggravated by the fact that proper three-dimensional geostatistical characterization of hydraulic properties needs such a high number of measurements that it cannot be obtained in practice. It appears that a reliable prediction of solute transport in natural fields requires the quasi-deterministic characterization of the largest spatial system structures, which are often on the same scale as the scale of interest (Vogel and Roth, 2003). This cannot be obtained by point measurements. Therefore, the further development of hydrogeophysical methods, possibly coupled with remote sensing technologies, and the linking of these data with functional hydraulic properties, for example, by stochastic data fusion (Yeh and Simunek, 2001), will play a crucial role in future developments.

Influence of Measurement Errors on Spatial Data Analysis

The analysis of spatial variability depends on measurements that are assumed to have little or no experimental or calibration error. Unfortunately, this is rarely the case. Many estimated hydraulic properties are likely to contain systematic error, or bias, in particular, if they are not measured directly. Although most studies carefully document instrumental procedures, the magnitude of errors in hydraulic property estimates and their impact on spatial statistics determined from field data are rarely evaluated. Ciollaro and Romano (1995), for example, used inverse modeling of evaporation experiments to derive the hydraulic properties of a 135-m transect, and found a discrepancy between optimized saturated conductivity and directly measured saturated conductivity by a factor of 10. Shouse *et al.* (1995) conclude that more information is needed on experimental error, its causes, and remedies.

If nonlinear inversion models, whether analytical or numerical, are used to infer property values from observed system responses and boundary conditions, random error in the observations (observation error) can lead to spatially correlated, systematic error, or bias, in the derived property value. Spatial bias may also result when the inversion model (e.g. governing equations, boundary conditions, initial conditions, constitutive models, etc.) is inadequate (inversion model error) (Kempthorne and Allmaras, 1986). Holt *et al.* (2002) used a Monte Carlo approach to explore the potential impact of observation and inversion model errors on the spatial statistics of field-estimated unsaturated hydraulic properties. For this analysis they simulated tension infiltrometer measurements in a series of idealized realities, each consisting of spatially correlated random property fields. They showed that estimated hydraulic properties are strongly biased even by small, simple observations, and inversion model errors. Error in spatial statistics was more than an order-of-magnitude, and artificial cross-correlation between measured properties occurred. Unfortunately, there are no unique indicators of bias, as property values may appear reasonable and spatial statistics may look realistic.

Errors in the spatial statistics of hydraulic properties cause critical stochastic model assumptions to be violated, limiting the usable parameter space for model predictions. Even where critical assumptions are valid, stochastic model predictions show significant error, and the magnitude and pattern of error changes with the true property means, the flow conditions, and the type of measurement error. Experimental technologies need to be developed that reduce experimental error and increase precision.

Scaling of Hydraulic Functions

A particular challenge for handling spatially variable unsaturated hydraulic properties lies in the fact that not just distributions of single parameters, like K_s, must be characterized, but the variability of the whole constitutive relationships, $K(\theta)$ and $\theta(h)$. A way to handle this is using the concept of similar media scaling. The objective of scaling is to coalesce a set of hydraulic relationships into a single reference curve using scaling factors that describe the set as a whole. This method was introduced by Miller and Miller (1956), and its concepts and limitations were reiterated and assessed later by Miller (1980), Tillotson and Nielsen (1984), and Sposito and Jury (1985). Simmons *et al.* (1979) extended similar media scaling theory to characterize the spatial variability of field water retention measurements. Jury (1985) indicated that an obvious limitation of scaling theories is that the errors involved in measuring the properties used to calculate the scale factors are carried along as a part of the scale factor sample variance. Reviews and application examples of scaling soil hydraulic functions are given by Hillel and Elrick (1990), Kutilek and Nielsen (1994), and Roth (1995).

Mean and Effective Soil Hydraulic Properties

Since the scale of interest is in general larger than a local REV, upscaling of hydraulic properties is required to get a proper description on the scale of interest. When nonlinear properties have to be averaged, the mean property is in the general case not identical to the "effective" property. An effective property represents a homogeneous medium with a macroscopic behavior that is quasi-identical to the heterogeneous system. For the unsaturated case, the differences between mean and effective properties are dependent on the spatial variability of the local properties, but furthermore also on the boundary conditions, as will be illustrated for the case of steady state water flow into a moderately heterogeneous soil.

Figure 4 shows a simulated domain of a weakly heterogeneous soil, composed of irregular lenses of sand and silt forming a 2-m deep soil body (Flühler and Roth, 2004). The structures have a wide extension in the horizontal and a small extension in the vertical scale. Water movement takes place from top to bottom. The water flux q through the upper boundary is continuous and constant. At the lower boundary there is contact to the groundwater table, that is, $h = 0$. The depicted structure is assumed to be periodic, that is, water flowing out through a vertical boundary is assumed to flow in at the opposite boundary. The hydraulic properties of the sand are given by the van Genuchten/Mualem coefficients $\alpha = 0.02\,\mathrm{cm}^{-1}$, $n = 4.0$, $\theta_s = 0.3$, $\theta_r = 0$, $K_s = 10^{-4}\,\mathrm{m\,s}^{-1}$, and those of the silt by $\alpha = 0.005\,\mathrm{cm}^{-1}$, $n = 1.33$, $\theta_s = 0.4$, $\theta_r = 0$, $K_s = 10^{-5}\,\mathrm{m\,s}^{-1}$. The situation shown in Figure 4 is the stationary flow field corresponding to a weak rain, with a flux density at the upper boundary of $1.8 \times 10^{-7}\,\mathrm{m\,s}^{-1} = 1.56\,\mathrm{cm\,d}^{-1}$. At this low infiltration rate, the silt in the upper 50-cm region, far from the groundwater table, has a much higher conductivity than the sand, and water flows convergent through the silt lenses. In this stationary situation,

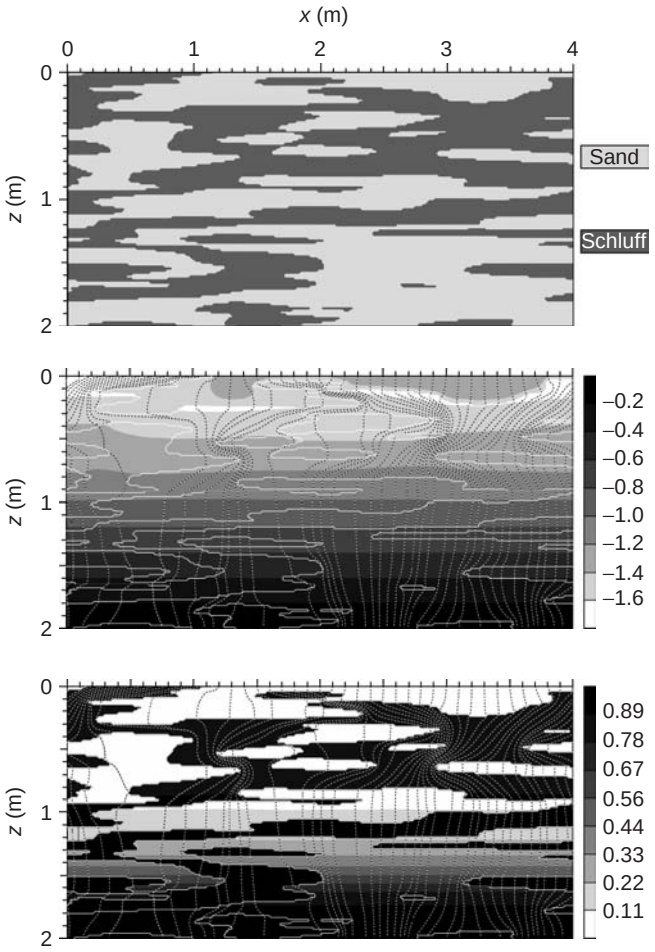

Figure 4 Hydraulic system properties in a soil with heterogeneous layers at a low constant infiltration. (a) Material distribution. (b) Pressure head distribution at a very low infiltration, $q = 1.56\,\mathrm{cm\,d}^{-1}$. (c) water saturation. The border sand-silt is indicated by the white drawn lines, the streamlines are shown by dotted white lines. (Courtesy of H. Flühler and K. Roth)

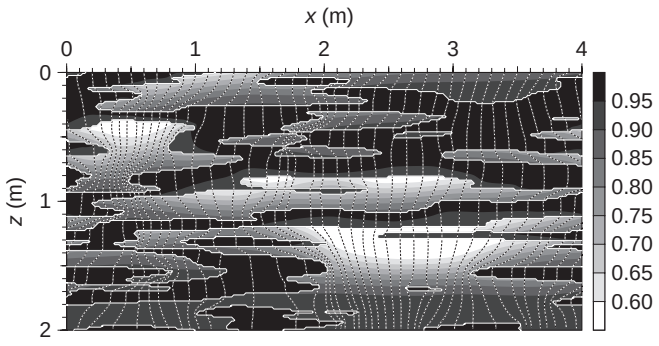

Figure 5 Water saturation during steady state infiltration with $q = 5.4 \times 10^{-5}\,m\,s^{-1} = 47\,cm\,d^{-1}$ into the heterogeneous soil of Figure 4 (Courtesy of H. Flühler and K. Roth)

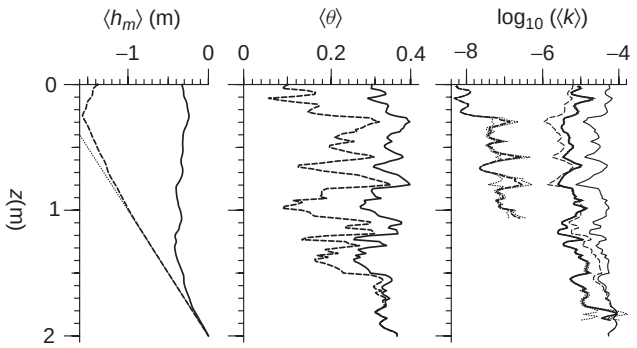

Figure 6 Mean and effective hydraulic properties of the heterogeneous soil of Figure 5 for a flux density of $1.8 \times 10^{-7}\,m\,s^{-1}$ (dashed lines) and $5.4 \times 10^{-6}\,m\,s^{-1}$ (drawn lines). (a) mean hydraulic head $\langle h_m \rangle$ [m]; the dotted line represents the hydraulic head at hydrostatic equilibrium. (b) Mean volumetric water content $\langle \theta_w \rangle$. (c) Mean hydraulic conductivity, $< k >$ (thin lines) and effective conductivity k_{eff} (thick lines), k in $[m\,s^{-1}]$. The thin dotted lines show uncertainty bands of one standard deviation of the estimation of k_{eff}, Values with an estimation uncertainty which is greater than the value itself are omitted (Courtesy of H. Flühler and K. Roth)

the water saturation reflects the substrate changes very sharply, whereas the lateral distribution of the pressure head is much smoother, in particular, close to the groundwater table. As a fundamental consequence, single point measurements of matric potential are more representative for the average pressure than point measurements of water contents for the average water content. At about 1.2-m depth, the two materials have essentially the same conductivity, leading to a uniform flow of water. Close to the groundwater table, the silt lenses are obstacles to water flow, and water flows preferentially in the sand matrix. Figure 5 shows the water saturation in the same profile, corresponding to a stationary flow with an increased infiltration rate of $q = 5.4 \times 10^{-6}\,m\,s^{-1}$. Now, the silt lenses are obstacles to water flow in the whole profile.

Figure 6 shows the corresponding depth profiles of the mean hydraulic properties $\langle h \rangle$, $\langle \theta \rangle$, and $\log_{10}\langle K \rangle$, obtained by horizontally averaging the local values of the heterogeneous soil. The dashed lines indicate the situation for the low water flux density, the drawn lines for the high flux density. It is apparent that the average water content, $\langle \theta \rangle$, varies much more than the average water potential, $\langle h \rangle$, which reflects a typical gravitational flow situation for the high flux rate (Figure 6, left, drawn line) and a situation close to hydrostatic equilibrium conditions for the low flow rate (Figure 6, left, dashed line). Figure 6 (right) depicts the mean (thin lines) and effective hydraulic conductivity (thick lines) for the corresponding one-dimensional water flux. We observe that even for the case of quasi-gravitational unit-gradient flow, the mean hydraulic conductivity, $\log_{10}\langle K \rangle$, in the upper part of the profile is higher than the infiltration rate, since the local water flux is strongly deflected from the straight vertical movement.

The *effective hydraulic conductivity* for the flow situation is obtained by dividing the macroscopic water flux density by the gradient of the mean water potential. For the high flux density, the resulting effective hydraulic conductivity is in the range of the infiltration rate, which is about 5 times smaller than the mean hydraulic conductivity. For the low infiltration rate, the difference between mean and effective conductivity is in the order of two magnitudes.

CONCLUDING REMARKS

Enormous advances have been made during the last few decades regarding our understanding and our ability to model flow and transport processes in the vadose zone (Simunek, 2005; *see* **Chapter 78, Models of Water Flow and Solute Transport in the Unsaturated Zone, Volume 2**; van Genuchten and Simunek, 2004). The current scientific perspective is that the Richards' equation provides the most appropriate tool on which any description of water transport in the vadose zone can be based. Other simplified descriptions, such as bucket models, are not considered as a viable alternative (Vanclooster *et al.*, 2004). More comprehensive descriptions, such as the use of two-phase flow models (for water and air) appear superfluous for standard uses. The validity of the Richards' equation for larger scales is a matter of ongoing debate. From a theoretical standpoint and based on stochastic hydrology a Richards'-type equation for water flow appears to retain its validity for larger scales, yet with different constitutive relationships, which are dependent both on the stochastic distribution of local soil hydraulic properties and also on the boundary conditions (Harter and Hopmans, 2004).

For the characterization of soil hydraulic properties the most critical problem lies in the derivation of effective properties for large-scale applications, such as for hill slopes,

catchments, or entire regions. Nevertheless, the description of hydraulic functions on the measurement scale, needs improvement as well, both in the moisture range near saturation (for solute transport and infiltration), and also toward dryness. The latter is of particular importance for simulating evaporation and transpiration under conditions where the conductivity of the soil becomes a limiting factor. Furthermore, a valid description of hysteresis in the intermediate moisture range is required for transient-flow conditions. The development of accurate, fast and reliable measurement methods, a further assessment of "dynamic effects", and the description of the hydraulic properties for shrinking and swelling soils (Smiles and Raats, 2005; *see* **Chapter 67, Hydrology of Swelling Clay Soils, Volume 2**) remain major challenges to soil scientists and hydrologists. Some important issues with respect to the future use of Richards' equation are (i) a suitable integration of boundary conditions on large scales (integration in landscape models), (ii) the adequate representation of soil hydraulic functions on large scales, (iii) hysteresis, (iv) spatial and temporal variability, (v) structured soils and macropores, and (vi) unstable wetting fronts as well as factors dealing with soil hydrophobicity.

75: Determining Soil Hydraulic Properties

WOLFGANG DURNER AND KAI LIPSIUS

Institute of Geoecology, Department of Soil Physics, Braunschweig Technical University, Braunschweig, Germany

Hydraulic properties are required for modeling water and solute transport in unsaturated soils. The bottleneck for the successful application of numerical simulation models lays usually in their parameter estimation requirements. Methods to determine hydraulic properties can be classified into indirect and direct approaches. Indirect methods encompass the estimation of hydraulic properties by pedotransfer functions from more easily measured soil properties, and the prediction of the unsaturated hydraulic conductivity function from the water retention curve (WRC). In direct methods, observations of flow attributes from laboratory or field experiments are evaluated. This article reviews common methods to estimate the hydraulic conductivity function from the water retention characteristic and various direct measurement techniques in the laboratory and the field. We conclude with an outlook on contemporary developments in measurement techniques, stressing the key role of inverse modeling of experiments to derive optimum hydraulic properties and the importance of a future combination of noninvasive measurement techniques with inverse modeling by stochastic data fusion.

INTRODUCTION

A proper characterization of water flow processes is needed in nearly all basic and applied aspects of soil, water, nutrient, and salinity management research (van Genuchten *et al.*, 1999b). Water flow in soils is typically described with the Richards equation (Richards, 1931)

$$C(h)\frac{\partial h}{\partial t} = \frac{\partial}{\partial z}\left[K(h)\left(\frac{\partial h}{\partial z} - 1\right)\right] + s \qquad (1)$$

where t is time [T], z is a spatial coordinate [L], positive downward, h is the matric potential, expressed as pressure head [L], $C(h)$ is the specific water capacity [L^{-1}], defined by the change of the volumetric water content θ [L^3 L^{-3}], with pressure head, $C = \partial\theta/\partial h$, $K(h)$ is the unsaturated hydraulic conductivity [L T^{-1}], and s is a source/sink term [T^{-1}]. The model is completed by appropriate initial and boundary conditions. Since C and K are nonlinearly dependent on h, its solution generally requires numerical methods. Equation (1) is derived from the combination of the Darcy-Buckingham equation and continuity considerations in the framework of the continuum theory, and is valid for the measurement scale (see Durner and Flühler, 2005; **Chapter 74, Soil Hydraulic Properties, Volume 2**). It is also frequently used as process model for water transport at much larger scales. The coefficients C and K are then used as *effective* properties, which have the same names as for the local scale, but their values are no longer necessarily consistent with the local definition. Determining hydraulic properties is the process of deriving the constitutive relationships $\theta(h)$ and $K(\theta)$, or $K(h)$, as used in equation (1). The relationship $\theta(h)$ is called (water retention curve) *WRC* . The dependence of the hydraulic conductivity, $K(h)$, on water content or pressure head is called '*hydraulic conductivity curve*'.

This article reviews the indirect and direct methods for the determination of soil hydraulic properties. Direct methods are based on flow experiments in the field or with soil samples in the laboratory. They rely on observations of flow attributes, such as water potential, water content or water flux density. These measurements are far from simple. Water content measurement is treated in this encyclopedia in **Chapter 72, Measuring Soil Water Content, Volume 2** (Topp and Ferré, 2005), soil water potential measurement is treated in **Chapter 73, Soil Water Potential Measurement, Volume 2** (Durner and Or, 2005). Water flux density can be determined at system boundaries,

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

using scales or burettes in the laboratory. For measuring fluxes *in situ*, there are no reliable and accurate methods. Accordingly, *in situ* flux measurements are not used up to date for the determination of hydraulic properties (Dirksen, 1999b).

Indirect methods are used to estimate hydraulic properties from more easily measured data, using regression or neural network algorithms. In particular, the unsaturated conductivity function is seldom measured, but commonly estimated from the WRC and matched to a single measured conductivity value. Because of the shortcomings of direct measurement procedures, indirect estimation methods are gaining popularity. All estimation procedures, however, need the results of direct measurements as benchmarks for validation. Furthermore, reliable and efficient experimental procedures are critical to improve the understanding of flow and transport processes in variably saturated media, regardless of the advances in the formulation of indirect methods.

A review on measurement methods needs to address aspects of sensor technology, instrumentation, experimental design, techniques to evaluate observed data, scale issues, parameterization of hydraulic functions, parameter estimation techniques, and uncertainty estimation and propagation. Covering all these issues in the required depth would be far beyond this contribution. So the focus is on principles of indirect estimation procedures (Section "Indirect estimation of hydraulic functions"), on direct laboratory measurement methods (Section "Laboratory methods"), and on field methods (Section "Field methods"). Topics that are closely related to soil hydraulic measurements are treated in the accompanying contributions in this encyclopedia. These are, in particular, soil water potential measurement (Durner and Or (2005), **Chapter 73, Soil Water Potential Measurement, Volume 2**), water content measurement (Topp and Ferrè (2005), **Chapter 72, Measuring Soil Water Content, Volume 2**), estimation of hydraulic properties by pedotransfer functions (Schaap, 2005, **Chapter 76, Models for Indirect Estimation of Soil Hydraulic Properties, Volume 2**), scale issues (Hopmans and Schoups, 2004, **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**), recent developments in parameter estimation techniques (Vrugt and Dane, 2005, **Chapter 77, Inverse Modeling of Soil Hydraulic Properties, Volume 2**), and uncertainty propagation in hydrologic models (Brown and Heuvelink, 2005, **Chapter 79, Assessing Uncertainty Propagation Through Physically based Models of Soil Water Flow and Solute Transport, Volume 2**). The definition of hydraulic functions in the framework of the continuum theory, the parameterization of the hydraulic functions including hysteresis, and the issue of scale dependence of hydraulic properties are treated by Durner and Flühler (2005)).

Methods and techniques to measure soil hydraulic properties are described in a series of monographs. The reference with the widest distribution is the classic monograph "Methods in Soil Physics – Physical Methods" of the American Society of Agronomy. The previous edition (Klute, 1986) has recently been revised (Dane and Topp, 2002), and covers almost all practical measurement techniques including soil sampling, uncertainty, and sensor technology. Hydraulic measurement methods are further discussed in some textbooks, for example, Kutilek and Nielsen (1994), Dirksen (1999a), and Flühler and Roth (2004). The scientific state of knowledge on direct, inverse, and indirect measurement methods at the time of the millennium is documented on 1600 pages in the "Proceedings of the International Workshop on Characterization and Measurement of the Hydraulic Properties of Unsaturated Porous Media" (van Genuchten *et al.*, 1999a). Direct measurement methods cover about a fourth of the volumes.

The Purpose of Hydraulic Measurements

Methods to determine hydraulic properties differ with respect to their accuracy, measurement range, difficulty of implementation, and demand for time and capital. Before selecting a specific measurement method, the purpose of the measurements must be manifest. Purposes may be classified into three groups.

(i) Soil hydraulic properties are often needed for a hydraulic classification of soils, in a similar manner as the particle size distribution is used for a textural classification. Knowledge of basic hydraulic properties, such as field capacity or plant available water content, is useful for a variety of purposes, where soil moisture storage, soil wetness (affecting oxygen supply for plant roots and redox state of soil), surface runoff, susceptibility to soil erosion, and other large-scale properties of soils are of interest. Indirect methods are often appropriate for this group (Schaap, 2005, **Chapter 76, Models for Indirect Estimation of Soil Hydraulic Properties, Volume 2**).

(ii) Today's prevalent demand for hydraulic properties is their use in numerical simulation of water transport by Richards' equation. Estimation of water recharge through the vadose zone for water balance calculations are a classic application, but more important is now their use for agricultural, ecological, and environmental purposes, such as irrigation control, fertilizer management, and contaminant fate modeling. The focus of subsurface models of water and solute transport has increasingly been shifted toward environmental research, with the primary concern on the subsurface fate and transport of various substances, such as nutrients, pesticides, pathogens, pharmaceuticals, viruses, bacteria, colloids, and toxic trace elements (Simunek, 2005, **Chapter 78, Models**

of Water Flow and Solute Transport in the Unsaturated Zone, Volume 2). The crucial bottleneck for the successful application of these models is their parameter estimation requirements.

(iii) Finally, accurate measurement of soil hydraulic properties is required for a further improvement in the basic understanding of soil hydraulic processes, that is, in order to test and improve the process knowledge we have. Examples are the understanding and assessment of nonequilibrium phenomena in water flow, further progress in describing hysteresis in soil water flow, and the question up to which scale the Richards equation process model provides an appropriate effective process representation for unsaturated water transport (Durner and Flühler, 2005).

Whereas the demand on accuracy, resolution, precision, and reliability of the measurements is moderate for the first group, it is higher for the second and third. For the second group, we are particularly faced with scale considerations. For the third group, the precision, reliability, and validity of measurements are of utmost importance, in order to avoid misconceptions.

The Challenge of Determining Soil Hydraulic Properties

Determining soil hydraulic properties is demanding for a variety of reasons. Soils are porous media with a three-dimensional arrangement of interconnected voids that form a highly complex pore system. The topology of this system shows, in general, a hierarchical arrangement, with spatial and temporal variability on a multitude of scales. The microscopic properties of the pore system determine the macroscopic hydraulic behavior. A complete understanding of water flow in soils requires a thorough understanding of processes on scales much smaller than the usual measurement scale and the ability to express effective hydraulic properties at scales much larger than the measurement scale (Durner and Flühler, 2005; Hopmans and Schoups, 2004, **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**).

A specific problem in the determination of soil hydraulic properties lays in the fact that quality control and validation of measurement results is extremely difficult. Contrary to soil chemical analysis, there is virtually no possibility for reliable interlaboratory comparisons (Dirksen, 1999b). The reasons for this are: (i) as opposed to consolidated porous media, the soil pore system is not a stable structure. Just those parts of the pore system, which control the water transmission near saturation, are most fragile, and there is always a danger that the measurement process itself changes the system (Ghezzehei and Or, 2003). Therefore, repetitive measurements on the same soil sample by different laboratories are impractical. The sampling process itself often causes the most severe disturbance, when an "undisturbed" soil sample is isolated from the natural embedding. (ii) Soils exhibit considerable temporal variability (Mapa *et al.*, 1986; Ahuja *et al.*, 1998; Leij *et al.*, 2002). Thus, measurements at the same site may yield different results if applied at different times (van Es *et al.*, 1999). (iii) Soil is a living organism and the pore system is affected by a variety of interacting biological, chemical, and physical processes. Matrix surface properties are variegated and may change depending on physical, chemical, and biological factors, thereby changing the macroscopic hydraulic behaviour. (iv) Spatial variability of hydraulic properties, finally, is probably the biggest problem (Nielsen *et al.*, 1973, 1986). Different measurement methods use different sample volumes and sample numbers, dictated by standard procedures and the apparatus available for the various methods. This implies that, in a comparison of measurement methods, considerable uncertainty about the result of the comparison will always be induced by natural variability (Stolte *et al.*, 1994; Munoz-Carpena *et al.*, 2002). For example, the determination of field-saturated conductivity, K_{fs}, may vary two or more orders of magnitude among different field and laboratory methods.

Testing measurement methods on synthetic soil-like porous media is not a solution to this dilemma. The pore system properties of repacked soil samples are often very different from the properties of an undisturbed soil (Torquato, 2001). It is notable that especially uniform fine sand, being the favorite material used for research purposes in soil physics, has properties that are quite untypical for a structured natural soil. Since the early observations of Kozeny (1927) on particle segregation during packing, the problem of constructing a synthetic porous medium in a fully reproducible manner, with pore system properties comparable to a natural soil, has remained unresolved (Lebron and Robinson, 2003).

An overview on various field and laboratory methods for determining unsaturated hydraulic properties shows that many techniques have been proposed, but most of them are limited to relatively narrow ranges of water potential (h) or water content (θ). Figure 1 illustrates this, showing results of five different measurement methods to determine the hydraulic conductivity. The existing experimental procedures all have their own unique advantages and limitations (Gee and Ward, 1999), and selecting the most appropriate measurement for a specific task is usually not trivial.

Classification of Methods

Determining hydraulic properties of soil encompasses direct measurements and indirect estimation methods. Because of the shortcomings of direct measurement procedures, *indirect estimation methods* are gaining popularity. Computers offer the possibility to generate indirect estimates using

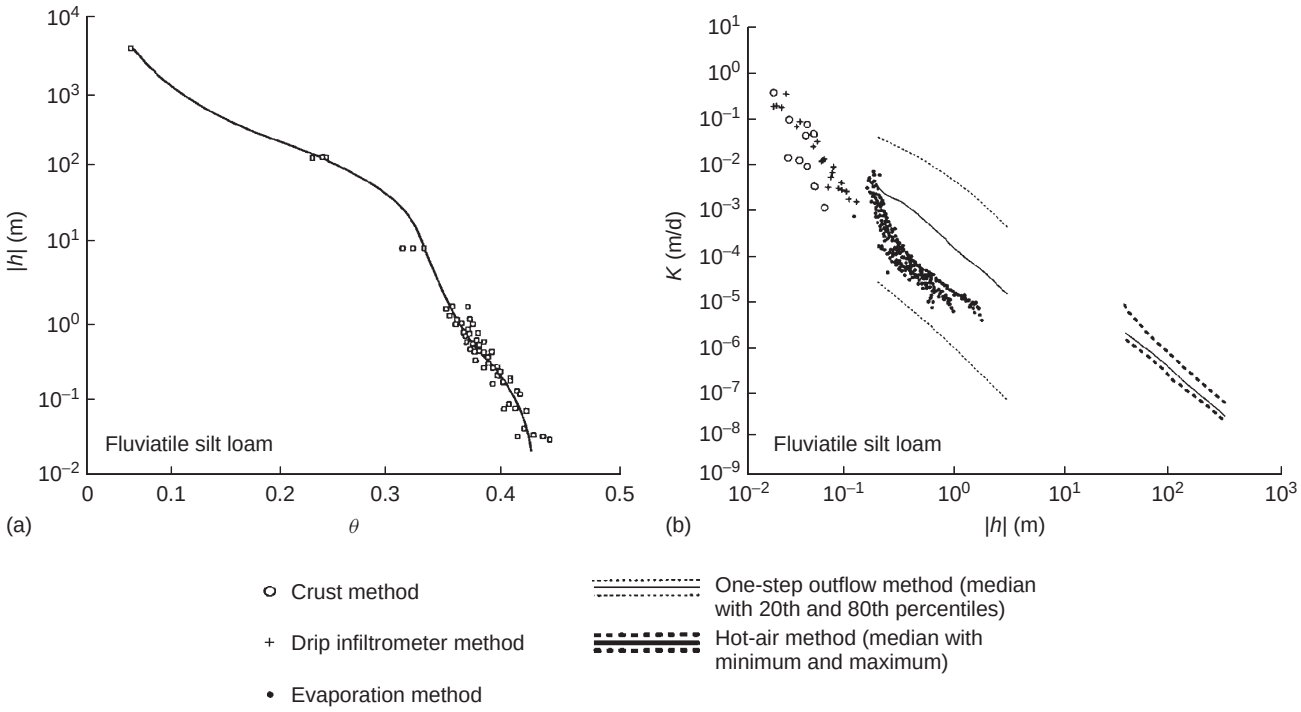

Figure 1 Hydraulic properties of a fluviatile silt loam. (a) Water retention curve measurements. (b) Unsaturated conductivity measurements, determined by five different methods (Reproduced from Stolte *et al.,* 1994 by permission of Soil Science Society of America)

regression or neural network algorithms. In practice, unsaturated conductivity is seldom measured, but estimated from the saturated conductivity (or preferably an other matching point) and the WRC. The principles of indirect estimation procedures are outlined in Section "Indirect estimation of hydraulic functions".

All estimation procedures need the results of *direct measurements* as benchmarks for validation of their results. Reliable and efficient experimental procedures are critical to improve the understanding of flow and transport processes in variably saturated media, regardless of the advances in the formulation of indirect methods. Experiments for measuring hydraulic properties are based on hydrostatic, steady state, or transient flow conditions. The methods can be grouped in those that aim at measuring (i) water retentivity, (ii) saturated conductivity, (iii) unsaturated conductivity or water diffusivity, and (iv) simultaneously retentivity and conductivity. We may further distinguish between *laboratory methods* and *field methods*. The reason for treating laboratory (Section "Laboratory methods") and field experiments (Section "Field methods") in this review in separate sections is less motivated by the different scale, but by the fact that in the laboratory a much better control of boundary conditions, fluxes across boundaries, and integral water content measurements can be achieved.

Finally, methods differ in how the observations of flow attributes, such as pressure heads, water contents or fluxes are evaluated. In the early stages of soil physics, methods have been developed for determining the WRC or the saturated conductivity (Gardner, 1986). Determination of the water retention characteristic can be done directly, by pairing water content and water potential measurements in the laboratory or in the field. The determination of saturated conductivity is achieved by a closed-form inversion of the flow equation. Analytical solutions for the unsaturated conductivity can be obtained in the laboratory by a series of consecutive unit-gradient experiments, where a constant flux or pressure head is applied at the top of a sample, and a corresponding suction at the bottom (Dirksen, 1991, 1999a, 1999b). These methods are conceptually straightforward and easy to implement. Their main disadvantage is that they take a long time, and are therefore tedious and expensive. In order to achieve hydraulic equilibrium, the sample sizes must be kept small and sizes are often below the representative elementary volume, REV (Durner and Flühler, 2005). Accordingly, the resulting properties are generally highly variable.

Measurement of unsaturated hydraulic conductivity and water diffusivity poses greater obstacles. The methods are based on solving the inverse problem, where a model of the flow process is optimized to match observations (Russo *et al.*, 1991; Hopmans *et al.*, 2002; Vrugt and Dane, 2005, **Chapter 77, Inverse Modeling of Soil Hydraulic**

Properties, Volume 2). For some simplified cases, solving the inverse problem is accomplished by closed-form solutions, such as the determination of diffusivity from a quasi-analytical solution of the Richards' equation. In most other cases, solution of the inverse problem can only be achieved by fitting numerically simulated data to observations. This requires the use of nonlinear parameter estimation techniques. In doing this, the next logical step is to simultaneously estimate retentivity and conductivity parameters by inverse modeling.

METHODS TO DETERMINE SOIL HYDRAULIC FUNCTIONS

Indirect Estimation of Hydraulic Functions

Estimation by Pedotransfer Functions

In pedotransfer functions, the water retention and conductivity functions are derived from more easily measured soil properties, such as soil texture, bulk density, and organic matter content. Methods to derive soil hydraulic properties indirectly include multiple regression, classification, and neural network predictions (van Genuchten *et al.*, 1999a). Comparisons of indirectly determined hydraulic properties to directly measured properties are manifold and remain a topic of ongoing research (Schaap, 2005, **Chapter 76, Models for Indirect Estimation of Soil Hydraulic Properties, Volume 2**). In general, it is found that the accuracy of pedotransfer estimates of hydraulic functions for characterizing field average is comparable to simple direct measurements, if spatial variability is considered. Depending on the desired use of these properties, indirect methods have evolved to a point where they provide reliable answers for many problems. However, further improvement of indirect methods hinges on experimental data, which must be obtained with direct procedures.

Conductivity Estimation by Statistical Estimation Methods

The most frequently practiced way to determine the unsaturated hydraulic conductivity function is by estimating its shape from the WRC. The equilibrium WRC can be regarded as an effective statistical cumulative distribution of equivalent pore sizes of a porous medium. From that, attempts to predict the conductivity curve based on capillary models of the pore space by application of Poiseuille's law have been early set (Kozeny, 1927; Purcell, 1949; Childs and Collis-George, 1950; Burdine, 1953; Fatt, 1956; Wyllie and Gardner, 1958; Marshall, 1958; Millington and Quirk, 1961; Mualem, 1976; Alexander and Skaggs, 1984). Capillary pore-bundle models are now routinely applied in an implicit manner, because they yield closed-form equations for the hydraulic conductivity function if combined with specific retention functions. Notable are the models Brooks-Corey/Burdine (Brooks and Corey, 1964), van Genuchten/Mualem (van Genuchten, 1980;), or Russo/Gardner (Russo, 1988). The model of van Genuchten/Mualem is nowadays the most frequently used. It is given by

$$S_e = (1 + (\alpha|h|)^n)^{-m} \tag{2}$$

where $S_e = (\theta - \theta_r)/(\theta_s - \theta_r)$ is a scaled water content, called "*effective saturation*", and $\alpha > 0$ [L^{-1}], $n > 1$ [$-$] and $m > 0$ [$-$] are empirical curve shape parameters. If m is related to n by $m = 1 - 1/n$, the corresponding conductivity function is given by

$$K_r(S_e) = S_e^l \left[1 - (1 - S_e^{1/m})^m\right]^2 \tag{3}$$

where the parameter l [$-$] is called "tortuosity factor". When applying the van Genuchten/Mualem conductivity model (3), the user should be aware of a model artifact for small values of the parameter n, which is discussed in Durner and Flühler (2005).

Despite the fact that these models often rely on oversimplified representations of the medium's pore space as a bundle of cylindrical capillaries, there is much empirical evidence that capillary models yield reasonable shapes for the conductivity curve in a limited range of matric potentials. However, the prediction of the absolute level of conductivities was never successful (Jackson *et al.*, 1965). Hence, "matching factors" are needed to match the unsaturated conductivity curve with observed conductivity values. A matching factor is used to scale a predicted value of the relative conductivity curve, K_r (θ), to a directly measured conductivity, K_{ref} (θ_{ref}), at a reference water content, θ_{ref}.

$$K(\theta) = \frac{K_{ref}(\theta_{ref})}{K_r(\theta_{ref})} K_r(\theta) \tag{4}$$

In practice, most often the saturated conductivity, K_s, is used as matching factor, because measurement of the saturated conductivity is relatively easy, both with respect to the experimental procedure and with respect to the inversion the Darcy-Buckingham flux equation. However, already as early as in the 1960s, the notorious instability of matching the predicted conductivity function to a measured value at saturation was evident (Jackson *et al.*, 1965). This is due to the extreme dependency of the conductivity near saturation on pore structure (Durner, 1994), which causes an enormous variability of the saturated conductivity in natural structured soils and makes the mathematical prediction near saturation unstable. The current recommendation is to use an unsaturated reference measurement, which leads to a more reliable description of the overall conductivity function (Hopmans *et al.*, 2002). This, however, leaves the

question open as to how the shape of the conductivity function close to full saturation should be described.

Also, the usual predictive models tend to fail at low matric potentials (Nimmo, 1999), with deviations up to five orders of magnitude (e.g. Kosugi, 1999). This was often attributed to the moisture dependence of pore tortuosity and connectivity, and was accounted for by introducing a tortuosity/connectivity term θ^l. Contrary to theoretical considerations of, for example, Mualem (1976), the analysis by Hoffmann-Riem *et al.* (1999) shows that the tortuosity factor l must be regarded as a (second) purely empirical matching factor, with a high variation from soil to soil. This is confirmed by the study of Schaap *et al.* (1999) who found an overall averaged optimum value of $l = -1$ for the van Genuchten/Mualem model when testing soils of the UNSODA database. If interpreted in the original model theory of Mualem (1976), this value would be "unphysical". Tuller and Or (2001) argue that the failure of predicted conductivity functions in the low moisture range is due to the lack of consideration of flow in thin liquid films and in crevices and corners of angular pores. In a series of papers (Tuller *et al.*, 1999; Or and Tuller, 1999; Tuller and Or, 2001) they developed a thermodynamically based conductivity estimation model that improves the predictions at low saturations significantly.

Estimation of Constitutive Relationships by Pore-network Models

Computational pore-scale network models describe two-phase porous media flow systems by resolving individual interfaces at the pore scale, and tracking these interfaces through the pore network (Celia *et al.*, 1995). Coupled with volume-averaging techniques, these models can reproduce relationships between macroscopically measurable variables like capillary pressure, water content, and relative permeability. Over the last decade, this approach has taken a tremendous development. This is due to rapid advances in instrumental techniques for a noninvasive three-dimensional characterization of the pore spaces and for flow and transport processes (Blunt and Hilpert, 2001). In connection to this, the use of fast computers allows to use sophisticated image analysis tools and tomography to reconstruct three-dimensional statistically equivalent pore-scale network models (for an overview, see Blunt and Hilpert, 2001). Also, simulation of water and air distribution and transport in reconstructed porous networks on the microscale, for example, by Lattice-Boltzmann techniques (Krafczyk and Rank, 1995), can be used to infer macroscopic hydraulic properties. On a macroscopic level, Liu and Bodvarsson (2003) modeled effective constitutive relationships for fracture networks and for dual-permeability media. Currently, the use of these techniques is in a research state, and aims more toward understanding various flow phenomena than on practical determination of hydraulic properties.

Laboratory Methods

Laboratory methods have the advantage of being conducted in a controlled environment. On the experimental side, significant progress has been achieved through the use of improved computer technology that lead to automation of experimental devices with flexible control of boundary conditions and precise data acquisition at high temporal resolution (Durner *et al.*, 1999a). Dirksen (1999b) states that measurements of hydraulic properties should be made in the laboratory, unless there are overriding reasons to perform them *in situ*, such as the presence of strongly layered soil profile, large unstable structural elements, and an abundance of stones. Vogel and Roth (2001) put forward that direct measurements of the hydraulic functions are only feasible on the scale of core samples treatable in the laboratory. Laboratory methods are, however, subject to the limitation that some disturbance is introduced in manipulating the sample, even if "undisturbed" soil cores are used. In addition, the measurements may be affected by hydraulic effects not present in the field (Munoz-Carpena *et al.*, 2002). Santos *et al.* (1999) pointed out the importance of *in situ* methods to obtain reference values against which laboratory methods should be tested.

Direct laboratory measurement methods can be grouped into static equilibrium methods to determine water retentivity (Section "Hydrostatic equilibrium methods"), steady-state flux methods to determine conductivity (Section "Steady-state laboratory methods"), and transient methods to determine unsaturated conductivity or diffusivity (Section "Transient laboratory methods"). Transient methods are increasingly replacing the conventional equilibration and steady-state methods, because they can be applied to larger soil samples and speed up the experiments considerably. Traditionally, transient methods focus on determining the unsaturated hydraulic diffusivity or conductivity by measuring water fluxes at the system boundary. However, simultaneous measurements of water content and pressure in a soil sample during computer-controlled transient experiments are probably the best and quickest method to derive, also directly, the water retention function (Schultze, 1998; Zurmühl, 1998).

Hydrostatic Equilibrium Methods

Hydrostatic equilibrium methods can be used to determine the WRC. There are several standard methods. For references to the primary literature and for details in the application of the methods, the reader is referred to Kutilek and Nielsen (1994) and Dane and Topp (2002). Nimmo (2002) compiled a table with useful guidelines for the selection of the most appropriate method for a given purpose, considering aspects of sample size, measurement range, difficulty, duration, and cost.

- *Long column method*: A long homogeneous column is put in contact with a water reservoir at its lower end.

Dependent on the initial state of the column, saturated or dry, an imbibition process or a drainage process will take place. After equilibration, the column is sliced and the water contents are determined. Problems of this method lie in the extreme long time demand necessary for equilibration, the limited pressure range, and in the difficulty of obtaining a homogeneous soil column. Advantage of the method is an almost arbitrary fine resolution with respect to $\theta(h)$.

- *Hanging water column*: A sample is placed on a fine sand bed or a porous plate. Suction is applied via a hanging water column, with a length smaller than the corresponding air-entry pressure of the sand, or via a controlled vacuum, which is applied to the space below the porous plate. After the sample has reached hydraulic equilibrium, its water content is determined gravimetrically. Advantages of this classic method are its relatively low cost and technical operating expense, which allows measuring many samples simultaneously.
- *Suction table*: the method is similar to the hanging water column, but instead of a water column, a technically controlled vacuum can also be applied to the water phase. The range of the method is limited by the atmospheric pressure.
- *Pressure plate extractor*: A sample is placed on a porous plate inside a pressure container. Air pressure is applied to the container, which induces displacement of water toward and through the porous plate to the free atmosphere. After reaching equilibrium, the water content is determined gravimetrically. This method can be applied in combination with the Hanging water column method, where it yields values for the dry range of the $\theta(h)$.
- *Pressure cell* (*Tempe cell*): A ring sample is mounted on a porous plate and connected to a top, through which the gas phase pressure can be regulated. Increasing the air pressure induces displacement of water through the porous plate, which can be measured in a burette that is connected to the outlet.
- *Centrifuge method*: An initially saturated sample is placed in a centrifuge and spinned with a specific velocity. After the centrifugal and capillary forces reach equilibrium the saturation can be determined. The method is well suited to determine residual water saturation. It has also been applied to measure hydraulic conductivity. The pressure range depends on the power of the centrifuge. Problems are costs and the mechanical destruction of the sample under high acceleration.
- *Controlled liquid volume*: In this method, defined points of $\theta(h)$ are determined by adding or extracting controlled volumes of liquid. Water then redistributes within the sample until the pressure is equalized. The main advantage of this method is that it achieves faster equilibration. However, during water redistribution part of the sample will be draining, and the other part will be wetting, and therefore hysteresis may affect the overall distribution.

The above listed methods are in most cases used in a series of equilibration steps to desaturate a soil from full saturation, thus yielding a drying curve. Common to all hydrostatic equilibrium methods is the considerable time requirement, in particular, if saturations at low potentials are to be determined. Since equilibrium time grows with the square of the length of the sample (Miller, 1980), equilibration times of large samples become prohibitively long for high suctions. Nonequilibration is in particular a problem for sands, where higher tensions can only be reached by equilibration via the gas phase (Gee *et al.*, 2002). For the dry range of a retention curve, there are not many alternatives. In the literature, the freezing method is described (Spaans and Baker, 2002; Bittelli *et al.*, 2003), which makes use of the thermodynamic equivalence between freezing and drying. Recently, vapor pressure measurements of soil with known water contents have been discussed (Nimmo and Winfield, 2002).

The usual way to evaluate equilibrium measurements is to pair the pressure at the center of the sample with the average water content of the whole sample. This linearization results in a retention characteristic that is smoothed around the air-entry point, as compared to the true point characteristic, in particular, for coarse porous media and for large samples. Liu and Dane (1995) and Jalbert and Dane (2001) provide correction procedures for this problem.

Steady-State Laboratory Methods

Steady-state methods aim at obtaining the hydraulic conductivity at a particular saturation, by inversion of Darcy's law. The procedure is based on the fundamental assumption that the rate of flow is proportional to the pressure gradient and the permeability constant is a property of the porous medium (Klinkenberg, 1941). We will restrict our discussion to methods that use water as a fluid. For practical recommendations and details on influences of temperature, ion composition, and other factors affecting fluid properties, see Dane and Topp (2002).

Steady-state in water flow is reached by applying either constant head or constant flux boundary conditions to the top or the bottom of soil samples. A flux boundary condition can be realized by drip irrigation (mostly through needles), by spraying (Dirksen and Matula, 1994), or by pumping water via a porous plate onto the top of the sample. None of these procedures is trivial. At the lower boundary, suction can be applied through a porous plate (sintered glass, metal, ceramic, or nylon). It is generally advisable to check the pressure head inside the sample by tensiometric measurements (Dirksen, 1991). For methods that aim at the saturated conductivity, K_s [L T^{-1}], it is important

that the flow resistance of the experimental device, in particular the membrane, is kept smaller than the resistance of the soil. Since K_s is extremely dependent on continuous macropores along the flow direction, any change of soil structure (compaction, sealing of water entry surface), and any bypass of water (gap between column casing and soil) must be avoided.

- *Constant head permeameter*: Water is applied by means of a mariotte device to the top of a soil sample at a constant head. Water leaving the sample at the bottom is also kept at a constant head, either at zero pressure by free drainage through a suspension mesh to the atmosphere, or to a positive pressure via an overflow vessel. The experiment can equally be performed with the flow direction of water from the bottom to the top. K_s is calculated by rearranging the Darcy equation. Limitations of the method are related to small or inadequate sample size, soil disturbance during core collection, and possible short-circuit flow through macropores along the core wall. On the other hand the method is simple, inexpensive, and convenient. Despite potential limitations, the method remains as one of the most popular means for measuring K_s and is often used as a benchmark for evaluating other methods (Reynolds *et al.*, 2000).
- *Crust method*: The crust method (Bouma *et al.*, 1983) determines hydraulic conductivity, *K(h)*, by measuring the water flux density into an unsaturated soil sample. Unsaturated conditions are obtained by supplying water through a crust made of sand and special cement with a lower hydraulic conductivity than the soil sample. In a typical setup, a saturated soil sample is placed on a long sand column to attain nearly gravitational flow in the sample. Water is supplied to the crust by ponding, using a Mariotte burette. A tensiometer is placed in the soil few centimeters below the top of the sample. The flux density is derived from the discharge from the burette. If only gravitational flow is assumed and steady-state is reached (e.g. 24 h no change in pressure head), the flux density, q [$\mathrm{L\,T^{-1}}$], equals the unsaturated hydraulic conductivity. To obtain information about the whole range of *K(h)*, several crusts would be needed. This makes the crust method very tedious. The crust method is also used in the field.
- *Drip Infiltrometer Method*: The drip infiltrometer method (Dirksen, 1991) determines the hydraulic conductivity by infiltration. Typically, the soil sample is placed on a sand box with a hanging water column. Water is applied from a reservoir through hypodermic needles on top of a sample. Tensiometers are placed in the soil at different depths. The pressure head gradient ($\mathrm{d}h/\mathrm{d}z$) in the sample can be controlled by adjusting the height of a hanging water column with overflow, attached to the sand box. Measurements start after steady-state is reached. By measuring the flux density (q) and the pressure heads (h), the unsaturated hydraulic conductivity *K(h)* is calculated for each compartment between two tensiometers with Darcy's law. Again it is very laborious to measure the whole range of *K(h)*. Obtaining values for low flux densities is limited by the application of a constant flux rate and very long times to attain steady-state.
- *Atomized Water Spray Method*: Delivery of water uniformly to the soil surface can also be accomplished with a controlled atomized spray. Dirksen and Matula (1994) constructed and tested a water spray system that delivers water accurately to the surface of a 20-cm diameter soil column at rates ranging from 10^{-4} to 10^{-7} cm $\mathrm{s^{-1}}$. The advantage of this method over more conventional laboratory methods is that large samples can be tested and it requires no ceramic plates and therefore does not have a contact resistance problem. However, the system is relatively cumbersome and does require thermal control for optimal results.
- *Steady-state evaporation method*: Fujimaki and Inoue (2003) introduced a method that determines hydraulic conductivity from a water content profile under steady-state upward flow. Steady-state was induced by setting both constant meteorological conditions and a constant inflow rate from the bottom, with evaporation demand being higher than the supply rate. After steady-state is reached, the soil column is sectioned to measure the water content profile. Isothermal water vapor flux is evaluated via inverse optimization. An independently determined $\theta(h)$ is also required. Unlike most other methods, this method is not limited to the wet range/tensiometer range ($h > -700$ cm).
- *Disc Infiltrometer method*: In the disc infiltrometer method (Simunek *et al.*, 1999), water is applied at negative pressure using a tension disc (see Section "Field methods") that is placed on top of the sample. The soil profile is instrumented with both Time domain reflectometers (TDR) (at one location) and tensiometers (at several locations). The measured data are analyzed using Wooding's (1986) analytical solution. Wooding's analysis requires steady-state infiltration rates at different supply pressure heads. Simunek *et al.* (1999) compared analysis by numerical inversion against results of Wooding's solution. Unsaturated hydraulic conductivities corresponded well, but K_s was overestimated.
- *Heat Pipe Method*: Very low unsaturated *K(h)* measurements (10^{-7}–10^{-12} cm $\mathrm{s^{-1}}$) have been reported by Globus and Gee (1995) using a heat pipe method. The method uses a partially wetted sample that is sealed and equilibrated with an applied thermal gradient. In the heat pipe method, equilibrium is attained when liquid water flow from the cool end equals water vapor flow from the warm end, and the water content profile

has become stable. After a given period, ranging from days to several weeks, the soil is removed from the column and sampled for water content. Water diffusivity values for the soil are determined from the measured water content gradients. *K(h)* is subsequently computed from an independently measured $\theta(h)$ for the soil. The method requires temperature control and is time consuming. *K(h)* is actually a lumped parameter, since it represents a combined estimate of the vapor and liquid conductivity (Gee and Ward, 1999).

Transient Laboratory Methods

With decreasing pressure head, steady-state methods loose their attractiveness, because constant fluxes and unit gradients are hard to obtain. Transient laboratory techniques do not employ equilibrium steps and are therefore much more rapid. Traditional transient laboratory methods, such as outflow or evaporation experiments, however, show relatively little sensitivity to the hydraulic conductivity at near-saturated conditions. Thus it is advisable to determine the hydraulic conductivity in the wet range with steady-state experiments, whereas transient conditions are used for the drier range (Wendroth and Simunek, 1999).

In the last few decades, several transient methods have been proposed for characterizing soil hydraulic properties, including one-step outflow, multistep outflow, evaporation, downward, and upward infiltration methods (UIMs). Each of these methods uses the change in column weight versus time to infer hydraulic properties. If simultaneous determination of retention and conductivity is sought, additional monitoring of matric potential changes at one or more positions in the samples, or independently determined $\theta(h)$ are required. Otherwise, only diffusivity can be determined. All transient methods assume uniform one-dimensional flux according to Richards' equation in a homogeneous porous medium, and apply constant or changing heads or constant or changing fluxes to the top or to the bottom of a soil sample. For unsaturated experiments, where matric potential is negative, a porous plate or a membrane with appropriate pore sizes is required to apply the pressure. In the following, the principles of the various methods are shortly described. For details in the experimental and evaluation procedures, the reader is referred to Kutilek and Nielsen (1994) and Dane and Topp (2002).

- *Falling Head Permeameter*: This method is used to determine K_s for samples with low conductivity. The upper surface of a soil sample is connected to a water-filled burette, and the lower face to a constant boundary pressure. When water is allowed to flow, the water level falls, and the pressure difference between the upper and lower boundary decreases exponentially. Since the pressure difference is large as compared to the length of the soil sample and the diameter of the burette is usually chosen to be considerably smaller than the diameter of the soil sample, a high hydraulic gradient is applied and the flux can be monitored with high precision. This speeds up the measurement process for soils with low hydraulic conductivity, as compared to the constant head method. Other shortcomings of the constant head permeameter method, however, cannot be overcome. The conductivity is calculated by

$$K_s = \frac{1}{(t_2 - t_1)} \frac{A_B L_S}{A_S} \ln\left(\frac{h_2}{h_1}\right) \tag{5}$$

where A_B and A_S are the areas of the burette and the soil, respectively, L_S = height of the soil, and h_1 and h_2 are the head differences between the upper and lower boundary at times t_2 and t_1, respectively.

- *One-step and Multistep Outflow method*: The one-step method was originally introduced by Gardner (1958) to determine the diffusivity, $D(\theta)$. Saturated soil samples on top of a ceramic plate are exposed to a high air pressure on top of the sample or to a sudden reduction in water pressure below the ceramic plate. The pressure change induces unsaturated flow in the soil sample, with the ceramic plate remaining saturated. The cumulative outflow of water is recorded in a burette or by a scale. The historic reasons for favoring the *one-step* method (Doering, 1965) lie in the possibility to apply semianalytical solutions of the flow equation to identify the hydraulic diffusivity function, provided the conductivity curve follows an exponential function (Gardner, 1958; Gardner, 1962). Since the mid-80s, following the pioneering work of Kool and coworkers (Kool *et al.*, 1985a,b; Kool and Parker, 1987) outflow methods are now evaluated by inverse modeling to determine the soil hydraulic functions $\theta(h)$ and *K(h)* simultaneously (Hopmans *et al.*, 2002). Because *one-step* experiments often yielded nonunique inverse solutions, investigators recommended to include additional $\theta(h)$ data (van Dam *et al.*, 1992; Bohne *et al.*, 1993), or tensiometric measurements in the object function (Toorman *et al.*, 1992; Eching and Hopmans, 1993). A major point of critique with respect to the one-step method has always been that the quick change of the boundary condition does not represent natural conditions (van Dam *et al.*, 1992, 1994), and the sensitivity of the method can be low if, as a result of a large pressure drop, a very thin drained soil layer next to the porous plate controls the total flow rate (van Dam *et al.*, 1992). For these reasons, the multistep method was suggested, where the pressure at the boundary is changed in several small steps (van Dam *et al.*, 1990). Eching *et al.* (1994), van Dam *et al.* (1994), Crescimanno and Iovino (1995), and Zurmühl (1996) demonstrated for the van Genuchten/Mualem model that the multistep method is superior to the one-step method because the hydraulic parameters are less correlated.

The outflow methods are constrained to the wet moisture range by the air-entry pressure of the porous plate.

- *Continuous Inflow/Outflow method*: Even with several small pressure changes as applied in the multistep outflow method, the pressure changes at the soil's boundary still occur shock-wise, which – at least for the drainage process – never occurs under natural conditions. As an alternative, Durner *et al.* (1999b) suggested a continuous smooth change of the boundary pressure, which showed to yield good results. A soil sample is placed on a membrane plate in contact with a pressure-controlled reservoir. The reservoir headspace is controlled by air pressure manipulation (Butters and Duchateau, 2002) to initiate water flow in the soil sample. Theoretically, both wetting and draining $\theta(h)$ and *K(h)*, up to the air-entry value of the membrane plate, including saturation can be measured. Butters and Duchateau (2002) used a combination of direct Darcian analysis and numerical inversion of Richards' equation for estimation of the hydraulic properties. The direct analysis provides K_s and θ_s that can be used to anchor these parameters in the inverse analysis. As a limitation, the direct K estimate applies to fairly short samples and is susceptible to tensiometer errors, especially of systematic nature. Durner (1994) recommended to directly and independently measure $K(h)$ in the range close to saturation where the inverse estimation from outflow experiments is insensitive.
- *Wind's Evaporation Method*: Similar to the outflow methods, Wind's evaporation method (Wind, 1968) aims at determining simultaneously $\theta(h)$ and *K(h)*. Tensiometers are installed at regular depth intervals in a saturated soil sample. The sample is placed on a balance and its surface is exposed to free or forced evaporation. Weight and pressure heads are recorded periodically. After completing the experiment, the volumetric water content of the sample is determined, which allows to recalculate the total water contents during the experiment. The water contents in the compartments around the tensiometers at different times are estimated from the measured pressure heads and the total water contents by fitting a parametric model of water retention characteristic to the observations. The subsequent evaluation is identical to the instantaneous profile experiment (see the Section on "Field Methods") by calculating the flux density from the decrease of the water contents of the compartments, and the pressure head gradient from the pressure heads of two adjacent compartments. Finally, the unsaturated hydraulic conductivity can be calculated with Darcy's law. The program package METRONIA (Halbertsma and Veerman, 1994; **`http://dino.wiz.uni-kassel.de/model_db/mdb/metronia.html`**) is available for this analysis. Bertuzzi *et al.* (1999) found that small uncertainties in tensiometer data greatly influence the hydraulic conductivity determined under wet conditions, but $\theta(h)$ estimates are relatively robust. Also, thermal effects on hydraulic conductivity estimates were far from negligible. Wendroth and Simunek (1999) reported that Wind's method (1968) method does not yield valid estimates of $\theta(h)$ and *K(h)* for layered soil samples. Finally the evaporation method fails in the near-saturation range where the hydraulic conductivity is highest, leading to very small hydraulic gradients that cannot be determined with sufficient accuracy (Wendroth and Simunek, 1999).
- *Hot-air Method*: The hot-air method (Arya *et al.*, 1975) determines the diffusivity function $D(\theta)$. With this method, hot air is blown over the surface of an initially uniformly wet soil column. Before the water content at the bottom of the sample starts decreasing, evaporation is stopped and the sample is cut into small layers. The water content of each layer is determined gravimetrically. The diffusivity $D(\theta) = K(\theta)/C(\theta)$, defined by the ratio of hydraulic conductivity, K, and the specific water capacity, C, at a water content, θ, can be calculated from

$$D(\theta_x) = \frac{1}{2t} \left.\frac{\mathrm{d}x}{\mathrm{d}\theta}\right|_x \int_{\theta_x}^{\theta_i} x \ \mathrm{d}\theta \qquad (6)$$

  where t = time [T], θ_i = initial volumetric water content [−], θ_x = volumetric water content [−] at distance x [L] from the evaporating surface. The method is known to be greatly affected by thermal effects.
- *Other Evaporation Methods*: Gabele and Hoch (1999) proposed to adapt the evaporation rate to the K-range of interest by either dividing the experiment into two or three sections, each starting with a different evaporation rate after a zero-flux period of several hours or continuous variation of the evaporation rate in response to measured state variables. Simunek *et al.* (1998) simultaneously estimated the van Genuchten parameters for $\theta(h)$ and *K(h)* from an evaporation experiment with parameter optimization techniques. Some uncertainty exists in the soil hydraulic parameters caused by high correlation between θ_r and n. Pressure heads measured close to the soil surface were found to be more valuable for the parameter estimation technique than those measured at lower locations. Tensiometer readings at one position are already sufficient to guarantee precise estimation of the soil hydraulic characteristics within the range of measurements (Simunek *et al.*, 1998). Extrapolation beyond this range involved a high level of uncertainty. Romano and Santini (1999) extended the analysis to compare various expressions for soil hydraulic properties. As for Wind's method, accuracy of hydraulic conductivity estimates is limited mainly due

to (i) near-zero hydraulic gradients close to saturation and (ii) extremely steep h-gradients at low conductivities.

- *Combined Outflow/Evaporation Method*: To reduce the duration of the evaporation experiment and to obtain the retention data in the low suction range, an outflow experiment can be conducted before the initiation of evaporation. After attaining near-equilibrium at negative pressure, the bottom boundary is sealed, the soil surface uncovered, and the evaporation rate at a controlled constant temperature measured. Fujimaki and Inoue (2003) determined $\theta(h)$ by curve-fitting of the equilibrium outflow and psychrometric data obtained from soil samples after evaporation, while the $K(\theta)$ was estimated inversely using cumulative evaporation amounts and the final water content profile.
- *Sorptivity Method*: This and the following methods combine laboratory experiments and parameter estimation for determining soil hydraulic properties in the wetting direction, rather than in the drying direction, as obtained through outflow methods. The sorptivity method (Dirksen, 1974) determines the soil water diffusivity function $D(\theta)$ by means of a series of one-dimensional absorption experiments in soil of constant initial water content θ_0. The sorptivity S [$\mathrm{L\,T^{-1/2}}$] is defined as proportionality constant between the cumulative amount of freely supplied water, I [L], infiltrating into an initially unsaturated horizontal soil column, and the square root of time, $S = I/\sqrt{t}$. Infiltration is controlled by mechanically supplying water to the absorption interface proportional to $t^{1/2}$. After supplying water for a certain time, the final water content of the top layer θ_1 is determined gravimetrically. The diffusivity can be calculated from

$$D(\theta_1) = \frac{\pi S^2}{4(\theta_1 - \theta_0)^2} \left[\frac{(\theta_1 - \theta_0)}{(1+\gamma)\log_e} \times \frac{\mathrm{d}}{\mathrm{d}\theta_1}(\log S^2) - \frac{1-\gamma}{1+\gamma} \right] \quad (7)$$

  where D = diffusivity [$\mathrm{L^2\ T^{-1}}$], θ = volumetric water content, S = sorptivity [$\mathrm{L\,T^{1/2}}$], and γ = weighting parameter [−]. For details, see Klute and Dirksen (1986) and Clothier and Scotter (2002).
- *Water Absorption into a Horizontal Column*: A horizontally placed soil column is connected to a water reservoir, causing absorption of water. The advance of the wetting front with time and the amount of water infiltrated are recorded. From these data, Shao and Horton (1998) estimated the van Genuchten parameters n and α by an approximate analytical solution. Additional information about K_s is needed. Wang *et al.* (2002) used analytical solutions of horizontal infiltration to estimate Brooks and Corey parameters. Input data needed are infiltration rate, cumulative infiltration, and distance of the wetting front with infiltration time.
- *Upward Infiltration Method*: In the upward infiltration method, UIM (Hudson *et al.*, 1996), a constant flux of water is imposed at the bottom of the soil sample, and pressure heads are measured inside the sample using tensiometers. To maximize information for the inverse analysis, Young *et al.* (2002) suggested to initiate infiltration by a certain tension at the bottom of the sample, using a Mariotte system, rather than by imposing a boundary flux. For tension infiltration, the soil controls the total amount of water being taken up, thus providing additional information and control for the numerical inversion. The method is most useful in the wet range of the retention and conductivity functions. Simunek *et al.* (2000) suggested a method based on modification of the UIM to capture nonequilibrium flow parameters. The observed nonequilibrium behavior could be described with the dual-porosity and dual-permeability models, but a unique set of soil hydraulic parameters could not be identified.
- *Downward Infiltration Method*: Water is supplied at the top of a soil sample at a prescribed head (usually ponding) or at a prescribed rate. Van Genuchten parameters can be estimated by numerical inversion of Richards' equation. Measurements needed for the inversion method include: soil water tension versus time at one distance from the soil surface, the initial water content, and a final steady-state water content behind the wetting front. The objective function used for parameter optimization is constructed from two parts, one from the transient tension versus time curve, and another from the steady-state water content data (Zou *et al.*, 2001).

Field Methods

Laboratory experiments have the advantage of being comparatively quick and precise, but they often lead to soil-physical properties that are not representative for the field. Direct *in situ* measurement of hydraulic and retention properties still provides perhaps the most reliable, and often, the only means for determining hydraulic properties, despite their high cost and extreme time demands (Tseng and Jury, 1993). Two distinct types of field procedures are in common use: internal drainage (ID) flux methods (Section "Internal drainage method") and infiltration methods. Infiltration methods can be further distinguished in steady water application flux methods (Section "Steady flow infiltration methods"), ponded infiltration methods (Section "Pressure ring infiltration"), tension infiltrometry (Section "Tension disc infiltration") and infiltration from wells or bore holes (Section "Infiltration from wells and bore holes").

Field methods have the advantage of dealing with soil in natural conditions. However, small-scale heterogeneity in

soil conditions may introduce large variation in measured values (Munoz-Carpena *et al.*, 2002). Since most field measurements are confined to produce a single measurement at a single field location, adequate evaluation of field hydraulic and chemical transport properties requires a large number of measurements.

Errors in the evaluation of unsaturated hydraulic conductivity under field conditions may arise from a number of sources. In the instantaneous profile experiment, measurements of pressure head and water content are uncertain owing to spatial variability, which leads to significant uncertainty by error propagation (Flühler *et al.*, 1976). Tension disc and ring infiltrometer also have limitations; most of them being associated with the simplifying assumptions of the analysis used to infer soil hydraulic properties from water and solute flow measurements. Infiltration rates during the measurement time can be variable, both increasing and decreasing (Logsdon, 1997). Factors affecting temporal variability of hydraulic properties during infiltration experiments are hydrophobicity and swelling (Roth *et al.*, 1999; Angulo-Jaramillo *et al.*, 2000). These limitations lead in general to uncertainty, whether or not there will be major advances in *in situ* determination of *K(h)*. In an extensive review on published field measurement data, Jury (1985) found extremely high variation of hydraulic conductivity parameters, which he attributed partly as apparent variability, caused by fitting oversimplified functions to the data. Tseng and Jury (1993) point out that since the true physical state of a soil can never be known in any field study, absolute comparisons of properties estimated from measurements, and thus actually occurring in the field, can never be made. Hence, method comparisons must always be relative, and absolute statements upon the accuracy of any method are not possible.

Internal Drainage Method

The internal drainage method, ID, or instantaneous profile method is regarded as a reference method to measure *in situ* unsaturated hydraulic properties for both homogeneous and layered soils (Hillel *et al.*, 1972). The method was first suggested by Richards *et al.* (1956) on the basis of simultaneous monitoring of water retention and flux in laboratory soil columns. Later, the method was adapted for practical field use (Watson, 1966). Simplified variants have been developed which require fewer *in situ* measurements but depend on flow approximations (Nielsen *et al.*, 1973; Ahuja *et al.*, 1988). Their use is mainly limited by high demands on equipment and time.

In the ID, large rings (about 2 m in diameter) are inserted into soil with a certain height left above ground. Within each ring, tensiometers and TDR are installed via an access tube. Water is ponded on the soil surface until the soil is wetted beyond the maximum depth for which the determinations are desired. The groundwater table should be sufficiently below this depth to obtain maximum possible unsaturated drainage. To minimize evaporation, temperature fluctuation, and protect the surface from rainfall during subsequent drainage, the soil surface inside the rings is covered. Both θ and h are monitored for weeks. Measurements are taken with decreasing frequency. Evaluation is performed using instantaneous profile data analysis, which is based on the Darcian analysis of transient soil water content and hydraulic head profiles (Watson, 1966). Zhang *et al.* (2003) presented an improved analysis of the data from drainage experiments using inverse modeling, which uses nonlinear regression methods to estimate hydraulic parameters. All van Genuchten hydraulic parameters could be estimated uniquely when both water content and pressure head data were used.

Errors in K values obtained during the early stages of drainage are primarily due to errors in determining the hydraulic gradient, while at later times, errors in water content measurement are more serious. Using typical measurement errors, the calculated uncertainty of K in the moist range is in the order of 40%, and in the dry range up to more than 100% (Flühler *et al.*, 1976). The failure of even one tensiometer, which is not uncommon in the field, will significantly affect the calculation of hydraulic properties. Because θ and h determination is needed over a long period of time, the ID is time- and equipment-intensive, and thus costly, especially if several sites must be monitored to estimate spatial variability.

Steady Flow Infiltration Methods

Infiltration rates effectively integrate properties of the porous media underneath the infiltrometer, including the influence of local-scale heterogeneity, different soil structure, and textural irregularities, preferential pathways, layering, and anisotropy. Hence, infiltration rates provide a good way for estimating the effective near-saturated soil hydraulic properties (Mertens *et al.*, 2002). Steady flux is achieved either by uniform application of water by sprinkler or trickler, or by creating a low permeability crust at the soil surface (Hillel and Gardner, 1970). Measurements taken under steady-state flow conditions are easier and less prone to errors (porous cup equilibration of tensiometers) than those taken under transient conditions. It is also possible to repeat pressure head, water content, and flow rate measurements at steady-state, whereas for transient conditions, the entire experiment must be repeated. However, considerable effort and time are required for the steady flux method to be of practical use in the field. The crust method, while accurate, cannot be used when the soil is wet and the method can be very costly to run, since up to 100 days may be required to complete the measurement of *K(h)* over the required potential range. In all steady flow methods only wetting is considered.

Recent innovations in steady flow infiltration methods include inverse estimation of soil hydraulic parameters in

combination with multipurpose probes that couple TDR and tensiometry used under constant flux infiltration (Gee and Ward, 1999). Si and Kachanoski (2000) used multipurpose TDR probes coupled with a series of constant-rate infiltration experiments to estimate the effective one-dimensional field-average hydraulic properties $K(\theta)$ and $\theta(h)$. The TDR probes are installed vertically to measure the rate of change of local soil water storage (q) along the probe during constant-rate water application. The values of q are equal to local soil water flux, and assuming unit gradient, are set equal to K at the steady-state θ and h measured at long times. The measured values of K, θ and h from different water application rates are combined to obtain average hydraulic functions.

- *Line Source Method*: Zhang *et al.* (2000a,b) estimated hydraulic properties by means of multipurpose TDR probes and existing quasi-analytical, steady-state solutions for infiltration from a surface line source. They installed 50 nests of multipurpose TDR probes with a between-nest spacing of 0.15 m, indicating the high costs connected with this method. Inverse procedures are used to estimate the inverse macroscopic capillary length scale, α, and K_s, from h, θ, and conservative ionic tracer travel time (T). Measurements of only h or only T will not give unique estimates of α and K_s. Combining measurements of θ with h and/or T gives unique estimates of α and K_s.
- *Point Source Method*: Al-Jabri *et al.* (2002) used a much simpler approach: The hydraulic properties were determined by applying three discharge rates higher than the infiltration rate. This produces circular saturated areas at the soil surface beneath each emitter that reach constant size depending on the irrigation rate. The radius, r, of the areas is measured. The method required only two days to collect data. Once steady-state occurs, Wooding's (1986) solution can be applied. K_s is yielded graphically as the intercept of a plot of discharge rate versus $1/r$. The mean K_s found were larger than with tension discs. Error sources are different radii for the same infiltration rate, and noncircular areas. The method does not offer a high level of control, but is very cheap. A single supply tube can allow for application of the point source method to multiple locations. Evaluation of the setup and procedure with natural field conditions, such as tillage practices is required for further establishment.

Pressure Ring Infiltration

Ring infiltrometers are probably the most widely used device for measuring field infiltration rates (Wu *et al.*, 1997). The technique is useful in the estimation of the *in situ* field-saturated hydraulic conductivity, K_{fs}, and matrix flux potential Φ_m. Water is supplied to the soil surface at a positive pressure head h_0 either by a Mariotte bottle allowing a wide range of h_0, or by a small capillary tube also acting as a measuring burette. Water can be infiltrated at a constant or at a continuous falling head. A double ring infiltrometer can be used to minimize lateral flow during the experiment. Infiltration from the outer ring before and during the measurement should guarantee one-dimensional downward flow from the inner ring. The analysis is performed only with infiltration from the inner ring, and is essentially the same as for single ring infiltrometers.

Various techniques based on either transient or steady-state water flow approaches have been used to infer soil hydraulic properties from ponded ring infiltration tests (Angulo-Jaramillo *et al.*, 2000). Basically the flow from a ring infiltrometer set at a positive pressure head h_0 is controlled by K_{fs} which accounts for the gravity effect and by Φ_m, the matrix flux potential for saturated conditions, which is defined as

$$\Phi_m = \int_{h_u}^{0} K(u)\,\mathrm{d}u \tag{8}$$

Constant head conditions have traditionally been used, because constant head devices are easy to maintain experimentally and because the analysis is relatively simple (Mertens *et al.*, 2002). It is possible to show (Elrick and Reynolds, 1992) that the steady-state flow rate out of a ring infiltrometer is given by

$$q_{0\infty} = K_{fs}\left(1 + \frac{H}{\pi r_d G}\right) + \frac{\Phi_m}{\pi r_d G}, \tag{9}$$

where G is a shape parameter, and r_d is the radius of the ring. Applying successively to the same ring two positive hydraulic heads H_1 and H_2 allows solving simultaneously the resulting two equations for K_{fs} and Φ_m. In highly heterogeneous and low permeable soils, the method can cause a large percentage of invalid (i.e. negative) and unrealistic K_{fs} and Φ_m. Here the one-dimensional steady-state saturated flow analysis can be replaced by a transient analysis using nonlinear least-squares inversion procedures.

Another possibility to analyze infiltration experiments is to use falling head methods, where a ring is inserted a known distance into the soil, and attached to a mariotte reservoir. Infiltration from the ring is allowed to come to steady-state under a constant ponded head, after which the head is allowed to fall and the head is measured as a function of time (Parkin *et al.*, 1999). A numerical inversion procedure is used to calculate the soil hydraulic properties. Measurements of early-time infiltration under both constant and falling head can better characterize the hydraulic properties of low permeability media.

Advances have been made in using ring infiltrometers and TDR to measure hydraulic properties in unsaturated soils (Parkin *et al.*, 1995). Estimates for hydraulic conductivity can be achieved for heads greater than −60 cm, which

is the range with most effect on ponded infiltration. However, generally ponded infiltration measurements are not sensitive for estimating unsaturated soil hydraulic conductivity (Bagarello *et al.*, 2000).

Tension Disc Infiltration

A tension disc infiltrometer (TI) is a constant head infiltrometer that can operate at either a positive or a negative head and thus it can be used for determination of both saturated and unsaturated hydraulic properties. TI have become very popular devices for the *in situ* estimation of soil surface hydraulic properties (Angulo-Jaramillo *et al.*, 2000). Because of their portability, disc and ring infiltrometers are useful instruments to investigate statistical distributions of hydraulic conductivities. While ponded infiltration is used to determine the saturated hydraulic conductivity, tension infiltrometry also provides an opportunity to estimate unsaturated hydraulic properties. TI associated with conservative tracers was also used for inferring parameters describing the water-borne transport of chemicals and other parameters such as mobile/immobile water content fraction or exchange coefficient (Clothier *et al.*, 1992; Jaynes *et al.*, 1995). A number of challenges still remain unresolved for both theory and practice for tension disc infiltrometers. They include questions on how to consider and characterize saturated-unsaturated preferential flow or preferential transport processes, and the problem of contact resistance between the tension disc membrane and the soil.

During tension disc infiltration, a reservoir tower provides the water supply, and a bubble tower with a moveable air-entry tube imposes the pressure head h_o of the water at the cloth base. For measurements under tension, intimate hydraulic contact between the soil surface and the source of water is essential. This is generally achieved by pouring at the surface a layer of sand that should be made as thin as possible. The contact sand can introduce flow impedance effects at the high infiltration rates associated with ponded conditions. The same is true for the porous membrane of the infiltrometer (Mohanty *et al.*, 1998). For every imposed value h_o, the cumulative infiltration, $I(t)$, is recorded either by noting the water level drop in the reservoir tower or by using pressure transducers (e.g. Ankeny *et al.*, 1988). Additionally, initial and final water content are determined. Water flow from a tension infiltrometer disk to the underlying soil follows a three-dimensional flow process. Various techniques have been developed to infer hydraulic properties from measurements of either transient flow rates, or steady ones, that emanate from a disc (Wang *et al.*, 1998). The methods of analysis of cumulative infiltration are based either on quasi-analytical solutions or on inverse parameter estimation techniques, depending on whether the soil profile is homogeneous or not (Angulo-Jaramillo *et al.*, 2000). Vandervaere *et al.* (2000) found for 7 largely different soils that the lateral capillary flow (S^2) dominates the gravity flow (K) during a disk infiltrometer experiment. Thus hydraulic conductivity must be considered as a variable playing a minor role, and hence difficult to determine accurately. Although performing infiltration experiments at the same location for several tensions can affect infiltration rates, TI causes relatively little disturbance of the soil macrostructure. Still the tension disc method yielded lower K_s values under high-permeability conditions relative to other methods, because the ring may be too small to adequately sample cracking clay loam soil (Reynolds *et al.*, 2000).

- *Steady-State Analytical Solutions* Wooding's equation (1986) equation is at the heart of most of these analyses. It approximates the steady infiltration rate, $q_{0\infty}$ from a disc as

$$q_{0\infty} = K_0 + \frac{4\Phi_0}{\pi r_d} \tag{10}$$

where Φ_0 is the matrix flux potential for unsaturated conditions defined by

$$\Phi_0 = \int_{\theta_n}^{\theta_0} D(u)\,du = \int_{h_n}^{h_0} K(u)\,du, \theta_0 \geq \theta_n, h_n \leq h_0 \tag{11}$$

In these equations, K_0 is the hydraulic conductivity at the imposed pressure head h_0, and $D(u)$ is the capillary diffusivity [L^2T^{-1}]. The subscript 0 refers to the condition imposed at the supply surface of the disc, and the subscript n denotes the antecedent condition prevailing in the soil before the infiltration takes place. Early-time infiltration data can be used to estimate the sorptivity (White and Sully, 1987) and, consequently, the matrix flux potential. Equation (10) can be solved for K_0 and Φ_0 by using either multiple radii (MR)(at the same value h_0) or multiple head (for a given disc radius) procedures. Drawback of the MR method lies in the fact that the two (or more) disk experiments must be performed at different locations, which introduces complications from the short-distance spatial variability of soil properties (Wang *et al.*, 1998).

Large variations or discrepancies are reported in the literature when comparing Wooding's method results with other methods. One possible source of error is its limitations for relatively small disk sizes. Several studies have shown that Wooding's approach will overestimate the soil hydraulic conductivity if steady-state infiltration is not reached. Discrepancies between tension infiltrometer and other methods in practice, however, are caused probably more by variability within each method such as soil heterogeneity or simplification of the hydraulic conductivity function to an exponential expression, than by inherent limitations of the steady-state solutions (Wang *et al.*, 1998).

- *Transient State: Quasi-analytical Solutions* Restrictions in the use of Wooding's equation, together with the fact that much useful information is lost by ignoring the

transient stage and large time savings can be achieved (Logsdon, 1997) have strengthened the need for a transient three-directional infiltration equation for disc infiltrometers. The most recent expressions (Warrick, 1992; Haverkamp *et al.*, 1994; Zhang, 1998) have in common the following two-term form of the cumulative infiltration equation:

$$I(t) = C_1\sqrt{t} + C_2 t \tag{12}$$

but they differ by the expressions of the coefficients C_1 and C_2. Haverkamp *et al.* (1994), for example, posed the following physically based expressions valid for times not approaching steady-state:

$$C_1 = S_0$$

$$C_2 = K_n + \frac{1}{3}(2-\beta)(K_0 - K_n) + \frac{\gamma}{r_d(\theta_0 - \theta_n)}S_0{}^2 \tag{13}$$

where β is a parameter depending on the capillary diffusivity function. It lies in the interval [0, 1], and γ is a constant approximately equal to 0.75.

Vandervaere *et al.* (2000) proposed several new methods for the analysis of tension disk infiltrometer tests and the determination of sorptivity and hydraulic conductivity. The single test method uses one disk radius and one value of pressure head. The multiradii method uses two or more disk radii and one value of pressure head. The multiple sorptivity methods use one or multiple disk radii and two or more values of pressure head. Method appropriateness was shown to be highly dependent on the ratio of K and S. A good experimental strategy consists of choosing the method of analysis on the basis of the dominant flow: vertical capillary flow, vertical gravity flow, or lateral capillary flow.

- *Transient State: Inverse Estimation* An alternative to direct estimates of soil hydraulic properties is the use of inverse methods when *in situ* conditions differ strongly from assumptions required for the use of semianalytical solutions of the flow equation, that is, nonuniform water content distribution, and multilayered soils. From an analysis of numerically generated data, Simunek and van Genuchten (1996) concluded that the cumulative infiltration curve by itself does not contain enough information to provide a unique inverse solution. Schwartz and Evett (2002) reported that inverse optimizations, which included in the objective function both, water retention and cumulative infiltration, led to excellent fits of this data for high initial volumetric water content. Simunek and van Genuchten (1997) put forward that the best practical scenario is to estimate the hydraulic parameters from the cumulative infiltration curve measured at several consecutive tensions applied to the soil surface, in conjunction with the knowledge of the initial and final water content.

Infiltration from Wells and Bore Holes

Tension disc and ring infiltrometers are constrained to the near-surface and are easily impacted by microtopography. These limitations can be partly overcome by infiltration from bore holes with or without cone penetrometers. Combinations of TDR and permeameters with cone penetrometer technology show promise for minimally intrusive, cost-effective measurements of $K(h)$ and $\theta(h)$ to greater depths (Gee and Ward, 1999).

Guelph Permeameter(GP) The Guelph Permeameter (GP) is a constant head well permeameter consisting of a mariotte bottle that maintains a constant water level inside a hole augered into unsaturated soil. Flow from this permeameter is assumed to reach steady-state after a transient state during which the soil saturated bulb and the wetting zone increase in size by migrating quasi-spherically from the infiltration surface. At steady-state, the saturated bulb remains essentially constant in size, while the wetting front continues to increase (Reynolds *et al.*, 1985). The analysis requires measurements from two different water levels in the same well. Munoz-Carpena *et al.* (2002) provided methods for inverse optimization for parameter identification. They found that GP gives lower K_s estimates compared to other methods. A multiplying factor of 2 to 3 has been proposed to account for air entrapment in the field soil.

Cone Permeameter The cone permeameter is fitted into a hole, where a soil core of smaller diameter was removed with a sampler. Water is injected into the soil through a screen, and the progress of the wetting front is measured with two tensiometer rings positioned above the screen. Tests are conducted with two sequentially applied pressure heads of different magnitudes. After the supply valve is closed, tensiometers monitor the redistribution of water in the soil profile. It is possible to evaluate wetting only, or wetting and drying simultaneously, via analysis of different parts of the experiment, that is, during water application and during redistribution. Cumulative inflow and pressure head readings are analyzed with inverse optimization. Final moisture content information improves estimates of unknown hydraulic parameters (Gribb, 1996). Soil densification caused by pushing the cone permeameter to the testing depth resulted in lower values of θ_s and K_s (Kodesova *et al.*, 1999).

Use of Tensiometer Response to Measure Soil Hydraulic Conductivity

The use of a ceramic cup tensiometer to measure soil hydraulic conductivity was proposed as early as 1937 by Richards *et al.* (1937). Recently, Hayashi *et al.* (1997) developed a method to determine the hydraulic conductivity of unsaturated soils from the response of a tensiometer to an artificially induced perturbation of pressure. The response

time of tensiometers is controlled by soil hydraulic conductivity when the flow resistance of the porous cup is sufficiently small. Advantages are the fast procedure (1 h) and the use of readily available equipment. Tests must be repeated over time to determine the *in situ* relationship between matric potential and hydraulic conductivity. The estimated conductivity is sensitive to the disturbance of the soil in close proximity to the porous cup. It is also sensitive to changes in the matric potential during a response test. Timlin and Pachepsky (1998) also developed a method to determine unsaturated hydraulic conductivity using tensiometers. They measured water flux into a tensiometer after a suction is applied to its inside. The reduced pressure in the tensiometer causes water to flow into the tensiometer from the soil leading to a decrease of the volume of air, and subsequently pressure increases. The unsaturated conductivity parameters are determined by using a two-dimensional finite element soil model coupled with inverse optimization. Shortcomings of the method are clogging of the tensiometer pores by fine soil material, which leads to a change of conductivity of the ceramic cup over time, and possible poor contact between tensiometer and soil.

Integrated Determination by Inverse Modeling

By the very nature of the unsaturated flow processes, the classic direct measurements of hydraulic properties remain extremely demanding with respect to experimental procedures, requiring, for example, excessive equilibrium times, small sample sizes, strictly stationary flow or pressure conditions, and perfect contact between porous membranes and measurement sensors. At the same time, they generally yield only limited information about the hydraulic properties, for example, one point on a moisture retention curve. In order to come to a faster and more integrated way to characterize hydraulic properties of soils, inverse simulation of transient flow processes on the laboratory and on the field scale will play the key role in future developments of measuring techniques. The highly dynamic and strongly nonlinear water flow in the unsaturated zone is clearly too difficult to represent in analytical or semiempirical approaches (Kutilek and Nielsen, 1994; Feddes, 1995). With the progress in computer simulation, an intensive further development of transient methods that aim on the simultaneous determination of the hydraulic properties over a wide moisture range by inverse simulation is currently underway (Vrugt and Dane, 2005, **Chapter 77, Inverse Modeling of Soil Hydraulic Properties, Volume 2**). Specifically, the inclusion of the measurement instrument itself and its interaction with the surrounding soil environment in the inverse analysis bears a tremendous potential to improve the precision of hydraulic properties estimates. Furthermore, developments in combined instrumentation, where controlled or uncontrolled water fluxes are measured together with water content and water potential simultaneously by the same instrument, will become more important.

Still, in the attempt to estimate soil hydraulic properties it appears that we are faced with an analogue to the Heisenberg uncertainty principle: The more precise the hydraulic properties are obtained for a point in space or an isolated soil sample, the less relevant this precision might be for characterizing the flux at the field scale. In the range where the process model is valid, we can now achieve an almost perfect history matching by inverse modeling of laboratory experiments, which allows characterizing the hydraulic properties of soil samples to an exceptional high degree of accuracy (Bitterlich *et al.*, 2004). This kind of measurement evaluation further allows to expand the limits of our conceptual understanding of the flow process (e.g. two-phase flow effects, hysteresis model inadequacies, dynamic effects). However, flow and transport processes in vadose zone hydrology may be controlled by structures, which have an extent similar to the scale of the system of interest (Vogel and Roth, 2003). This means that without identifying these structures, our efforts on local precision are futile. As hydraulic properties cannot be directly measured on larger scales, we depend on proxy variables. If structure is identified at the scale of interest, it might be sufficient to determine the hydraulic properties of the structural elements in an approximate manner. Stochastic fusion of a variety of moisture-related instrumental information by noninvasive sensoring methods (electrical resistivity tomography, passive microwave, ground-penetrating radar, and others) and its inverse evaluation (Yeh and Simunek, 2001) appears to be a promising direction.

While keeping in mind that the general interest clearly focuses on effective large-scale properties, it must be stressed that only a thorough understanding of the underlying point-scale processes allows to judge on appropriate ways to upscale local properties. For processes of dissipative nature, effective macroscale properties obtained just by averaging will be a valid description (e.g. Schmalz *et al.*, 2003). However, other processes must be known (and measured) in spatial and/or temporal detail, because neglecting them will lead to systematic misconceptions. For example, small changes in water content in the pressure range near saturation, as frequently encountered in natural soil samples, indicate a secondary pore structure, which controls preferential flow of water on the scale of interest. Neglecting this by fitting oversimplified models for the constitutive relationships will lead to a systematic misconception and systematic errors in modeling water and solute transport (Mahmood and Hubbard, 2003).

It appears that in the development of measurement techniques for hydraulic properties characterization there is currently a threefold transition:

- There is a transition from "classic" methods, which depend on equilibrium, steady-state flow, or strict boundary conditions, toward generalized nonequilibrium methods. This represents a change in paradigm from measurements that are based on high experimental and low calculus requirements towards measurements with great freedom in experimental boundary conditions, but high requirements with respect to sensor response (in particular, with respect to temporal resolution and signal accuracy) and with respect to a sophisticated and robust model inversion.
- There is also a transition from point measurement to large-scale measurements, based on a combination of new hydrogeophysical techniques that are applicable on large areas such as satellite-based ground-penetrating radar. The focus must be to identify the largest structures in the materials on the respective scale of interest because these determine the system behavior. Together with flow observations on large areas (drained land) and regional estimates of evapotranspiration, these observations can be evaluated by inverse modeling in order to search for the existence of effective processes and properties on the scale of interest (Feddes *et al.*, 1993).
- Finally, there is an increasing recognition that due to the overwhelming complexity of natural flow processes, the idea to measure "true" and "universal" hydraulic properties on a large scale must be replaced by object-dependent measurement methods and properties, where the target variable of interest (e.g. irrigation demand, mean flow to the groundwater, structure of flow field for solute transport) decides upon the most appropriate manner to evaluate the data (Abbaspour *et al.*, 2001).

CONCLUDING REMARKS

Our knowledge of basic vadose zone flow and transport processes has advanced considerably over the last several decades. Unfortunately, the ability to determine process parameters has not kept pace with the ability to put the processes into numeric models. Although various field and laboratory methods for determining unsaturated hydraulic properties have been proposed, there remains a glaring lack of standardized procedures. Despite enormous investments of time and money made by soil scientists, hydrologists, and others, improvements over several decades in direct methods to measure hydraulic properties of field soils have been rather marginally achieved. Specialized equipment to measure the unsaturated hydraulic properties is generally expensive because of a relatively small market. Therefore, a disproportionate amount of time and money is still being used to conduct routine experimental work. The difficulty to solve Richards' equation for transient flux conditions hindered for a long time the rigorous evaluation of experiments and the development of experiments that are designed to maximize the information content with respect to the properties of interest (Vrugt and Bouten, 2001). Furthermore, not much of the knowledge gained during the last decade on measurement methods is being used in management practices. Thus, narrowing the gap between the state of the art and the state of the practice is one of the fundamental issues required in order to solve problems such as contamination of the vadose zone and groundwater.

On the positive side, experimental procedures are now greatly benefiting from the use of flexible inverse estimation procedures, improved numerical models, more powerful computers, and increased automation in data collection efforts. For many years, measuring and monitoring methods have lagged behind numerical analyses of water flow and solute transport through the vadose zone. However, recent advances in electronic components, renewed interest in development of monitoring methods, and the infusion of geophysical methods into vadose zone hydrology have begun to address this imbalance. Future developments in instrumental field techniques and in improved inverse modeling techniques must direct toward a point where available tools will be so well adapted to the needs of soil physicists and vadose zone hydrologists, that they are also easy to use in practice. Essential in that is that inverse modeling techniques must not only be robust and thus lead to accurate results, but also must obligatorily indicate the adequacy of the underlying model assumptions and the uncertainty of the resulting estimates. Because of the increasing speed of computers, there is a rapid development in this area (e.g. Vrugt *et al.*, 2003), and the use of Monte Carlo based stochastic methods to estimate the uncertainties, appears very promising.

Probably the most challenging task with respect to determining hydraulic properties of soils is the coupling of soil mechanics, soil chemistry, and possibly soil biology, with soil hydraulics. Since there is an enormous sensitivity of parameters, such as the saturated hydraulic conductivity, on these factors, this is not merely an academic question. Despite the long-lasting knowledge upon the importance of the various feedbacks (e.g. Nielsen *et al.*, 1986), not much progress has been achieved in this field during the last decades. Substantial progress will depend on the ability of scientists to bridge the traditional disciplinary boundaries (US Department of Energy, 2001). To date, we still suffer from the *'inability to integrate simultaneously the most relevant physical, chemical, and biological processes in a unified theoretical framework'* (Nielsen *et al.*, 1986).

76: Models for Indirect Estimation of Soil Hydraulic Properties

MARCEL G SCHAAP

Department of Environmental Sciences, University of California, Riverside, CA, US

This article describes methods for the indirect estimation of soil hydraulic properties, such as soil water retention and hydraulic conductivity characteristics. Indirect methods can be classified into semiphysical methods that are based on mechanical assumptions regarding particle and pore arrangements, and statistical methods that are known as pedotransfer functions. Both classes are described and evaluated on their merits, and some characteristic examples are given. A list of applicable software is described at the end of the article and an extensive reference list provides sufficient material for further background information.

INTRODUCTION

Qualitative knowledge about soil hydraulic properties such as water retention and hydraulic conductivity has historically been an important factor for assessing the suitability of land for agriculture, settlement, or trafficability. In modern agricultural and engineering practices, varying degrees of quantitative detail about soil hydraulic properties are needed for determining the soil water holding capacity, infiltration, percolation, and runoff rates, or for quantifying the transport of pollutants in soil. Although automation and computer technology have certainly advanced the ease with which hydraulic properties can be measured (cf. Dane and Topp, 2002, *see* **Chapter 75, Determining Soil Hydraulic Properties, Volume 2** by Dürner), their determination has by no means become easy. Many measurement methods are still labor-intensive and expensive. In addition, soil hydraulic properties are often subject to considerable spatial and sometimes temporal variability, making measurements less representative. Measurements of hydraulic properties for regional, continental, or global scales are virtually impossible.

The expense and difficulty of performing soil hydraulic measurements in laboratory or field are often used as arguments for developing indirect methods for estimating soil hydraulic properties using widely available surrogate data. The general method is to define physical relations or find statistical correlations between predictors such as soil texture and the soil hydraulic properties. After the modeling exercise, the model can be tested on independent data, or be applied for common use. In the past decades, literally hundreds of such studies have been performed. This review considers two main classes of indirect methods, semiphysical and empirical approaches, and briefly discusses common modeling concepts. Reviews with slightly different perspectives concerning indirect models can be found in Rawls *et al.* (1991) and Wösten *et al.* (2001). Most model development is data-driven and requires soil databases in which both predictors and measured hydraulic properties are present. This review will therefore also discuss some pertinent databases and software packages.

SEMIPHYSICAL MODELS

Semiphysical methods recognize the shape similarity between the cumulative particle-size distribution and the water retention characteristic. Although none of the models can predict hydraulic properties from first principles, they do offer valuable conceptual insights into the physical relations between the texture distribution and the pore-size distribution. A drawback of these methods is that they often require very detailed particle-size distributions, making them almost as difficult to apply as direct measurements. Three model types can be discerned in the literature.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

The Arya–Paris Model

The Arya and Paris (1981) model uses information from k particle-size classes to estimate k pairs of water contents and pressure heads. Each class is thought of to consist of n_k spherical particles of mean radius R_k. The pore volume of this class is associated with a cylindrical pore of radius r_k. The Arya–Paris model assumes that the bulk density is the same for each particle class. The pore volume, V_k, for each particle-size class is then

$$V_k = \left(\frac{W_k}{\rho_s}\right)e \tag{1}$$

where W_k is the total mass in particle class k and ρ_s is the particle density. The water content follows by summing the V_k of all particle-size classes $1 \ldots k$, starting with the class with the smallest R_k. The void ratio, e, is given by

$$e = \frac{(\rho_s - \rho_b)}{\rho_b} \tag{2}$$

The radius of the pore belonging to class k is given by (Arya and Paris, 1981):

$$r_k = \frac{R_k\sqrt{2en_k^{(1-\alpha_{ap})}}}{3} \tag{3}$$

where n_k is the number of spherical particles of radius R_k required to fill the mass in the particle-size class. The corresponding pressure head is subsequently calculated with the capillary law. The empirical parameter α_{ap} accounts for non-spherical soil particles and should be equal or greater than 1. Arya and Paris (1981) initially determined that α_{ap} ranged between 1.31 and 1.43 for five texturally different soils, but later it was found that α_{ap} varied between 1.02 and 2.97 (Arya *et al.*, 1982; Schuh *et al.*, 1988; Mishra *et al.*, 1989). Arya *et al.* (1999a) modified the original Arya–Paris concept by allowing α_{ap} to vary according to particle size and extended the model to unsaturated conductivity (Arya *et al.*, 1999b). To our knowledge, this model extension has not yet been tested on independent data.

Fractal Approaches

Several studies used fractal concepts to develop indirect methods. Fractal patterns reveal themselves by exhibiting power-law scaling relations between the observed quantity and the measurement scale, R. Employing a somewhat similar logic as the Arya–Paris model, fractal behavior may be found on a particle number basis (e.g. Tyler and Wheatcraft, 1989) as

$$N \sim R^{-D_N} \tag{4}$$

where N is the number of particles greater than a measurement scale R, and D_N is the fractal dimension (ranging between 0 and 3). A fractal particle-size distribution thus exhibits a straight line in a simple log N versus log R plot. Tyler and Wheatcraft (1989) argued that the parameter α_{ap} in the Arya and Paris (1981) equation should be equal to $D_N - 1$. Tyler and Wheatcraft (1992), however, indicated that "soils that show fractal scaling are a rather small subset of the soils commonly encountered in the field". Indeed, using more than 1100 soil data sets, Tietje and Tapkenhinrichs (1993) demonstrated that the fractal approach of Tyler and Wheatcraft (1989) was not more accurate than the original Arya and Paris (1981) concept with $\alpha_{ap} = 1.38$. Other fractal-based approaches were proposed by Rieu and Sposito (1991a, b) and Bird *et al.* (2000) who included soil structure into the fractal concept.

The Haverkamp and Parlange Model

Haverkamp and Parlange (1986) built a semiphysical model around the simple assumption that the pore radius r is linearly related to the particle radius R

$$r = \gamma R \tag{5}$$

where γ is a factor of proportionality, requiring that pores of different sizes have the same shape. Combined with the capillary law that links pore size to capillary pressure, it follows that a retention characteristic can be derived from a cumulative particle-size distribution. Haverkamp and Parlange (1986) developed a somewhat complex model that included hysteresis phenomena to estimate Brooks and Corey (1964) retention parameters by curve fitting the van Genuchten (1980) equation to the cumulative particle-size distribution. This approach was later simplified and tested by Schaap and Bouten (1996), who showed that the model can successfully be applied to sandy soils. Bouraoui *et al.* (1999) showed that a modified and simplified Haverkamp and Parlange concept could be applied to a large part of the textural triangle. However, beyond these references, the Haverkamp and Parlange model has attracted little following in the literature.

EMPIRICAL MODELS

Empirical methods, often called *pedotransfer functions* (PTFs, Bouma and van Lanen, 1987), generally focus on practical applicability and often use more or less simple statistical models to estimate hydraulic properties. Contrary to most physically based models, empirical methods often require limited – but easily accessible – input data such as sand, silt, or clay percentages and porosity, although more elaborate combinations of input data are also possible (cf. Rawls *et al.*, 1991; Wösten *et al.*, 2001). There are many

different PTFs, and it is impractical to describe all these in detail. We will limit ourselves to describing some modeling concepts while giving some examples of characteristic PTFs. The concepts distinguished in this review are, class-based methods, point-based, and parametric approaches.

Class PTFs

Class PTFs provide hydraulic properties for particular soil classes. The advantage of class PTFs is their simplicity (essentially, they consist of lookup tables) and modest requirements regarding input data. Only class information is necessary, thus enabling estimates of hydraulic properties from qualitative field data. Class PTFs for the 12 USDA textural classes were reported by Clapp and Hornberger (1978), Rawls *et al.* (1982), Carsel and Parrish (1988), Rawls and Brakensiek (1985), and Schaap and Leij (1998), among others. Wösten *et al.* (1999) provided average van Genuchten (1980) retention- and unsaturated conductivity parameters for 12 soil classes based on the FAO textural classification but also made a further distinction for subsoils, topsoils, and organic soils. The resulting class average parameters were used in conjunction with a GIS system to estimate the available water content on a scale of 1 : 1 000 000 for most of the European Union. Other large-scale applications can be found in Kern (1995) and Imam *et al.* (1999). A drawback of class PTFs is that discrete changes of hydraulic properties occur between two adjacent classes (e.g. loam to sandy loam, or topsoil to subsoil). Such changes may not always be realistic, especially for small-scale applications. Instead, point-based or parametric PTFs provide continuously varying estimates that may be more useful in such cases.

Point PTFs

Point PTFs use simple linear expressions to estimate individual water retention or conductivity points (i.e. water content-pressure or conductivity-pressure points) from texture and other soils data. Point PTFs are arguably the most precise of PTFs because they estimate the hydraulic points directly, without relying on parameterized forms of the hydraulic characteristics such as done by parametric PTFs (cf. Schaap and Bouten, 1996; Minasny *et al.*, 1999 for some comparisons). A drawback of point PTFs is that they are limited in making estimates at specific pressure heads. However, if necessary, parameterized results can be obtained by fitting appropriate retention equations to the point estimates (e.g. Saxton *et al.*, 1986). In most cases, separate regression equations are used for each pressure. Tietje and Tapkenhinrichs (1993) noted that this causes some point PTFs to exhibit unrealistically increasing water contents with stronger suctions. Examples of point PTFs can be found in Rawls *et al.* (1982), Rawls *et al.* (1983), Ahuja *et al.* (1985), Rajkai and Varallyay (1992), Thomasson and Carter (1992), Bristow *et al.* (1999), Minasny *et al.* (1999), and Renger *et al.* (1999).

Parametric PTFs

Parametric PTFs estimate parameters of retention or conductivity equations, such as the Brooks and Corey (1984), van Genuchten (1980), and the Mualem (1976) equations. Contrary to class PTFs, these models estimate hydraulic parameters that vary continuously with input data. Contrary to point PTFs, parametric PTFs can provide hydraulic properties at arbitrary capillary pressures. It is impossible to describe all of these approaches; we will therefore give only a few well-known examples.

Brakensiek *et al.* (1984), Rawls and Brakensiek (1985), and Rawls *et al.* (1992) presented parametric PTFs that estimated Brooks and Corey (1964) parameters and saturated hydraulic conductivity from porosity, ϕ, and sand and clay percentages (S and C, respectively). In these PTFs, the saturated water content is set equal to the porosity while the other Brooks-Corey parameters and the saturated hydraulic conductivity are related to S, C, and ϕ, using the polynomial

$$\begin{aligned} p = {} & a_1 + a_2 S + a_3 C + a_4 \phi + a_5 S^2 + a_6 C^2 + a_7 \phi^2 \\ & + a_8 S\phi + a_9 C\phi + a_{10} S^2 C + a_{11} S^2 \phi + a_{12} C^2 \phi \\ & + a_{13} S C^2 + a_{14} C\phi^2 + a_{15} S^2 \phi^2 + a_{16} C^2 \phi^2 \end{aligned} \quad (6)$$

where p is a Brooks–Corey parameter or the saturated hydraulic conductivity and a_i are model coefficients.

Vereecken *et al.*, (1989, 1990) provided expressions for water retention and unsaturated hydraulic conductivity for 182 Belgian soil horizons. The water retention was described with a modified van Genuchten equation and the unsaturated hydraulic conductivity was described with the Gardner (1958) equation. Vereecken *et al.* (1989, 1990) provided a number of ways to estimate the seven hydraulic parameters in these equations. One of the approaches was fitting the parameters $a_1 \ldots a_6$ in the equation

$$\begin{aligned} f(p) = {} & a_1 + a_2 f(C) + a_3 f(Si) + a_4 f(S) \\ & + a_5 f(OM) + a_6 f(\rho_b) \end{aligned} \quad (7)$$

where p is the hydraulic parameter being estimated, S: Sand, C: clay, Si: silt, ρ_b: bulk density, OM: organic matter, and $f()$ indicates that a transformation (e.g. logarithms, exponents, etc.) may be applied to the parameter in ellipses.

Artificial neural networks form a special class of PTFs and were introduced by Pachepsky *et al.* (1996), Schaap and Bouten (1996), and Tamari *et al.* (1996). Neural networks are sometimes described as "universal function

approximators" that can "learn" to approximate any continuous (nonlinear) function to any desired degree of accuracy (cf. Haykin, 1994). An advantage of neural networks as compared to regression PTFs is that they require no *a priori* model concept (e.g. linear or exponential functions). This property makes ANNs well suited to build empirical PTFs. However, the method also results in black-box models in which the exact relations between predictors and hydraulic properties are difficult to determine.

Mixed results have been obtained with neural network PTFs. Schaap and Bouten (1996) and Schaap *et al.* (1998) showed that neural networks made estimates with significantly smaller errors than more traditional approaches. Pachepsky *et al.* (1996) found that neural networks perform better than multiple linear regressions when used as point PTFs, but that the two methods produced comparable results when used as parametric PTFs. Tamari *et al.* (1996) reported that neural networks were not better than multiple linear regressions if the uncertainty in the data was large. Minasny *et al.* (1999) found that nonlinear regression reached a similar performance as a neural network approach.

DATABASES AND SOFTWARE

Several public databases have been compiled that suit the development and testing of models for the indirect estimation of hydraulic properties. The oldest database is probably UNSODA (Nemes *et al.*, 2001 and available at: **www.ussl.ars.usda.gov/models/unsoda.htm**). This world wide database contains data about laboratory and field hydraulic and other relevant soil characteristics for 790 soils. The HYPRES database contains similar soils data as UNSODA, but for European soils. HYPRES was described in Wösten *et al.* (1999) and is available at **www.macaulay.ac.uk/hypres/index.html**.

Several software packages for estimating soil hydraulic properties are available on the internet. Soil Water Characteristics from Texture (SWCT) is based on Saxton *et al.* (1986) and estimates wilting point, field capacity, and available water content. SWCT is part of the Soil Plant Atmosphere Water (SPAW) Field and Pond Hydrology package and is targeted at farmers and resource managers interested in water and nutrient budgeting in soil and ponds, and is available at **http://www.bsyse.wsu.edu/saxton/spaw/**.

SOILPAR is a program developed by M. Donatelli and M. Acutis at the Research Institute for Industrial Crops (ISCI), Bolongna, Italy. The program implements 10-point PTFs and four parametric PTFs for water retention and hydraulic conductivity, and can be downloaded at **http://www.sipeaa.it/ASP/ASP2/SOILPAR.asp**. The program provides a wide range of plotting and data analysis functions.

Rosetta is a Windows-based program that implements artificial neural network PTFs published by Schaap *et al.* (1998), Schaap and Leij (1998), and Schaap and Leij (2001), and is available from **http://www.ussl.ars.usda.gov/models/rosetta/rosetta.HTM**. The program implements five parametric PTFs for the estimation of water retention saturated and unsaturated hydraulic conductivity. Rosetta uses a hierarchical approach to maximize the accuracy of the PTF estimates given a particular data availability.

Minasny and McBratney (2002) developed the Neuropack software package (**http://www.usyd.edu.au/su/agric/acpa/neuropack/neuropack.htm**). Unlike the other software packages that implement existing PTFS, Neuropack is primarily intended to develop neural network-based PTFs. Optimization results can be saved and or be tested using independent soils data.

CONCLUSION

Indirect methods are valuable assets in many soils applications because they allow estimation of soil hydraulic properties where none exist or where direct measurements would be prohibitive. The many different models that exist are mostly geared toward particular soils or datasets (Schaap and Leij, 1998). A number of common PTFs were tested for general applicability in Tietje and Tapkenhinrichs (1993), Kern (1995), Tietje and Hennings (1996), Schaap *et al.* (1998), Minasny *et al.* (1999), and Wösten *et al.* (2001). However, these studies showed that no clearly superior PTF exists that works well in all applications. When possible, it is therefore advisable to test several PTFs for accuracy before blindly trusting the results.

Some important issues exist that are worth considering within the context of indirect estimations. Most indirect methods are based on hydraulic data from laboratory measurements, yet are usually applied to field situations. Laboratory and field measurements do not necessarily yield similar results, so it is possible that estimates of indirect methods are biased. Another issue is that most indirect methods were developed using data from specific parts of the world, particularly for soils from temperate climates. With the exception of a few studies (e.g. Epebinu and Nwadialo, 1993; Tomasella and Hodnett, 1997; Bristow *et al.*, 1999), hydraulic data and corresponding indirect methods about tropical soils are a virtual *terra incognita*. Obtaining comprehensive soil and hydraulic data for regions beyond those now represented in regional and international databases will probably help improve the general applicability of indirect methods and aid the management of local natural and agricultural resources.

Numerical-simulation models of water flow and solute transport in the vadose zone are important tools in environmental research. The accuracy of predictions with these models heavily relies on accurate estimates of the unsaturated soil hydraulic parameters. Initial attempts on the estimation of the soil hydraulic parameters mainly focused on the use of relatively simple static or steady-state flow experiments. While these laboratory methods have the advantage of being relatively simple to implement, they are typically time consuming and require restrictive initial and boundary conditions to satisfy the assumptions of the corresponding analytical solutions. Significant advances in computational capabilities in the 1980s have stimulated research on the use of Inverse Modelling (IM) for the estimation of soil hydraulic properties. Parameter estimation using IM accommodates much more flexible experimental conditions than required for the static or steady-state flow methods, thereby enabling a rapid characterization of the hydraulic properties of the considered soil domain. This article explores the historical development of current perspectives on the identification of a single "best" set of soil hydraulic parameters using IM (thereby effectively neglecting the influence of possible sources of uncertainty on the final parameter estimates), and discusses alternative (Bayesian and multiple-criteria) parameter estimation strategies which can be used to quantify the uncertainty (probabilistic and multiobjective) associated with the inversely estimated soil hydraulic properties. Throughout this article, we use a classical transient laboratory outflow experiment to further illustrate the various aspects of the IM procedure for estimating the soil hydraulic parameters.

INTRODUCTION

An adequate hydrological description of water flow and contaminant transport in the vadose zone heavily relies on accurate estimates of the soil water retention and hydraulic conductivity function (hereafter referred to as soil hydraulic properties). To enable an accurate soil physical characterization, methodologies need to be developed which allow a rapid, reliable, and cost-effective estimation of the hydraulic properties of the considered soil domain, including its spatial variability. Most of the early work reporting on the estimation of the hydraulic properties of unsaturated soils focused on the use of relatively simple static or steady-state flow experiments. These static or steady-state flow experiments have the advantage of being relatively simple to implement. However, these methods are typically time consuming and require restrictive initial and boundary conditions to satisfy the assumptions of the corresponding analytical solutions.

Significant advances in computational capabilities in the 1980s have stimulated research on the use of Inverse Modelling (IM) for the estimation of soil hydraulic properties. While other applications of IM exist, such as retrieving the initial conditions of an initial/boundary-value differential equation (Press *et al.*, 1992) or reconstructing a contaminant source history (Neupauer *et al.*, 2000), this article primarily focuses on the inverse problem of parameter estimation applied to soil hydrology.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Parameter estimation using IM accommodates more flexible experimental conditions than required for the static or steady-state flow methods, thereby enabling a rapid characterization of the hydraulic properties of the considered soil domain. We share the recent opinion voiced by Hopmans and Šimůnek (1999) that parameter estimation using IM has tremendous potential in characterizing flow and transport processes in the vadose zone, while simultaneously presenting us with an additional tool to better understand the controlling mechanisms. However, when using an IM approach, the soil hydraulic properties can no longer be estimated by direct inversion, as applicable for the steady-state and static experiments (with a few exceptions, such as the instantaneous profile method for which both direct and indirect approaches exist), but only meaningfully inferred using an iterative solution of the flow process, thereby placing a heavier demand on computational resources. In this iterative process, repeated numerical simulations of the governing transient flow equations are performed, thereby minimizing the difference between the observed and model predicted flow variables. Nowadays, IM is a frequently employed approach within the hydrologic science community to estimate effective parameters, at scales ranging from laboratory samples to regional applications. While, IM has been applied successfully mostly to the parameter estimation of soil water retention and unsaturated hydraulic conductivity functions, recent progress is also reported in the description of water uptake by plant roots (Musters *et al.*, 1999; Vrugt *et al.*, 2001a,b; Hupet *et al.*, 2002) and estimation of soil thermal properties and water fluxes (Hopmans *et al.*, 2002). In this article, we shall focus our attention almost exclusively on the estimation of soil hydraulic properties using IM. Where necessary, reference is made to other articles in this Encyclopedia, whose reading will improve the understanding of the experiments and mathematical concepts underlying the IM procedure.

THE PROCESS OF PARAMETER ESTIMATION

The process of IM is closely related to parameter estimation or model calibration. Parameter estimation or model calibration is a common problem in many areas of process modelling, both in on-line applications, such as real time optimization, and in off-line applications, such as the modelling of reaction kinetics and phase equilibrium. The goal is to determine values of model parameters that provide the best fit to measured data, generally based on some type of least squares or maximum likelihood criterion. Usually, this requires the solution of a nonlinear and frequently nonconvex optimization problem.

Among the first to suggest the application of computer models to estimate soil hydraulic parameters were Whisler and Whatson (1968), who report on estimating the saturated hydraulic conductivity of a draining soil by matching observed and simulated drainage. Since their early endeavors, the application of IM to the estimation of unsaturated flow and transport properties has significantly evolved. In the field of vadose zone hydrology, the parameter-estimation technique usually involves the indirect estimation of the soil water retention and unsaturated soil hydraulic conductivity characteristics by repeated numerical solution of the Richards' equation (*see* **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**):

$$C(h_{\mathrm{m}})\frac{\partial h_{\mathrm{m}}}{\partial t} = \nabla \cdot [K(h_{\mathrm{m}})\nabla(h_{\mathrm{m}} + z)] \qquad (1)$$

where $C(h_{\mathrm{m}})$ is the so-called soil water capacity, representing the slope of the soil water retention curve, h_{m} (L) denotes the soil water matric head, t (T^{-1}) represents time, $\boldsymbol{K}$ (LT^{-1}) is the unsaturated soil hydraulic conductivity tensor, and z (L) is the depth included for the vertical flow component only.

In the IM procedure, both the soil water retention and unsaturated soil hydraulic conductivity relationship are described by an analytical model with yet unknown parameter values. Please refer to **Chapter 76, Models for Indirect Estimation of Soil Hydraulic Properties, Volume 2** for information about parametric expressions for the soil hydraulic properties. A transient experiment is performed under controlled conditions with prescribed initial and boundary conditions (*see* **Chapter 75, Determining Soil Hydraulic Properties, Volume 2**). During the experiment, one or more flow-controlled variables are measured. An extensive review on the measurement of flow- and transport processes across a range of spatial and temporal scales is given in **Chapter 72, Measuring Soil Water Content, Volume 2**. Subsequently, the parameters in the hydraulic functions are estimated by minimizing a user-specified measure, containing the difference between the observed and model-predicted flow variables.

To further illustrate the IM procedure, consider Figure 1, which presents a scatter-plot of measured (X,y) data. Also included are three different lines, corresponding to the fixed model structure $\hat{y} = \beta X$, with different values for the parameter β. The aim of the IM procedure is now to estimate that value of the parameter β that provides the best fit to the measured data. Note that, in this simple linear case, analytical solutions for estimating β exist. A more complex problem arises when the fitting model is represented by one or more differential equations, generally containing more than a single unknown parameter value. A typical example of such a problem involves the solution of the Richards' equation augmented with parametric forms of the soil water retention and unsaturated soil hydraulic conductivity function. In this particular case, the parameters can no longer be estimated by visually inspecting the agreement between observations and model predictions, and the search efficiency of computer-based solution algorithms is needed

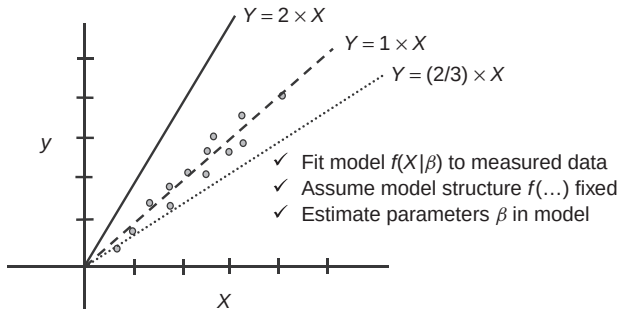

Figure 1 Scatter plot of measured (X, y) data. The three different lines, correspond to the fixed model structure $\hat{y} = \beta X$, with different values for the parameter β. The goal of the IM procedure is to find that value of β which generates the best fit to the measured data. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

to determine the unknown soil hydraulic parameters. The resulting iterative solution of the Richards' equation is in contrast to the direct inversion techniques, which are applicable when using linear models, or the static or steady-state flow experiments for which analytical solutions exist.

In summary, the aim of the IM procedure is to identify the parameter values, such that the difference between the observed and model predicted flow variables is minimized, while accounting for uncertainties in the measured input–output time series (data uncertainty) and uncertainties in the structural ability of the Richards–hydraulic model, to simulate the transient flow process (model uncertainty).

HISTORICAL BACKGROUND

During the last two decades, a great deal of research has been devoted to explore the applicability and suitability of the inverse approach for the identification of soil hydraulic properties. That research has focused primarily on five issues (i) the type of transient experiment and kind of prescribed initial and boundary conditions suited to yield a reliable characterization of the soil hydraulic properties (van Dam *et al.*, 1992, 1994; Ciollaro and Romano, 1995; Santini *et al.*, 1995; Šimůnek and van Genuchten, 1996, 1997; Šimůnek *et al.*, 1998b; Romano and Santini, 1999; Durner *et al.*, 1999; Wildenschild *et al.*, 2001), (ii) the determination of the appropriate quantity and most informative kind of observational data (Zachmann *et al.*, 1981; Kool *et al.*, 1985; Parker *et al.*, 1985; Kool and Parker, 1988; Valiantzas and Kerkides, 1990; Toorman *et al.*, 1992; Eching and Hopmans, 1993; Eching *et al.*, 1994; Durner *et al.*, 1999; Vrugt *et al.*, 2002; among others), (iii) the selection of an appropriate model of the soil hydraulic properties (Zachmann *et al.*, 1982; Russo, 1988; Zurmühl and Durner, 1998), (iv) the adoption and development of Bayesian and multiple-criteria techniques to quantify the uncertainty associated with the inversely estimated parameters (Kool and Parker, 1988; Hollenbeck and Jensen, 1998; Vrugt and Bouten, 2002; Vrugt *et al.*, 2003a), and (v) the construction and weighting of multiple sources of information in an objective function (van Dam *et al.*, 1994; Clausnitzer and Hopmans, 1995; Hollenbeck and Jensen, 1998; Vrugt and Bouten, 2002).

With respect to issue (i), various investigations have reported the usefulness of the evaporation method, multistep outflow (MSO), ponded infiltration, tension infiltrometer experiments, multistep soil water extraction, and the cone penetrometer method. For more information about these different methods and the measurement of flow- and transport processes across a range of spatial and temporal scales in general, please refer to **Chapter 72, Measuring Soil Water Content, Volume 2**. With regard to the information content of the measurements (issue ii), work reported by Kool *et al.* (1985) and Kool and Parker (1988) suggested that the transient experiments should cover a wide range in water contents (θ), and preferably include tensiometer measurements within the soil sample. The benefit of using tensiometer data, simultaneously with outflow measurements in the IM procedure is intuitively clear, as the optimized soil water retention curve is then forced to match the observed $\theta(h_m)$ data (Eching and Hopmans, 1993). Additionally, in the case of outflow experiments, van Dam *et al.* (1994) demonstrated that more reliable parameter estimates can be obtained by incrementally increasing the pneumatic pressure in several steps, instead of using a single pressure increment. From all transient experiments, the evaporation and an MSO method are most popular for inversely estimating the water retention and unsaturated soil hydraulic conductivity characteristics.

Throughout the remaining part of this article, we use, therefore, a classical transient laboratory outflow experiment to illustrate the various aspects of the IM procedure for estimating the soil hydraulic parameters. Observed outflow measurements combined with soil water pressure head data within the soil core were taken from Wildenschild *et al.* (2001). We revisited the data for the sandy (Lincoln) soil, consisting of an MSO experiment with 5 consecutive pressure steps (0-25-35-62-80-100 mbar). Figure 2 presents the observed outflow data, as well as the measured soil water pressure heads within the soil sample. The soil hydraulic properties (issue iii) are described with the closed-form parametric expressions of Mualem-van Genuchten (Mualem, 1976; van Genuchten, 1980; MVG). The unsaturated soil hydraulic parameters (θ_r, α, n, K_s, and l; where θ_r is the residual water content, α and n are curve fitting parameters for the water retention curve, K_s is the saturated hydraulic conductivity, and l is a fitting parameter for the hydraulic conductivity function) were inversely estimated using the HYDRUS-1D model (Šimůnek *et al.*,

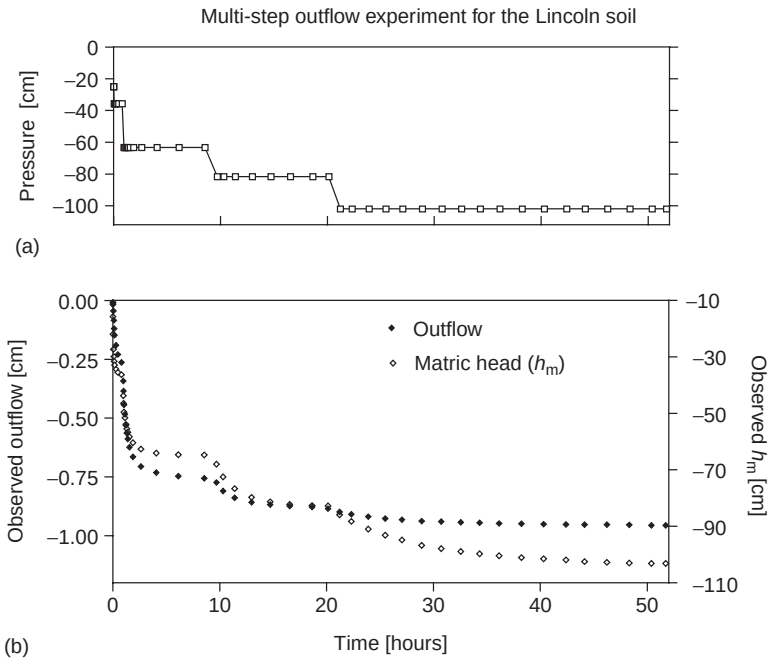

Figure 2 Example data of a transient outflow experiment which is extensively used throughout this article: (a) augmented pressure steps during the MSO experiment for the sandy (Lincoln) soil, (b) observed cumulative outflow and pressure head values as time develops within the soil sample during the transient experiment

Table 1 Prior parameter ranges of the MVG parameters for the Lincoln soil used throughout this article

Parameter	Unit	Min	Max
θ_r	[cm^3 cm^{-3}]	0.00	0.25
α	[cm^{-1}]	$4.5 \cdot 10^{-2}$	0.05
N	[−]	1.50	6.00
K_s	[cm h^{-1}]	0.25	3.00
L	[−]	−3.00	3.00

1998a). This model numerically solves the one-dimensional form of the Richards's equation, depicted in equation (1), using a Galerkin-type linear finite element scheme. The saturated water content (θ_s) of the Lincoln soil was fixed at its measured value of 0.37 m^3 m^{-3}. The prior ranges for each of the unsaturated soil hydraulic parameters are defined in Table 1. For more information about the experimental setup and soil, please refer to Wildenschild *et al.* (2001).

Although laboratory experiments have the advantage of being quick and precise, they do not necessarily lead to soil physical properties that can be considered representative for a field situation. Among the first to apply the IM approach to a field situation were Dane and Hruska (1983) who estimated soil physical parameters using transient drainage data. The application of IM to estimate soil hydraulic properties across spatial scales is very promising, yielding effective hydraulic properties that pertain to the scale of interest (*see* **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**). Sections "Confronting parameter uncertainty" and "Advances in inverse modelling" of this article extensively address issues of how to infer parameter uncertainty from IM studies (issue iv), and how to weigh multiple sources of information in one objective function (issue v). Finally, in Section "Closing comments", we briefly discuss the limitations of current IM/parameter estimation strategies and point to a more generic framework to account for input, output, parameter, and model structural uncertainty.

MATHEMATICAL DEVELOPMENT

To facilitate the description of the parameter estimation or IM procedure, let us write the combined Richards-hydraulic model f as

$$\hat{y} = f(X|\beta) + e, \tag{2}$$

where $\hat{y} = (\hat{y}_1, \hat{y}_2, \ldots, \hat{y}_m)$ is an $m \times 1$ vector of model predictions, $X = (X_{11}, X_{12}, \ldots, X_{mr})$ is an $m \times r$ matrix of input variables, $\beta = (\beta_1, \beta_2, \ldots, \beta_r)$ denotes the vector of r unknown parameters, and e is a vector of statistically independent errors with zero expectation and constant variance σ^2.

We assume that

$$\beta \in B \subseteq \Re^r \tag{3}$$

where $\Re^r$ denotes the r-dimensional Euclidean space. If B is not the entire domain space $\Re^r$, the problem is said to

be constrained. Given observed output values of $\boldsymbol{y}$, let us denote the residual errors from the predictions by

$$E(\beta) = G[\hat{y}(\beta)] - G[\boldsymbol{y}] = \{e_1(\beta), e_2(\beta), \ldots, e_m(\beta)\} \tag{4}$$

where the function $G(\cdot)$ allows for linear or nonlinear transformations of the simulated and observed data. The IM approach now relies on the estimation of the set of parameters β such that the measure E, commonly called *the objective function*, is in some sense forced to be as close to zero as possible. The development of a measure $E(\beta)$ that mathematically measures the "size" of $E(\beta)$ is typically based on assumptions regarding the distributions of the measurement errors presented in the data. By far the most popular measure for E is the simple least square (SLS) or maximum likelihood estimator, appropriate when the measurement errors are believed to be homoscedastic and uncorrelated. The SLS is expressed as

$$\underset{\beta}{\text{minimize}} \quad \text{SLS} = \sum_{j=1}^{m} e_j(\beta)^2 \tag{5}$$

Under these circumstances, Hollenbeck and Jensen (1998) stretched the importance of model adequacy before sound statements can be made about the final parameter estimates and their uncertainty. Model adequacy is determined from

$$p_{\text{adeq}} = 1 - Q\left(\frac{\text{SLS}}{\sigma_T^2}, m - r\right) \tag{6}$$

where σ_T denotes the error deviation of the measurements and $Q(\cdot)$ is the χ^2 cumulative distribution with $(m - r)$ degrees of freedom. Having homoscedastic and uncorrelated error residuals, the adequacy test gives us a measure of how well the optimized model fits the observations relative to their measurement precision. Using the definition of equation (6), models are adequate if $p_{\text{adeq}} > 0.5$, since then SLS $< m\sigma_T^2$. The validity and robustness of the standard SLS estimator has, however, to be questioned when significant outliers are present in the measurements (Finsterle and Najita, 1998). For these cases, more complex estimators can be used, which explicitly account for correlated and heteroscedastic error residuals (Sorooshian and Dracup, 1980).

FREQUENTIST VERSUS BAYESIAN APPROACH

While the Frequentist or classical statistics considers the model parameters β in equation (2) to be fixed but unknown, the Bayesian statistics treat them as probabilistic variables having a joint posterior probability density function (pdf), which captures the probabilistic beliefs about the parameters β in light of the observed data $\boldsymbol{y}$. The advantage of using Bayesian estimators rather than simple least-squares estimators for the problem of finding unsaturated soil hydraulic parameters has recently been discussed by Hollenbeck and Jensen (1998). The posterior pdf $p(\beta|\boldsymbol{y})$ is proportional to the product of the likelihood function and the prior pdf. The prior pdf with probability density (or mass) function $p(\beta)$ summarizes information about β before any data are collected. This prior information usually consists of realistic lower and upper bounds on each of the parameters, thereby defining the feasible parameter space, B, and imposing a uniform (noninformative) prior distribution on this rectangle.

Assuming that the residuals are mutually independent, each having the exponential power density, the likelihood of a parameter set β for describing the observed data $\boldsymbol{y}$ can be computed using Box and Tiao (1973)

$$L(\beta|\boldsymbol{y}, \gamma) = \left[\frac{\omega(\gamma)}{\sigma}\right]^m \exp\left[-c(\gamma)\sum_{j=1}^{m}\left|\frac{e_j(\beta)}{\sigma}\right|^{(2/d(1+\gamma))}\right] \tag{7}$$

where

$$\omega(\gamma) = \frac{\{\Gamma[3(1+\gamma)/2]\}^{1/2}}{(1+\gamma)\{\Gamma[(1+\gamma)/2]\}^{3/2}}$$
$$c(\gamma) = \left\{\frac{\Gamma[3(1+\gamma)/2]}{\Gamma[(1+\gamma)/2]}\right\}^{(1/(1+\gamma))} \tag{8}$$

in which Γ denotes the gamma operator. The parameter γ specifies the error model of the residuals. The residuals are assumed normally distributed when $\gamma = 0$, double exponential when $\gamma = 1$, and tend to a uniform distribution as $\gamma \to -1$. Assuming a noninformative prior of the form $p(\beta, \sigma|\gamma) \propto \sigma^{-1}$, Box and Tiao (1973) showed that the influence of σ can be integrated out of the likelihood function in equation (7), leading to the following form of the posterior density of β,

$$p(\beta|\boldsymbol{y}, \gamma) \propto [M(\beta)]^{-m(1+\gamma)/2} \tag{9}$$

where

$$M(\beta) = \sum_{j=1}^{m}\left|e_j(\beta)\right|^{2/(1+\gamma)} \tag{10}$$

For $\gamma = 0$, notice that M is simply the familiar "sum of squared residuals" function previously denoted in equation (5). For more information about the Bayesian inference scheme, please refer to Box and Tiao (1973).

MANUAL VERSUS AUTOMATIC SOLUTION ALGORITHMS

In the process of parameter estimation or model calibration, the hydrologist adjusts the values of the model parameters such that the model is able to closely match the behavior of the real system it is intended to represent. In its most elementary form, this calibration is performed by manually adjusting the parameters while visually inspecting the agreement between observations and model predictions (Dane and Hruska, 1983; Janssen and Heuberger, 1995). In this approach, the "closeness" of the model with the measurements is typically evaluated in terms of several subjective visual measures, and a semiintuitive trial-and-error process is used to perform the parameter adjustments (Boyle *et al.*, 2000). Because of the subjectivity and time-consuming nature of manual trial-and-error calibration, there has been a great deal of research into the development of automatic methods for calibration of hydrologic models (e.g., Gupta and Sorooshian, 1994). Automatic methods seek to take advantage of the speed and power of digital computers, while being objective and relatively easy to implement.

Automatic solution algorithms that have been developed in the past to solve the nonlinear SLS optimization problem, stated in equation (5), may be classified as local search methodologies, when seeking for systematic improvement of the objective function using an iterative search starting from a single arbitrary initial point in the parameter space or as global search methods in which multiple concurrent searches from different starting points are conducted within the parameter space.

One of the simplest local-search optimization methods, which is commonly used in the field of soil hydrology, is a Gauss–Newton type of derivative-based search

$$\beta^{(k+1)} = \beta^{(k)} - H(\beta^{(k)})^{-1}(\nabla f(\beta^{(k)}))^T \qquad (11)$$

where $\beta^{(k+1)}$ is the updated parameter set and $\nabla f(\beta^{(k)})$ and $H(\beta^{(k)})$ denote the gradient and Hessian matrix respectively evaluated at $\beta = \beta^{(k)}$

$$\nabla f(\beta) = \left(\frac{\partial f}{\partial \beta_1}(\beta) \ldots, \frac{\partial f}{\partial \beta_r}(\beta)\right)$$
$$H(\beta) = \left(\frac{\partial^2 f}{\partial \beta_i \partial \beta_j}(\beta)\right)_{i,j} \qquad (12)$$

From an initial first guess of the parameters $\beta^{(0)}$, a sequence of parameter sets, $\{\beta^{(1)}, \beta^{(2)}, \ldots, \beta^{(k+1)}\}$, is generated that is intended to converge to the global minimum of $E(\beta)$ in the parameter space. If $f(X|\beta)$ depends linearly on each parameter $\beta_j (j = 1, 2, \ldots, r)$, the minimization problem stated in equation (6) reduces to a Linear Regression problem for which analytical solutions exist. Doherty (1994) and Clausnitzer and Hopmans (1995) presented general local optimization codes, which can be coupled with any parameter estimation problem.

The derivative-based search defined in equations (11) and (12) will evolve towards the global minimum in the parameter space in situations where the objective function exhibits a topographical convex shape in the entire parameter domain. However, practical experience with hydrologic models suggests that the objective function seldom satisfies these restrictive conditions. To illustrate this problem, consider Figure 3 (taken from Vrugt and Bouten, 2002), which presents posterior marginal distributions (histograms) for two hydraulic parameters in the global minimum of the parameter space, derived using measured outflow dynamics from a transient one-step outflow experiment. If the objective function would exhibit a convex shape in the entire parameter domain, the histograms for each of the soil hydraulic parameters would exhibit a clear Gaussian distribution with a single mode. However, the large number of

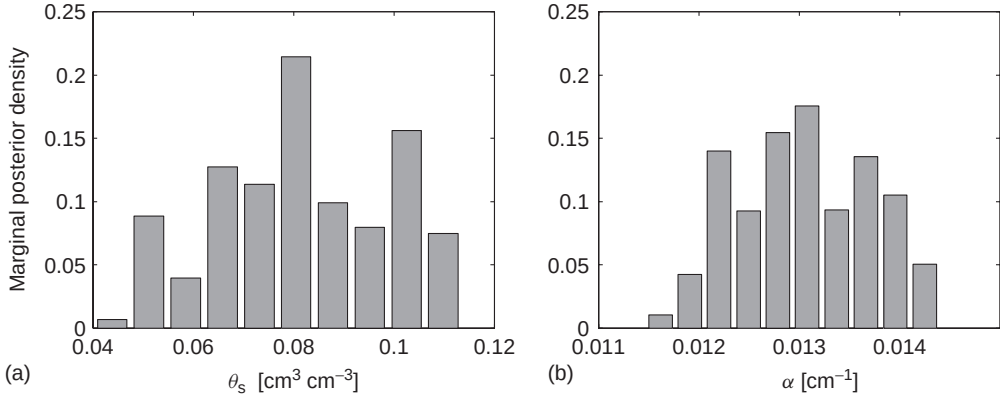

Figure 3 Marginal posterior probability density distributions for the soil hydraulic parameters (a) θ_r, and (b) α, in the MVG model using observed outflow dynamics during a transient one-step outflow experiment. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

different modes (local minima) for each of the parameters depicted in Figure 3 is the most probable reason for the numerous reports in the literature of the inability to find a unique set of hydraulic parameter values using observed outflow dynamics from MSO experiments (Kool *et al.*, 1985; Parker *et al.*, 1985; Toorman *et al.*, 1992; van Dam *et al.*, 1992; among others). As the local gradient-based search algorithms are not designed to handle the peculiarities of the response surface illustrated in Figure 3, they will terminate their search prematurely with their final solution essentially being dependent on the starting point in the parameter space. Another emerging problem, reported by Hopmans *et al.* (2002), is that some of the hydraulic parameters are typically highly correlated, further lowering the chance of getting a single unique solution with local-search methodologies.

The existence of nonuniqueness problems with local-search methodologies has led soil hydrologists to argue that there is not sufficient information in the conducted measurements to enable a unique characterization of the soil hydraulic properties. So even with laboratory experiments, where a soil can be manipulated with great flexibility, nonuniqueness problems are often experienced (van Dam *et al.*, 1992). Seemingly, there was a widespread conviction that the best way to solve the nonuniqueness problem would be to add more and better measurements (Eching and Hopmans, 1993; van Dam *et al.*, 1994). However, research into data requirements has led to the understanding that the information content of the data is far more important than the amount of data used for the identification of the model parameters (Sorooshian *et al.*, 1983; Gupta and Sorooshian, 1985; Yapo *et al.*, 1996; Vrugt *et al.*, 2002). Vrugt *et al.* (2003a) argued, therefore, that it is not the information in the measurements that is lacking to obtain a unique set of parameters, but the fact that the classical local-search optimization procedures utilized in soil hydrology are typically not powerful enough to solve the problems illustrated in Figure 3. Their arguments on uniqueness of parameters are not based on the convergence problems of the applied optimization methods, but on the shape of the posterior marginal distributions of the parameters. Hence, closer inspection of Figure 3 demonstrates that for each of the two parameters there is a single optimum with highest posterior probability in the global minimum. Indeed, although not shown here, the multivariate probability distribution of the parameters confirms that these regions with highest posterior probability for each parameter coincide. In other words, the uniqueness of parameter estimates is inferred from the shape of the univariate posterior probability distributions of the parameters. In particular, ill-posedness of an inverse problem due to data-noninformativeness issues, as demonstrated by Zijlstra and Dane (1996), would result in large uncertainties associated with the final parameter estimates. Thus, an optimization algorithm that successfully identifies the multivariate joint probability distribution of the parameters in the vicinity of the global minimum has desirable properties, since it not only provides useful information about the interactions of the parameters in the full parameter space, but also provides useful information about the quality of the data. Hence, ultimately, data quality still determines the reliability of the final parameter estimates.

In the development of suitable automatic calibration approaches, we must consider the fact that the hydrologic model optimization problem suffers from the existence of multiple optima in the parameter space (with both small and large domains of attraction), discontinuous first derivatives, and curving multidimensional ridges. These considerations inspired Duan *et al.* (1992), in a related field (surface hydrology) to develop a powerful, robust, and efficient global-optimization procedure, entitled, the Shuffled Complex Evolution (SCE-UA) global optimization algorithm, developed at the University of Arizona. By merging the strengths of the Downhill Simplex procedure (Nelder and Mead, 1965) with the concepts of controlled random search, systematic evolution of points in the direction of global improvement, competitive evolution (Holland, 1975), and complex shuffling, the SCE-UA algorithm represents a synthesis of the best features of several optimization strategies. The strength and reliability of the SCE-UA global optimization algorithm have since been independently tested and proven by numerous researchers, and the algorithm is now extensively used worldwide (e.g. Duan *et al.*, 1992, 1993; Sorooshian *et al.*, 1993; Luce and Cundy, 1994; Tanakamaru, 1995; Gan and Biftu, 1996; Kuczera, 1997; Hogue *et al.*, 2000; Boyle *et al.*, 2000; among many others). Application of the SCE-UA algorithm to the inverse estimation of soil hydraulic parameters has, to the authors' knowledge, been limited to the work by Vrugt and Bouten (2002) and Mertens *et al.* (2005). Other global optimization methods that have been used for the inverse estimation of soil hydraulic properties are the Annealing-simplex methods (Pan and Wu, 1998), Genetic algorithms (Takeshita, 1999; Vrugt *et al.*, 2001a), Grid sampling strategies (Abbaspour *et al.*, 1997), and Ant-colony methods (Abbaspour *et al.*, 2001). Notwithstanding their successful application, as compared with the SCE-UA algorithm, these global search algorithms are computationally very demanding, requiring a substantial number of model evaluations to converge to the global solution. With the current available SCE-UA algorithm, one can now have confidence that the global minimum of a predefined objective function is found. For more information about the current state-of-the-art in calibration in surface hydrology, the reader is referred to the work presented in Duan *et al.* (2003).

To demonstrate the features and applicability of the SCE-UA optimization procedure for estimating the soil hydraulic properties, consider Figure 4. It shows the evolution of the

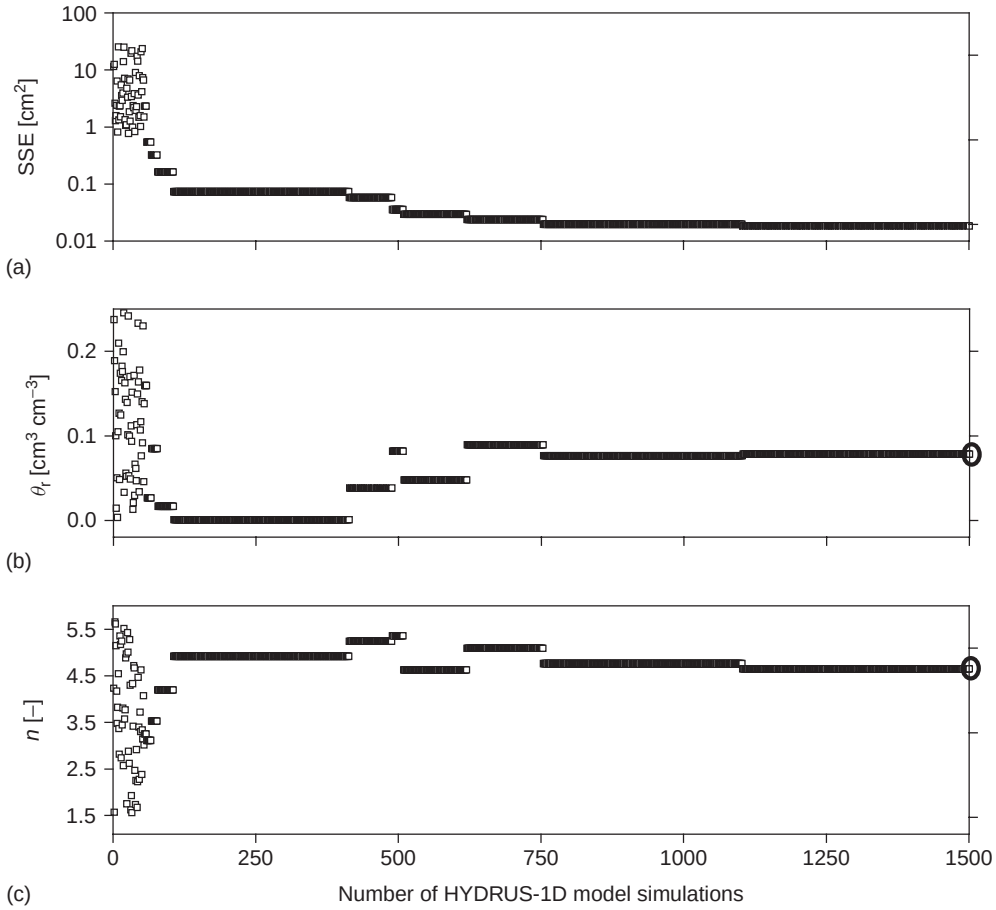

Figure 4 Evolution of the SLS objective function value and the best parameter values found so far with the SCE-UA algorithm as a function of the number of HYDRUS-1D model evaluations: (a) SLS-measure, (b) θ_r, and (c) α parameter. The circles indicate the best parameter values found with a traditional local-search methodology

best parameters as a function of the number of HYDRUS-1D model simulations for the MSO outflow experiment of the Lincoln soil. The objective function was the SLS estimator, defined in equation (5), containing only the residuals of the observed and predicted outflow. For the sake of brevity, we only display the results for the parameters θ_r and n. The circles indicate the best parameter values found with a traditional local-search methodology (Levenberg-Marquardt) using repeated optimizations with different starting points. The initial population of parameter samples used with the SCE-UA algorithm reflects the initial parameter uncertainty. After processing information about the shape of the response surface with the optimization algorithm, the best parameter values jump back and forth through the feasible parameter space. Finally, after approximately one thousand HYDRUS-1D model evaluations, the algorithm settles down in the most promising region of the parameter space (also referred to as global minimum), and the "best" parameter set, which minimizes the SLS criterion within this region is identified.

CONFRONTING PARAMETER UNCERTAINTY

Parameter estimates obtained using IM are generally error-prone because the data used for their estimation contain measurement errors and because the Richard's type of model never perfectly represents the actual flow and transport processes. Confidence intervals on the estimated hydraulic model parameters can be used to express the degree of uncertainty in the estimated values. Durner *et al.* (1999) recently pointed out that the improved interpretation of parameter uncertainty can yield valuable information to enable a better judgment of the limits of our theoretical understanding of unsaturated water flow in soils.

Traditional First-Order Approximation

A frequently employed approach, which is particularly popular in the area of vadose zone hydrology, is to obtain confidence intervals of parameters by utilizing a first-order approximation to the model f, previously defined in equation (2), near its minimum (see Carrera and Neumann,

1986 in groundwater hydrology, Kool and Parker, 1988 in unsaturated soil water flow, and Kuczera and Parent, 1998 in rainfall-runoff modelling). The estimated posterior distribution of β is then expressed as

$$p(\beta|\boldsymbol{y}) \propto \exp\left[-\frac{1}{2\sigma^2}(\beta-\beta_{\text{opt}})^T\ J^T\ J(\beta-\beta_{\text{opt}})\right] \quad (13)$$

where J is the Jacobian or sensitivity matrix evaluated at $\beta = \beta_{\text{opt}}$. All relevant inferences about β can be made from the knowledge that the posterior distribution of β is the multivariate normal distribution $N_p\ [\beta_{\text{opt}}, \sigma^2\sqrt{(J^T J)^{-1}}]$. Hence, the marginal posterior distribution of β_i is the multivariate normal distribution, $N_i\ [\beta_{i,\text{opt}}, \sigma^2 \sum_{ii}]$, where $\sum_{ii}$ is the ith diagonal element of $\sqrt{(J^T J)^{-1}}$ (Carrera and Neumann, 1986; Kool and Parker, 1988).

If the hydrologic model is linear (or very nearly linear) in its parameters, the posterior probability region estimated by equation 13 will give a good approximation of the actual parameter uncertainty. However, for nonlinear models (e.g., soil hydrological models), with strong parameter interdependence, this approximation can be quite poor (Kuczera and Parent, 1998; Vrugt and Bouten, 2002). Besides exhibiting strong and nonlinear parameter interdependence, the surface of the posterior parameter distribution $p(\beta|\boldsymbol{y})$ can deviate significantly from the multinormal distribution. It may also have multiple local optima and discontinuous derivatives (Duan *et al.*, 1992). Moreover, the ellipsoid region, defined by equation (13) may represent a very poor approximation of parameter uncertainty, as for example, in the case of a strongly hyperbolic banana-shaped curvature in the $p(\beta|\boldsymbol{y})$ surface.

Uniform Grid Sampling – Response Surface Analysis

Alternatively, a robust but computationally intensive method for the calculation of confidence intervals, contrasting the classical first-order approach, involves the generation of contour plots (Toorman *et al.*, 1992; Gribb, 1996; Romano and Santini, 1999; Vrugt *et al.*, 2001c). It requires exhaustive discretizing of the parameter space and computing the objective function for each grid point, which is a rather primitive approach. Recently, Abbaspour *et al.* (1997, 1999) used a similar kind of sampling strategy, entitled the Sequential Uncertainty Fitting algorithm (SUFI) for estimating subsurface flow and transport parameters. However, as simple as this approach might be, it requires massive computing resources for highly dimensioned parameter spaces. For example, if we wish to sample, on average, a parameter within a hypercube with resolution equal to one tenth of the parameter range in a 6-parameter space, we need 10^6 model runs. Moreover, failure to maintain an adequate sampling density may result in undersampling or too course sampling in certain regions of the parameter space. Consequently, this may lead to errors in the computed parameter confidence intervals.

A simplified two-dimensional approach using this uniform grid sampling strategy is often used in soil hydrology to study the shape of the objective function in the vicinity of the global optimum. These contour plots or response surfaces are obtained by contouring the objective function, previously defined in equation (5), for two selected parameters, while keeping the additional hydraulic parameters constant at their most optimal values. These response surfaces reveal the occurrence of local minima, the presence of a well-defined global minimum, the parameter sensitivity, and parameter correlations. If response surfaces do not display a well-defined global minimum in the two-dimensional parameter planes, the conventional inverse parameter estimation technique may certainly be expected to be unsuccessful in a multidimensional plane. Excellent examples of the use of response surfaces are presented in Toorman *et al.* (1992) and Šimůnek *et al.* (1998b). However, by limiting the number of parameters within a single response surface analysis, the behavior of the objective function in the different parameter planes can only suggest how the objective function might behave in the full parameter space. For example, local minima of the objective function could exist, but not appear in the cross-sectional planes (Šimůnek and van Genuchten, 1996). In the next section, we will describe a method that is especially designed to quantify the behavior of the objective function in the full parameter space, thereby simultaneously generating a description of the multivariate joint interaction between the soil hydraulic parameters.

To illustrate the usefulness and insights response surfaces can offer with respect to parameter identifiability, we generated contour plots of the SLS objective function in the vicinity of the most-likely parameter value using the outflow data of the Lincoln soil. The response surfaces were calculated on a rectangular grid. Each parameter domain, was discretized into 4 equidistant discrete points, with domain ranges as specified in Table 1, resulting in 1600 grid points for each response surface. Interpolation between points was done using MATLAB (MATLAB, 1999). The four, selected response surfaces, presented in Figure 5 are a representative set of the total of 10 possible response surfaces. The location of the optimum in the parameter space, previously identified using the SCE-UA algorithm, is indicated with a circle in each of the Figures. Most of the 10 response surfaces showed relatively well-defined global minima and no additional local minima. However, the shape of the contour lines in Figures 5b and d reveal the existence of a positive correlation structure between the parameters $\theta_r - n$, and $K_s - l$ in the HYDRUS-1D model. In other words, if θ_r or K_s is perturbed positively, then n or l will also be perturbed positively (Toorman *et al.*, 1992). So, response surface analyses reveal very useful information about parameter correlation and parameter identifiability or

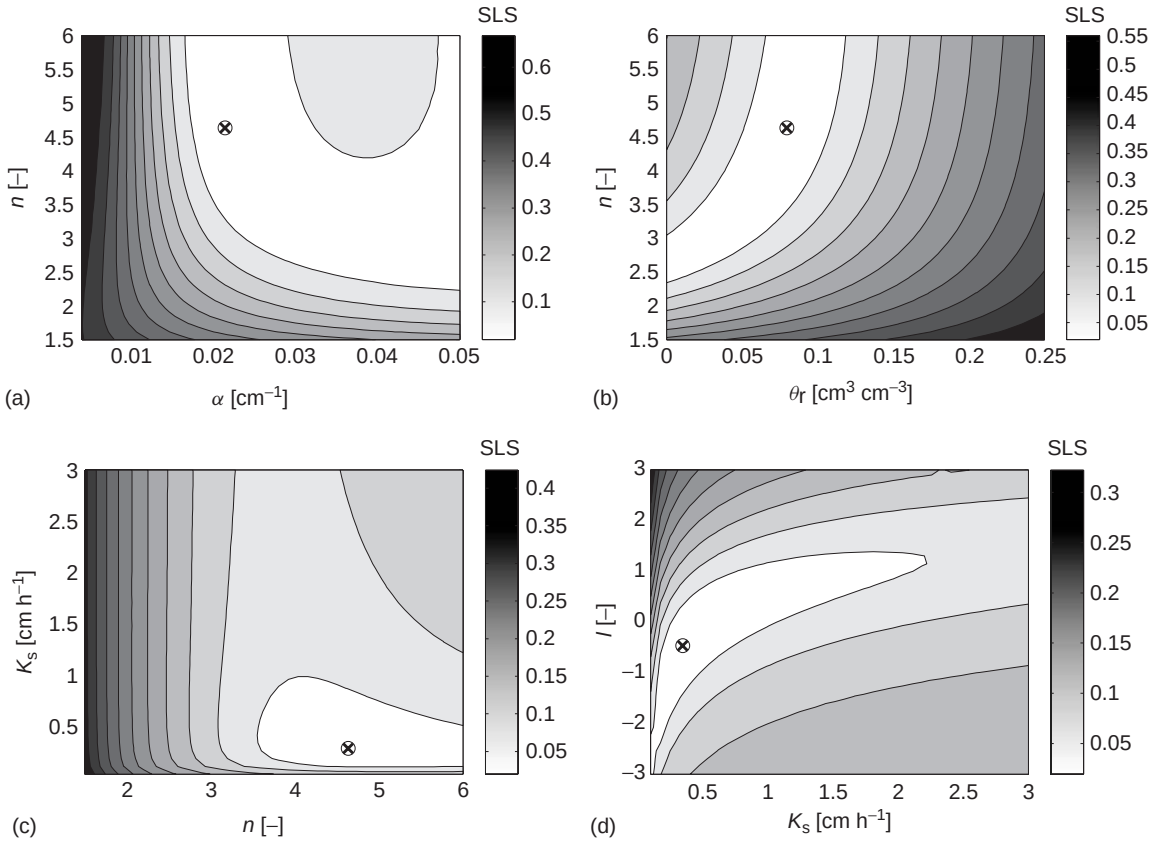

Figure 5 Contours of the square root of the SLS objective function, defined in equation (5) in the (a) $\alpha - n$, (b), $\theta_r - n$, (c), $n - K_s$, and (d) $K_s - l$ sliced parameter planes using the outflow data of the Lincoln soil. The SCE-UA identified ''best'' parameter values are indicated with circles in each of the graphs

sensitivity in the vicinity of the global optimum. However, as pointed out before, the method is computationally very demanding, as for each response surface a large number of simulations are needed, and it is graphically limited to two-dimensions.

Monte Carlo Sampling of Posterior Distribution

The Markov Chain Monte Carlo (MCMC) method for assessing parameter confidence intervals in nonlinear models is based on the idea that instead of explicitly computing the probability distribution, $p(\beta|\boldsymbol{y})$, as done in equation (13), it is sufficient to approximate the form of the density by drawing a large random sample from $p(\beta|\boldsymbol{y})$ (Mosegaard and Tarantola, 1995). Diagnostic measures of central tendency and dispersion of the posterior distribution can be estimated by computing the mean and standard deviation of the sample. This directly leads to the question of how to efficiently sample from $p(\beta|\boldsymbol{y})$. To address this question, Vrugt *et al.* (2003b) have developed a new algorithm, which merges the sampling strategy of the Metropolis-Hastings (MH) algorithm (Metropolis *et al.*, 1953; Hastings, 1970) with the strengths and efficiency of the SCE-UA population evolution method.

The goal of the original SCE-UA algorithm (Duan *et al.*, 1992) was to find a single best parameter set in the feasible space. The SCE-UA begins with a random sample of points distributed throughout the (bounded) feasible parameter space, and uses an adaptation of the Downhill Simplex search strategy to continuously evolve the population toward better solutions in the search space, progressively relinquishing occupation of regions with lower posterior probability. This genetic drift, where the members of the population drift towards a single location in the parameter space (i.e., the mode of $p(\beta|\boldsymbol{y})$), is typical of many evolutionary search algorithms. By replacing the adapted Downhill Simplex strategy with a MH strategy, the tendency of the algorithm to collapse into the relatively small region containing the "best" parameter set is avoided. The new algorithm, entitled the Shuffled Complex Evolution Metropolis (SCEM-UA) global optimization algorithm was developed in collaboration between the University of Arizona and the University of Amsterdam, and merges the strengths of the MH algorithm, controlled random search, competitive evolution, and complex shuffling. The stochastic nature of the MH annealing scheme avoids the tendency of the SCE-UA algorithm to collapse into a single region of

attraction (local minima), while the information exchange (shuffling) between parallel sequences allows the search to be biased in favor of better regions of the parameter space. The SCEM-UA is therefore able to infer ***both*** the most-likely parameter set and its underlying posterior probability distribution within a single optimization run.

In summary, the SCEM-UA algorithm begins with an initial population of points (parameter sets) randomly distributed throughout the feasible parameter space. For each parameter set, the posterior density is computed using a Bayesian inference scheme, such as the one presented in Section "Frequentist versus bayesian approach" of this article. The population is partitioned into complexes, and in each complex a parallel sequence is launched from the point that exhibits the highest posterior density. A new candidate point, in each sequence, is generated using a multivariate normal distribution, either centered around the current draw of the sequence or the mean of the points in complex, augmented with the covariance structure induced between the points in complex. The Metropolis-annealing (Metropolis *et al.*, 1953) criterion is used to test whether the candidate point should be added to the current sequence. Subsequently, the new candidate point randomly replaces an existing member of the complex. Finally, after a certain number of iterations, new complexes are formed through a process of shuffling. This series of operations results in a robust MCMC sampler that conducts a robust and efficient search of the parameter space. Diagnostic measures of parameter interaction and parameter identifiability can be estimated using the joint multivariate posterior distribution of the model parameters as inferred with the SCEM-UA algorithm. For more information about the SCEM-UA algorithm, please refer to Vrugt *et al.* (2003b).

The applicability and power of the SCEM-UA algorithm for estimating the unsaturated soil hydraulic parameters (θ_r, α, n, K_s, and l) from transient MSO experiments will now be illustrated. The stationary posterior distribution, corresponding to the density criterion specified in equation (9), was estimated with the SCEM-UA algorithm using observed outflow data for the Lincoln soil in combination with 10 000 HYDRUS-1D model evaluations. The most important results of this analysis are summarized in Figures 6, 7, 8, and 9.

Figure 6 presents the marginal posterior probability distributions for the parameters θ_r, α, n, K_s, and l in the MVG model. These histograms were derived from the SCEM-UA samples that were generated after convergence had been achieved to a stationary posterior distribution. The values

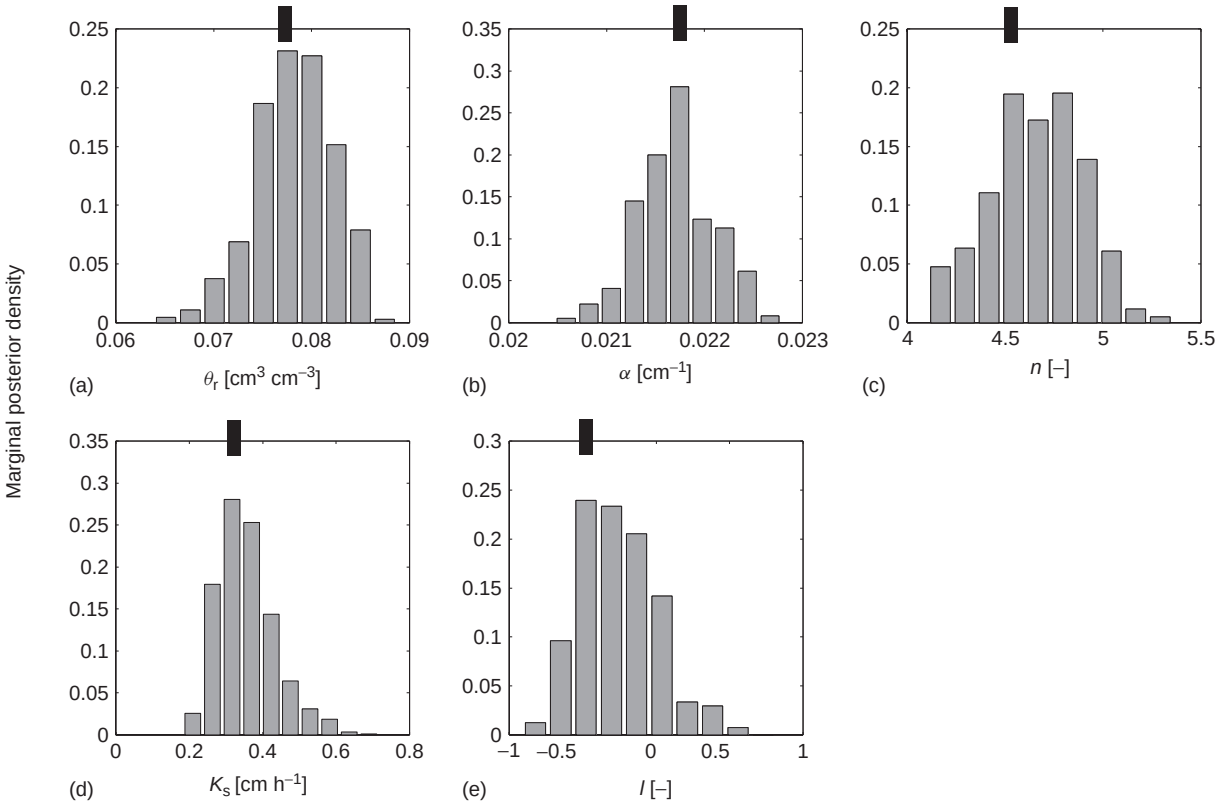

Figure 6 Marginal posterior probability distributions of the MVG parameters: (a) θ_r, (b) α, (c) n, (d) K_s, and (e), l. The SCE-UA estimated SLS parameter values are separately indicated with the squared symbols on top of each of the graphs. Figure 7 Scatter plots of 4000 combinations of (a) $\alpha - n$, (b), $\theta_r - n$, (c), $n - K_s$, and (d) $K_s - l$ parameters, sampled for the MSO experiment using the SCEM-UA algorithm

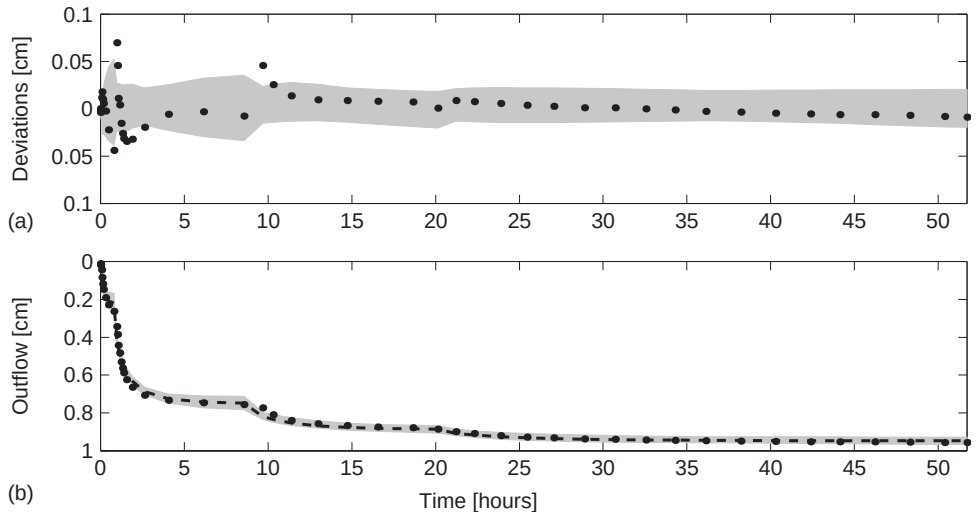

Figure 8 (a) Uncertainties in the simulated outflow associated with the most probable parameter set of the MVG model. The light-gray region denotes the residual parameter uncertainty. (b) Outflow prediction uncertainty ranges of the HYDRUS-1D model associated with the uncertainty in the parameter estimates. The black dots denote the observed outflow measurements of the Lincoln soil. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

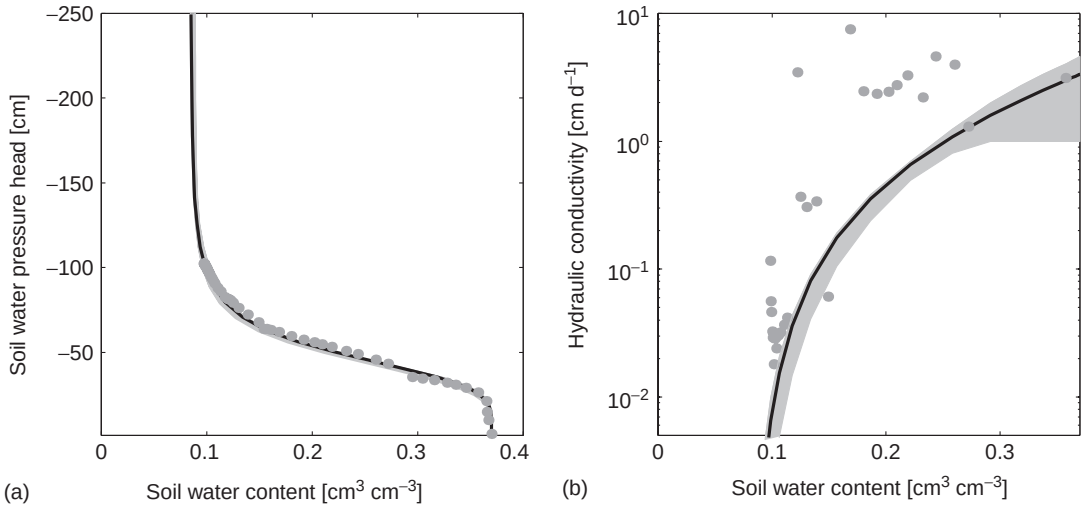

Figure 9 Prediction uncertainty intervals for the retention and hydraulic conductivity curves associated with the uncertainty in the parameter estimates for the MSO outflow experiment using the MVG parametric model. The black dots corresponds to the directly estimated retention and hydraulic conductivity points, whereas the dark lines resulted from the most-likely parameter sets. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

of the most-likely parameter estimates, previously identified with the SCE-UA algorithm, are separately indicated with squared symbols in each of the graphs. While the parameters θ_r (Figure 6a), α (Figure 6b), are reasonable well described by the multinormal distribution, as outlined in Section "Traditional first-order approximation", the remaining unsaturated soil hydraulic parameters n, K_s, and l are better described with bimodal or lognormal distributions respectively. Clearly, the SCEM-UA algorithm has many desirable features as it not only correctly infers the most-likely parameter set but also generates useful information about the shape of the response surface in the vicinity of the optimum, without having to do too many simulations.

To allow comparison between the SCEM-UA sampled parameter space and the response surfaces depicted in Figure 5, consider the scatter plots (Figure 7) of the sampled $\alpha - n$ (a), $\theta_r - n$ (b), $K_s - n$ (c), and $K_s - l$ (d) parameter space after convergence had been achieved to a limiting distribution. In general, the results of the classical response surface analysis presented in Figure 5, and the scatter plots presented in Figure 7 are conclusive. Indeed, a similar shape induced in the objective function, and thus, in the correlation structure between the parameters, is found in the vicinity of the optimum.

To verify the "correctness" of the Richards-hydraulic model, consider the residuals from the most probable parameter set found with the SCE-UA algorithm and the prediction uncertainty intervals of the HYDRUS-1D simulated outflows associated with the posterior parameter estimates (Figure 8; light-gray region). The black dots correspond to the measured outflow data of the Lincoln soil, whereas the most optimal parameter set is indicated with the dashed line. Note that the uncertainty ranges generally bracket the observed outflows during almost the entire period. However, the prediction uncertainty associated with the posterior parameter estimates does not include the observations and display bias (systematic error) at the beginning of the outflow experiment.

Finally, Figure 9 depicts how the posterior uncertainty associated with the soil hydraulic parameters for the MSO experiment for the Lincoln soil translates into uncertainty associated with the retention and unsaturated soil hydraulic conductivity curves. The directly estimated retention and hydraulic conductivity points are indicated with the black symbols. Note that the fit to the directly estimated hydraulic conductivity points is quite poor. This suggests that future attempts to improve the combined Richards-soil hydraulic model would be most productive if focused directly on the validity of the model assumptions.

ADVANCES IN INVERSE MODELLING

While considerable progress has been made in the application of automated optimization algorithms, the emphasis of most of this research has been on the estimation of a single optimal set of model parameters, thereby effectively neglecting the influence of possible sources of uncertainty on the final parameter estimates. Uncertainty is an unavoidable element of any modelling exercise in hydrology. Recently, however, there is an increasing awareness, that hydrologic model identification and evaluation procedures should explicitly include an estimate of the uncertainties associated with the model parameters and underlying model structure (Kuczera and Parent, 1998; Bates and Campbell,

2001; Thyer *et al.*, 2002; Vrugt *et al.*, 2003b). Recent investigations have therefore been directed towards the development of strategies that explicitly account for model structural uncertainty, input, state, parameter, and output uncertainty. Bayesian, pseudo-Bayesian, multiple-criteria, and recursive model identification strategies are currently receiving considerable attention to investigate their usefulness for quantifying the various sources of uncertainty associated with the application of hydrologic models. For instance, significant advances in computational capabilities now allow the use of MCMC samplers that are especially designed to converge to an ensemble of parameter sets, each associated with a certain likelihood, rather than a single "best" estimate, in the context of Bayesian model identification techniques.

The goal should therefore be to develop an IM strategy that can explicitly account for model structural, input and parameter uncertainty, can deal with multiple sources and types of information, and can simultaneously provide probabilistic estimates of the uncertainty associated with the model predictions. This is especially true now the interests have begun to switch to larger-scale applications of the IM approach in soil and surface hydrology, for which different types of data at a variety of temporal and spatial scales are available. For instance, many of the latest hydrologic watershed or land-surface models simulate several output fluxes (e.g., water, energy, chemical constituents, etc.) for which measurement data are available, and all these data must be correctly utilized to ensure proper model calibration (Beven and Kirkby, 1979; De Grosbois *et al.*, 1988; Kuczera, 1982, 1983; Woolhiser *et al.*, 1990; Kuczera and Mroczkowski, 1998; Gupta *et al.*, 1998). Madsen (2003) recently demonstrated the successful application of the SCE-UA algorithm to calibrate a multiparameter, semidistributed, watershed model, thereby yielding effective hydrologic parameter values at the support of interest.

One strategy to explicitly recognize the multiobjective nature of the calibration problem is to define several optimization criteria (objective functions) that measure different (complementary) aspects of the system behavior and to use a multicriteria optimization method to identify the set of nondominated, efficient, or Pareto optimal solutions. The Pareto solutions represent trade-offs among the different incommensurable and often conflicting objectives, having the property that moving from one solution to another, results in the improvement of one objective while causing deterioration in one or more others. To date, to the authors' knowledge, no applications of this approach are yet found in the area of IM of soil hydraulic properties.

The classical, single-objective optimization approach operates under the central assumption that a single objective function is able to properly extract all of the information contained in the time series of observations. However, practical experience with the calibration of hydrological models suggests that the magnitude of structural error in the model for some portions of the model response may, in general, be equivalent to or even substantially larger than the measurement error and that these structural or model errors do not necessarily have any inherent probabilistic property that can be exploited in the construction of an objective function (Gupta *et al.*, 1998). Due to the presence of these structural inadequacies in the hydrologic model, any single (scalar) objective function, no matter how carefully chosen, is inadequate to properly measure all of the characteristics of the observed data deemed to be important.

These considerations imply the design of an IM or calibration strategy that has the ability to simultaneously incorporate several competing objectives. A strategy that can address this challenge is multiobjective optimization, which has its roots in late-nineteenth century welfare economics, in the work of Edgeworth (1881), and can be stated as

$$\min_{\beta \in B} \; E(\beta) = \begin{bmatrix} E_1(\beta) \\ E_2(\beta) \\ \vdots \\ E_M(\beta) \end{bmatrix} \tag{14}$$

where $E_i(\beta)$ is the ith of M objective functions. The solution to this problem will, in general, no longer be a single "best" parameter set but will consist of a Pareto set $\boldsymbol{P}(B)$ of solutions in the feasible parameter space B corresponding to various trade-offs among the objectives. The Pareto set of solutions defines the minimum uncertainty in the parameters that can be achieved without stating a subjective relative preference for minimizing one specific component of $E(\beta)$ at the expense of another. Figure 10 illustrates the Pareto solution set for a simple problem where the aim is to simultaneously minimize two objectives (E_1,E_2) with respect to two parameters (β_1,β_2). The individual points C and D minimize objectives E_1 and E_2, respectively, whereas the solid line joining C and D represents the theoretical Pareto set of solutions. The black dots (Figure 10a) indicate an initial set of parameter estimates, while the number in subscript (Figure 10b) denotes their corresponding Pareto rank. Moving along the line from C to D results in the improvement of E_2 while successively causing deterioration in E_1. The points falling on the line CD represent trade-offs between the objectives and are called *nondominated, noninferior*, or *efficient solutions*. Put simply, the feasible parameter space can be partitioned into "good" or Pareto solutions and "bad" or "inferior" solutions. In the absence of additional information, it is impossible to distinguish any of the Pareto solutions (rank 1 points) as being objectively better than any of the other Pareto solutions. Furthermore, every member of the Pareto set will match some characteristic of the observed data better than any other member of the Pareto set, but the trade-off will be that some other characteristic of the observed data will not be as well-matched (Yapo

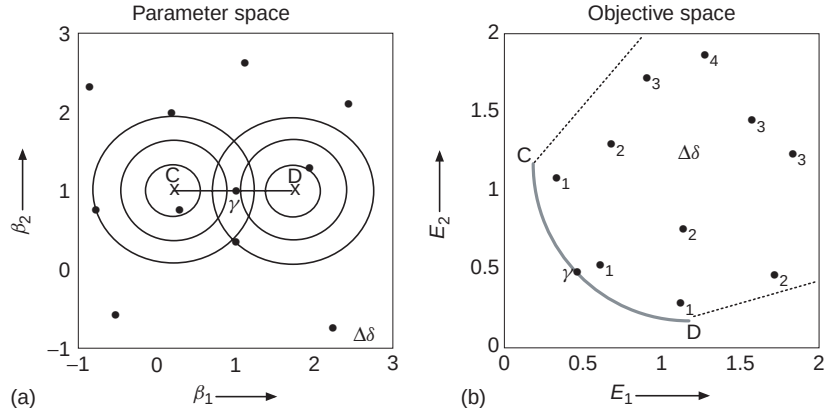

Figure 10 Illustration of the concept of Pareto optimality for a problem having two parameters (β_1, β_2) and two-criteria (E_1, E_2), (a) in the parameter, and (b) objective space. The points C and D indicate the solutions that minimize each of the criteria E_1 and E_2. The thick line joining C and D corresponds to the Pareto set of solutions; γ is an element of the solution set, which is superior in the multicriteria sense to any other point in δ

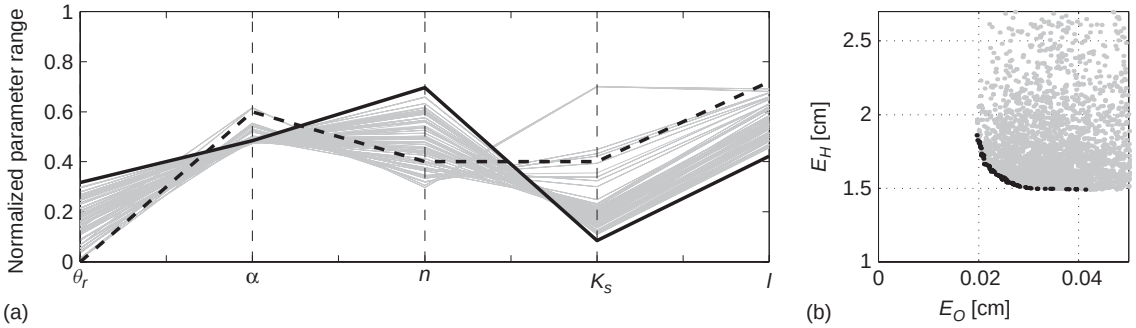

Figure 11 (a) normalized parameter plots for each of the unsaturated soil hydraulic parameters using a two-criteria $\{E_O, E_H\}$ calibration with the MOSCEM-UA algorithm. Each line across the graph denotes a single parameter set: gray – Pareto solution set, solid and dashed black lines are single criterion solutions of E_O and E_H respectively; (b) two-dimensional projection of the objective space. The Pareto solution set is indicated with black dots. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

et al., 1998). Because of errors in the model structure (and other possible sources), it is usually not possible to find a single point β at which all of the criteria have their minima. Note that this multiobjective equivalence of parameter sets is different from the probabilistic representation of parameter uncertainty, estimated using the SCEM-UA algorithm.

From another perspective, the multicriteria approach offers a way forward since it circumvents the problem of specifying user-subjective weights to different sets of observations, like outflow and tensiometer measurements. Improper selection of these weights can influence not only the confidence intervals of the parameters, but also the location of the minimum of the objective function (Hollenbeck and Jensen, 1998).

Finally, we will consider the estimation of unsaturated soil hydraulic properties using a Multiobjective parameter optimization approach. Again, the observed outflow and tensiometer readings during the MSO experiment of the Lincoln soil were used. A pair of Root Mean Square Error (RMSE) objective functions were computed. First, E_O was computed to measure the ability of the HYDRUS-1D model to simulate the observed outflow measurements. Second, E_H was computed to measure the ability of the model to simulate the observed tensiometer data within the soil sample during the outflow experiment. The Pareto optimal solution space for the two-criteria problem was estimated using a population size of 250 points and 10 000 calculations using the recently developed Multiobjective Shuffled Complex Evolution Metropolis (MOSCEM-UA) algorithm (Vrugt *et al.*, 2003c). This algorithm employs a similar evolution strategy as the SCEM-UA algorithm, with the small adaptation that the former algorithm uses the concepts of Pareto dominance rather than direct, single-objective function evaluations to evolve the initial populations of points towards a set of solutions stemming from a stable distribution (Pareto set). The results of this multicriteria $\{E_O, E_H\}$ calibration are summarized in Figure 11.

Figure 11a presents normalized parameter plots for each of the unsaturated soil hydraulic parameters (θ_r, α, n, K_s, and l) in the HYDRUS-1D model. The 5 parameters are listed along the x-axis, while the y-axis corresponds to the parameter values scaled according to their prior uncertainty ranges defined in Table 1 to yield normalized ranges. Each line across the graph represents one parameter set. The solid and dashed lines correspond to the single-objective solutions of E_O and E_H, respectively, obtained by separately fitting both criteria using the SCE-UA algorithm. The gray lines denote members of the Pareto set of solutions. The small plot at the right-hand side (Figure 11b) depicts two-dimensional projections of the bicriterion trade-off surface represented by the Pareto set of solutions. It clearly illustrates that the MOSCEM-UA algorithm has generated a fairly uniform approximation of the Pareto set, thereby containing the single criterion solutions at the extreme ends of the Pareto frontier (see Figure 11a). Because of errors in the model structure, it is not possible to find one single set of parameters that simultaneously minimizes both criteria. Instead, it is common to have sets of solutions with the property that moving from one to another results in improvement of the ability to fit the observed outflow while causing deterioration in fitting the soil water pressure head data. There is considerable uncertainty associated with the saturated hydraulic conductivity (K_s) and the parameter n, which primarily determines the slope of the retention curve in the intermediate water-content range. This indicates that the combined Richards'-hydraulic model structure is in need of further improvements. Although not further pursued here, the use of decoupled hydraulic functions might alleviate some of the errors in the model structure and further reduce the correlation among the model parameters.

CLOSING COMMENTS

Major weakness of all parameter estimation approaches include their underlying treatment of the uncertainty in the input–output representation of the model as being primarily (and explicitly) attributed to uncertainty in the parameter estimates, without explicit treatment of the input, output, and model structural uncertainties. Hence, uncertainties in the modelling procedure stem not only from uncertainties in the parameter estimates, but also from measurement errors associated with the system input (forcing) and output, and from model structural errors arising from the aggregation of spatially distributed real-world processes into a mathematical model. Not properly accounting for these errors during parameter estimation can result in model simulations and their associated prediction uncertainty bounds, which do not consistently represent and bracket the measured system behavior. This is usually evidenced by residuals, which exhibit considerable variations in bias (nonstationarity), variance (heteroscedasticity), and correlation structures under different hydrologic conditions (see, for instance, Figure 8a at the beginning of the outflow experiment). Several contributions to the hydrologic literature have, therefore, brought into question the continued usefulness of the classical paradigm for estimating model parameters (Beven and Binley, 1992; Gupta *et al.*, 1998), especially when multiple (and often conflicting) sources of information are available for parameter estimation (see, for instance, the trade-off in the fitting of the outflow and soil water pressure heads in Figure 11).

Some interesting methods for addressing these problems, particularly in the context of estimating reasonable confidence bounds on the model parameters and simulations, have recently begun to appear in the hydrologic model identification literature. One attempt to more completely treat input, output, parameter, and model structural errors is the Simultaneous Optimization and Data Assimilation (SODA) framework of Vrugt *et al.* (2005). This method merges the strengths of the search efficiency and explorative capabilities of the SCEM-UA algorithm with the power and computational efficiency of the Ensemble Kalman Filter (Evensen, 1994) to simultaneously estimate model parameters and state variables. The ability of SODA to explicitly deal with input, output, parameter, and model structural errors, results in improved estimates of parameter and model prediction uncertainty ranges.

78: Models of Water Flow and Solute Transport in the Unsaturated Zone

JIRKA ŠIMŮNEK

Department of Environmental Sciences, University of California, Riverside, CA, US

A large number of models for simulating water flow and solute transport in the unsaturated zone are now increasingly being used for a wide range of applications in both research and management. Modeling approaches range from relatively simple analytical and semianalytical solutions, to complex numerical codes. While analytical and semianalytical solutions are still popular for some applications, the ever-increasing power of personal computers and the development of more accurate and numerically stable solution techniques have motivated much wider use of numerical codes in recent decades. The wide use of numerical models is also significantly enhanced by their availability in both the public and commercial domains, and by the development of sophisticated graphics-based interfaces that can tremendously simplify their use.

In this paper I focus mainly on numerical models, give a brief history of their development, and discuss some of the more often used numerical techniques including relatively efficient matrix solvers that now are available for multidimensional models. Names and web addresses of some of the more popularly used numerical codes simulating vadose zone processes are also provided. Finally, some typical problems in which the numerical codes have been applied are identified.

INTRODUCTION

Many models of varying degree of complexity and dimensionality have been developed during the past several decades to quantify the basic physical and chemical processes affecting water flow and pollutant transport in the unsaturated zone. Computer models based on analytical and numerical solutions of the flow and solute transport equations are now increasingly being used for a wide range of applications in research and management of natural subsurface systems. Modeling approaches range from relatively simple analytical and semianalytical models to more complex numerical codes that permit consideration of a large number of simultaneous nonlinear processes. Whereas analytical and semianalytical solutions are still more popular for most relatively simple applications, the ever-increasing power of personal computers and the development of more accurate and numerically stable solution techniques have given rise to the much wider use of numerical models in recent decades. The wide use of numerical models has also been significantly enhanced by their availability in both public and commercial domains, and by the development of sophisticated graphics-based interfaces that tremendously simplify their use.

Analytical, semianalytical, and numerical models are usually based on the following three governing equations for water flow, solute transport, and heat movement, respectively:

$$\frac{\partial \theta(h)}{\partial t} = \frac{\partial}{\partial z}\left[K(h)\left(\frac{\partial h}{\partial z} + 1\right)\right] - S \qquad (1)$$

$$\frac{\partial \theta Rc}{\partial t} = \frac{\partial}{\partial z}\left[\theta D\left(\frac{\partial c}{\partial z}\right) - qc\right] - \phi \qquad (2)$$

$$\frac{\partial C(\theta)T}{\partial t} = \frac{\partial}{\partial z}\left[\lambda(\theta)\left(\frac{\partial T}{\partial z}\right) - C_{\mathrm{w}}qT\right] \qquad (3)$$

Suitable simplifications (mostly for analytical approaches) or extensions thereof (e.g. for two- and three-dimensional systems) are also employed. In equation (1), often referred to as the Richards equation, z is the vertical coordinate positive upwards, t is time, h is the pressure head, θ is

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

the water content, S is a sink term representing root water uptake or some other sources or sinks, and $K(h)$ is the unsaturated hydraulic conductivity function, often given as the product of the relative hydraulic conductivity, K_r, and the saturated hydraulic conductivity, K_s. In equation (2), known as the *convection-dispersion equation* (CDE), c is the solution concentration, R is the retardation factor that accounts for adsorption, D is the dispersion coefficient accounting for both molecular diffusion and hydrodynamic dispersion, q is the volumetric fluid flux density, and ϕ is a sink/source term that accounts for various zero- and first-order or other reactions. In equation (3), T is temperature, λ is the apparent thermal conductivity, and C and C_w are the volumetric heat capacities of the soil and the liquid phase, respectively. Solutions of the Richards equation (1) require knowledge of the unsaturated soil hydraulic functions, that is, the soil water retention curve, $\theta(h)$, describing the relationship between the water content θ and the pressure head h, and the unsaturated hydraulic conductivity function, $K(h)$, defining the hydraulic conductivity K as a function of h or θ. While under certain conditions (i.e. for linear sorption, a concentration-independent sink term ϕ, and a steady flow field) equations (2) and (3) are linear equations, equation (1) is generally highly nonlinear because of the nonlinearity of the soil hydraulic properties. Consequently, many analytical solutions have been derived in the past for equations (2) and (3) and these analytical solutions are now widely used for analyzing solute and heat transport under steady-state conditions. Although a large number of analytical solutions of (1) exist, they can generally be applied only to drastically simplified problems. The majority of applications for water flow in the vadose zone requires a numerical solution of the Richards equation.

ANALYTICAL MODELS

Analytical methods represent a classical mathematical approach to solve differential equations, leading to an exact solution for a particular problem. Analytical solutions are usually obtained by applying various transformations (e.g. Laplace or Fourier transformations) to the governing equations, invoking a separation of variables, or the Green's function approach (e.g. Leij *et al.*, 2000). Analytical models usually result in an explicit equation that, for example, states that concentration (or the pressure head, water content, or temperature) is equal to a certain value at particular time and location. One can therefore evaluate a particular variable directly without time-stepping, typical of numerical methods. Many analytical solutions lead to relatively complicated formulations that include infinite series and/or integrals that need to be evaluated numerically, which suggests some ambiguity in the often-claimed advantage of exactness of analytical methods over numerical techniques. On the other hand, using analytical solutions one can often more easily evaluate interrelationships among parameters, and get better insight into how various processes control the basic flow and transport processes (e.g. using dimensionless variables and parameters). Analytical solutions are often also used to check the correctness and accuracy of numerical models, although numerical models can equally well be used to check the correctness of the complex analytical solutions.

Analytical solutions can usually be derived only for simplified transport systems involving linearized governing equations, homogeneous soils, simplified geometries of the transport domain, and constant or highly simplified initial and boundary conditions. Unfortunately, analytical solutions for more complex situations, such as for transient water flow or nonequilibrium solute transport with nonlinear reactions, are generally not available and/or cannot be derived, in which case numerical models must be employed.

Solute Transport

Numerous analytical solutions of equations (2) and (3), or their two- and three-dimensional equivalents, have been developed in the last 40 years and are now widely used for predictive purposes and/or analyzing laboratory and/or field observed concentration distributions. The majority of these solutions pertains to equations (2) and (3) assuming constant water content, θ, and flux, q, values (i.e. for steady-state water flow conditions). Since equation (2) and (3) have the same form, analytical solutions derived for solute transport can often also be used immediately for many heat transport problems, and *vice versa*.

Some of the more popular one- and multidimensional analytical transport models have been CXTFIT (Parker and van Genuchten, 1984), AT123D (Yeh, 1981), and 3DADE (Leij and Bradford, 1994). A large number of analytical models for one-, two-, and three-dimensional solute transport problems were recently incorporated into the comprehensive software package STANMOD (STudio of ANalytical MODels) (Šimůnek *et al.*, 1999b) (**`http://www.ussl.ars.usda.gov/models/stanmod/stanmod.HTM`**). This Windows-based computer software package includes not only programs for evaluating analytical solutions for equilibrium convective-dispersive solute transport (i.e. the CFITM of van Genuchten (1980) for one-dimensional transport and 3DADE for three-dimensional problems), but also additional programs that solve more complex problems. For example, it also incorporates the CFITIM (van Genuchten, 1981) and N3DADE (Leij and Toride, 1997) programs for nonequilibrium convective-dispersive transport (i.e. the two-region mobile-immobile model for physical nonequilibrium and the two-site sorption model for chemical nonequilibrium) for one- and multidimensional formulations, respectively. STANMOD also includes CXTFIT2 (Toride *et al.*, 1995), an updated

version of CXTFIT to solve both direct and inverse problems for three different one-dimensional transport models: (i) the conventional CDE (1); (ii) the chemical and physical nonequilibrium CDEs; and (iii) a stochastic stream tube model based upon the local scale equilibrium or nonequilibrium CDE. All three models consider linear adsorption, as well as the zero- and first-order decay/source terms. In addition, STANMOD includes the CHAIN code of van Genuchten (1985) for analyzing the convective-dispersive transport of up to four solutes involved in sequential first-order decay reactions. Examples are the migration of radionuclides, in which the chain members form first-order decay reactions, and the simultaneous movement of various interacting nitrogen or organic chemicals. The latest version of STANMOD also includes the screening model of Jury *et al.* (1983) for describing transport and volatilization of soil-applied volatile organic chemicals.

Water Flow

The highly nonlinear Richards equation can be solved analytically only for a very limited number of cases involving homogeneous soils, simplified initial and boundary conditions, and relatively simple constitutive relationships describing the unsaturated soil hydraulic properties. The Richards equation for this purpose needs to be first linearized. This can be accomplished using several mathematical transformations, with the most common transformation being the Kirchhoff integral transformation:

$$\Phi = \int_{-\infty}^{h} K(h)\,\mathrm{d}h \tag{4}$$

Linearization of the Richards equation often also involves using an exponential law relating hydraulic conductivity and the pressure head (Gardner, 1958):

$$K(h) = K_s \exp(\alpha h) \tag{5}$$

where α is an empirical coefficient.

Development of analytical and semianalytical solutions of the unsaturated flow equations has been geared mostly towards infiltration problems (Wooding, 1968; Philip, 1969, 1992). While some analytical solutions are widely used, for example, for evaluating tension disc experiments (Wooding, 1968), designing irrigation systems (Philip, 1992), or studying flow around buried objects (Warrick and Knight, 2002), many others appear to be only of academic interest.

NUMERICAL METHODS

Numerical methods are superior to analytical methods in terms of being able to solve practical problems. They allow users to design complicated geometries that reflect complex natural geologic and hydrologic conditions, control parameters in space and time, prescribe realistic initial and boundary conditions, and to implement nonlinear constitutive relationships. Numerical methods usually subdivide the time and spatial coordinates into smaller pieces, such as finite differences, finite elements, and/or finite volumes, and reformulate the continuous form of governing partial differential equations in terms of a system of algebraic equations. In order to obtain solutions at certain times, numerical methods generally require intermediate simulations (time-stepping) between the initial condition and the points in time for which the solution is needed. The following two sections review the history of development of various numerical techniques used in vadose zone flow and transport models. The review is based in part on an earlier review by van Genuchten and Šimůnek (1996). After reviewing various numerical techniques I will also discuss the need for efficient matrix solvers for 2D and 3D models, and provide a list of some of the most often used flow/transport models.

Numerical Solution of Richards Equation

A variety of numerical methods may be used to solve the variably saturated flow equation. The popularity of numerical methods stems from the fact that the Richards equation can be solved analytically only for a very limited number of cases. Even so, the highly nonlinear nature of the Richards equation also hampered the development of computationally efficient numerical methods that are stable under all conditions, particularly for infiltration in very dry soils. Stable numerical solutions still require relatively fine discretizations of both the time and space domains, often resulting in excessive CPU and simulation times, especially for two- and three-dimensional problems and/or problems involving highly transient boundary conditions.

Early applications of numerical methods for solving variably saturated flow problems generally used classical finite differences. Integrated finite difference, finite volumes, and especially, finite element methods (Neuman, 1973; Huyakorn *et al.*, 1986; Šimůnek *et al.*, 1999a) became increasingly popular in the seventies and thereafter. While finite difference methods today are used in a majority of one-dimensional models, finite volume methods and/or finite element methods coupled with mass lumping of the mass balance term are usually used in two- and three-dimensional models. Finite element methods used with unstructured triangular and tetrahedral elements allow for a more precise description of complex transport domains compared to finite differences.

The Richards equation can be formulated in three different ways. A mixed formulation arises when both the water content and the pressure head variables appear simultaneously in the governing equation, such as in equation (1). The h-based formulation is obtained when the time derivative of the water content ($\partial\theta/\partial t$) on the left side of

(1) is rewritten using the soil water capacity C as follows: $C\partial h/\partial t$, where C is defined as the slope of the retention curve, that is, $\mathrm{d}\theta/\mathrm{d}h$. The θ-based formulation is obtained when the product of the hydraulic conductivity $K(h)$ and the pressure head gradient ($\partial h/\partial z$) on the right side of (1) is replaced with the product of the water diffusivity $D_{\mathrm{w}}(\theta)$ and the water content gradient, $\partial\theta/\partial z$. The θ-formulation allows for very efficient numerical solutions, even for infiltration into initially dry soils. The use of this formulation is, however, straightforward only for homogeneous and unsaturated soils. This is because, the driving force for water movement is not the water content gradient, but the pressure head gradient; water in heterogeneous soils hence does not necessarily flow from locations with a higher water content to locations with a lower water content. Special provisions must be taken for such heterogeneous systems (Hills *et al.*, 1989), a likely reason why θ-formulations are rarely used in numerical models.

Celia *et al.* (1990) suggested that numerical solutions based on the standard h-based formulation of the Richards equation often yield poor results, characterized by relatively large mass balance errors and incorrect predictions of the pressure head distributions in the soil profile. They solved the mixed formulation of the Richards equation using a modified Picard iteration scheme that possesses mass-conserving properties for both finite element and finite difference spatial approximations. Milly (1985) earlier presented two mass-conservative schemes for computing nodal values of the water capacity in the h-based formulation to force global mass balance. Several highly efficient numerical schemes based on different types of pressure head transformations were presented recently by Hills *et al.* (1989), Ross (1990), and Kirkland *et al.* (1992). Hills *et al.* (1989) showed that the θ-based form of the Richards equation can yield fast and accurate solutions for infiltration into very dry heterogeneous soil profiles. However, the θ-based numerical scheme cannot be used for soils having saturated regions. Kirkland *et al.* (1992) expanded the work of Hills by combining the θ-based and h-based models to yield a transformation method applicable also to variably saturated systems. Their approach involved a new dependent variable, being a linear function of the pressure head and the water content in the saturated and unsaturated zones, respectively. Additional transformations of the Richards equation, with the common goal of decreasing its nonlinearity and increasing the efficiency of the numerical solution, were reviewed by Williams *et al.* (2000). Many of these transformations were, however, used mostly by the authors themselves and have not reached wide acceptance. Most popularly used vadose zone flow models presently utilize the mixed formulation of Celia *et al.* (1990); these models include SWAP (van Dam *et al.*, 1997) and HYDRUS (Šimůnek *et al.*, 1998, 1999a).

Time and space discretization of the Richards equation generally leads to a nonlinear system of algebraic equations. These equations are most often linearized and solved using the Newton–Raphson or Picard iteration methods. Picard iteration is widely used in unsaturated zone models because of its ease of implementation, and because this method preserves symmetry of the final system of equations. The Newton–Raphson iteration procedure is more complex and results in nonsymmetric matrices, but often achieves a faster rate of convergence and can be more robust than Picard iteration for certain types of problems (Paniconi and Putti, 1994).

Numerical Solution of the Transport Equation

A large number of methods are also available to numerically solve the convection-dispersion solute transport equation. These methods may be broadly classified into three groups: (i) Eulerian, (ii) Lagrangian, and (iii) mixed Lagrangian–Eulerian methods. In the Eulerian approach, the transport equation is discretized by means of a usual finite difference or finite element method using a fixed grid system. For the Lagrangian approach, the mesh moves along with the flow or remains fixed in a deforming coordinate system. A two-step procedure is followed for a mixed Lagrangian-Eulerian approach. First, convective transport is considered using a Lagrangian approach in which Lagrangian concentrations are estimated from particle trajectories. Subsequently, all other processes including sinks and sources are modeled with an Eulerian approach using any finite element or finite differences method, leading to the final concentrations.

Standard finite difference and Galerkin-type finite element methods belong to the first group of Eulerian methods. Finite differences and finite elements methods provided the early tools for solving solute transport problems and still are the most popular methods being used. Numerical experiments have shown that both methods give good results for transport in which dispersion is a relatively dominant process (e.g. as indicated by the grid Peclet number, $v\Delta x/D$, where v is pore-water velocity and Δx the grid size). However, both methods can lead to significant numerical oscillations and/or artificial dispersion for convection-dominated transport problems. Still, a relatively simple method may be used to prevent or limit numerical oscillations. By selecting an appropriate combination of relatively small space and time steps, it is possible to virtually eliminate all oscillations. Perrochet and Berod (1993) developed criteria for minimizing or eliminating numerical oscillations based on a "performance index". They concluded that all oscillations should be eliminated when the performance index, defined as the product of the local Peclet and Courant ($v\Delta t/\Delta x$) numbers, is less than 2. When small oscillations in the solution can be tolerated, the performance index can be easily increased to about 5 or 10 (Perrochet and Berod, 1993).

One alternative is the use of upwind finite difference methods. This method virtually eliminates numerical oscillations, even for purely convective transport. The disadvantage of this method is that it may create significant and often unacceptable numerical dispersion. Similarly, upstream weighting has been proposed for finite elements. The method consists of using different weighting functions for terms having spatial derivatives than for other terms in the transport equation. This approach places greater weight on the upstream nodes within a particular element.

While Lagrangian methods (or method of characteristics) virtually eliminate problems with numerical oscillations, they may introduce other problems, notably artificial dispersion and nonconservative solutions. Lagrangian methods are also relatively difficult to implement in two and three dimensions. Instabilities resulting from inappropriate spatial discretizations may occur during longer simulations because of deformation of the stream function. Furthermore, nonrealistic distortions of the results may occur when modeling the transport of solutes that are subjected to different sorption/exchange or precipitation reactions.

The Eulerian and Lagrangian approaches can also be combined to the mixed Eulerian–Lagrangian method. Because of the different mathematical nature of the diffusive (parabolic) and convective (hyperbolic) terms in the convection-dispersion equation, the transport equation is best decomposed into a mixed problem consisting of a purely convective problem, followed by a pure diffusion-only problem. Methods based on this approach are called *operator-splitting* or *splitting-up methods*. Convective transport is then solved with the Lagrangian approach, while all other terms of the transport equation are solved using Eulerian methods.

Still other solutions exist, such as the use of a so-called "random walk" process or a combination of analytical and numerical techniques. In a random walk approach, solute transport is modeled using a large number of particles. Displacement of each particle during each time step is given by a certain distance, this being the sum of two velocity contributions – a deterministic and stochastic contribution. Studies with this type of method indicate that it may be necessary to use many thousands of particles in order to obtain relatively precise results. An example of a combination of analytical and numerical techniques is given by Sudicky (1989) who modeled solute transport using Laplace transforms with respect to time, and Galerkin finite elements for the spatial domain. The use of Laplace transforms avoids the need for intermediate simulations (time-stepping) between the initial condition and the points in time for which solutions are needed, while also less stringent requirements are needed for the spatial discretization. This combination of analytical and numerical techniques, unfortunately, has however, one important limitation. Since Laplace transforms eliminate time as an independent variable in the governing transport equation, all coefficients such as water content, flow velocity, and retardation factors, must be independent of time. This means that combination methods can only solve solute transport problems during steady-state water flow, and hence are inappropriate for transient variably saturated flow situations typical of most field problems.

Many of the above methods for numerically solving transport equation were developed primarily for saturated conditions, for which coarse spatial discretizations and large flow velocities often produce large Peclet numbers, which may lead to significant numerical oscillations. Flow velocities in the vadose zone are usually much smaller. Also, the nonlinearity of the Richards equation generally requires numerical solutions on much finer spatial grids than in groundwater studies. Consequently, the Peclet numbers are significantly smaller for vadose zone applications than in groundwater flow studies, thereby allowing the adoption of more oscillation-prone methods. The majority of vadose zone models therefore can use relatively standard finite element or finite difference methods, which, if combined with upwind or upstream weighting or proper self-adjusting or other time step scheme, should eliminate most or all numerical oscillations.

Matrix Solvers

Discretization and subsequent linearization (as needed) of the governing partial differential equations for water flow and solute transport leads to a system of linear equations

$$[\mathbf{A}]\{\mathbf{x}\} = \{\mathbf{b}\} \tag{6}$$

in which $\{\boldsymbol{x}\}$ is an unknown solution vector, $\{\boldsymbol{b}\}$ is the known right-hand-side vector of the matrix equation, and $[\boldsymbol{A}]$ is a sparse banded matrix, which is symmetric for water flow if the modified Picard procedure is used, but asymmetric for water flow if the Newton–Raphson method is used. Matrix $[\boldsymbol{A}]$ is generally asymmetric for solute transport, unless convection is not considered in the formulation. Matrix $[\boldsymbol{A}]$ is tridiagonal for one-dimensional applications and thus can be solved very quickly and efficiently using simple Gaussian elimination. For higher-dimensional application, matrix $[\boldsymbol{A}]$ is a sparse matrix with a number of lines equal to the number of nodes in the spatial discretization scheme. The number of nodes is on the order of tens of thousands for a typical two-dimensional application, and on the order of millions for a three-dimensional application. Since this matrix needs to be inverted many times during a typical numerical run (at each time step for solute transport, and additionally also at each iteration for unsaturated water flow), the need for very efficient solvers cannot be underestimated.

Traditionally, the matrix equations have been solved using direct methods, such as Gaussian elimination or LU decomposition. These methods usually take advantage of the banded nature of the coefficient matrices and, in the case of water flow, of the symmetric properties of the matrix. Direct solution methods have several disadvantages as compared to iterative methods. For example, they require a fixed number of operations (depending upon the size of the matrix), which increases approximately by the square of the number of nodes. Iterative methods, on the other hand, require a variable number of repeated steps, with the number increasing at a much smaller rate (about 1.5) with the size of a problem (Mendoza *et al.*, 1991). A similar reduction also holds for the memory requirement since iterative methods do not require one to store nonzero matrix elements. Memory requirements, therefore, increase at a much smaller rate with the size of the problem when iterative solvers are used. This memory requirement is associated with the need to minimize the size of the band (i.e. the largest distance between two neighboring nodal numbers) of matrix [***A***] for direct methods. While minimization of the matrix band is trivial for finite difference methods, it can be rather complex when unstructured triangular finite element meshes are used. Round-off errors also represent less of a problem for iterative methods as compared with direct methods. This is because round-off errors in iterative methods are self-correcting. Finally, for time-dependent problems, a reasonable approximation of the solution (i.e. the solution at the previous time step) exists for iterative methods, but not for direct methods. In general, direct methods are more appropriate for relatively small problems and for finite difference codes, while iterative methods are more suitable for larger problems and codes using unstructured finite element grids.

While many iterative methods have been used in the past for handling large sparse matrix equations, a variety of increasingly powerful preconditioned accelerated iterative methods, such as the preconditioned conjugate gradient method (PCG), are now becoming available also. Since the system of linear equations resulting from discretization of the solute transport equation is nonsymmetrical, it is necessary to either formulate the transport problem in such a way that it leads to a symmetric matrix, or to use an extension of PCG for nonsymmetrical matrices, such as ORTHOMIN (generalized conjugate residual method) (Mendoza *et al.*, 1991), GMRES (generalized minimal residual method), biconjugate gradients, TFQMR (transpose-free quasi-minimal residual algorithm), CGSTAB (conjugate gradient stabilized method), and conjugate gradient squared procedures. Both the preconditioned conjugate gradient and ORTHOMIN methods consist of two essential parts: initial preconditioning, and iterative solution with either conjugate gradient, CGSTAB, or ORTHOMIN acceleration (Mendoza *et al.*, 1991). Incomplete lower-upper (ILU) factorization can be used as preconditioning of matrix [***A***], which is then factorized into lower and upper triangular matrices by partial Gaussian elimination. The preconditioned matrix is subsequently inverted repeatedly using updated estimates to provide a new approximation of the solution.

Available Model for Unsaturated Zone

Most of the early models developed for studying processes in the near-surface environment focused mainly on variably saturated water flow. They were used primarily in agricultural research for the purpose of optimizing moisture conditions to increase crop production. This focus has increasingly shifted to environmental research, with the primary concern now being the subsurface fate and transport of various agricultural and other contaminants, such as pesticides, nutrients, pathogens, pharmaceuticals, viruses, bacteria, colloids, toxic trace elements, and/or fumigants, and also the evaluation of water recharge through the vadose zone. While the earlier models solved the governing equations (1) through (3) for relatively simplified system-independent boundary conditions (i.e. specified pressure heads or fluxes, and free drainage), models developed recently can cope with much more complex system-dependent boundary conditions evaluating surface flow and energy balances and accounting for the simultaneous movement of water, vapor, and heat. Examples are DAISY (Hansen *et al.*, 1990), TOUGH2 (Pruess, 1991), SHAW (Flerchinger *et al.*, 1996), SWAP (van Dam *et al.*, 1997), HYDRUS-1D (Šimůnek *et al.*, 1998), UNSATH (Fayer, 2000), and COUP (Jansson and Karlberg, 2001). Several models now account also for the extremely nonlinear processes associated with the freezing and thawing cycle (e.g. DAISY, SHAW, and COUP).

Models have recently also become increasingly sophisticated in terms of the type and complexity of solute transport processes that can be simulated. Transport models are no longer being limited to solutes undergoing relatively simple chemical reactions such as linear sorption and first-order decay, but now consider also a variety of nonlinear sorption and exchange processes, physical and chemical nonequilibrium transport, volatilization, gas diffusion, colloid attachment/detachment, decay chain reactions, and many other processes (e.g. the HYDRUS-1D and -2D codes of Šimůnek *et al.*, 1998, 1999a). For example, the general formulation of the transport equations in the HYDRUS codes allows one to simulate not only nonadsorbing or linearly sorbing chemicals but also a variety of other contaminants, such as viruses (Schijven and Šimůnek, 2002), colloids (Bradford *et al.*, 2002), cadmium (Seuntjens *et al.*, 2001), and hormones (Casey *et al.*, 2003), or chemicals involved in the sequential biodegradation of chlorinated

aliphatic hydrocarbons (Schaerlaekens *et al.*, 1999; Casey and Šimůnek, 2001).

Options to simulate carbon and nitrogen cycles are also becoming a standard feature of many environmental models, such as DAISY, LEACHN (Hutson and Wagenet, 1992), RZWQM (Ahuja and Hebson, 1992), and COUP. These models typically distribute organic matter, carbon, and organic and mineral nitrogen over multiple computational pools, while allowing organic matter to be decomposed by multiple microbial biomass populations. They can account for most of the major reaction pathways, such as mineralization-immobilization of crop residues, manure and other organic wastes, mineralization of the soil humus fractions, interpool transfer of carbon and nitrogen, nitrification (ammonium to nitrate-N), denitrification (leading to the production of N_2 and N_2O), volatilization loss of ammonia (NH_3), production and consumption of methane (CH_4) and carbon dioxide (CO_2), changes in the carbon nitrogen ratio of organic matter, and microbial biomass growth and death (Ahuja and Hebson, 1992).

Efforts are also on to couple physical flow and transport models with geochemical models to simulate even more complex reactions, such as surface complexation, precipitation/dissolution, cation exchange, and/or biological reactions (e.g. Ahuja and Hebson, 1992; Šimůnek and Suarez, 1994; Šimůnek and Valocchi, 2002; Jacques *et al.*, 2002). Models considering these chemical reactions, including the ability to simulate the transport of multiple chemical species and carbon dioxide, are required for studying water management practices and irrigation techniques under arid and semiarid conditions, evaluation of water suitability for irrigation, and reclamation of sodic soils (Šimůnek and Suarez, 1997).

Another active area of research involves attempts to extend existing models that simulate uniform flow to situations where nonequilibrium and/or preferential flow occurs. Examples of this are the MACRO (Jarvis, 1994) and HYDRUS-1D (Šimůnek *et al.*, 2003) models. Possible approaches for simulating preferential flow differ in terms of their underlying assumptions and complexity. They range from relatively simplistic models to more complex, physically based, dual-porosity, dual-permeability, and multiregion-type models. A relatively simple dual-porosity flow model results when the Richards equation is combined with composite (double-hump type) equations for the hydraulic properties to account for both soil textural (matrix) and soil structural (fractures, macropores, peds) effects on flow. A more complex dual-porosity, mobile-immobile water flow model results when the Richards or kinematic wave equations are used for flow in the fractures, and immobile water is assumed to exist in the matrix. Even more complex are various dual-permeability models such as the formulations of Gerke and van Genuchten (1993) and Pruess (1991), or the kinematic wave approach as used in the MACRO model of Jarvis (1994). These formulations all assume that water is mobile in both the matrix and fracture domains, while invoking terms that account for the exchange of water and solutes between the matrix and the fractures.

A large number of models are now available for simulating processes in the vadose zone. Some of these models are in the public domain, such as MACRO, SWAP, UNSATH (Fayer, 2000), VS2DI (Healy, 1990), and HYDRUS-1D (Šimůnek *et al.*, 1998), while others are in the commercial domain, such as HYDRUS-2D (Šimůnek *et al.*, 1999a). These models vary widely in terms of their complexity, sophistication, and ease of use. Although some models are still being run under the DOS operating system, with associated difficulties of preparing input files and interpreting tabulated outputs, many others, especially those in the commercial domain, are supported by sophisticated graphics-based interfaces that tremendously simplify their use (Šimůnek *et al.*, 1998, 1999a).

Table 1 gives a summary of some of the more widely used numerical models for simulating variably saturated water flow and solute transport in soils. This table also provides Internet addresses and references where additional information about each model can be found. With the exception of HYDRUS-2D, TOUGH2, and VS2DTI, all models given in Table 1 are one-dimensional models, perhaps reflecting the fact that the majority of applications for unsaturated zone models is still only one dimensional.

CONCLUSIONS

Much of the research in the field of soil science has focused in recent decades upon understanding the fundamentals of variably saturated water flow and pollutant fate and transport processes. As society continues its rapid technological development, the types of pollution problems and chemicals posing significant environmental threats, have become increasingly complex. Problems such as the transport of pesticides, colloids, bacteria, viruses, pharmaceuticals, reproductive hormones, nutrients, and toxic trace elements, carbon sequestration, and bioremediation of organic contaminants, all require a thorough understanding and coupling of multiple hydrogeological, geochemical, and microbiological processes. It is the continually increasing speed and power of modern computers that will enable such models to become convenient tools for analysis of complex geochemical systems. Although more and more complex models are being constantly developed, currently available models are still relatively specialized and no single model is presently available that can describe the multiple problems and chemicals mentioned above. Development of numerical models capable of describing unstable and/or preferential flow, as well as models coupled with sophisticated geochemical models capable of describing both instantaneous

and kinetic chemical and biological reactions will undoubtedly remain a focus of research in the near future.

The accuracy of the obtained predictions depend to a large extent upon the accuracy of available model input parameters and upon proper conceptualization of soil heterogeneity and other system complexities, such as the possible presence of nonequilibrium flow and transport, including preferential flow. Processes are often described and their parameters measured on a much smaller scale than those for which the model predictions are being sought. Consequently, many model parameters often need to be calibrated so that they reflect the bulk behavior of the heterogeneous system, in which case they can be used for larger scale predictions. New measuring techniques that provide model parameters on the scale at which predictions are made are badly needed for successful applications of unsaturated flow and transport models in a predictive mode at the larger scale.

One may expect that unsaturated zone flow and transport models will be used increasingly for integrating fundamental knowledge about the vadose zone to yield tools for developing cost-effective, yet technically sound strategies for resource management and pollution remediation and prevention. Unsaturated zone transport models are indispensable tools for analyzing complex environmental pollution problems, and for developing practical management strategies. Models can help guide field observations by identifying which parameters and processes control system behavior. Following Steefel and Van Cappellen (1998) and Šimůnek and Valocchi (2002), several specific key ways in which unsaturated flow and transport models can be used are identified below:

1. Physical, chemical, and biological processes are often studied in isolation either in the laboratory or in the field under controlled conditions. Mathematical models can be used to investigate the impacts of multiple coupled biogeochemical reactions and other interactions in the presence of complex flow fields and spatial heterogeneity. These models also enable extrapolation to environmentally relevant temporal and spatial scales.
2. Numerical transport models provide a useful tool for interpreting experimental results. Models can help understand qualitative and quantitative trends and relationships present in the data. Properly applied modeling to interpret results of field experiments can lead to more effective quantitative understanding of underlying biogeochemical processes.
3. One of the most powerful applications of numerical flow and transport models is conducting sensitivity

analyses. Such analyses permit a systematic evaluation of the impact of model parameters (physical, chemical, and/or biological), initial conditions, and boundary conditions upon the model output. The results of a sensitivity analysis provide insight into the relative importance of individual processes and reactions within a complex biogeochemical system. Results can help one identify the most important parameters and processes, and thereby provide guidance in allocation of resources for laboratory and field investigations.

4. Numerical flow and transport models are tools for integrating all of our knowledge obtained from simulations, sensitivity analyses, and laboratory and field experimentation. This integration will often lead to more coherent and rigorous conceptual models for the underlying coupled flow, transport, and reactions processes.

79: Assessing Uncertainty Propagation Through Physically based Models of Soil Water Flow and Solute Transport

JAMES D BROWN[1] AND GERARD BM HEUVELINK[2]

[1] *Universiteit van Amsterdam, Nieuwe Achtergracht, Amsterdam, The Netherlands*
[2] *Wageningen University, Wageningen, The Netherlands*

Soil hydrological models are inherently imperfect because they abstract and simplify "real" hydrological patterns and processes. Indeed, an important aim of modeling is to establish the simplest description possible for adequately addressing a particular problem. Also, models are frequently based on input data that are known to be inadequate for some practical purpose. Thus, uncertainties in model outputs originate from uncertainties in input data, which include measurement and interpolation errors, and in models that include conceptual, logical, mathematical, and computational errors. Understanding the causes and consequences of uncertainty in soil hydrological modeling is useful for: (i) establishing the utility of data and models as decision-support tools; (ii) directing resources towards improving data and models, and (iii) seeking alternative ways of managing soils when the opportunities for accurate modeling are limited. This chapter focuses on statistical methods for assessing uncertainty in soil data and models, propagating uncertainties through models, and assessing the contribution of different sources of uncertainty to the overall uncertainties in model predictions. In addition, it explores the impacts of scale, and changes between scales, on the outcomes of an uncertainty analysis. It concentrates on physically based models of soil water flow and solute transport, and provides numerous examples from the literature here.

INTRODUCTION

Soils are an elementary yet highly complex component of many natural, modified, and managed ecosystems with physical and hydrological properties that vary both systematically through space and time and in a seemingly erratic way (Webster, 2000). Soil properties are a product of underlying physical, chemical, and biological processes and, in turn, affect these underlying processes. The relationships between soil properties and processes are usually complex and often involve nonlinear interactions and scale-dependencies that are difficult to explain or to predict (Addiscott and Tuck, 2001). These complexities are evident when modeling soil water flows and solute transport. Thus, while hydrological data and models have continued to improve over recent years, they are rarely certain or "error-free". Rather, the combined effects of unpredictable variations in soil properties and simplified representations of complex hydrological processes lead to errors in model outputs (e.g. Zhang *et al.*, 1993; Leenhardt, 1995; Dillah and Protopapas, 2000; Dubus and Brown, 2002). These errors may be sufficiently large to result in poor decisions about the exploitation and management of soils. For example, poor estimates of soil hydraulic properties may encourage excess irrigation, leading to soil erosion and salinization. While it is generally accepted that soil data and models are not "error-free", these errors may be difficult to quantify in practice. Indeed, the quantification of error implies that the "true" character of soils is known (i.e., error is a specific departure from "reality"). In the absence of such confidence, we are uncertain about the "true" properties and processes that characterize soils. Understanding how these uncertainties affect model predictions is important for: (i) establishing the utility of data and models

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

as decision-support tools; (ii) directing resources towards improving data and models; and (iii) seeking alternative ways of managing soils when the opportunities for accurate modeling are limited.

Uncertainties in soil data combine with uncertainties in hydrological models and lead to uncertainties in model predictions. This article focuses on uncertainty propagation through physically based hydrological models and, specifically, models describing soil water flow and solute transport through the unsaturated zone. Solute transport is important because many practical applications require knowledge about the distribution of chemicals in soils (e.g. soil acidification, heavy metal pollution, nutrient availability, salinization, and nitrate leaching), and much of the research on uncertainty propagation in soil hydrology has focused on solute transport (e.g. McKone, 1996; Foussereau *et al.*, 2001; Seuntjens *et al.*, 2002; Sohrabi *et al.*, 2002; Vachaud and Chen, 2002a; De Vries *et al.*, 2003). While there are longstanding literatures on uncertainty propagation in other areas of hydrology, including groundwater hydrology (e.g. Christensen and Cooley, 1999; Wang and McTernan, 2002) and surface hydrology (e.g. Beven and Binley, 1992; Brazier *et al.*, 2001; Beven and Freer, 2001), these are reviewed elsewhere (*see* articles **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3**, **Chapter 77, Inverse Modeling of Soil Hydraulic Properties, Volume 2**, and **Chapter 156, Inverse Methods for Parameter Estimations, Volume 4**), and are only referred to in discussing methods for uncertainty propagation.

Uncertainties in soil data are discussed below under "Uncertainties in Model Inputs", while uncertainties in models are discussed in a later section. In the section "Uncertainty Propagation", the statistical procedures available for propagating uncertainties in model inputs and models through to uncertainties in model outputs are reviewed. Techniques for evaluating the contribution of different sources of uncertainty to the overall uncertainties in model predictions are discussed in the section "Evaluating the Contribution of Different Uncertainties". Finally, the section on "Scale and Uncertainty" considers the impacts of scale, and changes between scales, on the outcomes of an uncertainty analysis. First, however, it is useful to consider the nature of uncertainty and how it might be quantified.

WHAT IS UNCERTAINTY AND HOW CAN WE QUANTIFY IT?

Uncertainty is an expression of confidence about what we "know", both as individuals and communities, and is, therefore, subjective. Different people can reach different conclusions about how uncertain something is, based on their own personal experiences and world-view, as well as the amount and quality of information available to them (Cooke, 1991). It is not an inherent property of the environment (Quantum Theory can be ignored here), but may be encouraged in people by some aspects of the environment. For example, the environment may appear more complex than our abstractions and simplifications imply (e.g. kinetic processes in pesticide sorption), or too variable for us to capture (e.g. infiltration rates in Mediterranean soils), too large and interconnected (open) for us to observe everything at once (e.g. global weathering of minerals), or too small to observe at practical scales (e.g. soil pore volume in the field), too opaque for observation (e.g. hydraulic conductivity), or because we do not have the capacity to observe it (e.g. soil matrix over large areas). Uncertainty differs from ignorance, because ignorance involves a lack of awareness about our imperfect knowledge (Smithson, 1989). It also differs from error, because this involves a specific departure from "reality" (Heuvelink, 1998a).

Representing Uncertainty with Probability Distributions

Ideally, our representations of reality would be perfectly accurate or "error-free". In practice, however, they are not, and we are aware of this (otherwise we would be ignorant). Rather, we are uncertain about the errors in our representations. However, we may be able to specify some boundaries for our uncertainty, which would allow us to explore its impacts on the outcomes of a decision-making exercise (e.g. a hydrological model). For example, the nitrate concentration in a sample of soil water may be measured as $68.6\,g\,m^{-3}$. The "true" value remains unknown, but control experiments in a laboratory suggest that the measuring instrument is unbiased and has a standard deviation of $5\,g\,m^{-3}$. If measurement error is the only source of error in the sampled value and the laboratory measurements are relevant to the current situation, we know that the "true" value (t) lies within $58.8\,g\,m^{-3} < t < 78.4\,g\,m^{-3}$ 95% of the time. Thus, we can express our lack of confidence (uncertainty) about the "true" nitrate concentration with a probability distribution of possible nitrate concentrations (Heuvelink, 1998a). A probability distribution function (pdf) is characterized by its shape (e.g. Gaussian, exponential, and uniform) and by its parameter values. One important parameter is the variance, as this denotes the average magnitude of uncertainty in the variable of interest.

In order to represent uncertainty with a pdf, it is necessary to specify the "domain" of the probability model, to identify the parameters of the model, and to estimate the values of those parameters. In principle, a number of subjective decisions must be introduced at each stage in order to uniquely and completely define the pdf for a given variable (see Cooke, 1991). In practice, however, many of these "decisions" are assumed implicitly. It is, therefore, instructive to consider the range of conditions

and assumptions required. The "domain" of the probability model includes a set of conditions that describe: (i) the times for which the model is valid; and (ii) the locations or areas for which the model is valid. For example, the probability model may apply for a time frame of one week (e.g. a period of constant calibration for a measuring instrument) and for a spatial domain of one land use parcel. The second set of conditions govern the application of probabilities within this domain, and include: (i) the pattern of uncertainties in time; (ii) the pattern of uncertainties in space; (iii) the relationship between the size of the uncertainties and the size of the measured variable; and (iv) any restrictions on sizes and patterns imposed by other variables ("cross-correlation"). The patterns of uncertainty in time and space are important because the impacts of correlated error (or bias) may differ substantially from those associated with random error in environmental research. Similarly, when many different variables are used in a model, "cross-correlation" is important because extreme values in one variable may coincide with extreme values in another. For example, the cadmium, zinc, and lead concentrations in a polluted soil are strongly correlated, and, hence, the uncertainties associated with spatial interpolation of these properties are also correlated (Leenaers *et al.*, 1990). Examples of pdf*s* for uncertain environmental variables are shown in Figure 1. Figure 1(a) shows a pdf for a continuous numerical variable while Figure 1(b) shows a pdf for a discrete numerical variable. Figure 1(c) shows a joint pdf for two uncertain numerical variables, where the deviation from a circular shape denotes statistical dependence or "cross-correlation" between the variables. Figure 1(d) shows a semivariogram model, which describes the magnitude of variation as a function of distance (Goovaerts, 1997).

The conditions and parameters that specify a probability model may be determined through a data-driven approach based on "validation" or (geo)-statistical estimation or a people-driven approach based on expert elicitation. When more accurate data are readily available or observations of one variable can be used to diagnose uncertainties in another, expert opinions on the uncertainties in data and models may converge. In contrast, when a "people-driven

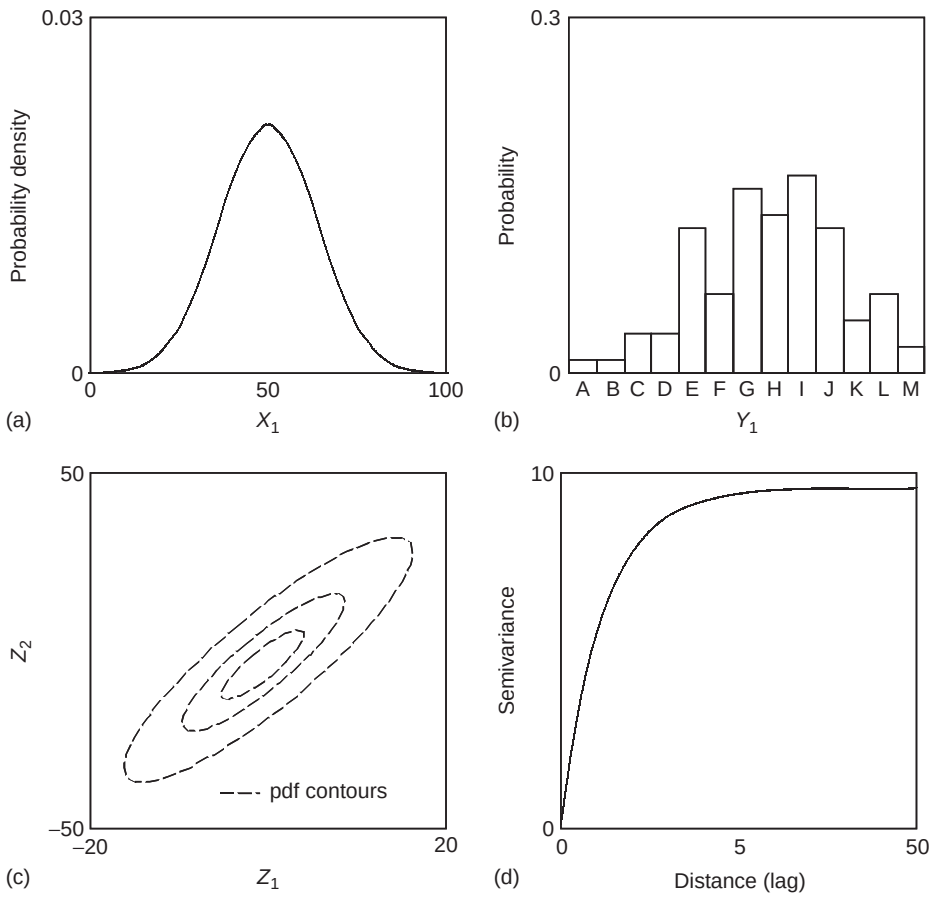

Figure 1 Example probability models for (a) a continuous numerical variable, (b) a categorical variable, and (c) two statistically dependent (cross-correlated) continuous numerical variables. Inset (d) shows the spatial patterns of uncertainty (autocorrelation) for a continuous numerical variable in the form of a ''variogram''

approach" is required, estimates of uncertainty may differ substantially between individuals, and also between groups of scientists.

UNCERTAINTIES IN MODEL INPUTS

As indicated above, the conditions and parameters that define a pdf may be estimated through a data-driven approach or through expert elicitation ("people-driven" approach). Data-driven approaches are considered first.

Data-driven Approach

Inputs to soil hydrological models include the "forcing inputs" required to generate flow (e.g. meteorological data), the boundaries in which flow occurs (positions of the air-soil and groundwater interfaces) and the characteristics of the soil within these boundaries. Many inputs are defined through measurements in the field or in the laboratory, which introduces measurement uncertainty. While soil properties vary continuously through space and time, measurements always occupy a limited number of space-time points (even remote sensing). When exhaustive inputs are required but only partial observations are available, they must be interpolated, which leads to interpolation uncertainty. Interpolation uncertainty generally increases with sample distance and soil variability, but also depends on the interpolation algorithm employed (Goovaerts, 2001). Measurement uncertainties can be estimated through comparisons with more accurate data, through laboratory testing of measurement instruments, or through repeat measurement with the same instrument (assuming constant environmental conditions). While the former provides an indication of accuracy or "bias", the latter two approaches only indicate precision.

In order to interpolate soil data, and to assess the uncertainties associated with space-time interpolation, some assumptions must be made about the behavior of soils at unmeasured times and locations. A common approach to sampling soil properties involves separating the field site into "homogeneous" units, sampling these units, and calculating a within-unit sample mean ("best estimate") and variance (uncertainty) (Voltz and Webster, 1990). This approach forms the basis for so-called "pedotransfer functions", which allow soil properties to be estimated at arbitrary locations within a "homogeneous" sample unit (Schaap and Leij, 1998; Wösten *et al.*, 2001; Minasny and McBratney, 2002). In practice, however, it may not be possible, or appropriate, to separate soil properties into "homogeneous" units, but to assume instead that soil properties vary continuously in space and time. Alternative statistical techniques, such as time-series analysis and geostatistics, are available to interpolate continuous data from partial measurements and to estimate the uncertainties associated with this interpolation (e.g. Angulo *et al.*, 1998; Goovaerts, 1997, 2001). In soil hydrology, geostatistics has been widely used to estimate interpolation uncertainty (e.g. *see* Goovaerts, 2001 for a review), both in spatial applications and in space-time interpolations (e.g. Kyriakidis and Journel, 1999; Snepvangers *et al.*, 2003). Spatial dependence between samples can be modeled with the sample semivariogram, and this information can be used for optimal prediction of soil properties at unmeasured locations through kriging (Goovaerts, 1997). The kriging variance provides an explicit measure of interpolation uncertainty.

Where soil characteristics are grouped into classes, categorical data may be used to describe soil properties for hydrological studies. In an uncertain categorical distribution, each location has a single "true" outcome (as far as the categories are identifiable and sufficient) but the precise outcome remains unknown. The probability of each outcome can be described with a discrete pdf for that location. A discrete pdf is simply a table listing each possible outcome and its associated probability. In practice, however, the distribution at one location may be sensitively dependent upon the distributions at surrounding locations, because classification errors are often statistically correlated (and, thus, dependent) in space and time. Capturing this dependence is important, but not straightforward, because multivariate discrete pdfs are characterized by a large number of parameters. In recent years, geostatistical techniques have been developed and applied for handling spatial autocorrelation in uncertain categorical data (e.g. Bierkens and Burrough, 1993; Finke *et al.*, 1999; Kyriakidis and Dungan, 2001), but identifying realistic pdfs remains inherently difficult in practice. Often, categorical data are not used directly in hydrological models, but, rather, continuous variables are related to categories of environmental variables using statistical models such as "pedotransfer" functions (see above). Here, uncertainties in the continuous variable become dependent upon (correlated with) those in the categorical variable. These uncertainties must be represented by a joint pdf when the parameters are used together in a hydrological model, otherwise the propagated uncertainties may become unrealistic.

People-driven Approach

Estimating the parameters of a probability model will always require "expert" judgment, because data must be processed and interpreted by people. However, in the absence of more accurate data, expert judgment may be the only means of estimating these parameters. So-called "expert elicitation", which formalizes the processes of estimating probability models through expert judgment (e.g. Cooke, 1991; Kaplan, 1992), has not been widely used in soil hydrology, but has been used successfully in other areas of environmental research (e.g. Morgan *et al.*, 2001). Here,

the probability models were found to be highly sensitive to the questions posed in eliciting a parameter value and to the people estimating those values (e.g. Morgan and Henrion, 1990). In principle, therefore, expert elicitation should aim to canvass a range of informed opinion about uncertainties in data, but in practice, this may not be possible, and excessive optimism or pessimism will not simply be confined to individuals. This is important because uncertainty is inherently a social construct, and will vary between people regardless of the focus of an argument (but not independently from it). For example, in a survey of soil scientists, Heuvelink and Bierkens (1992) found that respondents were overly optimistic about the predictive power of general-purpose soil maps. Nevertheless, it will often be necessary to quantify the uncertainties associated with input data for soil hydrological models through a "people-driven" approach (e.g. Keller *et al.*, 2002; Kroeze *et al.*, 2003).

UNCERTAINTIES IN MODELS

Environmental models are inherently imperfect because they abstract and simplify real patterns and processes that are themselves imperfectly known and understood. In physically based modeling, it is important to distinguish between the predictive performance of a model and its ability to explain environmental phenomena (Beven, 2001). Indeed, it is widely acknowledged that the ability of a model to predict environmental patterns satisfactorily does not mean that its explanations of these patterns are also satisfactory (e.g. Oreskes *et al.*, 1994; Rykiel, 1996; Anderson and Bates, 2001). This chapter focuses on the predictive power of models, but it is important to acknowledge that models may perform well for bad reasons, and explanatory uncertainty should, therefore, be investigated where possible (i.e., representing structural uncertainty as statistical noise is not sufficient).

Model uncertainties are "case-dependent" because hydrological models do not perform consistently for all applications involving soil water flow and solute transport. The definition of a "case" is important here, because experience is often used to "validate" models and to estimate the uncertainties associated with model parameters. In essence, a "case" refers to the circumstances in which a model performs consistently without needing to modify its underlying structure and parameter values. In accepting this case-dependence, it follows that model predictions can only be assessed through some form of comparison with direct observations or experience and, specifically, a comparison with observations or experience from the same "case" (which need not imply the same times or locations). Since observations are themselves uncertain, departures between predicted and observed outputs cannot simply be related to uncertainties in model predictions, but must also include uncertainties in empirical observations (Heuvelink and Pebesma, 1999).

Components of Model Uncertainty

Model uncertainty includes uncertainties in the structure of the model (conceptual or logical uncertainties), uncertainties in model parameters, and uncertainties in the solution of the model (Addiscott *et al.*, 1995). For example, a soil hydrological model may ignore macropore flow (structural uncertainty), may use uncertain estimates of hydraulic conductivity (parameter uncertainty), and may solve a set of continuous partial differential equations using a discrete numerical scheme (solution uncertainty). Uncertainties in model structure may originate from a perceived lack of knowledge about the real processes operating or a belief that the model intentionally abstracts and simplifies known processes. Model parameters are not inherently uncertain because they do not refer to real, measurable quantities, but are empirical quantities that allow general models to be applied to specific cases. For example, varying the friction coefficient in a hydraulic model allows the same model structure to be applied under different soil conditions, but the friction coefficient accounts for "surface roughness" at finer scales (among other things, in simple models) and cannot be measured at large spatial scales. In practice, therefore, it is difficult to define a single, optimal, set of parameters *a priori*. Moreover, nonuniqueness or "equifinality" of parameter values is common in environmental modeling because model structures only approximate reality. This leads to uncertainties in model predictions and explanations, and is particularly important where models are complex (many degrees of freedom) and observations are limited (few degrees of constraint).

If models cannot be identified uniquely, they must be represented by a probability distribution of possible models, each with a certain chance of performing well. Given uncertainties in model inputs and models, an uncertainty analysis aims to identify how these uncertainties "propagate" to model outputs (the forward problem). In practice, however, as model uncertainties are difficult to estimate *a priori*, it may be useful to compare the results of the "forward problem" to empirical observations. If these observations allow some of the original models to be rejected as improbable, the original assessment of model uncertainty should be improved (the inverse problem). When uncertainties in model inputs are known, solving the inverse problem allows model uncertainty to be identified explicitly, but only for that "case". However, model uncertainties cannot be disaggregated further into structural uncertainty and parameter uncertainty, because model parameter values do not refer to real quantities and cannot, therefore, be delimited by physical arguments or by comparisons with field observations.

Inverse Modeling

As initial estimates of model uncertainty may be no more than informed guesses, it is useful to update these estimates by comparing model predictions with empirical observations (see "Uncertainty Propagation" also). So-called "inverse modeling" has been widely used in uncertainty schemes over recent years (e.g. Abbaspour *et al.*, 1999, 2000; Schmied *et al.*, 2000; Beven and Freer, 2001; Vrugt *et al.*, 2003, and articles **Chapter 77, Inverse Modeling of Soil Hydraulic Properties, Volume 2** and **Chapter 156, Inverse Methods for Parameter Estimations, Volume 4**). Most of these schemes use Bayes' theorem, as this allows a "prior" distribution of uncertain input and parameter values to change in response to the amount and perceived (weighted) value of information available (Frenc and Smith, 1997; Bernado and Smith, 2001). The prior is sampled to provide a range of possible models for simulating the same problem, and uncertainties are propagated to model outputs by implementing the sample (running the models) and recording the results. This is known as *Monte Carlo simulation* because different possible models are sampled randomly from the prior distribution (Hammersley and Handscomb, 1979). Once the sample has been implemented, the results are compared with empirical observations and either accepted as possible or rejected as improbable (Beven and Binley, 1992). If some results are rejected, the corresponding sample can be eliminated from the prior and the resulting, calibrated distribution (posterior) used to reassess predictive uncertainty.

Two approaches are available for sampling the prior, namely: (1) a predefined probability sample from the entire distribution, which may consist of a simple random sample leading to standard Monte Carlo (e.g. the Generalised Likelihood Uncertainty Estimation (GLUE) approach of Beven and Binley, 1992), stratified random sampling, involving "Latin Hypercube" techniques (e.g. Stein, 1987), fully stratified sampling, involving the "Sectioning Method" (Addiscott and Wagenet, 1985), or (2) an interactive sample (optimization) based on a random walk approach (Markov Chain Monte Carlo or MCMC). Standard Monte Carlo and MCMC are not fundamentally different in principle. However, in practice, MCMC is more efficient because it attempts to minimize the sample required to "adequately" represent the posterior. It can, therefore, be distinguished from predefined probability sampling using arguments of acceptable risk; that is, the risk of taking too few samples from the prior to adequately determine the (posterior distribution of) model uncertainties. An important disadvantage of standard Monte Carlo, and Monte Carlo in general, is the time taken to perform an uncertainty analysis, and other types of propagation tools are available for simple models (see below). An important disadvantage of MCMC is that its predictions may be systematically biased, as the sampling algorithm may become caught in localized pockets of good performance without accommodating the full range of equifinality implied by the prior distribution (see Page *et al.*, 2003). The risk of bias can be reduced by employing a variant of standard MCMC, known as "*shuffled complex evolution*", which evolves different areas of the parameter space simultaneously (Vrugt *et al.*, 2003).

Another important application of inverse modeling in soil hydrology is for reducing "errors" in model predictions without an uncertainty analysis. Kalman filtering (e.g. Cahill *et al.*, 1999) is an example of this approach. Kalman filtering is used in dynamic modeling to update state variables and parameter values through time as new information becomes available, but has not, in general, been used to evolve different plausible parameter values (equifinality) within an uncertainty framework (although see Wendroth *et al.*, 1999).

Structural Uncertainty

To date, uncertainty analyses of environmental models have typically focused on model inputs and parameter values, as evidenced by the range of schemes available for input uncertainty propagation and for evaluating plausible parameter values (e.g. Janssen *et al.*, 1994; Bennett *et al.*, 1998; Clausnitzer *et al.*, 1998; Duke *et al.*, 1998; Haan *et al.*, 1998; Heuvelink, 1998a; Hanson, 1999; Beven and Freer, 2001; Dillah and Protopapas, 2000; Christiaens and Feyen, 2001, 2002; Vrugt *et al.*, 2003). The focus here partly reflects a consensus that model inputs and parameters are an important source of uncertainty in simulation predictions. However, it also reflects the relative ease with which uncertainty in model inputs and parameters can be quantified in comparison to assessments of structural uncertainty in models. In practice, structural uncertainty may be more important than parameter uncertainty in evaluating model performance, but such uncertainties are difficult to assess explicitly or to separate from other uncertainties during the calibration process (Beven and Binley, 1992). For example, in a study of the Uhlirska Catchment, Czech Republic, Blazkova *et al.* (2002) found that uncertainties in the water table depths predicted by TOPMODEL could be attributed to uncertainties in the topographic data or to structural uncertainties in the model, for which further interpretation was difficult. However, Mackay and Robinson (2000) successfully evaluated the internal contradictions or "semantic errors" (one form of structural problem) between hydrological submodels in predicting water table depths with TOPMODEL.

As indicated above, uncertainties in model structure may originate from a perceived lack of knowledge about the real processes operating, or a belief that the model abstracts and simplifies known processes. Both of these are relevant in modeling soil water flows and solute transport. At an elementary level, structural uncertainty need not exist

in hydraulic modeling, because Newton's laws (the general) cannot be improved, nor expressed more accurately in practice (Navier–Stokes equations). Rather, it is the simplification of these equations, their discretization in space and time, and their numerical solution that lead to uncertainty in specific cases. In this context, some types, scales or directions of flow may be deemed "less important" than others and either removed from the numerical model or their effects on the mean (important) flow incorporated through one or more empirical parameters. In practice, however, the distinction between "important" and "less important" flow requires "expert" judgment in specific cases, for which uncertainty (as well as ignorance) may be substantial. For example, while an empirical diffusion/dispersion parameter may be sufficient for describing the "mean flow" of water through a control volume (e.g. Darcy-Richards), it may not be appropriate for describing the "mean transport of solutes" within the fluid, as solute transport is sensitive to the "local" distribution of fluid velocities. Moreover, Newton's laws only resolve transfers of energy, matter, and momentum through the environment. They do not resolve the processes that lead to changes in the storage and transfer of these elementary units. For example, they cannot predict changes in rainfall inputs or in the hydraulic properties of the soil caused by vegetation growth. In practice, we are usually interested in the processes, as well as the transfers, because dominant process controls change through time and space, and, thus, Newton's laws cannot predict the future with some arbitrary degree of accuracy. In this context, structural uncertainty arises because our best representations of environmental processes are deemed insufficient.

In principle, the impacts of structural uncertainty can (and should) be evaluated by exploring different process formulations (explanatory uncertainty) or, less ideally, by adding correlated noise to model structures. In practice, however, identifying alternative process formulations or appropriate levels and patterns of noise is not straightforward.

UNCERTAINTY PROPAGATION

The combination of uncertainties in model structure, inputs, parameter values, and solution leads to a distribution of "models" for any given case, which expresses our lack of confidence about a "correct" model for that case. This leads to uncertainty in model outputs, as predictions will vary according to model inputs, structure, parameter values, and solution method (Figure 2). When uncertainties in input data and models lead to uncertainties in model output, the original uncertainties are said to have "propagated" through the modeling system. The Monte Carlo method, described above, is one (very useful) approach to this problem, but not the only one.

The problem of uncertainty propagation can be formulated generically as follows (Heuvelink, 1998a). Let y be the output of a model g that incorporates any number of

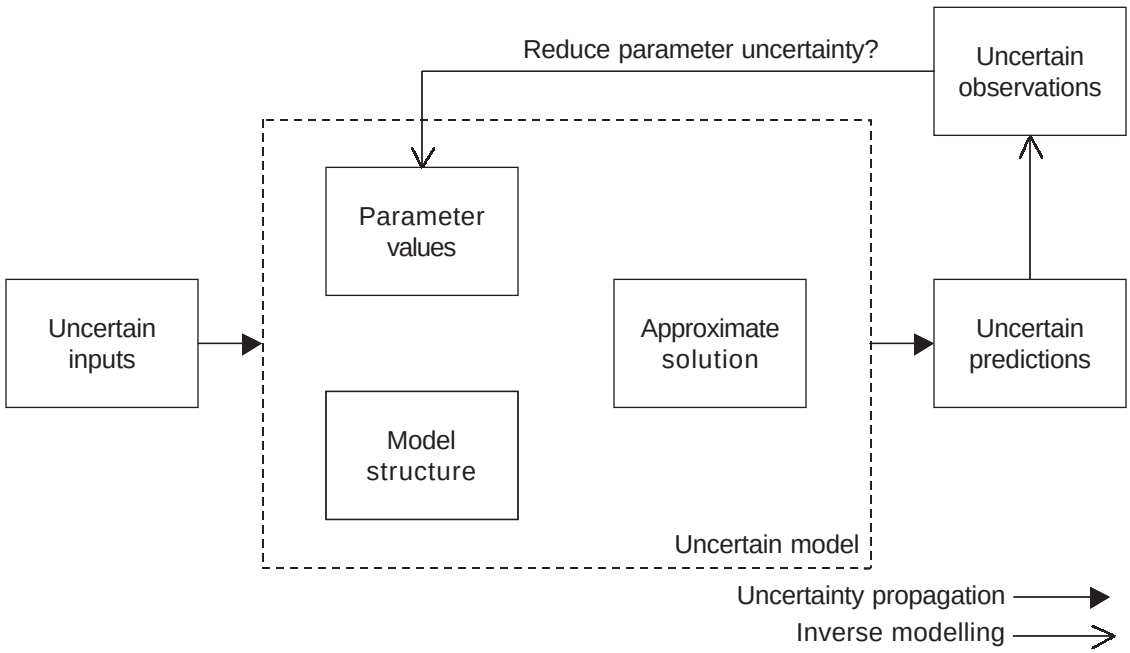

Figure 2 Uncertainties in model inputs combine with uncertainties in the model (parameters, structure, and solution) and propagate through the model leading to uncertainties in model predictions. Model parameter values may be calibrated against uncertain observations through ''inverse modeling''. Dependencies are not shown

certain elements, but m uncertain elements x_i:

$$y = g(x_1, \ldots, x_m) \quad (1)$$

The elements x_i represent input uncertainties as well as model uncertainties. Hence, they might refer to uncertainties in soil organic matter or porosity, but could also refer to uncertainties in van Genuchten parameters or in model structure. In terms of the latter, x_i could be a residual noise superimposed upon a deterministic model or a binary random variable that distinguishes between two alternative model structures. The aim here is to determine the uncertainty in the output y, given the operation g and the uncertainties in the inputs x_i. The output y will have a probability distribution, the variance of which is a measure for the propagated uncertainty in y. When g is linear and all uncertainties x_i are quantitative and quantified, the variance of y can be derived analytically. However, linear models are rare in soil hydrology, and it is, therefore, useful to consider numerical methods for solving equation (1). Two methods are considered below and, for simplicity, it is assumed that the uncertainties x_i are real numbers and are unbiased, although generalizations to the biased case are relatively straightforward, even if the quantification of bias is not.

Taylor Series Method

The Taylor Series Method (TSM), also known as *first-order analysis*, approximates g with a truncated Taylor series (Figure 3). It greatly simplifies the process of propagating uncertainty through a soil hydrological model. However, it also introduces an approximation error, which is proportional to the divergence of g from a linear form. The TSM yields analytical expressions for the mean and variance of the model output (Heuvelink, 1998a). The variance expression contains the correlations and standard deviations of the uncertain inputs and model parameters, as well as the mathematical derivatives of the model (which are assumed to exist). These derivatives reflect the sensitivity of the model to changes in each of the inputs and parameters. Rosenblueth (1975) proposed an alternative, but similar, approach to TSM, which allows the moments (e.g. mean and variance) of a function to be estimated from 2^m model outputs, evaluated at all 2^m corners of a "hypercube" representing the input space for m model inputs. The need to evaluate all 2^m outputs is a significant restriction for complex models, but can be reduced to 2^m outputs by using points on the diameters of a hypersphere, rather than the corners of the inscribed hypercube (Christian and Baecher, 2002).

The TSM has been widely used to evaluate uncertainty propagation in soil hydrological models, and particularly those involving solute transport (Kuczera, 1988; Bennett *et al.*, 1998; Tiktak *et al.*, 1999; Diaz-Diaz and Loague, 2000).

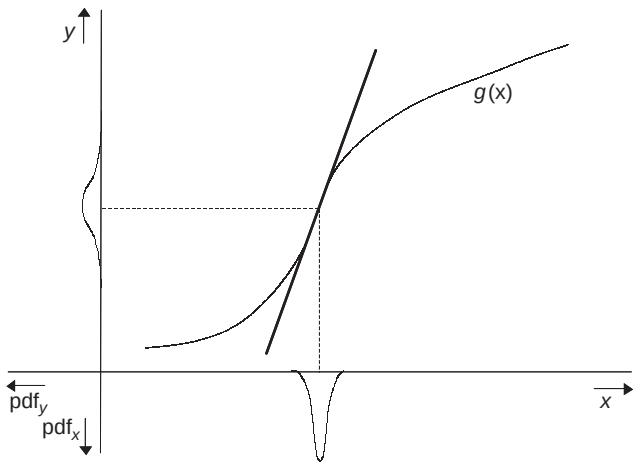

Figure 3 Uncertainty propagation with the TSM for a single input x. The curved line represents the function g, which is approximated by a linear function (dark solid line). The linear function has the same value and gradient as g when evaluated at the mean of x. After linearization, pdf$_y$ is easily computed from pdf$_x$. In this example, pdf$_y$ is much wider than pdf$_x$ because g is steep near the mean of x

Monte Carlo Method

The Monte Carlo method adopts an entirely different approach to TSM, as it retains the original model g, but randomly samples from the joint distribution of possible input and model uncertainty for g (Hammersley and Handscomb, 1979). The Monte Carlo method involves:

Repeat N times a, b:

a. Generate a set of realizations of the uncertain inputs and model parameters, structure, and solution.
b. For this set of realizations, compute and store the model output.

Compute and store sample statistics from the N outputs.

A representative sample from the joint distribution of uncertain inputs and model parameters, structure, and solution can be obtained using an appropriate pseudorandom number generator and a sufficiently large sample size (Ross, 1990; Van Niel and Laffan, 2003). The accuracy of the Monte Carlo method is inversely proportional to the square root of the number of runs N and, therefore, increases gradually with N. As such, the method is computationally expensive, but can reach an arbitrarily level of accuracy, unlike TSM or Rosenblueth's method. Of course, the time taken to perform an uncertainty analysis must influence the choice of propagation tool (Heuvelink, 2002). However, the Monte Carlo method is generic, invokes fewer assumptions, and requires less user-input than other propagation tools. Moreover, the accuracy of the method can

be fixed in advance according to the level of risk associated with a decision. The standard Monte Carlo method can be adapted to reduce the number of samples (model simulations) required for a given level of accuracy in the computed uncertainty. Examples of modified sampling schemes include Latin Hypercube sampling (e.g. Rossel *et al.*, 2001; Christiaens and Feyen, 2002; Sohrabi *et al.*, 2002; Minasny and McBratney, 2002) and MCMC (e.g. Soulsby *et al.*, 2003; Vrugt *et al.*, 2003; see also the discussion in "Uncertainties in Models"). The Monte Carlo method has been widely used to propagate uncertainties through soil hydrological models and has become increasingly popular over recent years as the computational overheads of performing such an analysis have declined. Examples in soil hydrology can be found in Petach *et al.* (1991); Bennett *et al.* (1998); Duke *et al.* (1998); Hansen *et al.* (1999); Kros *et al.* (1999); Dillah and Protopapas (2000); Thorsen *et al.* (2001); Keller *et al.* (2002); De Vries *et al.* (2003). For distributed modeling of soil water flows and solute transport, the sampling algorithm must accommodate spatial and temporal dependencies in model inputs and parameters (De Roo *et al.*, 1992; Endreny and Wood, 2001). This can be achieved through sequential simulation of distributed input or parameter values (e.g. Goovaerts, 1997).

EVALUATING THE CONTRIBUTION OF DIFFERENT UNCERTAINTIES

Prioritizing the Key Sources of Uncertainty

As indicated above, soil data and models are inherently imperfect because they abstract and simplify "real" soil properties and processes. However, it is neither possible nor desirable to eliminate all of the uncertainties associated with data and models, because resources are always limited and must be used effectively (Van Rompaey and Govers, 2002). Rather, an uncertainty analysis should aim to focus on those inputs and model entities that are likely to contribute most to the uncertainties associated with model predictions. The contribution of a specific, uncertain variable to the overall uncertainty in model predictions will depend upon the sensitivity of the model to that variable and the uncertainties associated with it. In general, models of soil water flow and solute transport will be highly sensitive to the specification of physical parameters, such as bulk density and hydraulic conductivity (e.g. Schaap and Leij, 1998; Abbaspour *et al.*, 2000; Christiaens and Feyen, 2001; Lenhart *et al.*, 2002; Vachaud and Chen, 2002b). As a calibration parameter in soil hydrological models, hydraulic conductivity may also be associated with the largest uncertainties (e.g. Rong and Wang, 2000; Schaap *et al.*, 2001; Foussereau *et al.*, 2001; Minasny and McBratney, 2002), although other parameters may be more important in specific cases (e.g. Seuntjens *et al.*, 2002; Dubus and Brown, 2002).

Evaluating the contribution of different sources of uncertainty to the overall uncertainties in model predictions is important for: (i) understanding where the greatest sources of uncertainty reside and, therefore; (ii) directing efforts towards these sources. For example, De Vries *et al.* (2003) found that denitrification in the soil column was the main source of uncertainty in predicting nitrogen inflow to groundwater in Dutch agricultural soils and suggest that improvements in field-based observations and process studies would lead to the greatest reductions in these uncertainties. Of course, too normative an emphasis on reducing uncertainty is inappropriate when the outcomes of an uncertainty analysis are highly sensitive to the assumptions made in performing that analysis (e.g. model uncertainty). Similarly, it is not appropriate to separately assess the contribution of model structure and parameter uncertainties because: (i) model parameters are empirical quantities; they are not inherently uncertain; and (ii) separate assessment is doubtful, as model uncertainties can only be assessed by comparing model predictions with independent observations. However, it should be possible to assess the contribution of different input uncertainties and the total model uncertainty to the overall uncertainties in model outputs.

In most cases, it is neither conceptually appropriate nor theoretically feasible to resolve every source of uncertainty in model predictions, but it is also important to consider practical arguments when addressing specific sources of uncertainty in models. In particular, there is a need for pragmatism when improving model inputs that do not contribute significantly to the overall uncertainties in model outputs. For example, Loague *et al.* (1989) suggest that improvements in a model of pesticide leaching should focus on soil organic carbon rather than bulk density, as model uncertainties were more sensitive to organic carbon content than bulk density. Equally, attempts to reduce uncertainty in model outputs must be balanced against the range of inputs for which uncertainties are poorly defined or remain unknown and against the practical benefits of improving model inputs or structures. For example, high quality input data are of little use when the models themselves are poor or inherently uncertain. Similarly, improvements in models should be justified against the need for additional complexity, the accuracy of new concepts, and their relevance, as well as the resources required to implement them (Van Rompaey and Govers, 2002).

Partitioning Property

Under the fairly strict assumptions that model and input uncertainties are mutually uncorrelated, only quantifiable uncertainties are involved, g is continuously differentiable with respect to all uncertain inputs, and the TSM approximation error is relatively small, the following holds

(Heuvelink, 1998a):

$$\mathrm{Var}(y) \approx \sum_{i=1}^{m} \mathrm{Var}(x_i) \cdot \left(\frac{\partial g}{\partial x_i}\right)^2 \qquad (2)$$

where the derivative of g with respect to each of the inputs x_i is evaluated about its mean. That is, the variance of y is the sum of the products of the variances from each uncertain input and the squared derivative of g with respect to that particular input. This partitioning property allows the user to determine which sources of uncertainty are the main contributors to uncertainty in model predictions. It also allows an assessment of how the output variance will decline for a given reduction in the variance from one or more inputs. Clearly, the output variance will mainly improve from a reduction of the input variance that contributes most to the uncertainties in model output (other factors being equal). However, this may not correspond to the input with the largest variance, because the hydrological model will display different sensitivities to each uncertain input. Similarly, the contributions of the input uncertainties, as well as the magnitude of the output uncertainty, will depend upon the specific "case" considered and the types of output predicted. While it is instructive to consider equation (2), its assumptions of near-linearity in g and zero correlation between input uncertainties are rarely met in practice. Rather, for most practical applications in soil hydrology, where these assumptions are deemed unacceptable, more advanced analysis techniques, often based on Monte Carlo simulation, may be employed (*see* Jansen *et al.*, 1994; Jansen, 1999; Chan *et al.*, 2000).

Examples from soil hydrology where the contributions of different sources of uncertainty were compared include Zhang *et al.* (1993); Finke *et al.* (1996); Piggott and Cawlfield (1996); Tiktak *et al.* (1999); Barlund and Tattari (2001); Dubus and Brown (2002); Keller *et al.* (2002); Sohrabi *et al.* (2002); De Vries *et al.* (2003).

SCALE AND UNCERTAINTY

Issues of scale have received increasing attention in soil hydrology over recent years (e.g. Blöschl and Sivapalan, 1995; De Vries *et al.*, 1998; Bierkens *et al.*, 2000). This partly reflects a consensus that hydrological patterns and processes are strongly scale-dependent (Blöschl and Sivapalan, 1995) and that the implications of scale, and changes between scales, have not been fully acknowledged in hydrological modeling (Beven, 1995, 2001). It also reflects an increasing demand for "policy-relevant" research in hydrology (Beven, 2000; Clifford, 2002), where there is a need to integrate social and physical perspectives on environmental problems that traverse a range of political and geographic scales (e.g. Dumanski *et al.*, 1998; Kros *et al.*, 1999; Kros *et al.*, 2002).

The need to operate at a range of scales, or to change between scales, introduces uncertainty because the dominant patterns and process controls may not be known at all scales, or incorporated practically in models at the scales of interest (e.g. Heuvelink and Pebesma, 1999; Vachaud and Chen, 2002b; Hennings, 2002). For example, while macropore and preferential flow are dominant at the "pedon scale", they remain important contributory processes to flow patterns at "field", "catchment", and "regional" scales (Heuvelink, 1998b; Heuvelink and Pebesma, 1999; Zehe *et al.*, 2001), but are difficult to parameterize from general-purpose soil survey data and, hence, to incorporate in large-scale models of soil water flow (Simmonds and Nortcliff, 1998).

Scale Dependence of Model Inputs

When model inputs, or the observations used to test model outputs, are defined with a different control volume or "support" from that required by the model, these data must be aggregated or disaggregated, or the model must be redefined at an appropriate scale (Heuvelink and Pebesma, 1999; Bierkens *et al.*, 2000). The basic elements of "support" include the domain chosen to represent a real entity, together with the size (resolution), shape, and orientation of the "building blocks" or space-time units used to discretize that entity (Webster and Oliver, 1990). An important consequence of representing model inputs as stochastic quantities is that changes in support will affect uncertain quantities (e.g. a variance) more than deterministic ones (e.g. an average). Thus, aggregating or disaggregating data may greatly affect the probability distribution for those data, and, particularly, its width, without significantly affecting the mean value (Heuvelink and Pebesma, 1999; Heuvelink, 2002). For example, in a study of soil acidification with the SMART2 model, Kros *et al.* (2002) found that predicted concentrations of aluminum and nitrate in the soil solution were highly dependent upon the support size of model entities. In practice, space-time aggregation should lead to a reduction in uncertainty and to an increase in the spatial autocorrelation of model inputs because much of the variability at finer scales is lost and, thus, disappears as a source of uncertainty (e.g. Heuvelink and Pebesma, 1999). By contrast, space-time disaggregation will lead to an increase in uncertainty and to a reduction in the spatial autocorrelation of model inputs because the attribute variability is increased at finer scales.

Scale Dependence of Models

Uncertainties in model structure (dominant process controls) and parameter values are also sensitive to changes in scale. However, unlike aggregation or disaggregation of data, model parameters cannot be transformed using

the original quantities alone because they do not, in general, refer to real, measurable things. Rather, upscaling or downscaling of model parameters can only be achieved by (re)-calibrating the model at another scale, and may require adaptation of the original model because functional relationships are typically nonlinear and process controls usually change with scale (Addiscott and Tuck, 2001). More fundamentally, upscaling or downscaling of model parameters may hide underlying problems with model structure if process controls are not simultaneously evaluated for their relevance and sufficiency at other scales (i.e., uncertainty in explanation).

CONCLUSIONS

A mismatch between the complexity of soil patterns and processes and our ability to capture them adequately for some practical purpose leads to uncertainty in the predictions of soil hydrological models. These uncertainties originate from a lack of confidence in model inputs, which include measurement and interpolation errors, and in models that include conceptual, logical, and computational errors. Uncertainties in model inputs and models can be described with probability distribution functions, for which a number of conditions and parameters must be estimated *a priori*. In principal, this can be achieved with a "data-driven" approach for model inputs. Where observations are lacking, a "people-driven" approach is required, but the resulting estimates may introduce bias into the uncertainty analysis. For estimating uncertainties in model parameters, a data-driven approach cannot be used because model parameters do not, in general, refer to real, measurable quantities. Here, a "people-driven" approach is useful for making an initial assessment of parameter uncertainties, which may be updated later through inverse modeling. In practice, uncertainties in model concepts (structural or explanatory uncertainties) are difficult to estimate *a priori* or to isolate through inverse modeling, but may ultimately determine the utility of model predictions.

Uncertainties in model inputs and models combine and propagate through a hydrological model, leading to uncertainties in model outputs, which can be quantified using a range of statistical techniques. In soil hydrology, the TSM and Monte Carlo Simulation (MCS) have been widely used for uncertainty propagation. In recent years, MCS has largely replaced the TSM, as it is generic, invokes fewer assumptions, and requires less user-input than other propagation tools. Moreover, continued improvements in computing hardware and sampling techniques (e.g. MCMC) have allowed MCS to be applied to increasingly complex models, including spatially and temporally distributed models of soil water flow and solute transport. Nevertheless, uncertainty analyses remain complicated when uncertain inputs are "autocorrelated" in space or time or "cross-correlated" between variables. More fundamentally, autocorrelation and cross-correlation will introduce more degrees of freedom than can be constrained uniquely through comparisons of model predictions and independent observations (i.e., inverse modeling), leading to the characteristic equifinality of hydrological models, but also implying sensitivity to the specific range of observations available. Indeed, while it has long been recognized that mathematical models should not be more complicated than specific applications require, recent research in soil hydrology has consistently reiterated the need to balance model complexity against the "testability" of model predictions. It has also argued for improvements in field observations as a key source of information for reducing uncertainties in soil hydrological models. In this context, it is helpful to identify those variables that contribute most to uncertainties in model outputs, because resources are always limited and must be used effectively.

In evaluating the contribution of different sources of uncertainty to the overall uncertainties in model predictions, it is instructive to consider the partitioning property for a multivariate distribution. In practice, however, more advanced analysis techniques based on Monte Carlo simulation are necessary for investigating the sources of uncertainties in complex hydrological models. While analysis of variance (ANOVA) techniques should assist in targeting resources towards those inputs and parameters that contribute most to uncertainties in model outputs, they are ultimately constrained by the interdependence of model inputs, structure, and parameters following calibration and the lack of physical reasoning attached to parameter uncertainties and, hence, the difficulties in separating model parameter and structural uncertainties. When evaluating predictive uncertainties, it is, therefore, important to distinguish between the predictive performance of a model and its ability to explain environmental phenomena. Indeed, estimates of uncertainty in model predictions will be unreliable if the explanations upon which they are based are inappropriate. In principal, this implies a detailed analysis of the "contingencies of place" associated with a particular modeling study and careful inspection of any modeling assumptions introduced within this context. In practice, however, this assumes a depth and breadth of expertise, including a detailed knowledge of mathematical modeling and field techniques, that is rarely, if ever, available (Blöschl, 2001). Thus, while decision-makers, and those affected by decisions, would benefit most from improved access to uncertainty tools, they currently benefit least because of the inherent limitations of existing tools and the practical disadvantages of performing such analyses. These issues must be addressed if an important aim of developing uncertainty tools is to encourage more widespread criticism of data and models in soil hydrology.

Given that uncertainty analyses are not benign instruments, with the capacity to both encourage unreasonable decisions and impede reasonable ones, there is a need to balance the complexity of an uncertainty analysis against the expertise of the user and the risks associated with bad decisions. While MCS dramatically simplifies the problem of propagating uncertainties through soil hydrological models, there are many problems of equal or greater complexity that remain. These include assessments of uncertainty in space-time categorical data, analyses of statistical dependence within and between uncertain inputs and parameters (autocorrelation and cross-correlation), assessments of structural uncertainty in models, and analyses of the scale-dependence of model input and model uncertainties. In evaluating modeling uncertainties, the importance of accounting for different modeling scales and changes between scales can hardly be over-emphasized because the consequence of using wrong (combinations of) support is to invalidate the uncertainty analysis. In soil hydrology, and in environmental science more generally, the need for interdisciplinary, "policy-relevant" research will only increase this problem in future. Here, the benefits of performing an uncertainty analysis are clear (e.g. Beven, 2000), but the challenges of balancing physical and statistical realism against the need for pragmatism in extending their application are considerable.

PART 7

Erosion and Sedimentation

80: Erosion and Sediment Transport by Water on Hillslopes

ANTHONY JOHN PARSONS

Department of Geography, University of Leicester, Leicester, UK

Much of the terminology and many of the concepts within the field of erosion and sediment transport by water on hillslopes, derive from the literature of agricultural engineering. Of particular importance has been the distinction between rills and interrill areas. One definition of the former is that they are channels small enough to be removed by ploughing; gullies, by contrast, are not. The distinction of gullies, rills, and interrill areas is artificial. None the less, it provides a convenient framework for an examination of the processes of hillslope erosion and sediment transport.

In interrill areas, the dominant mechanism of sediment detachment is that of raindrop impact. Sediment detached by raindrops may be split into that which is transported away from the location of detachment in splash droplets (rainsplash), and that which is simply dislodged by the impact of raindrops but which either remains at, or falls back to, the site of detachment. The former is relatively easy to measure; the latter is not, but may be quantitatively much more important. The rate of detachment is a function of the rainfall energy at the soil surface, so that where vegetation intercepts some of the energy of the rainfall, or a layer of surface water exists, some of the energy of the falling rain will be dissipated. The rate of detachment is also affected by surface gradient. Whereas detachment in interrill areas is due to the energy of falling raindrops, sediment transport is mainly controlled by flow energy. Several authors have attempted to apply transport-capacity equations developed for alluvial rivers even though the hydraulic conditions in shallow overland flow are very different from those in rivers. However, sediment transport by interrill flow needs to consider not only the capacity of the flow, but also its competence.

As threads of interrill flow become deeper and faster, a threshold is reached beyond which significant flow detachment begins to take place. Once this occurs the flow begins to erode definable channels, or rills. As with interrill overland flow, the transport capacity of rill flow has typically been estimated using equations taken from the literature developed for alluvial rivers. However, sediment transport by rill flow is equally determined by the competence of the flow. This is particularly the case for stony soils.

Gullies have been relatively neglected in the agricultural literature, so that, whereas there is considerable qualitative literature on gully growth and development, quantitative information is limited. However, gullies may account for between 10% and 94% of total soil loss on hillslopes.

Modelling of hillslope erosion and sediment transport has been undertaken by both geomorphologists and agricultural engineers. There is a shared history, inasmuch as, through time, both demonstrate increasingly explicit representation of processes in their modelling as understanding of processes has increased and increased computing power has become available.

On hillslopes, some of the highest rates of erosion and sediment transport are attained on bare, agricultural fields. Certainly, in such areas rates of erosion are of significant concern. Hence, it is not surprising that much of the research into rates and controls of hillslope erosion and sediment transport has been undertaken by agricultural engineers, and that much of the terminology and many of the concepts within this subject area derive from

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

the literature of agricultural engineering. Of particular importance into research on erosion and sediment transport on agricultural land has been the distinction between rills and interrill areas. One definition of the former is that they are channels small enough to be removed by ploughing (Soil Conservation Society of America, 1982). Gullies, by contrast, are not. Consequently, the existence of gullies precludes mechanized agriculture, a result of which is that they have been studied to a lesser degree than their significance for hillslope erosion may warrant. The distinction of gullies, rills, and interrill areas is artificial, both in agricultural fields and on hillslopes covered by natural or seminatural vegetation, because the former evolve from the latter. None the less, it provides a convenient framework for an examination of the processes of hillslope erosion and sediment transport.

INTERRILL EROSION AND SEDIMENT TRANSPORT

In interrill areas, the dominant mechanism of sediment detachment is that of raindrop impact. The kinetic energy of falling rain ranges from 1000 to 100 000 times that of shallow interrill flow (Ekern, 1953). Ghadiri and Payne (1981) calculated the maximum impact stress caused by a falling raindrop to be 2–6 MPa. However, Nearing *et al.* (1987) argued that the nonrigid, nonhomogeneous nature of soil surfaces reduced the impact pressure. These authors obtained maximum impact stresses between 190 and 290 kPa from a 5.6-mm diameter raindrop. Experiments by Young and Wiersma (1973) showed that when soils were protected from 89% of the energy of rainfall without reduction in the application of water rate, soil loss decreased by between 90 and 94% for the three soils they tested. Sediment detached by raindrops may be split into that which is transported away from the location of detachment in splash droplets (rainsplash), and that which is simply dislodged by the impact of raindrops, but which either remains at, or falls back to, the site of detachment. The former is relatively easy to measure, and several methods have been devised for its measurement (e.g. Ellison, 1944; Morgan, 1978; Parsons *et al.*, 1991. See also, Poesen and Torri, 1988; Torri and Poesen, 1988). Rates of rainsplash have been shown to be directly proportional to rainfall energy (Watung *et al.*, 1996) and intensity (Park *et al.*, 1983) and inversely proportional to soil shear strength (Cruse and Larson, 1977), such that general equations for rainsplash have the form

$$R = aE^b \tag{1}$$

and

$$R = cI^d \tag{2}$$

where R is rainsplash rate (Kg m^{-2} s^{-1}), a and c are soil erodibility coefficients, E is rainfall energy (J m^{-2} s^{-1}), I is rainfall intensity (mm s^{-1}), and b and d are exponents, the latter generally assumed to equal two (Sharma *et al.*, 1993). Equations (1) and (2) have been linked through relationships between rainfall energy and intensity, such as that given by Brandt (1990), where

$$E = 8.95 + 8.44 \log I \tag{3}$$

However, the assumption that there is a simple relationship between rainfall energy and intensity is questionable (see Parsons and Gadian, 2000; Salles *et al.*, 2002; van Dijk *et al.*, 2002). Consequently, rainfall kinetic energy is better calculated as the sum of the kinetic energy of individual raindrops (Sharma *et al.*, 1995), such that

$$E = k \sum_{i=1}^{N} d_i^3 v_i^2 n_i \tag{4}$$

where N is the number of drop diameter classes, n_i the number of drops in class I, d_i the mean diameter of drops in class I (mm), v_i is the impact velocity of drops of diameter d_i (m s^{-1}).

Cruse and Larson's experiments indicated a relationship between detachment D (g) and soil shear strength s (g cm^{-2}) of

$$(D^*10^4)^{0.5} = 6.4337 - 0.092s + 0.0004s^2 \tag{5}$$

Because shear strength decreases with the percentage of sand in a soil and increases with the percentage of silt and clay, detachment increases with the sand content of soils (Govers, 1991). Similarly, soil shear strength is affected by moisture content, such that detachment varies with moisture content (Truman and Bradford, 1990).

Dislodgement is difficult to measure, but laboratory experiments by Schultz *et al.* (1985) indicated that dislodged sediment may amount to around ten times that found in raindrop splash. This study remains unique in attempting to quantify dislodgement, despite its apparent importance to interrill erosion. Consequently, there remains a paucity of knowledge into rates of total detachment, as opposed to rates of rainsplash, (which are frequently, but incorrectly, equated with total detachment), that may be experienced under a range of rainfall and soil surface conditions.

Importantly, the rate of detachment is a function of the rainfall energy at the soil surface, so that where vegetation intercepts some of the energy of the rainfall, or a layer of surface water exists, some of the energy of the falling rain will be dissipated and be unavailable to cause sediment detachment. Wainwright *et al.* (1999) demonstrated that rainfall energy under creosotebush was reduced to 70% of that outwith the canopy during simulated rainstorms, whereas rainfall intensity was only reduced to 90%.

These authors argued that the difference in effective kinetic energy (that possessed by individual raindrops sufficient to cause soil detachment) was even greater (amounting to only 55% of that outwith the canopy), and that such differences in effective kinetic energy beneath vegetation canopies is responsible for the development of mounds beneath desert shrubs by the process of differential splash (Parsons *et al.*, 1992). In contrast, Morgan (1985) found an inverse relationship between rainfall energy and detachment beneath corn under simulated rainstorms of between 40 and 100 mm/hr, but a similar inverse relationship at only the lowest of these intensities under soybean, and a positive relationship between detachment and rainfall energy at the higher intensities. The argument is complex because interception by vegetation not only reduces the energy of falling raindrops available to detach soil particles, but also reduces their compaction effects. Thus, runoff is also likely to be less where rainfall is intercepted as found by Roy and Jarrett (1991), who investigated the effects of coarse surface fragments on interrill erosion. For a layer of water at the ground surface, Torri *et al.* (1987) demonstrated an exponential decrease in the detachment rate with increasing depth of surface runoff that could be described by the equation

$$A = A_0 e^{-qh} \tag{6}$$

where A is the rate of detachment ($m^3\,s^{-1}\,m^{-1}$), A_0 is the rate of detachment of at zero water depth, h is the depth of the water layer (m), and q is an empirical constant that varies with soil surface condition.

Finally, consideration needs to be given to the effect of surface gradient on rates of detachment. Poesen (1985) suggested that, under some circumstances, detachment varies with gradient so that there may exist a positive relationship between the rate of detachment and gradient. A more detailed examination of this phenomenon by Torri and Poesen (1992) demonstrated that this relationship results from a reduction of resistance to detachment with gradient that varies with its cohesion and angle of friction. Hence, the effect is more significant for some soils than others. For soils with a low (25°) angle of friction, the detachment rate doubles with an increase in gradient from 3° to 19°. In contrast, for soils with a high angle of friction (55°), there is only a 10% increase in detachment over the same range of gradient.

Whereas detachment in interrill areas is due to the energy of falling raindrops, sediment transport is mainly controlled by flow energy. Although splash droplets do transport some sediment, in most situations the amount is small in comparison. Kotarba (1980), however, argued that for the steppe zone of Mongolia, splash transport is the dominant form of sediment transport. On its granitic terrain, infiltration rates are high and overland flow is spatially of relatively little importance. In contrast, all rainfall causes some splash transport. Poesen (1985) proposed a sediment transport model for splash as follows:

$$qs = \frac{(KE)\cos a}{R(BD)}(0.301\sin a + 0.019(D_{50})^{-2.22})(1 - e^{-2.42\sin a}) \tag{7}$$

where qs is net downslope splash transport ($m^3\,m^{-1}\,a^{-1}$), KE is rainfall kinetic energy ($J\,m^{-2}\,a^{-1}$), R is resistance to detachment ($J\,kg^{-1}$), BD is bulk density ($kg\,m^{-3}$), a is slope (degrees) and D_{50} is median grain size (m).

For interrill flow, as with all sediment-transporting media, research has focused on the amount of sediment that can be transported – the sediment transport capacity, and the size of sediment that can be transported – the sediment transport competence. Several authors have attempted to apply transport-capacity equations developed for alluvial rivers (see the discussion in Ferro, 1998), and such derivations have been used in process-based models of soil erosion (e.g. Nearing *et al.*, 1989) even though the hydraulic conditions in shallow overland flow are very different from those in rivers. Everaert (1991) developed a range of equations for transport capacity TC ($g\,cm^{-1}\,s^{-1}$) of interrill flow for particles of different sizes D (μm), based upon Bagnold's (1980) modified stream power Ω ($g^{1.5}\,s^{-4.5}\,cm^{-0.67}$) that have the general form

$$TC = a\Omega^b D^c \tag{8}$$

where a is a constant and b and c are exponents that vary with particle size. Everaert noted that these equations were developed from experiments performed on regular beds, whereas interrill flow typically takes place on irregular surfaces. However, he argued that because stream power takes account of the effect of irregular beds on flow velocity, it is a suitable basis for interrill transport-capacity equations. Agarwal and Dickinson (1991) studied the effects of particle size, slope, and discharge on transport capacity of overland flow and undertook multiple regression to produce

$$q_s = Cq^{b1}S^{b2}D_{50}^{b3} \tag{9}$$

where q_s is sediment transport capacity ($Kg\,m^{-1}\,s^{-1}$), q is unit discharge, S is slope ($m\,m^{-1}$), and D_{50} is median particle size (mm).

Abrahams *et al.* (2001) proposed that sediment-transport capacity for turbulent interrill overland flow could be given by

$$\phi = a\theta^{1.5}\left(1 - \frac{\theta_c}{\theta}\right)^{3.4}\left(\frac{u}{u_*}\right)^c\left(\frac{w_i}{u_*}\right)^{-0.5} \tag{10}$$

where ϕ is the dimensionless sediment transport capacity, θ is the dimensionless shear stress, θ_c its critical value, u is

flow velocity, u_* is shear velocity, w_i is the inertial settling velocity (all $m\,s^{-1}$) of the sediment, and a is given by

$$\log a = \frac{-0.42C_r}{D_r^{0.2}} \tag{11}$$

where C_r is the concentration and D_r the size of the roughness elements (m), and c is given by

$$c = \frac{1 + 0.42C_r}{D_r^{0.2}} \tag{12}$$

However, much interrill overland flow is not fully turbulent, so that the validity of this equation for interrill flow, in general, may be questionable.

Wainwright and Parsons (1998) demonstrated the strong dependence of such equations on a knowledge of the hydraulics of flow. Such knowledge is seldom available. Even, as in their case, where a good estimate of the flow hydraulics is available, the differing relationships of these equations to depth of flow means that small errors in the estimation of this quantity can lead to markedly different predictions from the various equations.

The fundamental problem for understanding sediment transport in interrill flow is that sediment entrainment is achieved by the energy of falling raindrops (Young and Wiersma, 1973), whereas transport is mainly due to flow energy. Both Agarwal and Dickinson (1991) and Abrahams *et al.* (2001) sought to avoid the issue of sediment entrainment by delivering sediment to the flow from a hopper such that their analysis was concerned only with the ability of the flow to transport the sediment supplied to it. Parsons *et al.* (1998) argued that sediment transport by interrill flow needs to consider not only the capacity of the flow, but also its competence. Individual particles will be detached by raindrops and then transported a finite distance before coming to rest. Both the detachability and the transport distance of the particle are a function of its size. These authors undertook laboratory experiments and developed a general equation to predict travel distances of particles ranging from 3 mm to 10 mm in diameter under rain with intensities up to $138\,mm\,hr^{-1}$ falling onto shallow flow up to 5 mm deep. Their equation is

$$ML = 0.525RE^{2.35}FE^{0.981} \tag{13}$$

where M is particle mass (g), L is travel distance/unit time ($cm\,min^{-1}$), RE is rainfall energy ($J\,m^{-2}\,s^{-1}$), and FE is flow energy ($J\,m^{-2}\,s^{-1}$). Parsons and Stromberg (1998), using the same data set, developed a relationship for L against particle diameter D (cm). Their relationship

$$L = 9970D^{-3.44} \tag{14}$$

accorded with research undertaken by Church and Hassan (1992), showing that travel distance declines with particle size more rapidly than might be expected. They showed that this sharp decline in travel distance was due mainly to the fact that the probability of coming to rest increases rapidly with increasing particle size. In contrast, the probably of entrainment is much more weakly related to particle size. Such a relationship is consistent with the observation that sediment transported in interrill flow is finer than that detached by rainfall (Parsons *et al.*, 1991). Parsons *et al.* (2004) applied equation (13) to particles 80 μm in diameter and obtained good agreement between measured and predicted travel distances.

Since sediment detachment and transport are both dependent on the depth of interrill flow, the former inversely and the latter directly so, the two are not independent. Abrahams *et al.* (1991) investigated the downslope pattern of sediment transport on a large runoff plot in southern Arizona, and showed that initially sediment transport increased with distance from the top of the plot, but that it subsequently decreased. These authors attributed this pattern to downslope changes in the spatial pattern of interrill flow. However, an alternative interpretation that is consistent with the results of Parsons *et al.* (1998) is that sediment transport by interrill flow decreases downslope because of the reduction in detachment by raindrops with increasing flow depth (equation 6), and a less than compensatory increase in the effect of flow energy (equation 13).

RILL EROSION AND SEDIMENT TRANSPORT

As threads of interrill flow become deeper and faster, a threshold is reached beyond which significant flow detachment begins to take place. Once this occurs, the flow begins to erode definable channels or rills, on the hillslope. The threshold for erosion by flow and the formation of rills has been investigated by Govers (1985), Govers and Rauws (1986), and Bryan and Poesen (1989). These authors collectively came to the conclusion that a shear velocity of around $3–3.5\,cm\,s^{-1}$ was necessary for rills to develop. Rauws and Govers (1988) developed a relationship between the critical grain shear velocity and soil cohesion whereby

$$u_{*_{cr}} = 0.89 + 0.56C' \tag{15}$$

where $u_{*_{cr}}$ is critical grain shear velocity ($cm\,s^{-1}$) and C' is soil cohesion (kPa). However, as Nearing (1991) has pointed out, although the shear stress exerted by shallow flow around such a threshold is of the order of a few pascal, the typical shear strength of soils is several kPa. Furthermore, Nearing (1994) conducted laboratory experiments that demonstrated that, for similar mean shear stress, sediment entrainment by laminar flow is negligible compared to that for turbulent flow. These experiments

provide empirical support for the argument that sediment entrainment by shallow flow, and hence rill initiation, is only possible where the flow is turbulent. The important characteristic of turbulent flow is that, although mean shear stress may be only a few pascal, local and instantaneous shear stress can be two or more orders of magnitude higher, and hence sufficient to exceed soil shear strength. Parsons and Wainwright (in press) developed this argument further, noting that, whereas Nearing (1991) proposed that both turbulent-burst shear stresses and soil shear strength are normally distributed, the available evidence indicates that log-normal distributions are more characteristic (see Foster *et al.*, 1984; Parsons and Wainwright, in press). In addition, they drew attention to the study by Dunne and Aubrey (1986) which showed that, although incision may occur in response to soil detachment by flow, the formation of rills is inhibited by soil detachment by rainfall. Consequently, they proposed a threshold between rilled and unrilled surfaces that depended on three parameters: flow energy, rainfall energy, and soil-strength variability (Figure 1).

As with interrill overland flow, the transport capacity of rill flow has typically been estimated using equations taken from the literature developed for alluvial rivers. Govers (1992) undertook an analysis of the performance of these equations for shallow rill flow, and concluded that none performed well over the range of conditions he tested. He argued that previous positive results for some equations (e.g. the conclusion by Alonso *et al.* (1981) that Yalin's (1963) equation gave the best results, and Moore and Burch's (1986) successful application of unit stream power theory) were obtained because the experiments used in the evaluations were over a very limited range of conditions (e.g. in experiments by Alonso *et al.*, the slope never exceeded $0.07\,\mathrm{m\,m^{-1}}$, and all data used by Moore and Burch were collected on slopes of less than $0.05\,\mathrm{m\,m^{-1}}$),

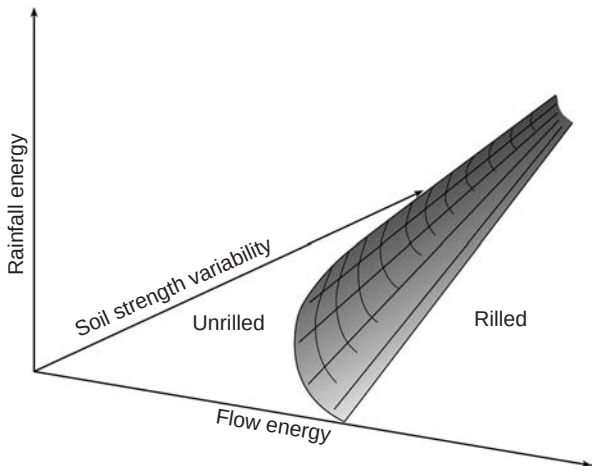

Figure 1 Parameters controlling the onset of rilling (after Parsons and Wainwright, submitter)

and that the empirical basis of all existing equations means that they are unlikely to be good predictors outside the domain for which they were developed. Nearing *et al.* (1991) demonstrated relationships between detachment by shallow flow and flow depth, slope, and size of aggregates. They showed that the detachment rate was not a unique function of either shear stress or stream power, and argued that if either variable were the correct one for determining detachment rates, then these rates would be equally sensitive to slope as to flow depth. However, their experimental results showed a greater sensitivity to slope than to depth. Brown *et al.* (1989) identified reduced rates of rill erosion as a result of incorporation of crop residue into the soil. They interpreted this result as caused by the stabilizing effect of crop residue on sand-sized aggregates.

Sediment transport by rill flow is equally determined by the competence of the flow. This is particularly the case for stony soils. Poesen (1987) undertook an analysis of sediment transport in rills in the loess region of central Belgium, and concluded that coarse rock fragments were more readily removed in shallow rill flow (implying a small ratio of flow depth to rock-fragment size) than might be anticipated from the Shields criterion, for which he proposed a critical value of 0.015 compared to the value of 0.05 used for flows on gentle gradients and for which the ratio of flow depth to sediment size is large. However, Abrahams *et al.* (1988) argued that higher values of the Shields criterion are needed to initiate movement of particles as the ratio of fragment size to depth decreases (particularly in cases where the ratio is <1).

GULLY EROSION AND SEDIMENT TRANSPORT

Thomas and Welch (1988) argued that the Universal Soil Loss Equation often underestimates erosion on agricultural land because it fails to take account of erosion from ephemeral gullies. More recent models for predicting soil erosion (e.g. EUROSEM, Morgan *et al.*, 1998), likewise, deal with rill and interrill processes but fail to model gully erosion. However, Foster (1986) suggested that gully erosion may be of equal importance to the sum of rill and interrill erosion. Osborn and Simanton (1989) noted that, whereas there is considerable qualitative literature on gully growth and development, quantitative information is limited. However, a more recent review by Poesen *et al.* (2003) presents data from a range of environments showing that gullies account for between 10% and 94% of total soil loss. Poesen and Govers (1990) distinguished between ephemeral gullies and gullies associated with banks. The former are continuous, temporary channels that may be capable of being obliterated by cultivation, but which recur in the same place during subsequent runoff events. Ephemeral gullies result from concentrated flow erosion,

that is, sediment detachment and transport are functions of flow intensity (Poesen and Govers, 1990). Begin and Schumm (1979) developed a relationship for the critical flow shear stress τ_{cr} whereby

$$\tau_{cr} = (c\gamma)A^{rf}S \tag{16}$$

where A is drainage area (ha), S is slope ($m\,m^{-1}$), rf is an exponent, c a constant and γ the weight of water per unit volume. Inasmuch as A and S together define threshold conditions for gully initiation, locations with and without gullies may be defined in terms of a discriminant function of the form

$$S = aA^{-b} \tag{17}$$

Vandaele *et al.* (1996) and Vandekerckhove *et al.* (2000) present a range of such functions for a number of sites and land-use conditions across Europe. Poesen and Govers subdivided ephemeral gullies according to their width–depth ratio (WDR): those that have a WDR ≤ 1, and those with WDR $\gg 1$. The latter can generally be removed by tillage, whereas the former cannot. Watson *et al.* (1986) developed a model to predict ephemeral gully width W where

$$W = 2.66Q_p^{0.396}n^{0.387}S^{-0.16}\tau^{-0.024} \tag{18}$$

where Q_p is peak flow discharge ($m^3\,s^{-1}$), n is Manning's roughness coefficient and τ_{cr} is critical flow shear stress (Pa). Nachtergaele *et al.* (2002) presented a simpler equation for the width of gullies in cropland where

$$W = 2.51Q^{0.412} \tag{19}$$

The similarity of the exponents in these equations around 0.4 also agrees with that obtained by Sidorchuk (1999). For ephemeral gullies in calcareous loess in central Belgium, Poesen *et al.* (1998) related detachment rate DR ($kg\,m^{-2}\,s^{-1}$) to concentrated flow shear stress τ ($N\,m^{-2}$), such that

$$DR = 0.75\tau - 0.08 \tag{20}$$

Gullies associated with banks form where a flow line crosses a steep bank in the landscape (often artificial). These gullies cannot be obliterated by tillage and are permanent. Poesen (1989) has shown that, unlike ephemeral gully erosion, flow intensity is not a dominant factor explaining erosion from gullies associated with banks. Local factors such as piping, mass movement and biotic influences play a significant role in the development of these gullies, and hence the amount of erosion that takes place in them. Gomez *et al.* (2003) used aerial photography to develop a relationship between sediment production and gully area over a period of 49 years in the Te Weraroa catchment in New Zealand. The relationship they obtained was

$$y = 460 + 2750x + 160x^2 \tag{21}$$

where y is sediment production ($m^3\,yr^{-1}$) and x is gully area (ha).

MODELING HILLSLOPE EROSION AND SEDIMENT TRANSPORT

Two main groups have undertaken modeling of hillslope erosion and sediment transport: geomorphologists and agricultural engineers. The latter group is concerned with soil erosion, particularly on agricultural land. The former group is concerned both with short-term modeling of erosion and sediment transport, where their work overlaps and can be considered with that of the agricultural engineers, and with long-term hillslope and landform evolution. There is a shared history, inasmuch as, through time, both demonstrate increasingly explicit representation of processes in their modeling as understanding of processes has increased and increased computing power has become available.

Modeling long-term hillslope and landform evolution can be dated at least as far back as the work of Fisher (1866), though the work of the likes of Bakker and Le Heux (1946, 1947, 1950), and Scheidegger (1961) and Hirano (1966, 1968, 1972, 1975, 1976). However, all such models are, at best, only weakly founded upon intuitive generalizations about the operation of hillslope processes (Parsons, 1988, p. 154). Kirkby (1971) argued that a general equation for the transport capacity C of hillslope processes that applies to all processes of entrainment and transport by water could be presented such that

$$C = f(a) \cdot \left(-\frac{\partial y}{\partial x}\right)^n \tag{22}$$

where a is the area drained per unit contour length, and n is a constant exponent describing the influence of increasing gradient. If it is assumed that erosion takes place at transport capacity and base level is fixed, then characteristic forms will evolve for each $f(a)$ and n. More recent long-term modelling of erosion has tended to consider three-dimensional landscape evolution and to adopt a numerical-simulation approach. Armstrong (1976) developed a similar transport-capacity driven model for landscape evolution, but allowed the rate of sediment removal also to be constrained by the rate of weathering. Willgoose *et al.* (1991a, b) developed the SIBERIA model in which

$$q_s = q_{sf} + q_{sd} \tag{23}$$

where q_s is sediment transport rate per unit width, q_{sf} is fluvial sediment transport, and q_{sd} is diffusive sediment transport (all $m^3 s^{-1} m^{-1}$ width). q_{sf} is given by

$$q_{sf} = \beta_1 q^{m_1} S^{n_1} \tag{24}$$

and q_{sd} by

$$q_{sd} = DS \tag{25}$$

where q is discharge per unit width ($m^3 s^{-1} m^{-1}$ width), S is slope ($m m^{-1}$), D is diffusivity ($m^3 s^{-1} m^{-1}$ width), and β_1, m_1 and n_1 are calibrated parameters. These, and other similar models share with Kirkby (1971) the representation of erosion processes and sediment transport as functions of slope length and/or gradient.

Soil erosion models have evolved to make explicit use of many of the erosion and sediment transport equations presented above. Early models, such as the USLE (Wischmeier and Smith, 1978), employed simple regression techniques to establish relationships between erosion rates and parameters of rainfall (intensity), soil (erodibility), slope (length and gradient), crop type and management practice, but without explicit representation of individual processes. More recent models (Nearing *et al.*, 1989; Morgan *et al.*, 1998) have taken explicit account of both interrill and rill erosion. In EUROSEM (Morgan *et al.*, 1998), for example, interrill detachment DR ($m^3 s^{-1} m^{-1}$) is modeled using the equation

$$DR = \frac{k}{\rho_s} KE e^{-qh} \tag{26}$$

which is equivalent to merging equations (1) and (6), with explicit determination of A_0, where k is an index of soil detachability ($g J^{-1}$), ρ is particle density ($kg m^{-3}$), and KE is rainfall kinetic energy ($J m^{-2}$), and interrill sediment transport capacity is modeling using the equation based on those developed by Everaert (1991).

Although members of this latest generation of soil erosion models make use of recent developments in understanding of erosion and sediment transport, they fail to include gully erosion (primarily because, as noted above, these models are for soil erosion on agricultural land, and the existence of gullies precludes mechanized agriculture), which tends to be studied separately (e.g. Sidorchuk, 1998; Woodward, 1999). However, to develop a full understanding of rates of erosion in different settings, gully erosion must be included. Furthermore, these models separate erosion and sediment transport in rills and interrill areas, whereas, in reality, there are dynamic changes during an erosion event such that rills grow in interrill areas. Favis-Mortlock (1998) developed a model to simulate the initiation of rills on previously unrilled surfaces. While this model is grounded in an explicit representation of erosion and transport processes, there remains some way to go, before a full understanding of the process of rill initiation is developed. The next step in modeling erosion and sediment transport processes on hillslopes needs to be the development of fully dynamic models that permit the growth of both rills and gullies.

81: Erosion Monitoring

BENT HASHOLT

University of Copenhagen, Copenhagen, Denmark

First the need for and relevance or erosion monitoring is stated, and then definitions, terms and classifications of the topic are described. The monitoring is treated for active erosive agents under natural conditions and at different scales. Monitoring in controlled systems and in laboratory experiments are treated separately. Special emphasis is on problem encountered in monitoring programs. References on key instrumentation are provided.

THE NEED FOR AND THE MEANS OF EROSION MONITORING

Erosion has a central role in global material cycling; our whole perception of the formation of the surface of the earth is based on knowledge of land forming processes and geological processes, such as orogenesis and the ensuing denudation of the mountain ridges. Monitoring of erosion is fundamental for establishing the rates of these processes. It is therefore of primary significance for the evolution of basic research in geosciences. Scientific subjects such as geomorphology, geochemistry, and geology need to monitor erosion processes in order to understand mechanisms and to extrapolate in space and time. Erosion monitoring is therefore one of the basic issues in quantitative interpretation of basic research in these fields (Loughran, 1989). It is of ultimate importance to be able to quantify the outcome of different processes in order to determine their relative significance. Within recent decades, modeling of the global material cycles has become increasingly important in order to assess the growing impact of man. To produce models that provide relevant and reliable results, it is important that all major processes are included, the mechanisms known and their relative importance quantified. Monitoring is therefore essential to provide knowledge of processes and to provide data for model testing and validation within basic research in the geosciences.

Erosion monitoring is of similar importance in fields of applied science, such as agricultural engineering and construction engineering. In these cases, there are direct practical needs for the results of the monitoring. The growth of the population of the Earth leads to utilization of former virgin land and often the more intensive use of already cultivated areas. Sustainable rates of erosion must be established for different types of land and different types of crops and agricultural practice. Other human activities that reshape the surface of the Earth include urbanization and large-scale construction works. Urbanization in developing countries might lead to severe erosion problems that need to be monitored, so that they can be taken into account in city planning. Engineers working in the field of river training and regulation have long recognized the need for monitoring, and much progress in the understanding of erosion and transport processes originate from this field. A specialist aspect of construction work is the building of large dams for power production, irrigation and flood control, and often all purposes are combined. The lifetime of these reservoirs is very dependant on erosion rates in their catchments, but also the effect of the dams on erosion and sedimentation in river-reaches below the dam might need to be monitored in order to cope with environmental problems, for example, scour at installations close to the river and/or damage to coral reefs due to flushing of reservoirs.

To summarize, erosion monitoring is of critical importance both for the further development of basic earth sciences and for applied sciences dealing with construction works of vital importance for sustainable human life.

DEFINITIONS, TERMS, AND CLASSIFICATION OF EROSION MONITORING

Erosion is the removal of material (as chemical compounds or in particulate form) from surfaces caused by one or more active agents. Active agents are: wind (sometimes including the content of snow or particulate matter), rain,

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

running water, sediment-laden water, mass movements, and glaciers. A complete review of erosion monitoring should therefore include all the agents mentioned However, most monitoring literature tends to concentrate on water and wind, probably because these are most often encountered when dealing with practical erosion problems in populated areas.

Different physical processes are active for the different agents; therefore, there is an interaction between monitoring and perception of process. Looking at erosion on a microscale, the monitoring could focus on the very moment that a chemical compound or a particle is removed from the surface; it could focus on the void left by the particle or the velocity and mass of the removed matter, that is, the transport. From a monitoring point of view, it is therefore important to distinguish the process of erosion, the forms caused by removal of material, or the transported matter released by the process. However, such a distinction is not always possible and must partly be considered as a scale issue. From the microscale to the global scale, erosion takes many different forms and could therefore be classified according to both agent and scale. Often monitoring embraces a cascade of processes and only considers the end result, for example, monitoring the sediment output from a plot, without considering the several phases of erosion and sedimentation occurring within the plot, before the sediment reaches the outlet of the plot.

Very often erosion is monitored by measuring the transport of material released by erosion. A problem related to measurements of transport is that the transport very often consists of different phases, for example, fluids and particles, which have to be monitored separately, for example, by filtering of water samples. Another classification of monitoring might be based on the methodology employed, but this approach is difficult because of conflicts with scale and process issues. An important precondition for the monitoring of erosion is the ability to identify types of processes and the related morphological forms, for example, drop marks, rills, and gullies. There is a clear need for standardized definitions of erosion patterns and their dimensions. An example of an attempt to standardize the recording and mapping of erosion features is found in Mollenhauer (1995) and Thorne (1998).

In the following section, the description of erosion monitoring is based on erosive agent and on types of erosion from small scale to larger scale, assuming that the practical use of an encyclopaedia will be to find examples of how to monitor different types of erosion, either for pure practical reasons or for experimental purposes.

EROSION BY WATER

Rain

The energy of falling raindrops can cause erosion, termed *splash erosion*, which can be separated into the detachment of particles and the associated saltation of the particle caused by the collision impact. Erosion can be measured as material removed from the surface by comparison of images obtained before and after the erosion event; the procedure is facilitated by image-analyzing software. Mass transfer can be determined using image analysis on records assembled using high-speed cameras. Tracers, for example colored particles, can be used to measure travel distances and particle sorting. Often different types of trap are used to collect the material moved by splash erosion, for example, splash boards or plates that are placed near the erosion surface and weighed before and after an erosion event. In other cases, funnels are located flush with the surface and the material is collected in a bottle below the funnel. In other cases, splash cups may be used. Here a sample of soil in the center of the cup is exposed to the rainfall and the detached material is collected in the surrounding tray (see Figure 1). The size of the splash cup influences the result and must be taken into account in correction of the result, (Poesen and Torri, 1988). Rainfall intensity and related energy are the most important causes of erosion, however, wind speed and direction relative to slope, and the aspect of the eroded surface, play an important role in influencing the amount of erosion; to explain differences in the results, it is important to include such measurements in the monitoring programe.

Running Water

Running water on the surface will occur either because of saturation of the soil with water (saturation overland flow) or because the infiltration capacity is exceeded by the rainfall intensity (Hortonian overland flow). Water on the surface is critical for the occurrence of erosion; however, it is rather difficult to observe this kind of flow and even more difficult to monitor it. Very often it is important just to

know if overland flow has occurred, and an overland flow sampler can be used (Figure 2). The sampler can be placed in minor depressions in the landscape but are often placed at "worst-case" locations, that is, places where overland flow will occur each time there is overland flow. The sampler will then indicate whether erosion by running water has been possible, but to quantify the amount, it is necessary to install several samplers. The small size of the sampling device reflects the need to place it in small depressions in the terrain, with the requirement that it should be easy to install and should not interfere with the management of agricultural fields. The flanges at the intake section assist water intake, prevent undercutting by running water, and define the width of the intake area (Hasholt, 1998). The time sequence of overland flow can be determined by installing a pressure transducer in the collecting bottle. Most eroded location spots commonly coincide with the concave parts of slopes with small depressions, protorills or previous pathways of running water.

The detachment of single particles can be observed either by the naked eye or using cameras. Often such observations are carried out in flumes where the bed is covered with homogenous material to determine critical bed shear stress or critical velocity. In nature, erosion by running water might be represented by linear features and particle separation on the surface, leaving streaks of sand and coarser particles. This type of erosion is termed *sheet erosion* or *interrill erosion. In situ* it can be observed using analysis of high-speed camera images. Often the erosion is determined using repeated surveys of the surface. The lowering of the surface is the net erosion after the erosion event. An alternative technique is to measure the lowering of the surface relative to markers placed in the surface, for example, erosion pins. The number of pins and their spacing determines the accuracy of the monitoring. The pins must not be too large and create their own scour patterns; on the other hand, they should be large enough to resist the erosive forces. Erosion might also be observed relative to natural objects in the field, for example, tree roots and rock outcrops. In urban areas, the erosion can be related to foundations of houses or fences. Due to its large area and its small vertical change, sheet erosion is difficult to monitor for shorter time durations or single events. An alternative approach involves the use of tracers; this will be described later in relation to erosion from slopes. Special problems occur on cultivated fields, because the tillage operations may allow only a small time "window" for operation of samplers that have to be removed before ploughing or harrowing. Larger samplers employing the same trapping principle have been constructed by Gerlach (1966). A gutter of approximately 50-cm width (Figure 3), is buried on the slope to be investigated, and several gutters are often placed *en echelon* on the slope. It is then important that the volume of the collection bottles for the lower troughs should match the larger runoff values. Several problems have been observed, in particular when freezing occurs, the lip can be displaced so that bypass and undercutting might occur, and the pits for the collecting bottles can be filled with water, unless they are properly drained. It is also difficult to determine the contributing area exactly. However, useful information about the occurrence and frequency of erosion events can be obtained. The samplers described above and other trap-type samplers are capable of monitoring interrill erosion and to indicate whether erosion by running water has occurred. Rain splash can impact through the film of running water, so that soil detachment and transport occur simultaneously.

Rill erosion is characterized by recognizable micro "stream channels", as a certain critical shear velocity must

be surpassed in order to initiate rills, the amount of surface runoff, and therefore, the contributing area needs to be greater than for sheet erosion. The slope length needed to initiate rills is usually more than 10 m. To monitor rill erosion in nature, one has to be able to find places of occurrence and to identify the form. Risk maps might be used to assess the areal extent of rill erosion, but field observations are often needed to test the predictions from the risk maps. Once the location of rills is satisfactorily determined, a measuring program can be initiated. If the dimensions of a single rill are measured in selected cross-sections, the eroded volume for a reach of the rill can be determined by multiplying the cross-sectional area by half the length of the rill between consecutive cross-sections. Assuming that a correct volume can be determined by measurements of cross-sections every 50 cm, it was found that the rill volume can be determined within ± 5 % using a spacing of *circa* 5 m between cross-sections. To monitor the erosion from a whole rill system, a transect must be laid out along the contours and the cross-section of the intersecting rills must be measured. Counting of rills and measurement of representative rills might also be applied. Large-scale aerial photos or satellite images can be applied to locate rill systems, and, to a certain level, to also measure the lengths of rills. However, minor rills might only be observed by careful fieldwork. Major effort has to be spent on representative evaluation and calculation to obtain accurate observations.

Gullies are relatively permanent steep-sided water courses that experience ephemeral flows during rain storms; they are often characterized by a head cut and various steps or knick-points along their course. They can be monitored in the same way as for rills; however, their larger dimensions might call for use of theodolites and optical distance meters. For the location of gully areas, aerial photos and satellite images might be more useful. Measurements of the volumes of both rills and gullies will not include sediment transported from the interrill and intergully areas, and the overall erosion therefore tends to be underestimated. Theoretically, this erosion could be monitored if the flow of water and sediment in rills and gullies were recorded during erosion events. However, as these forms originate during the erosion event, choosing the right location for monitoring equipment is nearly impossible. Furthermore, because of the ephemeral character of the flow, very frequent sampling is needed. Because of the large range of particle sizes transported, the sampler also has to be capable of dealing with this. Another problem, particularly in the case of rills, is that farmers till the soil as soon as the soil is dry enough after the winter, when erosion often occurs. This leaves a very small "time window" for monitoring of rill systems in cultivated areas. Monitoring of erosion on hillslopes must include measurement of the deposition of material at the lower part of the slopes; otherwise the net erosion is overestimated. On its way to the permanent drainage system, the eroded material, when passing across the banks of streams, might cause bank erosion, which can be monitored using surveying methods or erosion pins. Erosion associated with channel, bed, and bank erosion can be monitored using surveying methods. However, this approach cannot account for rapid changes. A method for continuous registration of bank erosion (PEEP) has therefore been developed by Lawler (1992).

An evaluation of sediment mobilization within a catchment must in principle be undertaken at all erosion localities in the catchment, for example, hillslopes and streams. However, such a task is huge and therefore unrealistic, and the catchment is commonly divided into smaller representative areas. Such sampling areas are chosen to represent different scales, from single field to slope units and first order catchments nested inside the study catchment.

Another method used to describe the areal extent of erosion and deposition is measuring the redistribution of selected tracers (Zapata, 2002). Caesium-137 is the most commonly used tracer in soil erosion measurements. This radionuclide was produced from the 1950s to the 1970s by atmospheric testing of nuclear weapons. After it was distributed globally in the stratosphere, it was subsequently deposited on the Earth's surface by rain and as dry fallout. Regional variations in fallout as a result of precipitation-amount occur, but within small areas a reasonably uniform spatial distribution can be assumed. After reaching the surface, the isotope is quickly and strongly adsorbed to clay and fine silt particles in the soil, and an absence of particles capable of adsorbing the isotope is a potential limitation for the application of the method. Since the method was pioneered in the United States by Ritchie and McHenry (1975), it has been applied successfully in many regions. A thorough description is given in Walling and Quine (1990). The radiocaesium content of soil cores collected on a grid system varying in density from 10×10 m to 20×20 m is determined and the spatial pattern of caesium-137 inventories is established. Figure (4) (Walling and Quine, 1990) illustrates the principles of the method. An area that has no erosion or deposition and has not been cultivated is commonly used as reference site, most of the isotope being found near the surface. The presence of the radiocaesium at depth is assumed to be caused by biological activity, for example, earthworms. Cultivated land is characterized by a more even distribution down to the plough depth. At sites with no erosion, the inventory is the same as at the reference site. At eroded locations, the inventory is less and at deposition sites the inventory is larger than at the reference site. The radiocaesium inventory can be calibrated to estimate erosion and deposition rates by comparison with samples collected from erosion plots, where the erosion rate is known (see below). Point estimates of soil loss may differ by as much as an order of magnitude;

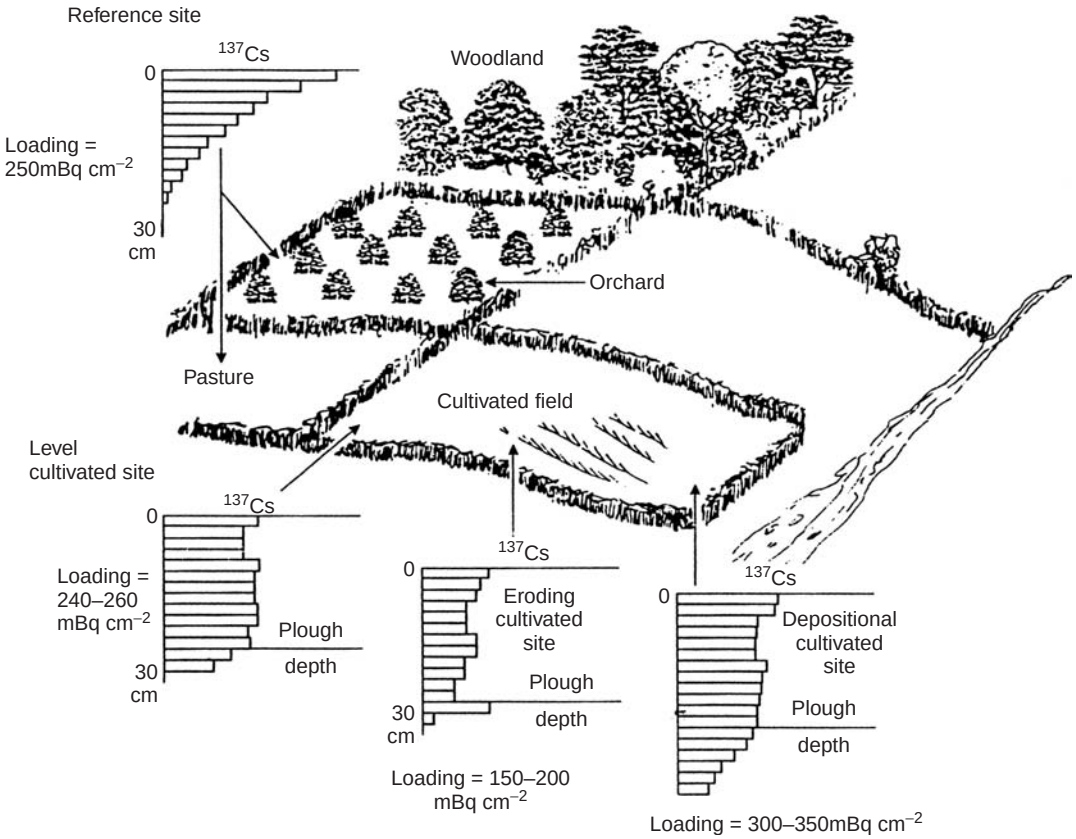

Figure 4 Schematic representation of the effect of erosion and deposition upon the loading and profile distribution of caesium-137. (Reproduced from Walling and Quine, 1990, by permission of John Wiley & Sons)

possible errors include uneven mixing of the radionuclide in the cultivated layer and changes in land use since fallout. Preferential adsorption of the isotope during the processes of erosion, transport, and deposition may be another source of error. The method accounts for the sum of all erosion processes, whereas other measurements, for example, erosion plots, may represent only the influence of interrill and rill erosion.

When delivered to the drainage system, the eroded material can be monitored while passing a gauging station located at a cross-section near the catchment outlet. Eroded material is carried by the water either in solution or as particles. In both cases, the concentration has to be determined, either by chemical analysis, by filtering, or by centrifuging. The transport rate is calculated as the flow of water multiplied by the sediment or solute concentration.

Water flow can be monitored using weirs and current meters, or electromagnetic sensors, (Hershey, 1999). Water samples used to measure suspended sediment concentrations should be collected using isokinetic samplers so that particle separation is avoided, (Hershey, 1999). Sampling must represent the actual distribution of the particulate matter, and an average concentration can be obtained using depth-integrated sampling, and standardized methods are described in ISO manual 4363. Several investigations have demonstrated that very frequent sampling is necessary to obtain accurate and reliable results in the case of erosion events caused by storms. Several types of automatic water sampler have been constructed to overcome this problem. Water is drawn into an evacuated sampling bottle or pumped using different types of pumps, for example, peristaltic pumps as in the ISCO sampler.

The main problems using automatic water samplers are finding of a representative location for the intake and the need to regulate the flow velocity in the intake to avoid particle separation. Indirect measurements for determining the concentration of specific ions and of particles have been employed, but all methods need calibration against standard analysis. Successful application of transmissometers that measure the obscuration or attenuation of white or infrared light in a measuring gap due to the presence of particles has, for example, been reported by Walling (1977) using Partech equipment. Other sensors measure the optical backscattering caused by the presence of particles. In the case of very high concentrations, measurements of the attenuation of γ-radiation have been employed. The location of the sensors can be a problem, together with the fouling of the sensors. Sensors must be located where the

stream is flowing freely, without influence from upstream point sources; in some cases they must be located within a stream concentrator, Hasholt (1991). If the sensors are located in the stream, false results may occur because of drifting debris collecting on the sensor. In this case, self-cleaning, for example swing mountings, can be used. To minimize fouling, at least weekly cleaning may be necessary. Some sensors wipe themselves clean at regular intervals or keep the measuring gap protected until the measuring time. A particular problem is the monitoring of bed load together with the unsampled zone below the intake of the samplers mentioned above. In principle, bed load can be monitored using different types of traps. Pit traps are buried flush with the riverbed; it is, however, very difficult to keep the pit-sampler flush with the mobile bed surface. Another type of sampler, the so-called pressure-difference sampler, has a smaller intake section that is gradually widened so that the streamlines inside the sampler diverge causing velocity to drop and the moving sediment to settle. After a period of time, the sampler is brought to the surface and the collected sediment is weighed and the transport rate is calculated from the time of exposure of the sampler on the riverbed. Another method involves repeated surveys of moving bed-forms; the velocity of the bed-form may be found and multiplied with the average height of the bed-form along its full length. Tracers can also be used, for example, magnetic particles, or particles dyed with fluorescent colours that can be counted under ultraviolet light. In the case of bed load consisting of larger particles, pebble size, built-in radio transmitters may be traced using special antennas (Ergenzinger *et al.*, 1989). Continuous recording of bed load has been carried out using pressure transducers built into the riverbed, or underwater microphones that record the noise of the impact of the transported particles. A thorough review of bed load monitoring methods is presented in Hubbel (1964) and new techniques are described in Kuhnle and Derrow (1994).

The results from gauging stations are often considered evenly distributed over the catchment area, however, if the catchment is large, for example, greater than 10 km^2, it may be very difficult to relate the transport at the gauging station to erosion events or certain types of erosion directly, because of delivery delays and sedimentation within the catchment. Lakes and reservoirs in catchments may be used to measure sedimentation. The volume of the reservoir can be surveyed at successive occasions, and the difference between survey is then the sedimentation volume caused by net upstream erosion in the catchment. To determine the erosion by weight, the density of the deposited sediment must be determined by analyzing representative cores. The volume differences can be determined quite rapidly using echosounders and a combined positioning system based on GPS. Before the results are applied, they must be corrected for bypass loss based on knowledge of the trap-efficiency of the lake or the reservoir (Brune, 1953).

MASS MOVEMENTS

Water plays a role in debris flows and mass movements, mostly by increasing mass beyond a critical point or by providing lubrication and the presence of slip surfaces. Large masses of material may be eroded and moved by these processes. Monitoring is mainly carried out using surveying techniques, as discussed above. Mass movements can be monitored using laser distance meters or transmitting GPS location devices. Because of the episodic occurrence of mass movements, it is very difficult to establish monitoring programs, and monitoring is therefore often *ad hoc* and carried out at places where these movements interfere with road works or other technical installations. Very few, if any, investigations of mass movements in whole catchments exist (Temple and Rapp, 1972; Selby, 1993).

EROSION BY WIND

Erosion by wind can be monitored using the same surveying methods that are applied for water erosion. An indication of the efficacy of wind erosion may be obtained by grain size analysis of eroded surfaces and surfaces in depositional areas. Often, wind erosion on fields can be estimated by measuring the depth of sediment deposited against hedges and shelter belts, although fine material can be carried very long distances. From personal experience, for example, in Ghana during the Harmattan, dust from source areas 1000 km away can be caught in traps. As a result of shifting wind directions and simultaneous changes in the length of fetch, it is very difficult to relate wind erosion to specific areas.

On site, different types of trap are applied for monitoring the transport caused by the erosion. The horizontal pit type is buried level with the eroding surface, the catch of sediment varying with the length of the sampler along the wind direction (Borsy, 1972). It is very difficult to estimate the contributing area because of shifts in the direction of the wind. Other types of samplers are trays placed vertically above the surface; they are operated by the pressure-difference principle, like many river bed load samplers. To keep the orifice orientated into the wind, the sampler can be mounted with bearings and a vane so it can follow the shifting wind directions. Several types are described by Bagnold (1941), and Nickling and McKennea Neuman (1997), for example. Such equipment can also be made continuously-recording by mounting the collecting tray on a recording balance. Other automatic monitoring devices are based on acoustics, and record the noise created by the impact of the moving particles on a membrane

with a microphone behind, for example, the saltiphone developed at the Agricultural University, Wageningen, in the Netherlands (Spaan and van den Abeele, 1991). Calibration against other traps is, however, needed.

EROSION BY ICE

This kind of erosion is rarely included in normal monitoring programs, probably because it acts over longer timescales and is not active close to populated areas. Recently, this type of erosion has become of interest because of the growing interest in global material budgets and the development of hydropower plants in glaciated areas. The effect of glacial erosion can be monitored using surveying methods to measure the volume of the landforms created by the moving ice. Subglacial erosion has been monitored at Bondhusbreen, Norway (Østrem, 1975), where eroded sediment was collected in a sedimentation chamber close to the sole of an active glacier. This chamber acts as a sediment trap, which is emptied from time to time. From the same area, information about eroded volume can be obtained from cores taken in a proglacial lake where the thickness of varves can be measured. Glacial erosion is often quantified by establishing a gauging station on a proglacial river, just outside the terminus of the glacier. Such investigations are described by Gurnell and Clark (1987), and Hasholt (1992).

MONITORING OF EROSION IN CONTROLLED SYSTEMS

Measuring erosion in nature and under natural climatic conditions is difficult because of the random location of erosion sites, and the episodic nature of the climatic conditions leading to erosion. The need for information about the effect of changes in single parameters such as soil type, crops and tillage practices has led to the development of controlled installations, where factors determining erosion can be manipulated and the resulting erosion measured accurately.

A major problem concerning measurement of erosion under natural conditions involves the determination of the contributing area. The controlled system is therefore most often a bounded area, a so-called plot. The plot edges are made of stable material, sheets of metal, plastic, or similar material that does not leak or rust. The edges should be embedded deep enough to avoid loosening by freeze thaw or drying of the soil, and so that no undercutting by running water can take place.

The edges should extend well above the surface to avoid overtopping by running water and significant in-splash; normally a height of 15–20 cm is chosen. The size of such plots ranges from 0.5 m^2 up to about 400 m^2. The

Figure 5 Erosion plot with rainfall simulator. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

choice of plot size depends on the processes to be studied; splash and interrill erosion can be studied using the smaller plots, but for studies of rill erosion, plots must be at least 10 m long. Normally the plots (Figure 5) are rectangular with the longest side parallel to the slope direction. In order to evaluate the effect of slope gradient, plots of same area and length may be established on slopes of varying steepness, representing typical conditions in the surrounding catchment. A standard plot with a length of 22 m, a width of 1.8 m, and a slope of 5° has often been used in soil erosion studies all over the world. At the downslope end of the plot, the eroded sediment is trapped in a gutter or collecting trough covered with a lid to prevent direct entry of rainfall. From the gutter, the water and sediment is led to a measuring and collecting system, which can be designed in many different ways. The construction of the gutter and the measuring and collecting system is critical to the ability of the system to provide accurate results for the time resolution required. In many cases, the gutter bottom has a gentle slope or is horizontal, causing the deposition of the larger and heavier fractions of the eroded material. The gutter therefore has to be emptied separately after a storm, and it is impossible to measure the true sediment concentration distribution during the storm. To facilitate this, the gutter must be constructed so that its slope exceeds that of the plot. From the gutter, runoff and sediment are channeled into collecting tanks. The number and construction of the collecting tanks depends on the size of the plot and the volume of runoff. In the case of large plots and runoff volumes, the overflow from the first tank passes into another tank through a divisor which splits the flow and passes one part as a sample into the next tank. Examples of divisors are the Coshocton wheel (see Figure 6) and the Geib multislot divisor. The sediment in the water can be allowed to settle or a flocculating agent

Figure 6 Coshocton wheel. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Figure 7 Sediment sampler funnel in collecting position. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

can be added. The clear water is drawn off and the volume of remaining sediment is measured, dried, and weighed. If the volume is too large, only a sample of known volume is weighed and the total weight in the tank is found by multiplication by the sample value. Where a divisor is used, the volume from the measuring tank must be multiplied by the division factor. The volume of water and sediment may also be measured using flumes or weirs. Often, an H-flume is used because it is nonsilting and unlikely to become blocked by debris. Thompson type triangular weirs, with different angles, are also often used. Flow can also be registered by counting the rotations of the Coshocton wheel or the number of tips with a tipping-bucket device.

If the objective of the sampling is to determine the time variation of the sediment concentration in the runoff from the erosion plot, the methods above are insufficient. If observers are present, manual in-stream sampling is an option, assuming that no sedimentation take place in the collecting system before the sampling point. If manual sampling is not possible, automation is needed. Several automatic samplers are available. However, an important problem is that high concentrations and large particle sizes can clog sampler tubes, and it may also be difficult to obtain velocities large enough in the sampling tubes to prevent separation of particle sizes. Another possibility is the application of transmissometers or backscatter sensors. Practical experiences have, however, proved that these sensors are very difficult to install in the system without causing disturbance of flow, resulting in particle separation. To overcome these problems, an automatic sampler without pumps has been constructed (Hasholt, 1998). The water and sediment mixture is passed through a moveable funnel. When not sampling, flow is passed directly to a main collecting tank; when sampling, a solenoid places the moveable funnel above a fixed funnel that directs the water and sediment mixture directly into a sampling bottle placed on a conveyor belt (Figure 7). After sampling over a predetermined time interval, the moveable funnel swings back, activated by a spring. The collecting tank is placed on a balance capable of weighing 1500 kg with a resolution of ± 100 g. Simultaneously the level of the water in the collecting tank is measured with an ultrasonic distance meter with a resolution of ± 1 mm. Theoretically, the flow mass can be calculated by the simultaneous solution of two equations with two unknowns, knowing the density of water and of sediment. Because the accuracy of volume determination is an order of magnitude less than that of weight, the overall accuracy is not good enough for a calculation of the flow for time intervals shorter than hours. Instead, the increase in weight is used as a measure of flow rate; the calculated flow rate is used to trigger flow-proportional sampling and to calculate the opening time of the moveable funnel, so that for a given rate of flow the sampling bottles (250 ml) are filled approximately to 0.75 of their volume. After sampling, the conveyor belt moves the bottle away and places a new bottle underneath the fixed funnel. The number of bottles on the conveyor belt is 149 on a 1×1 m table, (Figure 8). The sampler can be operated using both 220 Volt AC and 12 Volts DC, so that it can be used at remote locations with no access to mains power. Further automation was employed to monitor the erosion; sampling triggered a video camera overlooking the plot, so that the initiation of rills and melting of snow cover could be observed. To give enough slope to avoid sedimentation in the system, the vertical interval for the installation needed to be approximately 1 m. Further details of this installation are presented in UNESCO Technical Documents in Hydrology No. 60 (cf. Walling and Summer, 2002).

In many installations, the collecting tanks have to be placed in pits or cellars up to 3 m below the intake gutter, at the downslope end of the plot. In case of the presence

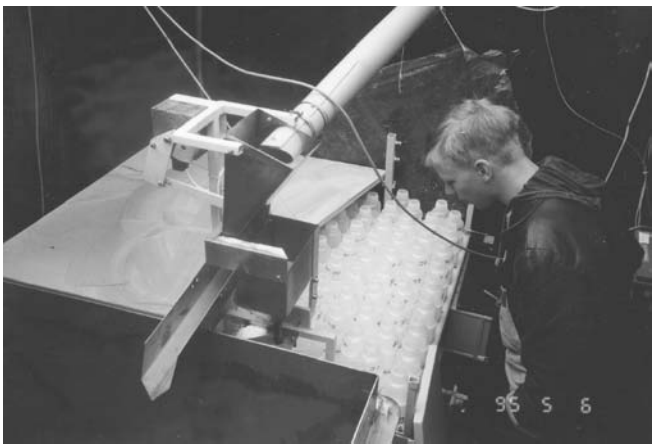

Figure 8 Sediment sampler with collecting trough and conveyor belt. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

of shallow groundwater, the construction of cellars may seriously disturb the natural groundwater flow and prevent the formation of saturated overland flow that can occur frequently in areas experiencing high rainfall of moderate intensities. This is believed to be the explanation of cases of very low erosion rates recorded on some Danish plots. To overcome this problem, a watertight steel cellar was built in an area where the groundwater during winter time was only 50–100 cm below the surface. To prevent the cellar from being lifted by buoyancies of up to 9 tonnes, the bottom of the cellar was extended with flanges, so that the weight of soil on these flanges was able to keep the cellar in position.

U.S.D.A. Agricultural Handbook No. 224 provides full details of the equipment, and manufacturing instructions for divisors and the operation of erosion plots. The construction, maintenance, and running of such plot installations is very expensive, plots are therefore mainly employed at permanent research stations to study factors affecting erosion, for example, tillage practices and crop types, because the conditions on each plot can be controlled. Usually, experiments are carried out to assess the influence of one or more factors on the erosion. Assuming the aim is to study the effect of slope steepness; all other factors in the experimental design are kept constant, while the erosion from a range of slopes of different steepness is measured. This is kept within the range expected in the application area. The actual magnitude of the factors to be held constant also has to be decided, for example, slope length and soil type. Because measurements are subject to error, no single measurement of soil loss from a plot can be considered as the absolutely correct value. Errors can be assessed in respect of variability. Several replicate experiments are required to determine mean values and coefficients of variation. From a review of field and laboratory experiments, Luk (1981) found values from 10 to 40% for the coefficient of variation, while extreme values of soil loss ranged from 40–120%. If more variables are involved, the number of replicates needed increase dramatically. Several plots should be investigated simultaneously, with the treatment and factors of the individual plots randomized to fulfill statistical demands. A thorough discussion of experimental design is presented in Morgan (1995).

The measurement of natural erosion or erosion on plots under natural climatic conditions can be tedious, and it can be nearly impossible to obtain homogenous experimental conditions. Therefore, many experiments on plots are carried out using artificial rainfall Figure 5 or runoff. The obvious benefit is that it is possible to choose the starting conditions and, in particular, the time and duration of the application of the rain and/or overland flow. The crucial point is if the simulator is able to produce the right characteristics of the rainfall, for example, drop-size distribution and fall velocities. Rainfall simulators are classified according to the drop-formers used, either tubing tips or nozzles. Reviews of simulators produced by different researchers have been published by Bubenzer (1979) and Hudson (1971). Recently, a rainfall simulator to cover different sizes of plots has been designed by Bazzofi *et al.* (1980).

LABORATORY EXPERIMENTS

It is tempting to carry out controlled, quantitative experiments in laboratories, however, it is very difficult, if not impossible, to construct a scaled-down version of field conditions, because scale equivalence cannot be maintained in soil particles and raindrops without changing their basic properties or behaviour. Laboratory measurements must therefore be treated as representing true-to-scale field simulations. To initiate erosion, artificial rainfall and/or runoff have to be applied. It is important that the simulator produces a correct drop-size distribution, fall velocities, and intensities. Most laboratories have insufficient heights for drops to reach terminal velocities during their fall, so that their kinetic energy is too low. This could be overcome using pressurized water, but that influences drop-size and intensity. Studies of splash erosion have been carried out by Høgh-Schmidt and Brogaard (1975) in elevator shafts where the terminal velocity could be obtained to study erosion from splash cups. To evaluate soil erodibility, a Kamphorst rainfall simulator can be placed on different types of soil. The fall height is too small, but the energy of the artificial rainfall is considered close to natural conditions (Kamphorst, 1987). Small installations can be useful to evaluate the relative effect of different soil conditions, but they are not able to deal with processes acting beyond their scale. Different experimental set-ups are found at individual research institutes. At Silsoe College, UK, the set-up comprises a metal soil tray, 1.0 m wide, 0.5 m deep, and

2.5 m long. A mesh, or a geotextile membrane, is placed below the soil layer to allow infiltration. Runoff can be supplied at the upstream end of the tray. Slope steepness can be adjusted and a rainfall simulator can be positioned over the tray. At the Experimental Geomorphology Laboratory, University of Leuven, Belgium, the flume is 0.4 m wide and 4 m long. It is fed by water at its upper end and slope can be adjusted. The smaller the installation, the more serious are the edge effects. However, these can partly be reduced by using only the central parts of the plot for measurement. At the Centre for Geomorphology in Caen, France, a flume with a length of 20.4 m, width 1.4 m, and a depth of 0.7 m has been constructed for studies of rill erosion. Another long flume has been constructed at the Soil Erosion Laboratory, University of Toronto, Canada; the flume consists of 10 flexible modules, each 2.45 m long, 0.85 m wide, and 0.31 m deep. The elements can be tilted to produce varying profile shapes. The rainfall simulator is placed 8 m above the flume (Bryan and Poesen, 1989).

Laboratory studies on wind erosion have mainly been carried out in wind tunnels. Tunnels can either be of the open-circuit type or the closed-circuit type. Scale problems occur, because it can be difficult to reproduce a wind profile similar to nature, as the height in the wind tunnel is too small. It is also difficult to control the humidity of the air, which is an important factor determining the critical wind velocity. Principles of wind tunnel design are described by Pope and Harper (1966).

In laboratory experiments, the natural packing of soil, soil moisture level and groundwater are difficult factors to reproduce. The installation of vegetation in laboratory erosion experiments has also created difficulties. Therefore, a tendency in recent years has been a combination of laboratory experiments and rainfall simulators on plots with natural vegetation and soil conditions.

FUTURE MONITORING OF SOIL EROSION

Experiments to elucidate erosion processes will continue to develop improved algorithms for erosion models that, over time, may replace the costly hardware experimental set-ups. In particular, there is a need for research on erosion related to frozen soil and winter conditions.

In cases where experiments are carried out using experimental facilities, the need for automation is less, because the experiments using rainfall simulators can allow the experiments to be carried out within normal working hours. Automation, however, will be needed on remote locations, for example, after cultivation of virgin land with unknown soil and microclimate. The principles behind the sampler mentioned above (Walling and Summer, 2002), may be useful in construction of a commercial sampler that can cope with the large range of particle sizes observed during erosion events.

The development of sensors that do not disturb the flow, for example, arranged around the tubes transporting water and sediment from the erosion plot, is an important requirement for accurate studies of processes.

New, fast image analysis programs combined with digital video cameras may provide new methods for monitoring erosion by quantifying the so far subjective visual observations carried out by human observers.

82: Erosion Prediction and Modeling

MARK NEARING, KEN RENARD AND MARY NICHOLS

Southwest Watershed Research Center, Tucson, AZ, US

Models of soil erosion by water historically have been primarily either empirically-based or process-based (sometime referred to as physically-based). The first models of soil erosion were empirically-based. The prime example of the empirically-based model is the Universal Soil Loss Equation (USLE). More recent models have been based on equations that describe the physical, biological, and/or chemical processes that cause or affect soil erosion. It is important to understand that both the process-based and the empirically-based model possess a major empirical component, in the sense that the constitutive equations use parameters based on experimental data. This chapter details some of the important elements of soil erosion models and factors that influence their use.

INTRODUCTION

Soil erosion models play an important role both in meeting practical needs of soil conservation goals and in advancing the scientific understanding of soil erosion processes. They are used to help land managers choose practices to reduce erosion rates. Erosion prediction models are used for assessment and inventory work to track temporal changes in erosion rates over large areas. Erosion models are also used for engineering purposes, such as predicting rates of sediment loading to artificial reservoirs. Increasingly, governments are using erosion models and their results as a basis for regulating conservation programs. Models are used wherever the costs or time involved in making soil erosion measurements are prohibitive.

Erosion models play at least two important roles with respect to the science of soil erosion. First, erosion models are necessarily process integrators. Most often our knowledge of erosion mechanisms from experimental data is limited in scope and scale. Information may sometimes be misleading in terms of the overall effects on large integrated systems where many processes act interdependently. If individual processes that are well described from erosion experiments are correctly integrated via a process-based model, the result may be used to study model predictions and assess the behavior of the integrated system. Secondly, erosion models also help us to focus our research efforts. They help us to see where the gaps in knowledge exist and where to best focus our efforts to increase our overall erosion prediction capabilities.

In selecting or designing an erosion model, a decision must be made as to whether the model is to be used for on-site, off-site concerns, or both. On-site concerns are generally associated with degradation or thinning of the soil profile in the field, which may result in crop productivity loss. Conservationists refer to this process as *soil loss*, referring to the net loss of soil over only the portion of the field that experiences net loss over the long term. Areas of soil loss end where net deposition begins. Off-site concerns, on the other hand, are associated with the sediment that leaves the field, which we term here *sediment yield*. In this case, we are not necessarily concerned with the soil loss, or for that matter the amount of sediment deposited prior to leaving the field, although estimation of both of these may be used to estimate sediment yields. Ideally, a model will compute soil loss, deposition, and sediment yield, and thus have the capability to address both on-site and off-site issues.

Models of soil erosion by water historically have been primarily either empirically based or process-based (sometimes referred to as physically based). The first models of soil erosion were empirically based. The prime example of the empirically based model is the Universal Soil Loss Equation (USLE) (Wischmeier and Smith, 1960, 1965, 1978). More recent models have been based on equations that describe the physical, biological, and/or chemical

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

processes that cause or affect soil erosion. It is important to understand that both the process-based and the empirically based models possess a major empirical component, in the sense that the constitutive equations use parameters based on experimental data.

CHOOSING AND USING AN APPROPRIATE MODEL

Choosing how to manage land, from the practical perspective, is often a matter of choosing between an array of potential options. Often, therefore, what we need to know is not necessarily the exact erosion rate for a particular option to a high level of accuracy, but rather we want to know how the various options stack up against one another. We may certainly be interested to have a general quantitative idea of the erosion rate, but for purposes of land management, this is not critical. Choosing which model to use then becomes a matter of (i) what type of information we would like to know, and (ii) what information (data) we have for the particular site of application. We may know, for example, that the USLE provides only estimates of average annual soil loss on the portion of the field that experiences a net loss of soil. If we have an interest in off-site impacts, then we probably want to choose a process-based model that will provide estimates of the sediment leaving the hillslope or watershed. If we have an interest in obtaining other auxiliary information about our choice of management strategy, such as soil moisture or crop yields, we might also decide to use a process-base that provides such information. On the other hand, if data are limited for the situation to be modeled, then a simple empirical model might be the only viable option.

Making broad-scale erosion surveys in order to understand the scope of the erosion problem over a region and to track changes in erosion over time can be done with many models. A statistical sampling scheme to take random points over the area of interest can be made, and the erosion model then applied to each point (USDA, 1996). In this case, we are not so concerned about the individual prediction for each point of application, but rather the ability of the model to predict overall averages of soil loss in a quantitatively accurate manner. While we know that none of the erosion models will necessarily predict erosion for a particular site to the quantitative level of accuracy we would like to see for survey assessment purposes (Nearing, 2000), many models do predict the averages for treatments quite effectively (Risse *et al.*, 1993; Rapp, 1994; Zhang *et al.*, 1996). The issues related to choosing the correct model are related to the information desired and the available data.

Conservation compliance, governmental policy making, and regulation of land user's actions follow the same guidelines as for applications of erosion assessment and conservation planning. The information desired and data availability are again the keys to choice of model. In this case, however, the argument is often given, most often by the farmer who is being regulated, that if we know that there are uncertainties in the erosion predictions for individual applications, how can we be sure that his field is being evaluated accurately. The answer is, of course, that we cannot be sure. If the model predicts that the farmer's field is eroding at a rate in excess of what our society's policy indicates to be acceptable, the model could well be wrong for this particular field. This problem is really no different than that faced by insurance companies as they set rates for insurance coverage. My home may be more secure from the possibility of fire than my neighbor's home because I am more careful than my neighbor. But unless my home falls in a different category (e.g. better smoke-alarm protection), I will not have much luck in going to my insurance company and asking for a lower payment rate. Likewise, if I am the farmer, I cannot expect to give a coherent argument for lower soil loss than the model predicts unless I conduct some practice, such as reduced tillage or buffers, which arguably reduces erosion.

Complexity and uncertainty are key issues relative to the development, understanding, and use of erosion models for conservation purposes. They are inevitable considerations because of the many complex interactions inherent in the erosional system as well as the enormous inherent variability in measured erosion data. These issues do not, however, prevent us from using models effectively for conservation planning. In fact, the scientific evidence indicates that choice of models, which implies choice of model complexity, is more a matter of the type of information desired and the quality and amount of data available for the specific application. If our goal is to know to a high level of accuracy the erosion rate on a particular area of ungauged land, we cannot rely upon the models. Natural variability is too great, and uncertainty in predictions is too high (see Nearing *et al.*, 1999; Nearing, 2000). For appropriate and common uses, such as those discussed above, models can be effective conservation tools.

THE UNIVERSAL SOIL LOSS EQUATION

Undoubtedly the prime example of an empirically based model is the USLE, which was developed in the United States during the 1950s and 1960s (Wischmeier and Smith, 1960, 1965). This equation has been adapted, modified, expanded, and used for conservation purposes throughout the world (e.g. Schwertmann *et al.*, 1990; Larionov, 1993).

The USLE was originally based on statistical analyses of more than 10 000 plot-years of data collected from natural runoff plots located at 49 erosion research stations in the United States, with data from additional runoff plots and experimental rainfall simulator studies incorporated into the final version published in 1978 (Wischmeier and Smith,

1978). The large database upon which the model is based is certainly the principal reason for its success as the most used erosion model in the world, but its simplicity of form is also important:

$$A = RKLSCP \quad (1)$$

where A ($t\,ha^{-1}\,yr^{-1}$) is average annual soil loss over the area of hillslope that experiences net loss, R ($MJ\,mm\,hr^{-1}\,ha^{-1}\,yr^{-1}$) is rainfall erosivity, K ($t\,hr\,MJ^{-1}\,mm^{-1}$) is soil erodibility, L (unitless ratio) is the slope length factor, S (unitless ratio) is the slope steepness factor, C (unitless ratio) is the cropping factor, and P (unitless ratio) is the conservation practices factor. Terminology is important here. Note first that the USLE predicts soil loss (see discussion above) and not sediment yield. Second, the word erosivity is used to denote the driving force in the erosion process (i.e. rainfall in this case) while the term erodibility is used to note the soil resistance term. These two terms are not interchangeable. Third, the model predicts average annual soil loss: it was not intended to predict soil loss for storms or for individual years. Conservationists often describe the predictions as long term, while from the geomorphic perspective the predictions would be referred to as medium term (Govers, 1996).

The units of the USLE appear a bit daunting as written (equation (1)), but become somewhat more clear with explanation. The units were originally written, and are still used in the United States, as Imperial, but conversion to metric is generally straightforward (Foster *et al.*, 1981a). The key to understanding the dimensional units lies with the definition of rainfall erosivity and the concept of the unit plot. Wischmeier (1959) found for the plot data that the erosive power of the rain was statistically best related to the total storm energy multiplied with the maximum 30-min storm intensity. Thus, we have the energy term (MJ) multiplied by the intensity term ($mm\,hr^{-1}$) in the units of R, both of which are calculated as totals per hectare and per year. The unit plot was defined as a standard of 9% slope, 22.13 m length (most of the early erosion plots were 1.83 m (6 ft) wide. A length of 22.13 m (72.6 ft) and a width of 1.83 m (6 ft) resulted in a total area of 1/100 of an acre. Prior to the days of calculators and computers, this was obviously a convenient value for computational purposes), and left fallow (cultivated for weed control). The K value was defined as A/R for the unit plot. In other words, erodibility was the soil loss per unit value of erosivity on the standard plot. The remaining terms, L, S, C, and P are ratios of soil loss for the experimental plot to that of the unit plot. For example, the C value for a particular cropped plot is the ratio of soil loss on the cropped plot to the value for the fallow plot, other factors held constant.

The USLE reduced a complex system to a quite simple one for purposes of erosion prediction. There are many complex interactions within the erosional system which are not, and cannot be, represented within the USLE. On the other hand, for the purposes of general conservation planning and assessment, the USLE has been, and still can be, used with success.

THE REVISED USLE: RUSLE1 AND RUSLE2

The USLE was upgraded to the Revised Universal Soil Loss Equation (RUSLE1) during the 1990s (Renard *et al.*, 1997) and evolved to the current RUSLE1.06c released in mid 2003 (USDA-ARS-NSL, 2003). RUSLE1 is land-use independent and applies to any land use having exposed mineral soil and Hortonian overland flow. RUSLE2 was also released in mid 2003, and it too is land-use independent (USDA-ARS-NSL, 2003).

RUSLE1 and RUSLE2 are hybrid models that combine index and process-based equations. RUSLE2 expands on the hybrid model structure and uses a different mathematical integration than does the USLE and RUSLE1. Both are computer based, and have routines for calculating time-variable soil erodibility, plant growth, residue management, residue decomposition, and soil surface roughness as a function of physical and biological processes.

RUSLE1 and RUSLE2 compute deposition on concave slopes, for vegetative strips, in terrace channels, and in sediment basins using process-based equations for transport capacity and deposition. RUSLE2 also computes an enrichment ratio for the sediment leaving the end of the slope. The model uses 10 yr–24 hr precipitation amounts to compute runoff. Enrichment ratio is the ratio of specific surface area of the sediment to specific surface area of the soil subject to erosion, and is useful for assessments of chemical carrying capacity of sediment.

RUSLE1 and 2 both have new relationships for L and S factors which include ratios of rill and interrill erosion, and additional P factors for rangelands and subsurface drainage, among other improvements. Within the United States, RUSLE2 uses updated values for rainfall erosivity (R), based on weather data collected from 1960 to 1999. RUSLE1 and 2 have the advantage of being based on the same extensive database as is the USLE, with some of the advantages of process-based computations for time-varying environmental effects on the erosional system. They still have the limitations, however, in model structures that allow only for limited interactions and interrelationships between the basic multiplicative factors of the USLE (equation (1)).

REPRESENTATIONS OF RILL AND INTERRILL PROCESSES

Differentiating between rill and interrill erosional areas is a useful, if somewhat arbitrary, division between dominant processes of erosion on a hillslope surface. In the

original description of the processes, Meyer *et al.* (1975) differentiated between areas of the hillslope dominated by shallow sheet flow and raindrop impact and those of small concentrated flow channels, which they termed rills. The concept is useful in terms of mathematical descriptions of erosion, and serves as a basis for many process-based erosion simulation models. The concept is also useful in terms of focusing experimental research on the two primary sources of eroded soil. The separation of the two primary sediment sources facilitates the mathematical modeling of nonpoint source pollutants in surface runoff. However, the concept is somewhat arbitrary because it implies a clear delineation between dominant processes on a given area, where, in fact, overlap occurs. Flow depths on a hillslope would be more correctly described in terms of frequency distributions of depth where processes tend more towards rill or interrill depending on the flow depth (Lewis *et al.*, 1990). Nevertheless, the introduction of the concept of rill versus interrill sediment source areas is the cornerstone of current erosion research and development of process-based erosion prediction technology. It is this subdivision of the erosion process which opened the "black box" which was employed earlier by empirically based erosion models.

Rills are conceived as being the primary mechanism of sediment transport in the downslope direction. Depths of flow in rills is considered to be relatively large (normally on the order of cm) compared to average broad-sheet flow depths (on the order of mm). Detachment of soil in rills is primarily by scour, whereas the principal mechanism of detachment in interrill areas is by raindrop splash. Models of rill and interrill erosion generally treat interrill areas as being sediment feeds for rills. The rills then act to transport the sediment generated in the interrill areas, as well as the soil detached by scour in the rills, down the slope.

PROCESS-BASED MODELS

Various process-based erosion models have been developed in the last 10 years including EUROSEM in Europe (Morgan *et al.*, 1998), the GUEST model in Australia (Misra and Rose, 1996), and the WEPP model in the United States (Flanagan and Nearing, 1995). We will focus here on the example of the WEPP model, largely because it is the technology most familiar to the author.

The Sediment Continuity Equation

Process-based (also termed physically based) erosion models attempt to address soil erosion on a relatively fundamental level using mass balance differential equations for describing sediment continuity on a land surface. The fundamental equation for mass balance of sediment in a single direction on a hillslope profile is given as:

$$\frac{\partial(cq)}{\partial x} + \frac{\partial(ch)}{\partial t} + S = 0 \qquad (2)$$

where c (kg m^{-3}) is sediment concentration, q (m^2 s^{-1}) is unit discharge of runoff, h (m) is depth of flow, x (m) is distance in the direction of flow, t (s) is time, and S [kg (m^{-2} s^{-1})] is the source/sink term for sediment generation. Equation (2) is exact. It is the starting point for development of physically based models. The differences in various erosion models are primarily: (i) whether the partial differential with respect to time is included, and (ii) differing representations of the source/sink term, S. If the partial differential term with respect to time is dropped then the equation is solved for the steady state, whereas the representation of the full partial equation represents a fully dynamic model. The source/sink term for sediment, S, is generally the greatest source of differences in soil erosion models. It is this term which may contain elements for soil detachment, transport-capacity terms, and sediment deposition functions. It is through the source/sink term of the equation that empirical relationships and parameters are introduced.

The sediment continuity equation in physically based models is normally written in terms of a single flow direction, x. The equation could be written and solved for the x and y directions to describe sediment continuity on a two-dimensional surface. To date, however, the approach taken to describe sediment continuity on two-dimensional surfaces has been to use the unidirectional equation with the x-direction being the direction of water flow at a given point on the landscape surface. Modeling of erosion on watersheds in current process-based erosion models generally involves dividing the watershed area into overland flow elements and channel elements. The overland flow elements are typically either rectangular, representing hillslopes adjacent to channel elements, or they are squares within a pattern of a grid which overlays the watershed. In both cases rill and interrill erosion processes are described in the overland flow elements, and sediment generated from those overland flow elements is considered to be delivered to the channel elements to be transported through the channel network. In some cases, sediment from an overland flow element may be routed to and potentially through another overland flow element before reaching a channel element.

In this chapter, we will address the application of the sediment continuity equation to the routing of sediment within overland flow elements. In doing so, we will focus on two of the many existing models to exemplify the concepts introduced. The Water Erosion Prediction Project (WEPP) Hillslope Profile Model (Lane and Nearing, 1989; Nearing *et al.*, 1989; Flanagan and Nearing, 1995) derives from a family of models developed by Foster (see Foster,

1982), and shares common descriptions of erosion with CREAMS (Foster *et al.*, 1981b). WEPP is a steady-state model which is intended to be used at the field planning level in much the same way as the USLE is currently used for conservation planning. As such, the model places a strong emphasis on the effects of soil and plant management practices on erosion. It is a continuous simulation model which operates on a daily time-step. The Hairsine and Rose model (Hairsine, 1988; Hairsine and Rose, 1992a, b) is a single-event dynamic model. This model derives from previous models discussed by Rose *et al.* (1983) and Rose (1985).

Forms of the Sediment Continuity Equation

For the case of steady state conditions, and using the concepts of rill and interrill erosion, the sediment continuity equation (2) may be rewritten as it is in the WEPP model as

$$\frac{\mathrm{d}G}{\mathrm{dx}} = D_r + D_i \tag{3}$$

where G [kg $(\mathrm{m}^{-1}\,\mathrm{s}^{-1})$] is sediment load per unit width in the flow (equal to cq in equation 2), D_r [kg $(\mathrm{m}^{-2}\,\mathrm{s}^{-1})$] is net rill erosion rate per unit area of rill bottom, and D_i [kg $(\mathrm{m}^{-2}\,\mathrm{s}^{-1})$] is interrill sediment delivery to the rill (as with rill erosion, expressed on a per unit rill area basis). For a given set of conditions, the interrill sediment delivery may be calculated and set as a constant in equation (3). For the case of net detachment in a rill, the D_r term will be positive, indicating a net increase in sediment load with downslope distance. For the case of deposition, the D_r term is negative.

In the WEPP model the sediment continuity equation is applied within the rills, which are described hydraulically as small rectangular shaped channels. This approach contrasts with most other erosion models, such as CREAMS (Foster *et al.*, 1981b), KINEROS (Smith *et al.*, 1995), and the model of Rose *et al.* (1983), which use uniform flow hydraulics to describe detachment of soil and transport of sediment by flowing water. The recent model of Hairsine and Rose (1992b), however, also uses rill hydraulics for describing rill erosion processes.

In formulating equation (3) from equation (2), several major assumptions and decisions regarding the representation of erosion have been made. In dropping the dynamic term, one must be able to establish a representative steady-state erosion rate and erosion time period which will provide a good estimate of the overall erosion rate for a storm. It has also been decided in formulating equation (3) that the rill and interrill formulation is appropriate and will provide a reliable framework for making erosion predictions. The fact that D_r and D_i represent "net", rather than instantaneous terms, is also important. For the interrill case, D_i is an estimate of the amount of sediment delivered to the rill from interrill areas. It does not explicitly account for the individual processes of splash detachment, deposition of splashed materials on interrill areas, and transport of the splashed materials in the shallow interrill flow. For the rill case, D_r represents a net movement of soil to the flow from the bed. This implies physically that detached sediment, once in the flow of the rill, will be transported downslope in the rill flow until an area of net deposition is reached, whereby the sediment may fall out and rest on the bed. The net rill detachment rate, D_r, is a function of four primary factors: (i) the amount of sediment in the flow, (ii) the hydrodynamics of the flow, (iii) the resistance of the soil to detachment by flow, and (iv) ground surface cover. The mathematical representation of each of these factors will be addressed below.

The Hairsine and Rose erosion model describes erosion as a balance of several instantaneous processes, rather than net detachment or deposition in rill or interrill areas. In that model, net detachment or deposition rate is conceived as a balance between several processes which occur simultaneously, those being: (i) the movement of sediment particles which are in the flow to the bed, (ii) the movement of previously detached sediment into the flow, and (iii) the detachment of soil particles from the bulk soil mass. The model assigns a separate term for each of these individual processes. The movement of sediment particles which are in the flow to the bed is "deposition", the movement of previously detached sediment into the flow is "reentrainment", and the detachment of soil particles from the bulk soil mass is "entrainment". Hairsine and Rose introduced entrainment and reentrainment terms for both rill and interrill erosion. Hairsine and Rose's model (from Hairsine, 1988) uses a sediment continuity equation of the form

$$\partial \frac{(c_i q)}{\partial x + \partial} \frac{(c_i h)}{\partial t} = e_i + e_{di} + r_i + r_{ri} - d_i \tag{4}$$

where e_i is entrainment by rainfall, e_{di} is reentrainment by rainfall, r_i is entrainment by surface water flow, r_{ri} is reentrainment by surface water flow, d_i is the continuous deposition term, and the subscript i indicates particle settling velocity class of the sediment. Net rates of detachment, deposition, as well as sediment transport capacity are implicit concepts embodied in this type of representation.

Because the concepts of transport capacity, T_c, and detachment rate capacity, D_{rc}, are not introduced *a priori*, Rose (1985) argues that the model of Rose *et al.* (1983) (which is a predecessor to Hairsine, 1988) is conceptually simpler than the model of Foster and Meyer (1972) (which is a predecessor to WEPP). On the other hand, as noted by Yu (2003), both of the models result in similar patterns of erosion behavior for similar conditions.

USING THE MODELS

The erosion portion of erosion prediction technology is actually only a small portion of the functioning whole. In order to be useful, a model must have the auxiliary components that describe the state of the system during the rainstorm that causes the erosion. The WEPP computer model includes seven major components, including climate, infiltration, water balance, plant growth and residue decomposition, surface runoff, erosion, and channel routing for watersheds. The climate component of the model, CLIGEN (Nicks, 1985), generates daily precipitation, daily maximum and minimum temperature, and daily solar radiation based on a statistical representation of weather data at a particular location. The climate model has been tested for erosion and well parameterized for the United States (Baffaut *et al.*, 1996). The infiltration component of the hillslope model is based on the Green and Ampt equation, as modified by Mein and Larson (1973), with the ponding time calculation for an unsteady rainfall (Chu, 1978). The water balance and percolation component of the profile model is based on the water balance component of the Simulator for Water Resources in Rural Basins (SWRRB) (Williams and Nicks, 1985; Arnold *et al.*, 1990), with some modifications for improving estimation of percolation and soil evaporation parameters. The plant growth component of the model simulates plant growth and residue decomposition for cropland and rangeland conditions. The residue and root decomposition model simulates decomposition of surface residue (both standing and flat), buried residue, and roots for the annual crops specified in the WEPP User Requirements (Flanagan and Livingston, 1995) plus perennial crops of alfalfa and grasses. Surface runoff is calculated using a kinematic wave equation. Flow is partitioned into broad-sheet flow for interrill erosion calculations and concentrated flow for rill erosion calculations. The erosion component of the model uses a steady-state sediment continuity equation that calculates net values of detachment or deposition rates along the hillslope (Nearing *et al.*, 1989). The erosion process is divided into rill and interrill components where the interrill areas act as sediment feeds to the rills, or small channel flows. The model is applicable to hillslopes and small watersheds.

Because the model is based on all of the processes described above, and more, it is possible with WEPP to have an enormous array of possible system interactions represented in the simulations. Just to name a few examples, slope length and steepness effects are functions of soil consolidation, surface sealing, ground residue cover, canopy cover, soil water content, crop type, and many other factors. Ground residue cover is a function of biomass production rates, tillage implement types, residue type, soil moisture, temperature and solar radiation, previous rainfall, and many other factors. Rill erosion rates are a function of soil surface roughness, ground cover, consolidation of the soil, soil physical and chemical properties, organic matter, roots, interrill erosion rates, slope, and runoff rates, among other factors. The lists continue *ad infinitum*. These are interactions which are simply not possible to represent with an empirical model. WEPP is a complex model in this sense.

The disadvantage of the process-based model is also the complexity of the model. Data requirements are huge, and with every new data element comes the opportunity to introduce uncertainty, as a first order error analysis would clearly indicate. Model structure interactions are also enormous in number, and with every structural interaction comes the opportunity for error, as well. In a sense, the goal in using the process-based model is to capture the advantages of the complexity of model interactions, while gaining the accuracy and dependability associated with the simpler empirically based model. This can be done, and was done with the WEPP model, using a combination of detailed sensitivity analyses and calibration of the model to the large database of natural runoff plot information used to develop the USLE and RUSLE. Without the tie between model and database, and without knowledge of the sensitive input variables so as to know where to focus efforts, turning a complex model such as WEPP into a useful conservation tool would not be possible. Thus in a sense, even though WEPP routines are process-based descriptors of various components of the erosional system, ultimately the model must be empirically based on the same type of data as was used to develop the USLE and RUSLE, along with additional experimental data collected specifically for WEPP.

83: Suspended Sediment Transport – Flocculation and Particle Characteristics

IAN G DROPPO

National Water Research Institute, Environment Canada, Burlington, ON, Canada

In the history of sediment transport research within hydrological sciences, there has possibly been no greater paradigm shift than that which has been provided by the identification of flocculation as a dominant mechanism operating within, and mediating, cohesive suspended sediment transport. Flocculation (the process of aggregating smaller particles together to form larger particles) significantly modifies the hydrodynamic properties of the sediment by altering their effective size, shape, density, porosity, and composition. Such changes have a dramatic impact on the downward flux of sediments and as such influence the transportation and fate of suspended sediments. The traditional assumption of suspended sediment being inorganic individual grains for the quantification and modeling of sediment transport is likely to result in erroneous results and management decisions. Flocs settle faster than their individual constituent particles (but orders of magnitude slower than that predicted by Stokes' equation for a similar size), and, for large flocs, can have porosity close to 100% and a corresponding density close to that of water. Flocs are composed of significant living organic components (primarily bacteria) which produce an extracellular polymeric substance (fibrils) which glues particles together giving them greater strength than an electrochemically bound floc, and a pseudo plastic nature. Because of this active living component, flocs should be thought of as micro ecosystems (composed of a matrix of water, inorganic, and organic particles) with autonomous and interactive physical, chemical, and biological functions or behaviors operating within the floc matrix. A better understanding of how floc structure influences floc behavior will help to refine our knowledge and management of suspended sediment transport in a variety of aquatic ecosystems.

INTRODUCTION

In the transport of suspended sediment, particles, and their interactions with the terrestrial and aquatic environment, have both theoretical and practical relevance within hydrological sciences (*see* **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**, **Chapter 80, Erosion and Sediment Transport by Water on Hillslopes, Volume 2**, **Chapter 81, Erosion Monitoring, Volume 2**, **Chapter 82, Erosion Prediction and Modeling, Volume 2**, **Chapter 84, Floodplain Sedimentation – Methods, Patterns, and Processes: A Review with Examples from the Lower Rhine, the Netherlands, Volume 2**, **Chapter 88, Reservoir Sedimentation, Volume 2**, **Chapter 85, Sediment Yields and Sediment Budgets, Volume 2**, **Chapter 86, Measuring Sediment Loads, Yields, and Source Tracing, Volume 2**, **Chapter 87, Sediment Yield Prediction and Modeling, Volume 2**, **Chapter 89, On the Worldwide Riverine Transport of Sediment – Associated Contaminants to the Ocean, Volume 2**, **Chapter 90, Lake Sediments as Records of Past Catchment Response, Volume 2**, **Chapter 111, Rainfall Excess Overland Flow, Volume 3** and **Chapter 140, Transport of Sediments, Volume 4**). Physical, chemical, and biological processes at play with or within particles exert an important controlling influence on sediment transport. Not only is the sediment transport itself dynamic due

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

to hydrologic, hydraulic, and sedimentological variables but so too are the particles themselves. The unstable nature of suspended cohesive sediment particles, relative to their surrounding environment, result in the majority of these fine-grained sediments (silts and clays) existing primarily as flocculated or aggregated particles (Bale and Morris, 1987; Asper, 1987; van Leussen, 1988; Walling and Moorehead, 1989; Burban *et al.*, 1990; Azetsu-Scott and Johnson, 1992; Droppo and Ongley, 1992, 1994; Phillips and Walling, 1995, 1999; Droppo *et al.*, 1997, 1998a, 2000). The flocculation process can be defined simply as the aggregation of smaller inorganic and organic particles by various complex physical, chemical, and biological means to form larger composite particles (Droppo, 2001). Flocculation has the effect of altering the downward flux of sediment during transport due to changes in the effective particle, size, shape, density, porosity, and composition. A flocculated particle is in continuous interaction with its aquatic surroundings; as the medium in which it is transported provides the floc with further building materials, energy, nutrients, and chemicals for biological change, chemical reactions, and morphological development.

Flocs are generally considered to form within the water column or on the surface of the bed (Droppo, 2001), while aggregates are generally considered to form outside of, and be transported to, the aquatic system as water stable soil aggregates (Wall *et al.*, 1978). The differentiation of these two sediment particle forms is difficult due to their similar optical properties (particularly when the two flocculate together to form hybrid particles) (Droppo and Stone, 1994; Droppo and Ongley, 1994), and as such, this contribution uses the terminology floc/flocculation and aggregate/aggregation interchangeably. Given the complex composition of flocs and the complicated physical, chemical, and biological interactions within flocs and within the systems where they occur, Droppo *et al.* (1997) define a flocculated particle as "a microecosystem (composed of a matrix of water, inorganic, and organic particles) with autonomous and interactive physical, chemical, and biological functions or behaviors operating within the floc matrix". That is to say, these are not static physical entities transported within the water column, but rather, are dynamic particles with a significant "living" component mediating the physical, chemical, and biological behavior of the sediment and the water column as well.

While the awareness of flocculation as an important factor influencing sediment transport is increasing, the lack of a standard method for the assessment of floc structure and size, in conjunction with no standard equation to characterize the interaction and formation of flocculated particles, means that a poor understanding of how floc structure influences sediment transport prevails. This contribution provides a description of particle characteristics (composition, size, shape, porosity, density) and how these play a deterministic role in sediment transport behavior. The contribution represents an overview of research carried out on the structure and behavior of cohesive fine-grained sediments in river and lake systems. The contribution does not attempt to characterize a specific site's sediment characteristics, but rather, focuses on the general characteristics of sediment and its influence on behavior.

Floc Structural and Behavioral Issues

The process of flocculation increases the effective particle size by orders of magnitude over the absolute particle sizes and, as such, also changes the effective particle shape, density, porosity, and composition of the characteristic particle (suspended or bed sediment) within a system (Gibbs, 1985; Li and Ganczarczyk, 1987; Nicholas and Walling, 1996; Droppo *et al.*, 1997, 1998b; Phillips and Walling, 1999; Droppo, 2001). As floc form is in a continuous state of change due to the complex interactions of the physical, chemical, and biological factors controlling flocculation (Droppo, 2001), floc settling velocity and, therefore, sediment transport, will also be controlled by these factors in conjunction with the turbulence of flow. As such, floc form (size, density, porosity, shape, composition) controls, to a large extent, floc behavior (transport/settling) and will be discussed below. All floc sizing, density, porosity, shape, and settling velocity data which follows were measured following the computer image analysis methods of Droppo *et al.* (1997).

Particle (Floc) Morphology and Size

Figure 1 illustrates the complex structure of cohesive sediment flocs at a gross scale (Figure 1b) and the complexity of the internal floc structure at a fine scale (Figure 1c). Figure 1(a) illustrates the primary particles which compose the floc sample of Figure 1(b) (imaged after whole floc sample was sonicated to break up flocs and diluted). It is evident that flocs are very different from their individual primary particle components as they are irregular, porous, heterogeneous, composite structures. Flocs are composed of an active biological component (primarily bacteria, although at times other organisms can be incorporated), a nonviable biological component (e.g. detritus, extracellular polymeric substances), inorganic particles (e.g. clay particles), and water held within or flowing through pores (Ongley *et al.*, 1981; Peart and Walling, 1982; Walling and Kane, 1984; Droppo and Ongley, 1992, 1994; Ongley *et al.*, 1992; Leppard, 1992; Woodward and Walling, 1992; Walling and Woodward, 1993; Liss *et al.*, 1996; Droppo *et al.*, 1997; Droppo, 2001). The arrows in Figure 1(c) point out examples of extracellular polymeric fibrils produced by bacteria; a very important part of the floc discussed below. The dark regions represent clay platelets. All of these components are

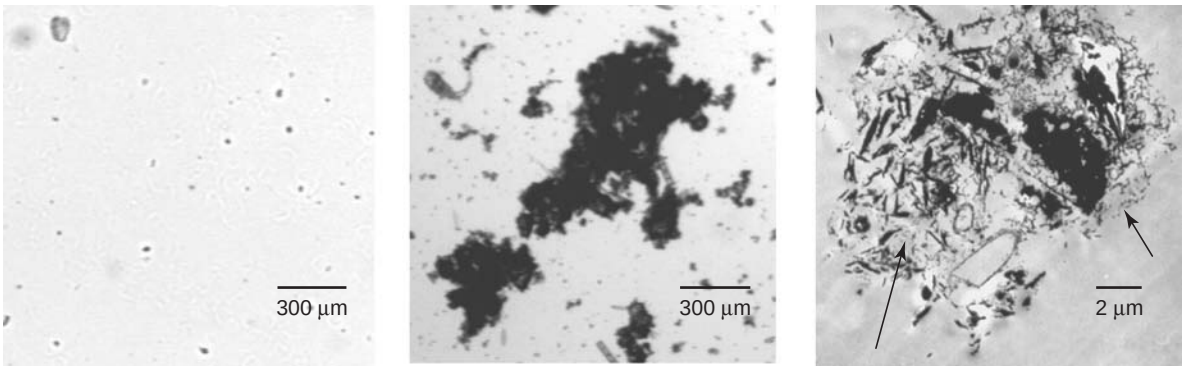

Figure 1 Micrographs illustrating the complexity of flocs from a river environment. (a) Primary particles (imaged with a conventional optical microscope), (b) natural floc particles (imaged with a conventional optical microscope), and (c) transmission electron micrograph of internal matrix of a floc (arrows denote examples of extracellular polymeric fibrils produced by bacteria with the matrix of the floc. Dense dark regions are clay particles)

linked together in the matrix by various physical, chemical, and biological mechanisms (Droppo, 2001). While electrochemical flocculation exists, it is believed that the biological bonding/bridging, primarily through extracellular polymeric substances (EPS) (Figure 1c), is the main component promoting floc building and stability (Liss *et al.*, 1996). EPS is manifested as micro fibrils (5–20 nm in diameter) or fibril bundles which has a "sticky" consistency (Leppard, 1992) often promoting flocs with pseudo plastic nature (Liss *et al.*, 1996). It is also this material which results in the development of micro pores within the floc (Figure 1c). These micro pores exhibit significant surface tension which results in bound water being an integral part of the overall floc structure. This has concomitant effects on the floc density and therefore sediment transport as described below.

Figure 2 provides a conceptual diagram which is specific to how floc structure can influence sediment transport. It is by no means a complete comprehensive evaluation of the process of flocculation (the process is too complex and still not fully understood to provide such a model), but rather provides the rationale for considering flocs to be micro ecosystems unto themselves which can actively mediate sediment transport through the dynamic process of flocculation. In Figure 2, the floc is broken down into its primary components (water, inorganic particles, organic particles, and pores) with substantive structural characteristics stated. The individual components influence the transport of the sediment by mediating factors such as particle size, density, water content, cohesiveness, and stability. Obviously each of these components operates interactively with one another and cannot, in reality, be isolated. It is the interaction of these components and the resultant structures which can modify a floc's transport behavior with concomitant effects on the overall transport of suspended sediment. From Figure 1 and 2, it is apparent that cohesive suspended sediment should be viewed as a collection of dynamic flocs and not simply as the traditionally viewed collection of discrete individual grains of sediment. For a comprehensive discussion on floc structure, the reader is referred to Liss *et al.* (1996) and Droppo (2001).

The dramatic influence of flocculation on *in situ* particle size is shown in the ternary plot of Figure 3. Particle distributions were classed by percent sand, silt, and clay size for both their natural (flocculated) and sonicated (primary) distributions. The floc distribution classes were primarily within the sand and silt size classes even though their constituent material was primarily clay size as illustrated by the primary particle data points on the plot. The difference between the primary particles and flocs is so extreme that the points lie on the edge of the ternary plot. Such a high degree of flocculation has been observed before for multiple river samples (Petticrew and Droppo, 2000).

The Effect of Floc Size on Sediment Transport

As flocculation significantly alters the effective size and structure of particles, it will also have an influence on settling velocity and, therefore, sediment transport. While it is accepted that flocs will settle at different rates than individual constituent particles (Hawley, 1982; Ozturgut and Lavelle, 1984; Gibbs, 1985; Li and Ganczarczyk, 1987; Burban *et al.*, 1990; Azetsu-Scott and Johnson, 1992; van Leussen and Cornelisse, 1993), the theories of particle/floc settling are still centered around the balance of forces of a single particle settling under gravity in a viscous fluid (Tambo and Watanabe, 1979; Li and Ganczarczyk, 1987; Fennessy *et al.*, 1994). The balance of forces is based on a gravitational force acting downwards, a buoyant force acting upwards and a drag force acting upwards. The resulting equation which balances these forces is given in

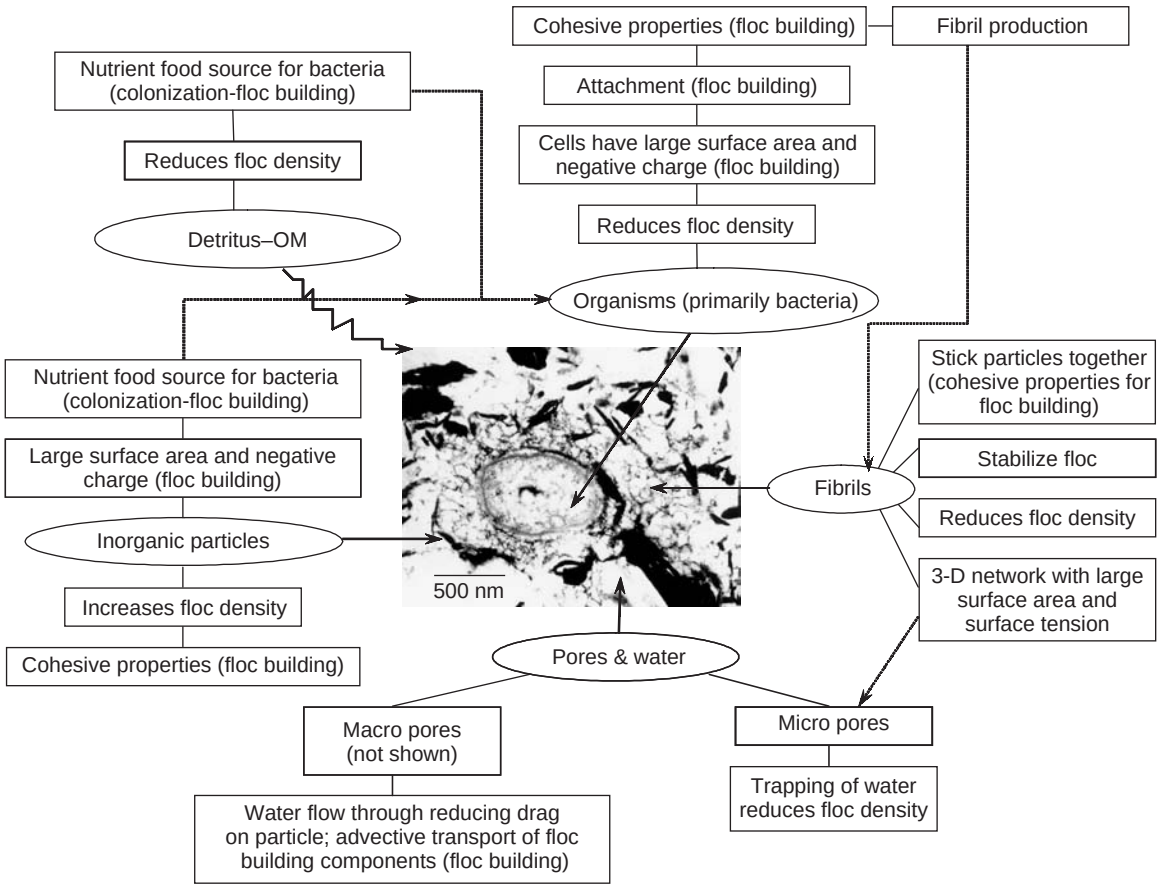

Figure 2 Conceptual diagram of the complex linkage of the floc components and their behavior/functions within the floc which influence suspended sediment transport. Jagged line implies not differentiable within micrograph but present

equation (1).

$$\frac{1}{6}\pi d^3(\rho_s - \rho_w)g = \frac{1}{2}\frac{24}{R_e}\rho_w\overline{\omega}^2\frac{\pi d^2}{4} \quad (1)$$

$$R_e = \frac{\overline{\omega}\rho_w d}{\mu} \quad (2)$$

Where: $\overline{\omega}$ = settling velocity
d = particle diameter
ρ_s = density of the solid particle
ρ_w = density of the water
μ = dynamic viscosity (kinematic viscosity $\times\rho_w$)
g = acceleration due to gravity
R_e = Reynolds Number (see equation 2)

On the left-hand side of equation (1) are the forces acting downwards on a particle [mass $1/6\pi d^3(\rho_s - \rho_w)$; and acceleration due to gravity (g)]. On the right-hand side of equation (1) are the forces acting upwards on a particle (the coefficient of drag ($Cd = 24/R_e$); shear effects ($Cd\rho_w\overline{\omega}^2$) and particle area ($\pi d^2/4$).

By solving equation (1) for $\overline{\omega}$, the Stokes' equation is derived (equation 3).

$$\overline{\omega} = \frac{1}{18}d^2(\rho_s - \rho_w)\frac{g}{\mu} \quad (3)$$

Stokes' Law is based on the settling of single impermeable spherical particles in a laminar region ($R_e < 0.2$) (Allen, 1990), and is therefore not ideal for the determination of floc settling velocity, density, or porosity due to a floc's general irregular shape, porous, and heterogeneous nature (Figures 1b and 1c). Settling in the laminar region may or may not be met, given differences in particle morphology and environmental conditions. In addition, Stokes' Law requires knowledge of the particle density which is generally assumed to be 2.65 g cm^{-3} (the density of quartz particles) for solid particles (ρ_s). However, the wet floc density (ρ_f) is known to be substantially less than this, often close to the density of water (Droppo, 2001). Density and porosity effects will be discussed below. Stokes' Law, or a modification thereof, is nevertheless often used to determine one or more of settling velocity, wet density, and porosity of individual flocs (Tambo and Watanabe, 1979; Li and

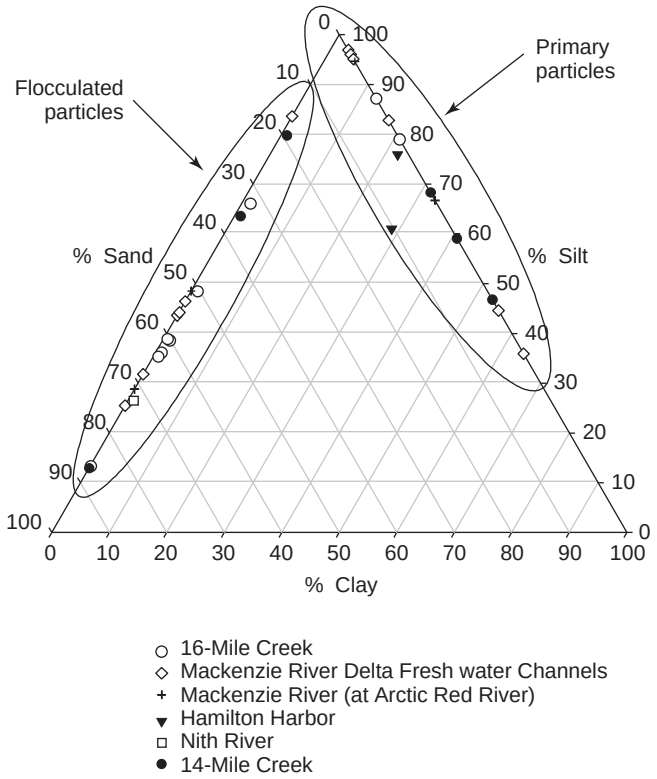

Figure 3 Ternary plot showing the relative proportions of sand, silt, and clay sizes for both original floc distributions and their primary distributions after undergoing sonication. The plot shows the significant influence that flocculation has on particle size

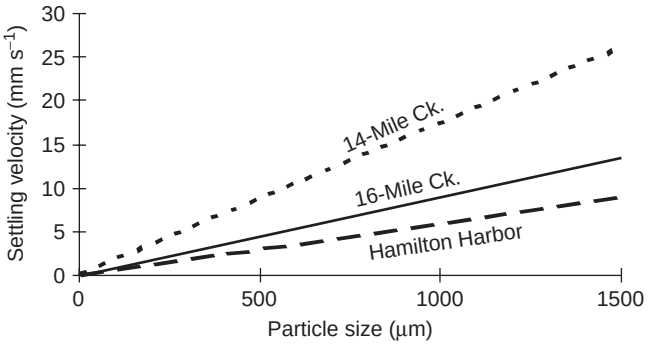

Figure 4 Regression lines for three floc samples. All regression lines are significant at $p = 0.05$. The plot shows that site-specific variables will influence floc settling velocity and transport

Ganczarczyk, 1987; Fennessy *et al.*, 1994), and does provide an indication of how these variables are related to floc size. Modifications of Stokes' Law, to improve floc settling velocity predictions, have generally relied on the use of shape factors in the calculation of drag coefficients as a correction for the influence of flocculation (Klemetson, 1985; Allen, 1990). Shape effects on floc settling behavior are also discussed below.

It has been well documented that as floc size increases so too does its settling velocity (Hawley, 1982; Li and Ganczarczyk, 1987; Burban *et al.*, 1990; Lick *et al.*, 1992; Eisma *et al.*, 1997; Hill *et al.*, 1998; Curran *et al.*, 2002). The relationship of floc size to settling is, however, very different from that predicted by the Stokes' equation. The Stokes' equation predicts that settling velocity will be proportional to the diameter of the particle squared (equation 3); however, multiple samples from multiple environments have shown that this relationship is in fact linear (Droppo *et al.*, 2002). This difference is owing to floc structure being dramatically different from the Stokes' assumed solid spherical particles (Figure 1b and 1c). Example linear regression lines are shown in Figure 4 for three different samples (two river and one lacustrine). As is characteristic from multiple samples, the lacustrine flocs settle slower for similar sizes, which is likely to be related to compositional and formational (shear) differences. Given the lower turbulence of lake environments, lacustrine flocs are often shown to be less dense and of a more open matrix than river flocs which were formed in a higher shear environment resulting in more compact flocs.

If Stokes' equation were used for flocs, it could overestimate settling velocity by orders of magnitude (e.g. for a 500-μm particle, Stokes predicts a settling velocity of 225 mm s^{-1} (assuming a density of 2.65 g cm^{-3}), while a measured 14-Mile Creek floc of similar size only has a settling velocity of 9 mm s^{-1} (actual density estimated to be approximately 1.1 g cm^{-3})). If such calculated settling estimates were used for sediment transport prediction, it could seriously underestimate the transport distance of particles and associated contaminants. On the other hand if only the primary particle size was used for prediction (as often they are), an overestimate of sediment transport would be predicted with concomitant management errors owing to the smaller size of the primary particles relative to the floc particles. The assumption of particles settling within the Stokes' region ($R_e < 0.2$) is also not always met for flocs as Droppo *et al.* (2002) found that the largest fluvial flocs often settle well out of this zone. Often these larger flocs represent the majority of sediment volume in transport (Droppo and Ongley, 1994).

There is consistently a high degree of variation for the relationship of floc size to settling velocity (e.g. r^2 values for the regression lines plotted in Figure 4 ranged from 0.4 to 0.6). This low explanation of variance is typical and is attributed to the morphological and compositional differences between flocs within a sample site. Flocs with similar measured diameters may have very different, shape, porosity, density, and composition and as such will settle with different rates. While it is evident that floc size is an important factor in influencing settling velocity, the other

characteristics of density, porosity, and shape (see next section) all interact resulting in a particle settling velocity which is well below that predicted by Stokes' equation.

The Effect of Floc Shape on Sediment Transport

Sediment transport will also be influenced by the shape of the particles. While cumulatively (from a sediment load perspective) this factor may not noticeably influence the overall flux of sediment in a river, it is important to understand its influence on individual particle behavior. The shape of a particle is known to influence settling velocity due to resistance effects against flow (fluid drag forces) (Richards, 1982; Li and Ganczarczyk, 1987). Particles which have the same density and diameter of an equivalent sphere but have a different shape exhibit different settling rates (Krumbein, 1942; Lerman, 1979; Richards, 1982; Ozturgut and Lavelle, 1984). The shape of a floc is influenced by its source, composition, and by the flow field in which it is transported and/or eroded in. While it is difficult to experimentally determine the effect of floc shape on settling velocity due to the difficulty in making or maintaining realistic flocs with realistic mass and density in the laboratory, it has been found that elongated flocs settle slower than spherical flocs in quiescent settling columns (Droppo *et al.*, 1998b). This relationship is likely to be related to elongated flocs preferentially settling with their long-axis parallel to the direction of settling (Figure 5), thus promoting more fluid drag on the particle and a slower settling velocity in theory. In later work, Droppo *et al.* (2002), however, found the opposite relationship which would suggest that floc shape may have a minimal influence on settling velocity. Plotting multiple data sets of aspect ratio to settling velocity showed no significant relationship. While it is likely that size is a much better predictor of settling velocity than shape, Droppo *et al.* (2002) found that generally a power function of the form $S_f = ad^m$ could be used to explain the relationship between shape factor and floc size (although the fit was generally poorly defined), where: S_f was the shape factor defined in equation (4), d was diameter and a and m are parameters which are dependent on the type of particle being investigated and the condition under which the flocs were formed (a and m are derived empirically). As a floc increases in size, generally it becomes more convoluted in shape (Droppo *et al.*, 2002) and more elongated (de Boer, 1997; de Boer *et al.*, 2000). In reality, for turbulent environments, flocs, if able to settle, will due so in a tumbling fashion. Such a motion in settling would further suggest that the influence of individual floc shape on settling velocity is limited and is likely of limited use for the prediction of sediment transport. For quiescent environments such as lakes and backwater areas of rivers, the settling and shape results above may be more characteristic.

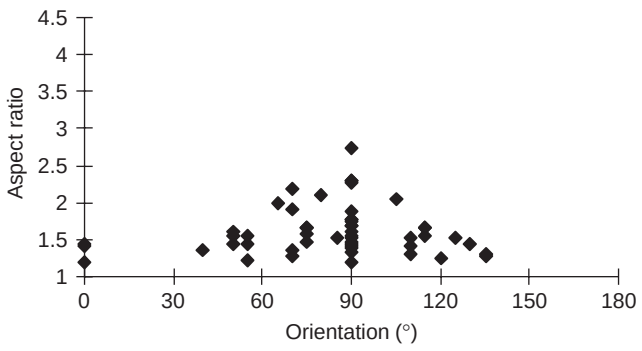

Figure 5 Example of the relationship between floc settling orientation and aspect ratio (floc length/floc width) for a lacustrine sediment (Hamilton Harbour). Note the bell shape of the distribution suggesting a predominance of long-axis settling

$$S_f = \frac{4\pi \times \text{Area}}{\text{Perimeter}^2} \quad (4)$$

($S_f = 1$ for a perfect circle, successively lower factors represent a more convoluted floc, and close to 0 = approaching a line).

The Effect of Floc Density and Porosity on Sediment Transport

While floc density will influence the downward flux of sediments (equation 1), no standard relationship exists between floc density and floc size or settling velocity. This is due to the complexities of the floc matrix and high variability within a natural system in terms of fluid shear and floc morphology. The density of a floc is influenced by its composition (inorganic and organic particles, EPS, water content, etc.) and its porosity (pore size and structure) and has typically been derived from equation (3) (ρ_f is substituted for ρ_s, where ρ_f is the wet density of the floc).

It has been shown constantly, regardless of the environment (e.g. marine, estuarine, wastewater, fluvial), that floc density decreases as floc size increases (Hawley, 1982; Gibbs, 1985; Andreadakis, 1993; Fennessy *et al.*, 1994; Droppo *et al.*, 2002). This is shown in Figure 6 for multiple river and lake samples. The variation between the lines is reflective of the different factors and relative importance of each, in influencing floc growth and structure between environments and sample times (Li and Ganczarczyk, 1989; 1990). Petticrew and Droppo (2000) and Droppo *et al.*, (1998b) found that flocs derived from the bed of two different rivers settled faster than those formed within the water column. This was attributed to density differences between the two floc populations with the suspended flocs being of a more open matrix, lower density structure with characteristic lower settling velocity as compared to the more dense bed-derived flocs.

Lagvankar and Gemmel (1968) suggest that for very large flocs there is less dependency of density on size since

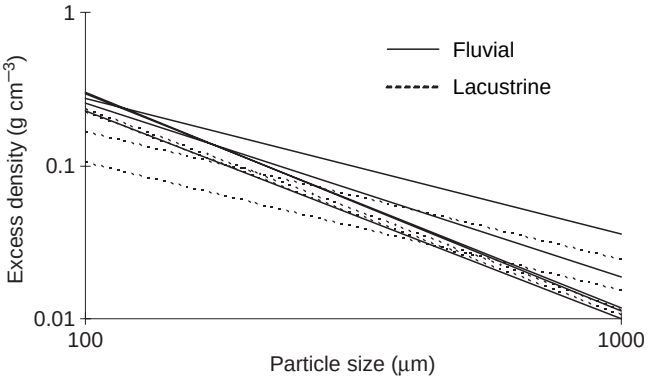

Figure 6 Examples of the inverse relationship of floc size to floc density for five river and four lake samples. Variations in slope are related to structural floc differences driven by site and time specific variables

the density becomes, in effect, constant for large flocs. This trend is shown in Figure 7 where for the larger flocs the particle density approaches the density of water. Given this relationship, and the fact that the range in floc densities is small (density typically ranges from 1.0 to 1.4 g cm^{-3} with the majority of flocs below 1.1 g cm^{-3}; Figures 6 and 7 and Riley, 1970; Krone, 1972; Shiozawa *et al.*, 1985) and close to the density of water (over a wide range of floc sizes), it is unlikely that density plays a strong role in particle settling and transport relative to the effect of floc size. This has been discussed in Droppo (2001) and Droppo *et al.* (2002).

The floc characteristics of size, shape, and density are highly influenced by floc porosity, which is developed through the heterogeneous arrangement of various floc constituents and dictated by such factors as the flow field (energy), biological colonization and metabolic production of sticky fibrils, and the trapping of additional inorganic or organic particles via surficial or internal physical (collision), chemical (electrochemical) or biological means. Once formed, the pores may provide an active micro environment which may support the uptake and/or transformation of various chemicals/nutrients. Pores may further influence electrochemical and/or diffusional gradients or advective-driven chemical/nutrient removal (Sherman, 1953; Li and Ganczarczyk, 1988; Logan and Hunt, 1987, 1988). All of these may in turn influence the hydrodynamics of a particle during transport through structural and density modifications (Droppo, 2001).

Porosity cannot be measured directly, due to the three-dimensional and tortuous nature of flocculated sediment and as such it is generally estimated using a mass balance of respective densities (equation 5). Porosity influences settling velocity indirectly by being one of the primary factors controlling density. As a floc grows, the amount of open void space (pores) increases simply due to the nature of the contact points between particles forming the matrix. With an increase in void space (porosity), there will be a proportional increase in water content. As such, the greater the porosity, the greater the water content, the lower the density, and, in theory, the slower its settling velocity (assuming constant floc size and no flow through the floc). Figure 7 shows that as a floc increases in size the porosity increase, approaching 100% which corresponds to the density of water. This relationship has been shown by numerous researchers (Tambo and Watanabe, 1979; Logan and Hunt, 1987; Li and Ganczarczyk, 1987, 1988).

$$\varepsilon = \frac{(\rho_s - \rho_f)}{(\rho_s - \rho_w)} \tag{5}$$

Where ε = floc porosity

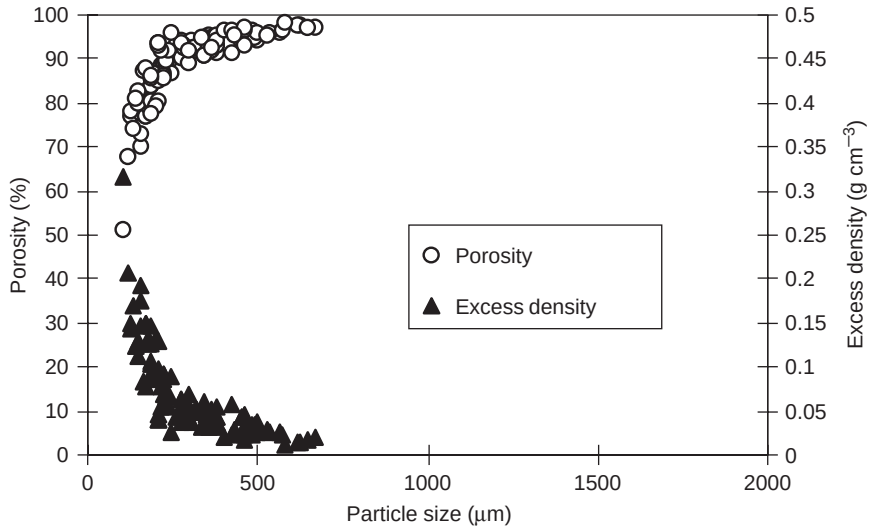

Figure 7 Example of the relationship between calculated floc porosity and density for a river suspended sediment sample

For the data in Figure 7, a value of $1.65\,g\,cm^{-3}$ was used to represent the dry density of the flocs (ρ_s) in equation (5) as the organic content of the flocs will reduce the density substantially below that of the traditionally used $2.65\,g\,cm^{-3}$ (Droppo *et al.*, 1997). This lower value is higher than those stated in the literature for microbial dominated flocs (Li and Ganczarczyk, 1987 (assumed $1.45\,g\,cm^{-3}$), Andreadakis, 1993 (assumed $1.34\,g\,cm^{-3}$)) given the mix of inorganic and organic particles in aquatic suspended sediments.

Porosity directly influences floc density and settling as individual large pores may potentially act as passages for the flow-through of water during settling. Such movement of water through the floc will, in theory, increase the settling velocity of the floc due to a reduction in drag (Zahid and Ganczarczyk, 1990). Thousands of low-resolution observations of freshwater flocs have revealed very few macro pores which may be capable of "flow-through". Multiple high resolution observations of floc pores (e.g. with electron microscopy) such as those in Figure 1(c) and 2 reveal the prevalence of EPS fibrils which may in fact fill much of the grossly observed pores with micro pores. These micro pores will have a high capacity for the retention of water with concomitant effects on density. As such the majority of water within freshwater flocs is believed to be bound and not free flowing. As porosity is strongly correlated to floc density, it is likely that porosity's influence on settling velocity is minimal relative to floc size (Droppo *et al.*, 2002)

The Effect of Floc Strength on Sediment Transport

Given that a floc is exposed to a variety of forces during its formation and transport, floc strength, or its ability to withstand shear, is a critical characteristic which will dictate the transport and fate of suspended sediment. The strength of a floc is dependent on its physical structure and composition and on the external forces operating on the floc. A discussion of the physical forces (stress relationships) acting on a particle is beyond the scope of this contribution. The reader is referred to Tambo and Hozumi (1979) and Partheniades (1986) for a discussion on this aspect. However, it is worth considering the potential scenarios or "life cycles" of a floc within a turbulent regime as related to floc strength.

As described above, flocculation influences the downward flux of sediment by principally increasing the particle size. While the floc may settle faster than individual particles (flow dependent), its ability to settle out of suspension at a given flow is dependent on its strength and its ability to withstand the higher shear stresses imparted onto the floc by the near bottom zone. As a floc approaches this near bottom zone, if the critical shear stress for floc break up is lower than the bed shear stress then the flocculated particle will break up and be resuspended potentially to go through the flocculation process again and attempted settling further down flow. If the floc enters a zone where its strength is greater than the bed shear stress, then it may settle out of suspension (Partheniades, 1986) forming a surficial fine-grained laminae (SFGL) (Droppo and Stone, 1994). This vertical and horizontal loop in floc transport has been called "floc recycling" by Droppo *et al.* (1998b).

Within river systems, this SFGL may in itself undergo a form of recycling as entrainment of the deposited flocculated material is dependent on the critical bed shear stress for erosion being surpassed. Once the flocs are resuspended, they then re-enter the floc recycling process only to at some point (shear dependent) redeposit in short-term storage as a new layer of SFGL or longer-term storage as over bank sediment or reservoir/lake/oceanic deposits. This linkage of floc and SFGL recycling is illustrated in Figure 8. Floc strength is therefore a critical characteristic which will dictate its transport history.

CONCLUSIONS

Suspended sediment particles are often implicitly or explicitly assumed to be single grain objects of inorganic composition. This is motivated by numerous constraints/biases (e.g. an individual's discipline, focus of research, laboratory/field capabilities and the scale of interest) as well as a lack of a standard method for sampling, observing, and measuring floc/aggregate particles. In addition, the lack of a standard defining equation, which can explain the formation and interaction of flocs/aggregates with their surrounding aquatic environment, has furthered this assumption. It is, however, well documented that cohesive suspended sediment is preferentially transported as flocculated material. Flocs are very different from their constituent primary particles as they are complex, heterogeneous, porous structures, composed of inorganic particles, organic particles (viable and nonviable), and water. Flocculation, because of its ability to alter the structure (size, shape, composition, density, and porosity) of suspended sediments has significant implications for the transport and fate of suspended sediment in aquatic systems. The study of floc characteristics and their influence on sediment transport is complicated by the dynamic nature of flocculation. Flocs are in a continual state of change due to the flow dynamics of the system and because of the complex interactions between the principle components of the floc (water, inorganic particles, organic particles, and pores). The significant "living" component of the floc (primarily bacteria) plays a strong role in mediating the structure, and therefore transport of flocs due to their secretion of extracellular polymeric fibrils (EPS). This material promotes floc building by its sticky nature, and provides the floc with a plastic/elastic nature which results in a relatively strong structure. In this review, the transport of sediment is analogous to particle

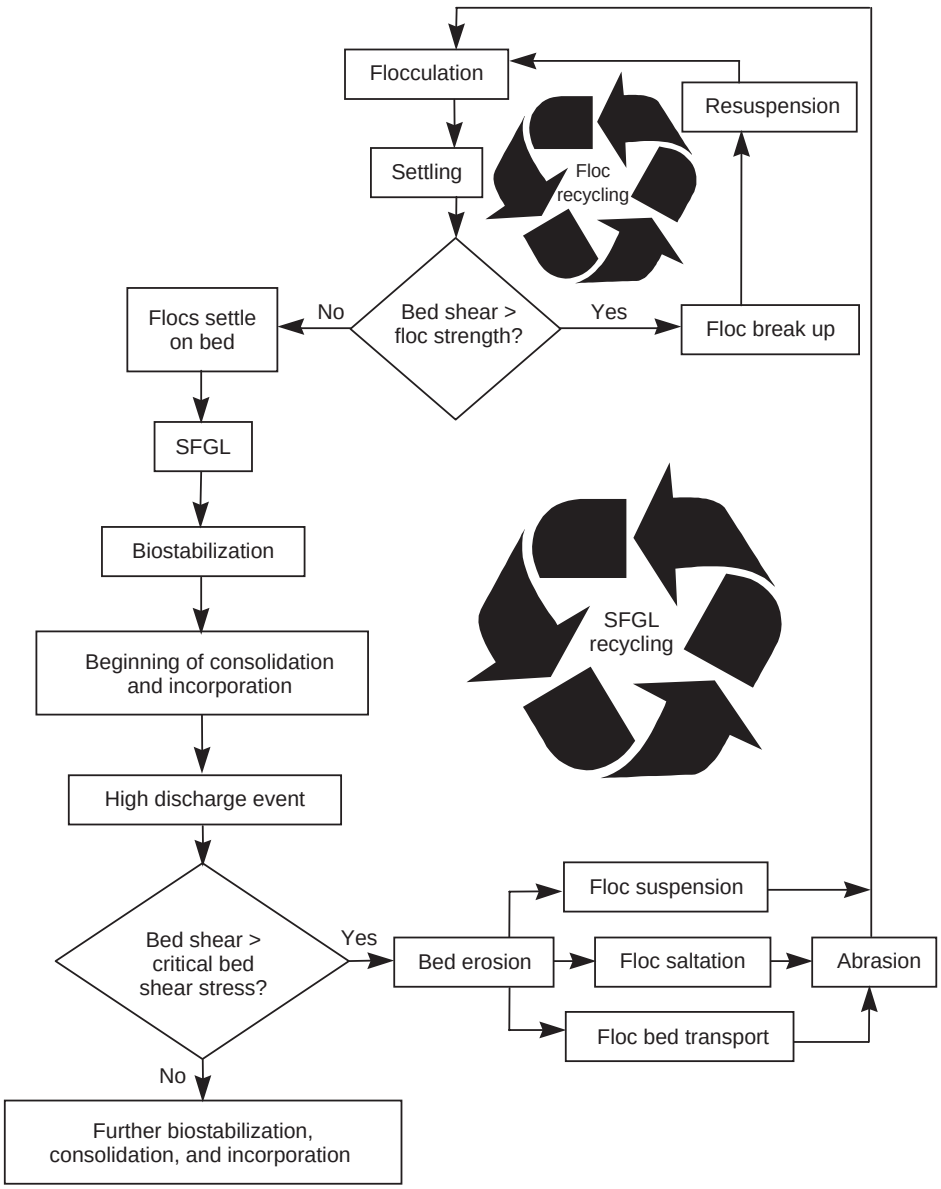

Figure 8 Conceptual model of SFGL and floc recycling loops linked for a river system (Reprinted from Droppo *et al.*, 2001. © 2001, with permission from Elsevier)

settling velocity. A positive linear relationship between floc settling velocity and size is standard. Generally, there is a high degree of variability in this relationship which is related to differences in floc structure (i.e shape, composition, density, porosity) over a narrow size range. Floc density decreases as floc size increases with densities of very large flocs (i.e. $>500\,\mu m$) approaching the density of water. Conversely, the porosity of a floc increases with floc size, approaching 100% (corresponding to the density of water). Floc size is the dominant factor influencing sediment transport relative to floc density, porosity, and shape. This is due to porosity being directly related to density and the range of floc densities being relatively small (1.0 to $1.4\,g\,cm^{-3}$) and close to that of the water. As such, a change in floc density or porosity does not have a significant effect on settling velocity. Floc shape was found to have minimal effect on the settling velocity of the flocs and is believed to be even less significant in influencing sediment transport in turbulent environments. Given the significant influence that flocculation has on the transport of suspended sediment, it is important that the structure and behavior (transport/settling) of flocculated particles be known. A better understanding of flocculated particle characteristics will help to refine our knowledge of cohesive suspended sediment transport within a variety of aquatic ecosystems.

84: Floodplain Sedimentation – Methods, Patterns, and Processes: A Review with Examples from the Lower Rhine, the Netherlands

HANS MIDDELKOOP

Department of Physical Geography, Utrecht University, The Netherlands

Floodplain sedimentation plays a keyrole in the sediment budget of river basins, but it also relates to river management, flood protection, civil engineering, and ecological rehabilitation of rivers. Understanding of the process, therefore, is essential both from a geomorphologic and river management points of view. This paper provides a review of recent research on floodplain sedimentation, focusing on field-based methods to reconstruct and document spatial patterns of overbank sedimentation, as well on mathematical modeling approaches. Examples of floodplain sedimentation over various timescales are given for the lower Rhine River in the Netherlands. The final section synthesizes the processes, their controls, and the resulting patterns and amounts of floodplain deposition.

INTRODUCTION

A floodplain comprises the area next to a river channel that is inundated once during a given recurrence interval. Floodplains are complex assemblages of landforms built up by channel bars and bed forms, lateral accretion scroll bars and natural levees, point bars overlaid by overbank deposits, old channels, backswamps, and crevasse splays (Figure 1). Many lowland floodplains undergo regular flooding, causing deposition of fine material from suspension during inundation. In spite of the infrequency or irregularity of flooding, extensive bodies of overbank fines may accumulate by vertical aggradation over a period of decades to centuries. At this timescale, only a small fraction of the total alluvium in a river valley is transported by the river; the bulk is stored in floodplains.

The earliest studies on floodplain sediments and fluvial architecture were concerned merely with lateral accretion, whereas relatively little attention was paid to overbank deposition rates (Marriott, 1992). Estimates of overbank deposition rates initially relied on visually distinct soil profile characteristics such as color or texture to discern flood deposits, whereas analysis of deposition processes focused on crevasse spay development or analysis of deposits after rare, extreme flood events (Simm, 1995). However, little progress was made in documenting spatial patterns of overbank deposition resulting from the more frequent and moderate-magnitude floods. This may be due to the difficulties associated with sampling small quantities of spatially and temporally highly variable overbank deposition over large floodplain areas. Another practical limitation is that sampling surveys are difficult to plan because of infrequent or unpredictable inundation of the area of interest, while equipment and fieldwork are faced with potentially hazardous flood conditions.

In recent years, the study of floodplain deposition has gained interest due to the increased awareness of the geological, geomorphological, environmental, and societal significance of the process. Floodplain deposition is now known as a key component in the sediment budgets of catchments, since floodplains may form significant sinks for suspended sediment transport through a river system (Walling *et al.*, 1998a; Walling, 1983) (*see* **Chapter 85, Sediment Yields and Sediment Budgets,**

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

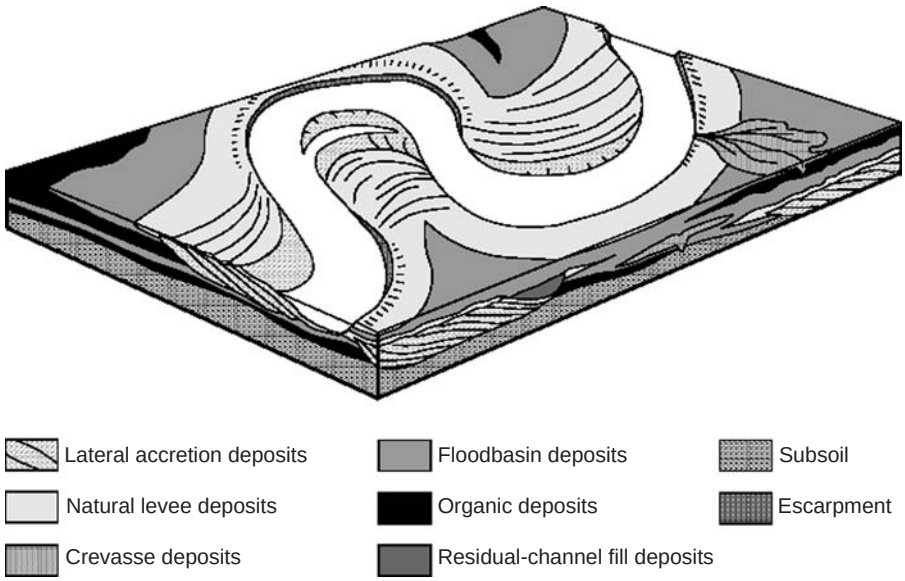

Figure 1 Block diagram of a meandering river. River flow is to the left

Volume 2). On the geological timescale, alluvial deposits are volumetrically important sediment bodies in the rock record. Furthermore, suspended sediment plays an important role of in the transport of particulate-bound pollutants and contaminants through fluvial systems, and their accumulation in floodplain environments (Salomons and Förstner, 1984; Foster and Charlesworth, 1996). In addition to their functioning as sediment sinks in catchments budgets, floodplain deposits provide aggregated information about sediment delivery and changes in sediment yield from the upstream catchments, associated with changes in climate and land use (Hudson, 2003) (*see* **Chapter 85, Sediment Yields and Sediment Budgets, Volume 2** and **Chapter 86, Measuring Sediment Loads, Yields, and Source Tracing, Volume 2**).

Understanding of floodplain processes also relates to river management, flood protection, civil engineering, and river rehabilitation. For centuries, floodplains have been areas of preferred and most intense human settlement, due to the proximity of water for transport and supply, and abundant fertile land for agriculture. Floodplains have become densely populated areas with extensive urban and industrial areas and intensive farming. Recent years have witnessed major river floods causing extensive floodplain inundation with severe human and economic losses. This has led to a growing concern over the frequency and magnitude of river floods and floodplain inundation and their relationship to intensified floodplain occupation, river canalization, and the potential implications of climate change (Knox, 1993). The development of appropriate flood management strategies has raised the need of a sound understanding of the hydraulic characteristics of overbank flows, and the ability to quantify and predict the relationships between river discharge, floodplain topography and the resulting patterns of overbank flow, and deposition of sediments and associated pollutants. Finally, river rehabilitation projects that involve landscaping measures such as reopening of secondary channels, lowering the floodplain surface, removing minor embankments, or the introduction of floodplain forests (Silva *et al.*, 2000) will lead to major changes of the floodplain topography and vegetation, which in turn may considerably affect overbank sedimentation rates (Middelkoop and Van der Perk, 1998).

These issues demand knowledge and understanding of the process of overbank deposition, the quantification of the spatial and temporal variability of contemporary deposition, as well of the main controls of these related to flood magnitude, sediment load in the river, and floodplain topography. Given the possible effects of climate change and changes in land use and management on river flow and catchment sediment budgets, there is a need to place information on contemporary suspended sediment fluxes and overbank deposition rates into a longer-term context to identify long-term budgets and trends (Owens *et al.*, 1999a).

Overbank Deposition

Overbank deposition of suspended sediment upon floodplains occurs during periods of high discharge when fine-grained material, supplied to the fluvial system by catchment runoff, is transported out of channel over the floodplain and deposited in regions of reduced flow competence (Nicholas and Walling, 1997b). Mean annual overbank sedimentation rates are controlled by factors such as flood

frequency and magnitude, concentration and settling characteristics of the transported suspended sediment, and floodplain topography. Contemporary floodplain sedimentation rates reported in the literature typically range between 0.5 and 20 mm $year^{-1}$, with maximum values observed during extreme flood events up to several centimeters (e.g., Simm, 1995; Terry *et al.*, 2002). Deposition rates show considerable spatial variation not only between different floodplains but also within individual floodplain reaches. Observed *spatial patterns* of overbank deposition are associated with local differences in flooding duration, floodplain topography, and distance to the river channel, and have been related to the influence of floodplain topography and surface roughness upon overbank flow patterns and flow competence (Middelkoop and Asselman, 1998; Middelkoop and Van der Perk, 1998). *Temporal* variations in floodplain sedimentation rates are generally related to hydrologic changes and to changes in land use and soil conservation practices in the upstream areas.

Although deposition rates are often low and in some cases almost imperceptible, substantial amounts may be deposited when large areas are involved (Walling and Owens, 2003). Consequently, because of overbank deposition, floodplains may trap a considerable part of the suspended sediment load transported through a river system to the catchment outlet (*see* **Chapter 85, Sediment Yields and Sediment Budgets, Volume 2** and **Chapter 86, Measuring Sediment Loads, Yields, and Source Tracing, Volume 2**). The resulting conveyance losses of suspended sediments may be in the order of 10% to more than 40% of the annual load entering the reach (e.g. Lambert and Walling, 1986; Walling *et al.*, 2003). In contrast with channel-bed storage where the residence time of sediments is usually in the order of a year, sediment deposited on the floodplain may remain stored for decades to centuries before reentering the river system due to overbank erosion. This role as sink for sediments may complicate the interpretation of downstream sediment yields in terms of upstream sediment budgets of drainage basins, particularly in larger drainage basins (Walling *et al.*, 1998a; Asselman *et al.*, 2003).

Contaminant Deposition

Many contaminants, including heavy metals and pesticides, as well as nutrients are transported through the fluvial system in association with fine sediment (Salomons and Förstner, 1984; Foster and Charlesworth, 1996) (*see* **Chapter 89, On the Worldwide Riverine Transport of Sediment – Associated Contaminants to the Ocean, Volume 2**). Consequently, sediment-associated contaminants will also be deposited on river floodplains during overbank flooding. In polluted river basins particularly, because of the release of large volumes of wastes in the nineteenth and twentieth centuries from mining and industrial activities, floodplain soils may have become heavily contaminated by pollutants, owing to the deposition of contaminated sediments over many years.

Initial studies on sediment-associated river pollution tended to focus on the analysis of suspended sediment in the river, but increasingly it is being recognized that floodplain deposits should also be considered when analyzing the fate of contaminants and the temporal and spatial patterns of contaminant distribution within river systems (Salomons and Förstner, 1984; Leenaers, 1989; Owens *et al.*, 2001; Walling *et al.*, 2003). Because of overbank sedimentation, floodplains function as sinks in sediment-associated contaminant budgets of catchment contaminants (Walling and Owens, 2003; Owens *et al.*, 2001). This can result in a reduction of the nutrient or contaminant flux at the catchment outlet, such that the contaminant flux measured at the catchment outlet may significantly underestimate the total mass of the contaminants mobilized within the catchment. Conversely, contaminant tracers contained in floodplain soils may allow determination of sediment sources by means of fingerprinting (He and Owens, 1995; Collins *et al.*, 1997; Owens *et al.*, 1999a), and may help estimate and understand contaminant budgets of river catchments (e.g. Walling and Owens, 2003).

Within the floodplain environment, the accumulation of contaminants may lead to severely enhanced levels of contamination within the floodplain ecosystem and food webs. Nature rehabilitation projects that involve excavation of floodplain deposits may be confronted with high sanitation costs of the contaminated sediments (Thonon *et al.*, 2002), while geochemical mapping of floodplains may become problematic because of large spatial variations in contamination, associated with the history of pollutant release into the river system as well as spatial patterns of past overbank sedimentation rates (Bradley, 1995).

As a consequence of the role of floodplains as a sink for contaminants, contaminated overbank deposits present a potential source for future contamination of the river system, when these are mobilized because of bank erosion (e.g., Bradley and Cox, 1990; Bradley, 1995; Walling *et al.*, 2003). While mine wastes and other point sources are important primary supplies of metals into the river system, significant quantities of metals are cycled through the river system as a result of floodplain deposition and the subsequent erosion of contaminated floodplain deposits. This causes heavily polluted floodplains to be considered as "chemical time bombs". This cycling of metals may continue for many years, even if direct inputs to the river were to cease. Understanding the rate and scale of this continued cycling of metals in river catchments relies on the analysis of the interaction between floodplain and the channel, and on the processes of sedimentation and erosion involved.

Outline

The present paper focuses on the deposition of overbank sediments and associated particulate-bound heavy metals outside the channel of meandering lowland rivers. It first gives a review on methods of documenting floodplain sedimentation rates and patterns in the medium-term (10^1-10^2 years) and event-based timescale, as well as concepts applied for modeling the process of overbank deposition. Subsequently, examples of floodplain sedimentation over various timescales are shown for the lower Rhine distributaries in the Netherlands. This is followed by a more general overview of the main mechanisms and controls of the sedimentation process. Finally, an outlook is given on research issues for improving our present understanding of floodplain sedimentation and its geomorphologic and ecologic significance.

QUANTIFICATION OF MEDIUM-TERM AMOUNTS AND PATTERNS OF FLOODPLAIN SEDIMENTATION

Introduction

Investigation of floodplain sedimentation at medium-term (10–100 years) timescales is carried out to reconstruct changes in overbank sedimentation rates and sediment sources in historic time (Walling *et al.*, 1999; Owens *et al.*, 1999a), and to determine the role of floodplains storage as sink in the suspended sediment budget of river systems. Within the floodplain area, these reconstructions are needed to understand the relationships between average deposition rates and distance to the main channel, relative elevation, and other aspects of floodplain topography.

Estimates of sedimentation rates averaged over a number of years rely on determining the date of one or more particular levels in the sediment layer, and calculating the average rate of deposition of the material overlying these levels. Methods to determine the age of levels within the profiles may be based on (Simm, 1995): (i) Historic data and map comparison (e.g., Wolfenden and Lewin, 1977; Magilligan, 1985), and impressively long records from China (Xu, 2003), (ii) previous benchmark studies (e.g. Leopold, 1973) (iii) buried soils, roads, or artifacts (e.g. Costa, 1975), (iv) dendrochronology of floodplain vegetation (Nakamura and Kikuchi, 1996), (v) radiocarbon dating (e.g. Alexander and Prior, 1971; Baker *et al.*, 1985; Brown, 1987), (vi) using fallout radionuclides such as ^{10}Be, ^{210}Pb and ^{137}Cs as tracers (e.g. Campbell *et al.*, 1982, 1988; Osterkamp, 1989; Walling *et al.*, 1986b; Walling *et al.*, 1989; Walling and Bradley, 1989; Walling *et al.*, 1992; Walling and He, 1993, 1994a, 1994b; Simm, 1995, He and Walling, 1996), and (vii) relating trace metal concentrations in the sediment profile to the known history of mining activities in the upstream catchment (e.g. Magilligan, 1985; Lewin and Macklin, 1987; Knox, 1987, 1989; Leenaers, 1989; Bogen *et al.*, 1992). Measurements of the depth distribution of fallout radionuclides and heavy metals within a sediment core collected from a floodplain provide an effective means to determine past sedimentation rates. The basis of using these tracers to establish a chronology of sediment cores is that their input into the environment is constant, or shows an *a priori* known variation in time. Differences in total amounts of tracers, or in the depth at which characteristic changes in tracer concentrations within the soil profiles occur, are a measure of deposition rates.

Fallout Radionuclides

The basis of using fallout radionuclides in sediment budget investigations is that their fallout input can be assumed to be effectively uniform over a relatively small area, and that the fallout is rapidly and firmly fixed by the surface soil. Subsequent redistribution of the particle-bound fallout in the environment will therefore reflect erosion and deposition of sediment particles. Measurements of the spatial distribution of radionuclides in floodplain soils can therefore be used to investigate spatial patterns of sediment deposition. As sorption of fallout radionuclides by sediment particles generally is associated with cation exchange at the surface of sediment particles, and hence depends on their grain size, comparison of fallout concentrations in different sediment samples should be done for similar grain size fractions taken from each sample (Walling and Woodward, 1992; He and Owens, 1995; Walling *et al.*, 1998a). Since different source areas of sediments deposited on floodplains may contain different amounts of radionuclides, these can also be used as "fingerprints" to reconstruct the sediment source areas (e.g. He and Owens, 1995).

^{210}Pb

The unstable isotope ^{210}Pb is one of the products of the ^{238}Uranium decay series, with a half-life of 22.3 years. ^{210}Pb in surface sediment has two sources: *in situ* production and atmospheric deposition, both of which can be considered constant through time. For age determination it is essential to separate the ^{210}Pb content of a sample into these two components. Uranium-238 is present in rocks and soils and decays to ^{226}Radium (half-life 1622 years), which in turn decays to ^{222}Radon. This is an inert gas (half-life 3.8 days) that decays through a series of short-lived processes to ^{210}Pb. The ^{210}Pb produced by the *in situ* decay of ^{226}Ra is called "supported", and will be in equilibrium with ^{226}Ra. Part of the ^{222}Radon gas, however, escapes to the atmosphere, where it decays to ^{210}Pb. The atmospherically produced ^{210}Pb is subsequently deposited into surface waters through precipitation and dry deposition, where it is readily adsorbed by suspended sediment. This atmospheric deposition is called the *unsupported* or *excess* lead, as

it is not supported by decay of its *in situ* parent. In the upper part of a sediment core, the unsupported lead is recognized as an excess activity over the supported activity, expressed in $Bq\,kg^{-1}$. After a period of about 100 years (i.e. 5 half-lifetimes), this excess ^{210}Pb has become too small to be determined, thereby confining the applicability of the method to this period. As supported ^{210}Pb will be in equilibrium with ^{226}Ra, the amount of unsupported ^{210}Pb can be determined by measuring both total ^{210}Pb and ^{226}Ra, and subtracting the supported component. Another method is to estimate the supported ^{210}Pb from samples in deep, old parts of the sediment core, where the supported component has decayed. At sites with constant sedimentation rates (such as floodplains), the intensity profile of the excess ^{210}Pb will show an exponential decrease with depth, the decrease rate of which is determined by the deposition rate (Appleby and Oldfield, 1978; Dominik *et al.*, 1981, 1984). Alternatively, the sedimentation rate can be determined from the total excess ^{210}Pb activity over an entire sediment core (Walling and He, 1994a).

^{137}Cs

^{137}Cs is an artificial fallout radionuclide with a half-life of 30.2 years that has been introduced into the atmosphere by nuclear tests in the 1950s and 1960s. It circulated globally in the stratosphere, and fallout was associated with precipitation. The temporal pattern of this fallout is well documented and is assumed relatively uniform over relatively small areas. Fallout was first detected in the early 1950s; it reached a peak in 1963, and declined after the Nuclear Test Ban Treaty to low levels by the mid-1970s. Since the 1980s the ^{137}Cs fallout has become negligible, with exception of areas of Europe and adjacent regions affected by a short-term fallout due to the Chernobyl nuclear power plant incident of 1986. The deposition patterns of the Chernobyl fallout show considerable variation even at the local scale, associated with the pathway of the radioactive cloud and local rainstorms (De Cort *et al.*, 1998; He and Owens, 1995). With time, ^{137}Cs may migrate slightly down the profile, due to diffusive and convective processes and bioturbation (He and Owens, 1995; Walling and He, 1997b). The time-variable ^{137}Cs inputs can be detected from sediment cores in deposition zones such as floodplains, allowing the establishment of the chronology of the sediments and thereby estimating sedimentation rates over the past 40 years. To determine the deposition rates, three approaches can be followed (Walling and He, 1997b): The first is to compare the shape of the ^{137}Cs depth profiles with that in a reference site that does not experience flooding (Figure 2). The degree of vertical stretching of the ^{137}Cs profile is a measure of the deposition rate. The second approach uses the depth at which significant ^{137}Cs concentrations are first recorded to estimate the position of the surface in the mid-1950s, and the position of the levels with peak activity to estimate the depth of the 1963 and 1986 surfaces. However, in both these cases, it is necessary to take account of the potential for postdepositional redistribution of ^{137}Cs in the sediment profile, since this influences the depth of ^{137}Cs peaks within the profile. Furthermore, this approach requires a high-resolution sampling of a sediment core and subsequent detection of ^{137}Cs activities. An alternative and third method therefore is to measure the total ^{137}Cs inventory for single whole core obtained from floodplain sites and subsequently comparing this with the total ^{137}Cs amounts in sediment cores obtained at nearby undisturbed and nonaccumulating reference sites above the floodplain level. The excess ^{137}Cs in the floodplain core compared to the reference is a measure of the floodplain sedimentation rate (Walling and Bradley, 1989; Walling *et al.*, 1992, 1998a; Walling and He, 1994a, 1994b, 1997b; Nicholas and Walling, 1997b). In this case, it is important to retrieve the complete ^{137}Cs profile, but the advantage is that only a single determination of ^{137}Cs is required at each sample location. Using bulk ^{137}Cs inventories of entire cores is believed to yield more representative estimates of spatial variability in overbank sedimentation than if only a small number of sectioned cores are analyzed (Walling *et al.*, 1998a). With increasing sensitivity of modern γ-ray measurement devices, however, it has become possible to analyze ^{137}Cs activities over an entire sediment core at centimeter resolution. An example is the PHAROS high-resolution radiometric core analyzer that allows measuring radionuclides in a drill core to determine sedimentation by the peak and onset of ^{137}Cs (Rigollet and De Meijer, 2002; Van Wijngaarden *et al.*, 2002).

Because of their different age ranges represented by ^{210}Pb and ^{137}Cs, ca. 100 years and ca. 40 years respectively, combining these tracers may allow determining changes in historic sedimentation rates (Walling and He, 1994b; Owens *et al.*, 1999a; Owens and Walling, 2002) (Figure 2). Radiometric dating of floodplain sediment has been applied in many river systems across Europe, with many examples from the United Kingdom, but also from other rivers within and outside Europe (e.g. He and Owens, 1995; Nicholas and Walling, 1997b; Siggers *et al.*, 1999; Owens *et al.*, 1999a; Stam, 1999; Saxena *et al.*, 2002).

Heavy Metals

In most catchments with intensive mining and industrial activity, large amounts of pollutants including heavy metals are released into the fluvial system. Because of rapid and firm adsorption to sediment particles, heavy metals will be transported in association with sediments through the fluvial system, and will also be deposited on floodplains during overbank flow. In many fluvial systems metal contamination has been present for more than a century, during which time the metal concentrations in the river sediment have varied greatly, depending on the intensity and type of

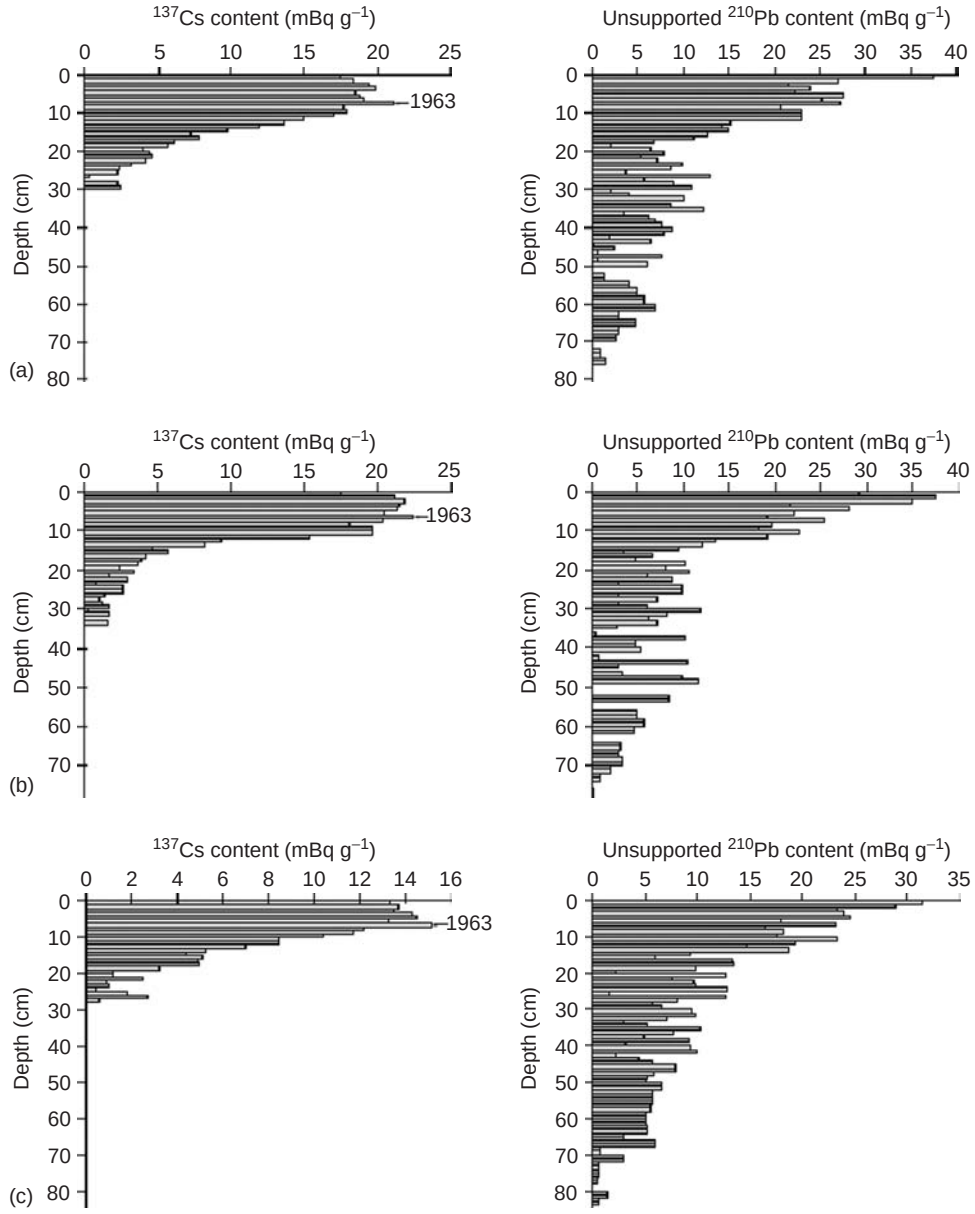

Figure 2 The depth distributions of ^{137}Cs and unsupported ^{210}Pb concentrations in the floodplain cores collected from the three sites along the Teviot and Tweed rivers, Scotland (Reproduced from Owens and Walling, 2002 by permission of John Wiley & Sons Ltd)

mining and industrial activity (e.g. Swennen *et al.*, 1994; Taylor, 1996; Owens *et al.*, 1999a; Middelkoop, 2000; Owens and Walling, 2003). Heavy metals can be used as tracers to estimate average floodplain sedimentation rates by comparing spatial differences among different concentration profiles in the floodplain soils, or by comparing concentration profiles with the chronology of the metal pollution of the river sediment, which has been reconstructed from historic or other independent sources. Because of their preferential bonding to finer sediment fractions and organic matter, metal concentrations may demonstrate large variability within floodplains due to varying grain size and organic matter contents of the sediment (Leenaers *et al.*, 1998; Middelkoop, 2000). These differences must be isolated first from the variations in pollution due to upstream pollution of the catchment to enable establishment of the sediment chronology (Owens *et al.*, 1999a; Middelkoop, 2002a; Owens and Walling, 2003).

1D Sedimentation Models

Attempts to use heavy metal profiles in floodplain sediment for establishing chronologies by only considering

characteristic changes or peaks in the concentration profile may encounter some major limitations. Firstly, a high sampling resolution is required to enable precise determination of the depth of peaks or of other characteristic changes in contaminant concentration profiles. Secondly, there has to be a detailed and accurate record of historic river pollution. Finally, postdepositional redistribution of the contaminants by chemical, physical, or biological processes may result in changes in the vertical profiles, which lead to inaccurate assignments of ages to profile depths (Hudson-Edwards *et al.*, 1998). Therefore, instead of directly assigning ages to characteristic horizons in a floodplain profile, depth–age relationships may be determined using 1D models that replicate the development of a floodplain soil profile.

Middelkoop (2002a) determined average sedimentation rates along the Rhine from heavy metal profiles in floodplain soils by means of inverse modeling. This was done with a one-dimensional model of sedimentation and postdepositional mixing that simulates the development of a metal profile in a floodplain soil using the annual amounts of sediment deposition and concentrations of Cu, Pb, and Zn in the deposited sediment as input. For this purpose, the trends in metal pollution of the Rhine river sediment deposited on the floodplain during the past century were reconstructed independently from dated sediment cores from small ponds within the floodplain. Estimation of the average sedimentation rate during the development of a floodplain metal profile was done by calibration of the model against the observed metal profile in the floodplain soil, thereby varying the input sedimentation rate. The advantage of this method is that it uses information over an entire profile, while it requires only a limited number of samples, accounts for postdepositional redistribution of the metals, and provides quantitative estimates of the precision of the obtained sedimentation rates.

In a study on the Powder River, Montana, USA, Moody and Troutman (2000) used a simple one-dimensional model of floodplain growth by vertical aggradation to demonstrate the monotonic growth of floodplain, as deposition rate of sediment during overbank flooding for the duration that the threshold discharge corresponding to the floodplain height was exceeded. Because of increasing floodplain elevation the annual duration of deposition gradually decreases, the growth rate of the floodplain decreases over the years. Net annual deposition rates were estimated by comparing floodplain growth curves with empirical growth curves based on dendrochronology and direct field measurements.

QUANTIFICATION OF SHORT-TERM AMOUNTS AND PATTERNS OF FLOODPLAIN SEDIMENTATION

Studying shorter-term (e.g. annual, flood event) rates and patterns of floodplain deposition is essential to understand the relationships between sedimentation, flood characteristics (magnitude and sediment concentrations in the main channel), and floodplain properties and site characteristics (local elevation, distance to the main channel, topographical elements). Over the past decennia, different methods have been employed for measuring and quantifying shorter-term rates. A recent review of these approaches is given by Steiger *et al.* (2003) and the most generally used ones are summarized here.

Estimation of Average Deposition from Conveyance Losses

From observations of suspended sediment transport along a river reach, conveyance losses over the reach under consideration can be determined. These can provide estimates of average sedimentation rates along river reaches between gauging sites during individual flood events or over longer periods of time (e.g. Lambert and Walling, 1986; Gretener and Strömquist, 1987; Walling *et al.*, 1986a; Walling and Bradley, 1989). The reliability of observations of suspended sediment transport is heavily dependent upon the temporal frequency of transport observations, particularly during a flood event when concentrations are high and change rapidly in time, and upon the degree to which the observations represent sediment transport over the entire river channel cross section (e.g. Walling, 1983; Walling and Webb, 1987). Furthermore, suspended sediment input through bank erosion or from tributaries in between the upstream and downstream sample stations, and varying within-channel storage of fine sediments may lead to inaccurate estimates of conveyance loss due to floodplain deposition. Comparison of estimated conveyance losses along a stretch of the River Culm, Devon, UK with ^{137}Cs measurements and sediment trap measurements indicated that the conveyance loss approach only provides tentative estimates of average sedimentation rates (Walling *et al.*, 1986a).

Post-event Field Surveys

When no sampling or monitoring devices have been installed prior to a flood event, deposition patterns resulting from the flood must be documented by post-event field surveys onto the horizontal distribution of the deposition using aerial photographs or multispectral remote sensing images. The deposition depth is determined using existing marker horizons, or using techniques to analyze subsurface sedimentary structures. Such approaches are particularly suitable in mapping sandy deposits. Discrimination of freshly deposited sediment may be based upon burial of natural marker horizons such as the vegetation growing on the pre-event ground surface, or upon differences in colour or texture between the deposited and pre-event surface sediments. This method has been used for more than 60 years, initially in US surveys, but later

also reported from European rivers (e.g. Mansfield, 1939; Wolman and Eiler, 1958; McKee *et al.*, 1967; Kesel *et al.*, 1974; Brown, 1983; Gomez *et al.*, 1995, 1997, 1998; Ten Brinke *et al.*, 1998; Wyźga, 1999). Ten Brinke *et al.* (1998) determined thickness of sand splays deposited during two high-magnitude floods along the lower Rhine by field measurements, and subsequently extended these observations over the entire bank of the lower Rhine distributaries using aerial photographs to estimate the total deposited sand volume. Magilligan *et al.* (1998) did the same for overbank deposits after an extreme flood on the Upper Mississippi River using aerial survey and Landsat-5 TM satellite data. Mertes (1994) calculated a mass balance of the sediment transported along floodplain transects on the Amazon River from patterns of sediment concentration on a Landsat TM satellite image, from which he estimated amounts of floodplain deposition as well as order-of-magnitude calculations of vertical deposition rates.

Analysis of subsurface annual layers of sandy overbank deposits and crevasse splays can be made using ground-penetrating radar or electromagnetic induction. Ferguson and Brierley (1999) discriminated well-sorted sandy beds and thicker silty-sand beds in river levees using ground-penetrating radar profiles run across the levee and adjacent geomorphic units. Bristow *et al.* (1999) used the same equipment to survey the depth of crevasse splays. Kitchen *et al.* (1996) coupled electromagnetic induction, ground conductivity sensing, and locational information derived using a global positioning system to map sand deposition depth after major floods.

Artificial Marker Horizons

Instead of depending upon naturally occurring marker horizons, artificial markers spread over the floodplain in advance of a flood can locate the pre-event surface after deposition has occurred. Examples of marker types are based on colour differences of red sand, brick dust, coal dust, or white clay, mostly used in coastal marshes and wetlands (Steiger *et al.*, 2003). This approach has the advantage that the pre-event surface is clearly marked and that the marker has negligible influence on the hydraulic resistance of the surface for which sedimentation rates are estimated. Nevertheless, the method may fail when the marker horizon is eroded or redistributed. Also, difficulties may arise when trying to remove the freshly deposited sediment from the underlying marked sediment without contaminating the new deposits with the underlying pre-event deposits.

Erosion Pins

Erosion pins are long, thin metal pins inserted into river banks so that repeated measurement of the exposed length of each pin provides an estimate of the local bank erosion rate. Where net deposition of sediment occurs, repeated measurements of pin burial have shown an accurate approach to estimate depths of sedimentation, particularly on plane surfaces within wetlands (e.g. Ranwell, 1964). Automated continuous measurement of erosion–deposition can be made using photoelectronic erosion pins (PEEP) introduced by Lawler (1991). Erosion pins are inexpensive tools that can be used in large numbers. Although they do not disturb the sediment, the pins may have an important impact on local flow patterns and therefore, on local sedimentation rates. Erosion pins may also be unstable in noncohesive sediment or when exposed to floating matter such as woody debris. Consequently, erosion pins are most likely to generate accurate results in lower energy environments (Steiger *et al.*, 2003).

Sediment Traps

Numerous recent studies to quantify spatial patterns of overbank sedimentation resulting from individual floods have employed sediment traps placed directly on the floodplain surface in advance of a flood event. (e.g. Mansikkaniemi, 1985; Gretener and Strömquist, 1987; Lambert and Walling, 1987; Walling and Bradley, 1989; Asselman and Middelkoop, 1995; Simm, 1995; Middelkoop and Asselman, 1998; Steiger *et al.*, 2001a,b). Mansikkaniemi (1985) pioneered with different sediment samplers of about 0.5×0.5 m in size, including simple plywood boards with 5–7-cm long bristles and rubber sheets with a rough surface. Sedimentation results showed no significant variation between the different types of traps. Over the past years, various trap types have been applied such as, fire-clay roof tiles (approximate size: 20×30 cm) (Brunet *et al.*, 1994; Steiger *et al.*, 2001b; Steiger and Gurnell, 2003), 15-cm diameter plastic circles with roughened upper surface to reduce sediment wash-off, used within a bottomland hardwood wetland (Kleiss, 1996; Wardrop and Brooks, 1998), simple flat smooth plates or sheets of plastic (area 0.06–0.08 m^2) (Pinay *et al.*, 1995; Dezzeo *et al.*, 2000), and carpet squares (20×20 cm) stitched onto aluminum frames (Walker, 1995).

Most studies employed sediment traps consisting of 1–2-cm-long tufts of artificial grass attached to a pliable base varying in size between 0.01 and 0.25 m and fixed onto the ground by steel pins. After the flood the sediment is removed using a high-pressure cleaner (Asselman and Middelkoop, 1995; Steiger *et al.*, 2001a), or through careful brushing after drying. This type of sediment traps is an adequate method for sampling sediment deposited by flowing water, particularly where sites are subject to repeated inundation, because (Steiger *et al.*, 2003) (i) the surface roughness of the mats reduces problems of sediment removal by floodwaters or rainfall, (ii) they are easily manipulated in the field, (iii) their pliable base permits installation on irregular surfaces and slopes, (iv) they can be

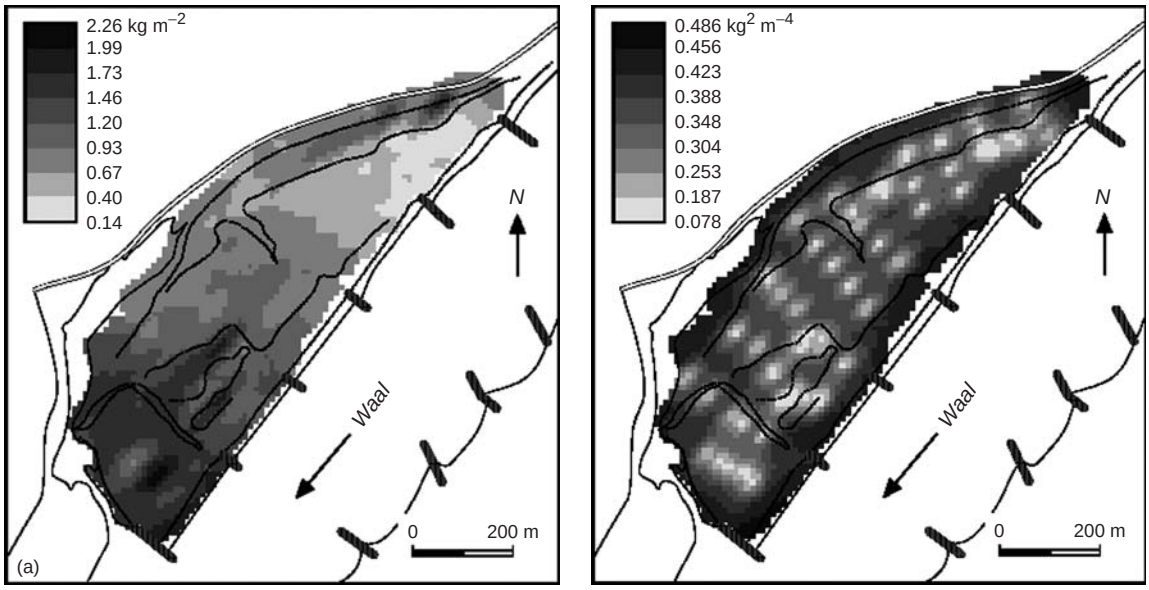

Figure 3 Interpolation result of sediment deposition on a floodplain section along the Wall River, The Netherlands, sampled with sediment traps. (a) interpolated deposition. (b) estimation variances of interpolation. The position of the sediment traps is marked by the low variances

securely attached to the ground and so can resist relatively high local shear stresses, (v) they can withstand repeated flooding and laboratory processing, (vi) they allow to sample a wide range of deposition amounts (10^{-1}–10^{4} kg m^{-2}), and (vii) it is possible to fully recover the deposited sediment to determine the amount of sediment deposited and to support a range of other analyses.

Sampling Design and Interpolation

To document the deposition patterns, traps have been distributed over the floodplain using a variety of sampling designs. Instead of placing single traps to collect "representative" samples of sedimentation rates, traps can be arranged in clusters to determine at-the-site variation and to calculate average deposition rates from clusters of replicate traps (cf. Asselman and Middelkoop, 1995; Steiger *et al.*, 2001b; Steiger and Gurnell, 2003). The sampling layout may be along transects perpendicular to the main channel or along the *a priori* expected largest gradient in deposition. Other sampling schemes may include a stratified random sampling based on different morphological, topographical, and land use settings (e.g. Walling and Bradley, 1989; Simm, 1995; Steiger and Gurnell, 2003), or sampling in a semiregular grid, consisting of several transects oriented in the direction perpendicular to the main stream, with sampling intervals increasing away from the main channel from about 1 to about 100 m in the distal parts (Asselman and Middelkoop, 1995). Differences in sediment accumulation over short distances can be determined by including clusters of several traps within the sample layout.

To calculate the total amount of deposited sediment, and to determine the full 2D pattern of the sediment deposition, the trap measurements can be interpolated using different techniques. An adequate method for this purpose is kriging, which is a form of weighted local averaging where the interpolation weights are determined from variograms (Burrough, 1986). To cope with anisotropy of spatial variability, separate variograms can be determined for sediment deposition in the direction parallel and perpendicular to the main flow direction (Asselman and Middelkoop, 1995; Middelkoop and Asselman, 1998). When considerable trends exist in the sampled deposition, interpolation should be carried out using "universal kriging", while "block kriging" produces interpolations results as a raster to match the format and spatial support of raster-based model output. This enables calibration and validation of model results, where the cell-by-cell comparison of observed and calculated deposition can be weighed according to the estimated interpolation variances of the observed data (Middelkoop and Asselman, 1998; Middelkoop and Van der Perk, 1998) (Figure 3).

MODELING FLOODPLAIN SEDIMENTATION

Introduction

The spatial variability of observed sediment deposition on floodplains can usually be correlated with floodplain topography, flooding frequency, and distance to the main river channel. However, these relationships are essentially empirical, and they do not provide quantitative predictive schemes that link hydraulic and sedimentological variables

on a conceptual basis. Predicting sedimentation rates in a quantitative way using empirical relations may become unsuccessful when large floodplain areas with irregular topography are concerned, and becomes even more difficult when important boundary conditions of sedimentation change, that is, river discharge and suspended sediment concentrations change. For those cases, a process-based or deterministic model is needed.

Large-scale 1D Sedimentation Model

To assess the impact of large-scale landscaping measures along a 100-km floodplain reaches of the lower Rhine distributaries in the Netherlands on the sediment budget of the lower Rhine, Narinesingh *et al.* (1999) and Asselman and Van Wijngaarden (2002) developed a 1D floodplain sedimentation model that simulates sedimentation as a function of hydraulic conditions and different silt-sized sediment fractions. The modeling approach is based on a procedure to estimate sedimentation in settling tanks, depending on the trapping efficiency of the tank. This efficiency is a function of the ratio between the tank area and the discharge through it, which can be regarded as a measure of the residence time of the water and the sediment particles in the tank. The equation for the sediment trapping efficiency (E) reads:

$$E = 1 - \mathrm{e}^{\left(-w_\mathrm{s}\frac{A}{Q}\right)} \tag{1}$$

where w_s is the settling velocity of the suspended sediment particles, A is the surface area of the tank and Q is the discharge through the basin. Sedimentation is computed as: $S = Q_\mathrm{s}E$, with S is the sedimentation in kg/ day, Q_s is the suspended sediment load transported into the tank in kg/day. In the application of this method to river floodplains, the river was schematized as a main channel with a number of floodplain sections in connection (Figure 4). Within a floodplain section, different stream "tubes" were schematized, each representing an individual settling basin with an inlet at the upstream end and an outlet at the downstream end. The model was calibrated using sediment loss along an entire river branch at varying discharges, and by comparing the predicted sediment accumulation with the observed sediment deposition during a major flood event.

Models of Lateral Sediment Transfer

During floods, flow is fast and deep in the main channel and shallow and slow over the floodplain. The strong lateral interaction between the two flows results in a transfer of momentum as the flow is decreased in the channel and increased over the floodplain. This is evident in turbulent eddies along the interface between the main channel and the floodplain. Furthermore, suspended sediment concentrations are higher in the main channel due to its greater transporting capacity. Consequently, the interaction between the channel and the floodplain leads to lateral transfer of sediment.

Allen (1985), James (1985), and Pizzuto (1987) considered the lateral transfer and deposition of sediment particles onto the floodplain by a diffusion analogy. Pizzuto (1987) derived a mathematical model for the lateral transfer of suspended sediment in cross section from the main channel to the floodplain under conditions of steady river flow, with no current directed perpendicular to the channel, and with constant diffusivity coefficients along distance from the main channel. His model predicts, for a particular grain size, an exponential decrease in sediment deposition H with increasing distance from the main channel as:

$$H = \left(\frac{\mathrm{V}_\mathrm{s}^2}{e_z}\right) Z_0 t \left[\left(\frac{\sin h(Gn)e^{-G})}{\cosh(G)} + e^{-Gn}\right)\right] \tag{2}$$

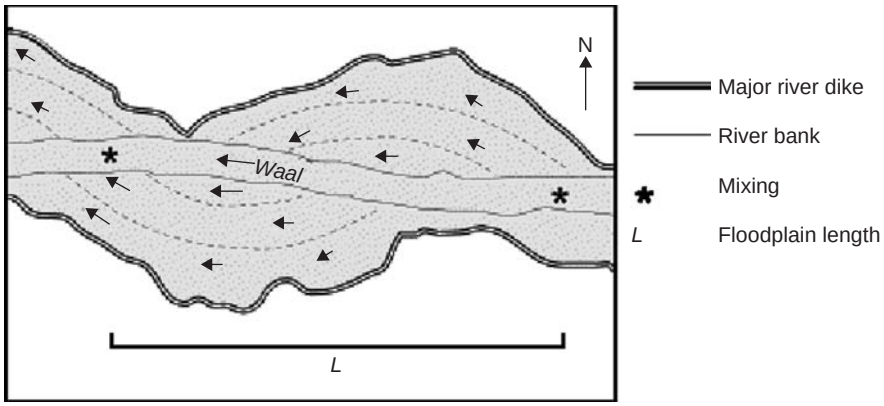

Figure 4 Embanked river floodplains of the Waal, each schematized as three parallel settling reservoirs. (Reprinted from Asselman and Van Wijngaarden, 2002. © 2002, with permission from Elsevier)

where H = deposited sediment thickness after a time t; t = time; V_s = settling velocity of the sediment, calculated using Stokes' Law; e_z = vertical sediment diffusivity; Z_0 = suspended sediment concentration; n = distance across the floodplain as a proportion of the total floodplain width W; G = a dimensionless variable that relates to the floodplain width W, sediment settling velocity and the vertical and horizontal diffusivities. G is calculated using $G = W V_s/(e_y\, e_z)^{0.5}$, where e_y = horizontal sediment diffusivity.

According to the model, the thickness of sediment deposition drops rapidly within a short distance from the main channel for floods of short duration (0.5 h). As modeled flood duration increases, the curve of deposition becomes increasingly concave upward, and reaches a constant shape after more than 10 h of modeling. Pizzuto (1987) assumed that this represented an equilibrium sediment concentration, and used the patterns resulting from the equilibrium state for comparison with field observations of thickness of overbank sediment. The model concept fairly well predicted the distribution of fine sediments, but sand-sized material was actually carried farther across the floodplain than the profile simulated by the steady-state model, unless unrealistically large diffusion coefficients were invoked (Pizzuto, 1987; Marriott, 1996). James (1985) used a numerical model to simulate the transfer of sediments from the channel to the adjacent floodplain in which he combined a diffusion analogy with an element of convection. The model was run using different grain sizes, resulting in sediment concentrations dominated by sand-sized grains near the channel, while silt-sized grains occur in gradually decreasing concentrations across the whole width of the floodplain.

In the past two decennia, different numerical models for simulating floodplain deposition of meandering channels, and avulsion-controlled alluvial architecture have been developed, all of which consider overbank deposition as one of the processes in the long-term ($\sim 10^2$–10^3 years) development of floodplains. Examples are the model of Allen (1978), who assumed deposition to be uniform over the entire floodplain, the model of meander migration and floodplain deposition of Howard (1992, 1996), and the alluvial stratigraphy model of Bridge and Leeder (1979), who adopted an empirical approach to relate overbank deposition rates to the distance from the main channel.

Howard (1992, 1996) developed a heuristic relationship for long-term overbank sedimentation as a function of local elevation and distance from the main channel in a model that simulates river meandering, as:

$$r = \left[\nu + \mu\ \mathrm{e}^{\left(\frac{-D}{\lambda}\right)} \right] \mathrm{e}^{[-\gamma (E_{\mathrm{act}} - E_{\mathrm{bed}})^W]} \qquad (3)$$

where r = long-term average overbank sedimentation, ν = a position-independent deposition rate of fine sediment, μ = overbank deposition rate of coarser sediment by overbank diffusion, λ = a characteristic diffusion/advection length scale, D = distance to the nearest channel, E_{act} = local floodplain elevation, E_{bed} = mean bed elevation, γ = elevation decay rate, and W = exponent, set to 2.0.

In the three-dimensional alluvial stratigraphy model version of Bridge and Leeder (1979) (Bridge and Mackey, 1993; Mackey and Bridge, 1995), overbank aggradation rate decreases exponentially with distance from the channel, according to:

$$r_z = a_0\ \mathrm{e}^{\left(\frac{-bz_c}{z_m}\right)} \qquad (4)$$

where r_z = time-averaged deposition at distance z from the channel-belt edge, a_0 = channel-belt aggradation rate at zero distance from the channel, z_c = cross-valley distance from the channel-belt edge, z_m = maximum floodplain distance from the channel-belt edge, and b = aggradation coefficient, defining the rate of decrease of overbank aggradation with distance from the active channel belt. The exponent b must be derived from field observations. Estimates of b vary between about 0.35 based on medium-term ($\sim$100 years) reconstructions to values of 5–10 based on single-flood observations (Törnqvist and Bridge, 2002).

Although the results have been supported by both laboratory measurements and field observations (Marriott, 1992, 1996), the ability of these models to predict and explain sediment deposition on natural floodplains has not been accurately established. It is difficult to apply such models when the channel sinuosity is high, when the flow over a floodplain is not uniform, or when this flow pattern changes under varying river discharge. In fact, the model of Pizzuto (1987) reduces the process of sediment deposition to a simple function of distance to the main channel, suspended sediment concentrations, particle fall velocity, and a diffusion constant. As these models all tended to examine floodplain sedimentation in cross section, they all predict an exponential decrease in deposition with increasing distance from the main channel, which is the expected pattern along straight river channels (Nicholas and Walling, 1997a,b).

Two-dimensional Mathematical Modeling of Overbank Flow and Sediment Deposition

The complex topography of natural floodplains substantially controls the local floodplain inundation frequency, as well as overbank flow patterns and flow velocities (Lewin and Hughes, 1980; Simm, 1995; Nicholas and Walling, 1997a, Nicholas and McLelland, 1999). Consequently, the overbank flow is generally not parallel to the main channel but has a component perpendicular to the main channel. In this situation, sediment transport over the floodplain occurs mostly by convection, and the spatial distribution of sediment deposition will be controlled by the water flow pattern. Therefore, to simulate sediment transfer and deposition, a model must be capable of predicting detailed

flow patterns and relating these to sediment transport and deposition processes. This is done in a two-stage approach with coupled models of water flow and sediment transport and deposition. Once a detailed model of the hydraulic flow pattern is obtained, the sedimentation process is determined by using the hydraulic pattern as a basis.

Water Flow

Over the past decennium, various two-dimensional hydraulic models have been developed for simulating patterns of floodwater flow, and which serve as a basis for calculating overbank deposition on natural floodplains (*see* **Chapter 141, Computer Modeling of Overbank Flows, Volume 4**). Recent overviews and evaluations of these models are reported by Hervouet and Van Haren (1996), Horritt and Bates (2002), and Nicholas and Mitchell (2003). Different approaches have been developed to model flow over the river channel and floodplain, varying from simple diffusion-wave approaches to models that solve the full set of Navier–Stokes equations of continuity of mass and momentum. Using these equations, the model calculates water depth h and flow velocity in x and y directions. The latter type of models considers two-dimensional shallow-water equations (Sain-Venant), in which depth-average values of the Navier–Stokes equations are used (Hervouet and Van Haren, 1996). An example of this type is the 2D finite-volume *Hydro2de* model (Beffa and Connell, 2001; Nicholas and Mitchell, 2003; Sweet *et al.*, 2003) that was applied to explore the relations between floodplain topography, floodwater hydraulics, and sedimentation patterns in British lowland floodplains. This model considers the depth-averaged Navier–Stokes equations of conservation of mass and momentum for shallow-water flow over a DEM.

The conservation of mass and momentum can be written as

$$\frac{\partial h}{\partial t} + \frac{\partial q}{\partial x} + \frac{\partial r}{\partial y} = 0 \tag{5}$$

$$\frac{\partial q}{\partial t} + \frac{\partial (q^2/h)}{\partial x} + \frac{\partial (qr/h)}{\partial y} + \frac{g}{2}\frac{\partial (h^2)}{\partial x} + gh\frac{\partial z}{\partial x} - \frac{1}{\rho}\frac{\partial (h\tau_{xy})}{\partial y} - \frac{1}{\rho}\frac{\partial (h\tau_{xx})}{\partial x} + \frac{\tau_{bx}}{\rho} = 0 \tag{6}$$

$$\frac{\partial q}{\partial t} + \frac{\partial (r^2/h)}{\partial y} + \frac{\partial (qr/h)}{\partial x} + \frac{g}{2}\frac{\partial (h^2)}{\partial y} + gh\frac{\partial z}{\partial y} - \frac{1}{\rho}\frac{\partial (h\tau_{yx})}{\partial x} - \frac{1}{\rho}\frac{\partial (h\tau_{yy})}{\partial y} + \frac{\tau_{by}}{\rho} = 0 \tag{7}$$

where h is flow depth, q and r are unit discharge in x and y directions, respectively, t is time, z is bed elevation, g is acceleration due to gravity, ρ is the water density and τ_{xx}, τ_{yy}, τ_{xy}, τ_{yx} are turbulent stresses and τ_{bx} and τ_{by} are bed shear stresses. Assuming turbulent normal stresses to be negligible, shear stresses are modeled using the Boussinesq approximation:

$$\tau_{xy} = \tau_{yx} = \rho \nu_t \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right) \tag{8}$$

where $u = q/h$, $v = r/h$, $\nu_t = ku^*h$, with u^* is the friction velocity and k is a constant of which the value is assumed to equal 0.067 for two-dimensional open-channel flows. Details of implementation of the shallow-water equations in the model and numerical solutions for these models are given in Connell *et al.* (2001), Hervouet and Van Haren (1996), and Beffa and Connell (2001).

A relatively simple method is the concept of diffusion wave as used by, for example, Nicholas and Walling (1997a) and the LISFLOOD model (Bates and De Roo 2000). In their models, water flow is described in terms of continuity of mass and momentum equations discretized over a grid of cells, assuming that the flow is simply a function of the free surface height difference between those cells. The model only represents mass transfer from the channel to the floodplain and neglects transfer of momentum. The model assumes that the flow between two cells is a function of the free surface height difference between those cells, and the equations read (Horritt and Bates, 2002):

$$\frac{\mathrm{d}h^{i,j}}{\mathrm{d}t} = \frac{Q_x^{i-1,j} - Q_x^{i,j} + Q_y^{i,j-1} - Q_y^{i,j}}{\Delta x \Delta y} \tag{9}$$

$$Q_x^{i,j} = \frac{h_{\text{flow}}^{5/3}}{n} \left(\frac{h^{i-1,j} - h^{i,j}}{\Delta x} \right)^{1/2} \Delta y \tag{10}$$

where $h_{i,j}$ is the water-free surface height at cell (i, j), Δx and Δy are the cell dimensions, n is the Manning's friction coefficient for the floodplain, and Q_x and Q_y describe the volumetric flow rates between floodplain cells. Q_y is defined analogously in equation (10). The flow depth h_{flow} is defined as the difference between the highest water surface in the two cells and the highest floodplain surface. Although this approach does not accurately represent diffuse wave propagation on the floodplain, the model is computationally simple and results have been shown to be consistent with models that faithfully consider the diffusive wave equation.

A distinction can be made between finite element and raster-based (finite difference) approaches to represent the spatial layout of the model. Finite element models operate on a mesh of nodes connected in the form of triangular elements. This allows using a finer mesh within the main channel, while the mesh is coarser over the floodplain where flow is spatially more constant. Floodplain topography is often sampled onto the mesh using nearest

neighbor interpolation from a digital terrain model (DTM), while the elevations of the channel and bank nodes are usually obtained from channel surveys (e.g. Horritt and Bates, 2002). An example of finite element models is the TELEMAC-2D model (Galland *et al.*, 1991). In raster-based models, the hydraulic equations are discretized over a grid of square or curved cells, usually based on gridded DTMs.

These models have been applied to natural river floodplains of a range of sizes, using different spatial resolutions of the model mesh or raster grid to represent the floodplain topography. Studies in 5–30-km-long floodplain reaches (e.g. Bates *et al.*, 1996; Hervouet and Van Haren, 1996; Connell *et al.*, 1998) typically were conducted using low-resolution models (10–100 m spacing of grid nodes) that represent the overall valley floor topography and channel planform, but have a poor resolution to represent small-scale characteristics of the floodplain surface topography, such as small embankments, depressions, drainage ditches, or abandoned channels. Since these topographic features are important controls of overbank inundation sequences and sediment transfer over the floodplain (Nicholas and Walling, 1997a; Middelkoop and Van der Perk, 1998), finer grids were applied in models covering floodplain sections of a few square kilometers, while recent studies (e.g. Nicholas and Mitchell, 2003) used increasingly finer resolutions (1 to 2.5 m) to represent floodplain topography in high detail.

Hydraulic roughness of the floodplain surface is an important control of flow patterns. Two types of roughness may be distinguished in hydraulic modeling (i) form-scale roughness associated with channel and floodplain topography, which can be represented when using an accordingly fine model grid; and (ii) subgrid-scale roughness, which is usually parameterized by a friction coefficient (Manning's n, Nikuradse k or Chézy coefficient). This friction coefficient is spatially variable and usually has to be determined by calibration. To reduce the number of parameters to be determined by calibration, several studies used one Manning's n value for the channel and one for the floodplain (e.g. Horritt and Bates, 2002; Nicholas and Mitchell, 2003), although Hesselink *et al.* (2003) used four different roughness values associated with different land use types on the floodplain.

Floodplain vegetation exerts considerable resistance to the overbank flow, and hydraulic roughness of vegetation is increasingly being considered in modeling studies (e.g. Fischer-Antze *et al.*, 2001; Stoesser *et al.*, 2003; Nicholas and McLelland, 2004). This is represented by a drag force exerted by a vegetative element (usually a cylindrical stem) on the flow, while the total resistance depends on vegetation height, average number of stems per unit surface area, and average stem diameter.

Boundary conditions of these models are the upstream discharge and an imposed downstream water surface elevation. Laterally, the models are closed. The models are calibrated against observed area of inundation or stage-discharge relations (e.g. Horritt and Bates, 2002). Simulations of flood events occur by dynamically simulating an entire flood wave. Alternatively, the hydraulic equations may be solved for a number of different stationary upstream discharge conditions, resulting in a set of stationary flow surfaces (Nicholas and Walling, 1997a, 1998; Middelkoop and Van der Perk, 1998). This latter approach neglects differences in discharge–stage relationships between rising and falling stages of a flood, as well as backwater ponding. The advantage is that it allows the determination of average conditions based on long-term frequency distributions of discharges.

The recent more complex models based on highly detailed DEMs allow simulating the transition between critical and subcritical flow, as well as inundation of previously dry surfaces (Nicholas and Mitchell, 2003; Hesselink *et al.*, 2003). Still, varying the spatial resolution of the calculation mesh discretization may affect the model results considerably in a complex way, and therefore may be considered at least as important as a typical calibration parameter (Hardy *et al.*, 1998).

Sediment Deposition

Sediment transport and deposition models of overbank fines are essentially based on horizontal convection-diffusion fluxes of sediment along with the overbank flow, in combination with settling velocity rates of the conveyed particles. Amounts of floodplain sedimentation S_i over a certain interval of time at each point i in the model grid are calculated using the following equation (Nicholas and Walling, 1997a; Middelkoop and Van der Perk, 1998; Sweet *et al.*, 2003):

$$S_i = \sum_{Q=Q\mathrm{bf}}^{Q\,\mathrm{max}} T_Q c_{Q,i} D_{Q,i} \tag{11}$$

where T_Q = the duration that discharge Q occurs, $c_{Q,i}$ = the suspended sediment concentration over this period of time at location i, D_{Qi} = the rate of deposition per unit of sediment concentration for this discharge at location i. The summation is done over all discharges occurring between bankfull (Q_{bf}) and the maximum discharge (Q_{max}) occurring at the site.

S_i can be determined for a flood event by subdividing the flood wave into a number of discrete discharge situations Q with associated sediment concentrations in the river, $c_{Q,r}$, with duration T_Q. Similarly, average annual deposition can be calculated by deriving T_Q for all Q from flow-duration curves, and by estimating suspended sediment concentrations $c_{Q,r}$ associated with Q from rating curves (Middelkoop and Van der Perk, 1998). The sediment deposition term $D_{Q,i}$ for discharge Q at position i can be approximated by assuming a linear dependency on

sediment concentration and particle settling velocity V_s: $D = kc_i V_s$, where k is an empirical coefficient that controls the proportion of sediment that is deposited.

Instead of using an empirical coefficient k, both depositional (D) or erosional (E) fluxes can be calculated, using the Krone and Partheniades formulae, respectively:

$$D = V_s c\left[1 - \left(\frac{u^*}{u^*_d}\right)^2\right] + c\left[\frac{UhpE}{\Delta x}\right] \quad (12)$$

$$E = M\left[\left(\frac{u^*}{u^*_e}\right)^2 - 1\right] \quad (13)$$

where u^* = critical or friction velocity at the bottom, u^*_d and u^*_e are critical shear velocities for settling and erosion respectively, and M = the Partheniades constant. The second term in the Krone equation (12) represents deposition due to sediment trapping by vegetation (Sweet *et al.*, 2003), with U = flow velocity; h = flow depth, p = proportion of the depth occupied by vegetation, E = trapping efficiency by vegetation, and Δx = grid spacing.

Concentration patterns of suspended sediment in the floodwater c_Q resulting from convection, dispersion, and deposition of suspended sediment are predicted by solving the depth-averaged mass balance equation for transport by convection and diffusion in the two horizontal dimensions for each node in the model grid (Nicholas and Walling, 1996, 1997a,b; Cancino and Neves, 1999), written in conservative form as:

$$\frac{\partial c}{\partial t} + uh\frac{\partial c}{\partial x} + vh\frac{\partial c}{\partial y} + D = \frac{\partial}{\partial x}\left(\varepsilon h\frac{\partial c}{\partial x}\right) + \frac{\partial}{\partial y}\left(\varepsilon h\frac{\partial c}{\partial y}\right) \quad (14)$$

where u and v are flow velocity components in x and y directions, h = water depth, c = depth-integrated suspended sediment concentration, ε is a horizontal mixing coefficient and D is the net rate of deposition. Under steady-state conditions, $\partial c/\partial t = 0$. Horizontal mixing coefficients can be determined using $\varepsilon = \lambda h u^*$, where λ is a constant (assigned a value of 0.17 by Nicholas and Walling (1997b)) and u^* = shear velocity given by $u^* = (ghS_f)^{1/2}$, where g = acceleration due to gravity and S_f = water surface slope. These equations must be solved in an iterative way, as D depends on the local sediment concentration.

In ponded areas, an additional amount of sediment deposition from trapped sediment occurs. Assuming that all suspended sediment in ponded areas settles, this can be calculated using (Nicholas and Walling, 1997b; Middelkoop and Van der Perk, 1998):

$$D_{p,i} = h_{p,i} c_i \quad (15)$$

where $D_{p,i}$ = deposition at location i resulting from settling of trapped sediment; $h_{p,i}$ = depth of ponded water at location i; c_i = sediment concentration in the ponded water. This amount is added to the total deposition.

The sediment characteristics that control deposition (and erosion) rates depend on grain size distribution of the suspension load. Consequently, the total suspension load must be subdivided into j sediment grain size fractions, each with different values for sediment concentrations in the water (c_j), settling velocities (V_{sj}), mixing coefficients (ε_j), and critical shear velocities for deposition and erosion (u^*_j), which results in j deposition rates D_{Qj}, that are added proportionally to the relative frequency of each sediment fraction j in the total sediment load to obtain the total deposition rate D_Q (e.g. Nicholas and Walling, 1997b). In this respect, a distinction must be made between the so-called *ultimate* grain size, which relates to the distribution of the discrete primary particles of the suspended sediment, and the *effective* grain size. Because of flocculation, settling velocity (V_s) cannot be determined from the ultimate grain size using Stokes' law, but it must be derived from estimated effective sizes of the sediment flocs (Peart and Walling, 1982; Nicholas and Walling, 1996, 1997b) (*see* **Chapter 83, Suspended Sediment Transport – Flocculation and Particle Characteristics, Volume 2**), or it must be measured *in situ* during overbank flooding (Thonon and Van der Perk, 2003).

Several model parameters are not *a priori* known, and must be determined by model calibration. This is also the case for parameters that have been determined at the point scale, but whose values may considerably change at the modeling resolution over large floodplain areas (Middelkoop and Van der Perk, 1998). Calibration and validation of sedimentation models is usually done by comparing predicted patterns of floodplain deposition with medium-term floodplain deposition rates reconstructed from ^{137}Cs measurements or heavy-metal concentrations in floodplain soil profiles (Nicholas and Walling, 1997a,b; Simm *et al.*, 1997; Sweet *et al.*, 2003), or with observed sediment deposition after a flood event (Nicholas and Walling, 1997a,b; Middelkoop and Van der Perk, 1998; Middelkoop, 2002b).

Sedimentation modeling becomes computationally expensive because the equations that determine the concentration pattern must be solved in an iterative way, while several model parameters must be determined by calibration. Alternatives that have been applied to reduce model complexity include (i) omitting the diffusion terms in the sediment transport equations for situations in which convective transport is presumed the dominant transporting mechanism to reduce the number of model parameters (Middelkoop and Van der Perk, 1998), (ii) neglecting erosion or reentrainment of sediment, or (iii) considering the

mass balance as a one-dimensional case, thereby allowing to solve the decline in sediment concentration by a noniterative means (Sweet *et al.*, 2003). A last simplification of these modeling approaches is that they do not consider the changes in topography due to deposition.

The choice for the modeling concept used and the number of grain size classes considered should be guided by the objectives of the study, the spatial scale considered, and the available data. A lack of reliable reference data at the required scale, particularly concerning small-scale turbulent flow patterns, sediment settling velocities or effective grain size distributions, or effective shear stresses for deposition may not justify the development and use of a complex, physically detailed model to simulate overbank deposition. Instead, a simpler sedimentation model may have a higher predictive capability, when it considers the dominant processes and whose model parameters can be more likely calibrated (Anderson *et al.*, 1996; Van der Perk, 1997; Middelkoop and Van der Perk, 1998). Improvements of sedimentation models in the future should aim at determination of *in situ* effective grain sizes, inherent settling rates and reentrainment of sediment, and a better treatment of interactions between floodplain vegetation and hydraulics and sedimentation.

Three-dimensional CFD Modeling of Floodplain Processes

In recent years, computational fluid dynamics (CFD) modeling of three-dimensional flow hydraulics and sediment transport has increasingly been applied to fluvial and estuarine systems. This modeling approach is indispensable to study three-dimensional aspects of flow, such as complex flow patterns in natural river channel bends, strong vertical gradients in flow velocity over rough areas, or stratified tidal flow patterns in estuaries (e.g. Cancino and Neves, 1999; Fischer-Antze *et al.*, 2001; Rodriguez *et al.*, 2004; Stoesser *et al.*, 2003; Lesser *et al.*, 2004). These models basically solve the three-dimensional Navier-Stokes equations and consider turbulence of flow, and often consider both suspended sediment transport and bottom sediment transport. Examples that have been applied to simulate channel processes are the TELEMAC-3D model (**`http://www.hrwallingford.co.uk/software/telemac.html`**), or the Delft3D model (**`http://www.wldelft.nl/soft/d3d/intro/index.html`**) (Lesser *et al.*, 2004). Still, few studies using CFD modeling have been undertaken for floodplain areas. Apart from the computational requirements, there are several reasons for this. (i) When compared to channel hydraulics, floodplain flow, and sedimentation processes can often be well predicted by two-dimensional approaches; (ii) it is difficult to specify the model boundary conditions; (iii) CFD modeling demands a good estimation of flow resistance structures of vegetation; and (iv) it is difficult to collect precise field measurements of 3D flow patterns and sediment conveyance over an inundated floodplain, necessary to validate the model.

Nicholas and McLelland (2004) simulated 3D overbank flow patterns on a 1-km-wide section of the River Culm (UK) natural floodplain. They showed the occurrence of complex 3D overbank flow patterns that are stage-dependent and topographically driven. Stoesser *et al.* (2003) were able to predict overbank flow velocities on vegetated floodplains using a 3D numerical model. Both studies indicated that compared to traditional 2D models, the 3D CDF approach may considerably reduce the modeling uncertainty associated with calibration of flow resistance and provide vertical flow profiles, in spite of the above-mentioned difficulties.

OVERBANK SEDIMENTATION ON THE EMBANKED FLOODPLAIN OF THE LOWER RHINE

Introduction

The lower Rhine River in the Netherlands (Figure 5) has been embanked by artificial levees since late Middle Ages. In subsequent centuries, people have increasingly affected the main channels and the floodplain by cutting-off meanders, modifying the bifurcations of the Rhine distributaries in the eighteenth century, and narrowing the main channel to a standard width, and fixing the banks

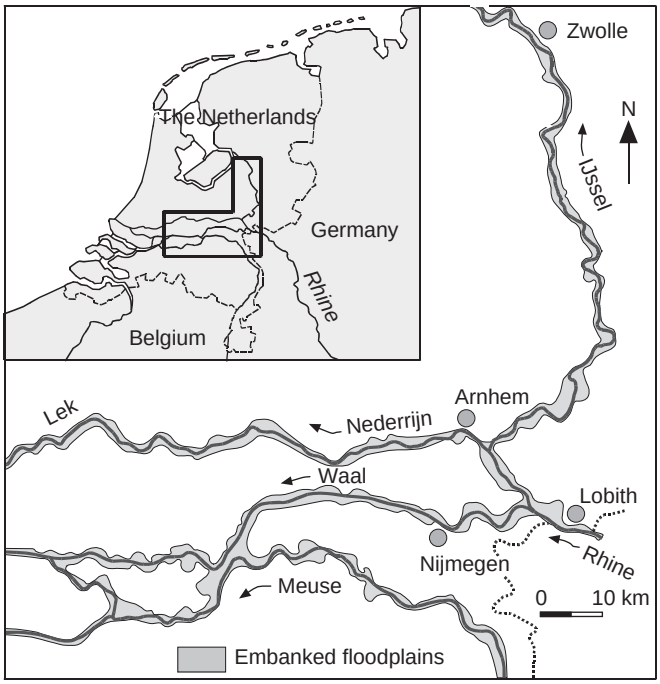

Figure 5 The embanked floodplains of the lower Rhine and Meuse in the Netherlands

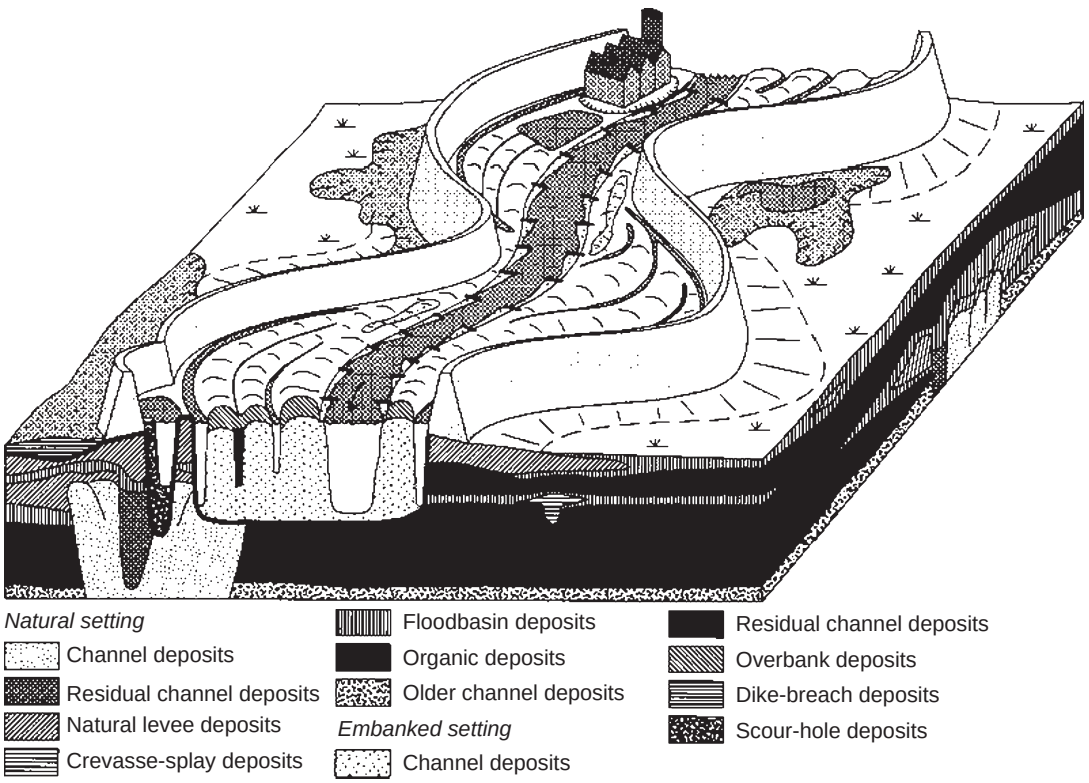

Figure 6 Architectural elements of the embanked floodplain of the lower Rhine (*Source*: Hesselink, 2002)

with a regular array of groins in the late nineteenth century. The floodplains have been extensively used for agriculture, and several floodplain sections have been protected from minor floods by small embankments ("minor dikes"). To date, the sedimentological structure of the embanked Rhine-Meuse floodplains consists of ridges of sandy channel-bed sediments overlaid by a 1–2 m thick body of overbank sediments, intersected with silted-up swales and residual channels (Figure 6). Using different methods, overbank deposition on the embanked floodplain of the lower Rhine was analyzed over various timescales: historic (centuries), the past century, and contemporary deposition rates.

Average Sedimentation Rates During the Past Centuries

Before 1850, the Rhine distributaries had low-sinuous meandering channels that slowly migrated in a downstream direction as the river dikes prevented lateral expansion of the meanders. Groins placed along the inner bends artificially enhanced lateral accretion, resulting in land reclamation from the river. The resulting growth of newly formed floodplain sections was mapped in detail, for example, to delineate new accretions of disputed ownership and to determine tax rates (Hesselink, 2002). Using old river maps made since the sixteenth century, the age of different floodplain sections and thus of the beginning of overbank sedimentation was determined (Middelkoop, 1997). From these the average deposition rates of the overbank sediments were determined. Figure 7 shows average overbank deposition rates, for floodplains of different ages, varying between 5 and 15 mm year^{-1} for the past 100–300 years. The decreasing trend of average sedimentation rates with increasing floodplain age indicates that deposition rates decrease

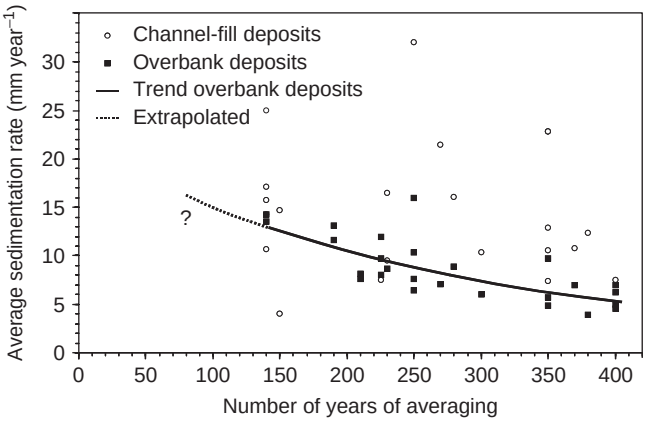

Figure 7 Estimated average floodplain sedimentation rates for varying floodplain ages, based on historic data

with time, as the floodplain elevation increases due to sedimentation.

Sedimentation Rates over the Past Decennia

Because of the heavy metal pollution of the river Rhine during the past century, the embanked floodplains of the lower river Rhine in the Netherlands contain large amounts of heavy metals. Deposition of heavy metals has occurred since the end of the nineteenth century. Periods of maximum pollution occurred in the 1930s and 1960s, when Cu, Pb, and Zn concentrations were about 6 to 10 times higher than background values (Figure 8) (Middelkoop, 2000).

Depending on local sedimentation rates and changing pollution trends in the past, the metal pollution varies greatly between different floodplain sections, as well as vertically within the floodplain soil profiles (Figures 9 and 10). Maximum metal concentrations in floodplain soils vary from 30 to 130 mg kg^{-1} for Cu, from 70 to 490 mg kg^{-1} for Pb, and from 170 to 1450 mg kg^{-1} for Zn. Although the investigated profiles of the lower Rhine floodplains reflect similar pollution trends, several differences between the profiles can be observed:

- Total metal contents and maximum metal concentrations in the Waal floodplain are generally higher than in the Nederrijn-Lek and IJssel floodplains;
- Low floodplain sections along the Waal that are not bordered by a minor river dike (e.g. Klompenwaard and Variksche Plaat) are contaminated by heavy metals to a great depth, usually more than 1 m below surface. Here, the metal concentrations in the upper parts of the profiles are considerably lower than the concentrations at several dm depth;
- The metal pollution is much greater in the natural levees and at a short distance from the main channel, than in the distal parts or behind a minor dike. These differences are demonstrated in the profiles of Huissen, Amerongen, and Vorchten. Metal accumulations in depressions are slightly greater than at nearby elevated sites.

The metal profiles measured in these soil profiles were used as a tracer to estimate average floodplain sedimentation rates over the past 150 years by comparing the concentration profiles in the floodplain soils with the chronology of the metal pollution of the river Rhine sediment. Reconstruction of sedimentation rates was done with a 1D simulation model of floodplain sedimentation with contaminated sediments, from which deposition rates were determined using an inverse modeling calibration procedure (Middelkoop, 2002a).

The model results for the heavy metal profiles are summarized in Table 1. Average sedimentation rates over the past century have varied between 0.18 and 11.6 mm year^{-1}. Estimation errors of the sedimentation rates were of the order of 5% (for high sedimentation rates) to 70% (for the lowest sedimentation rate) of the mean value. Lowest sedimentation rates (0.2 to 1 mm year^{-1}) were found along the rivers Nederrijn-Lek and IJssel, at sites behind a minor dike or natural levee. Near the channel banks, sedimentation rates are 1 to 3 mm year^{-1}. Along the river Waal, the lowest values were obtained at sites behind a minor dike (1.2 to 3 mm year^{-1}). Sedimentation rates for sites on natural levees or close to the river channel vary between 3 and 7 mm year^{-1}. The highest sedimentation rates (>10 mm year^{-1}) have occurred at the low floodplains Variksche Plaat and Klompenwaard. Thus, sedimentation rates on the Waal floodplain have been generally higher than those in the Nederrijn-Lek and IJssel

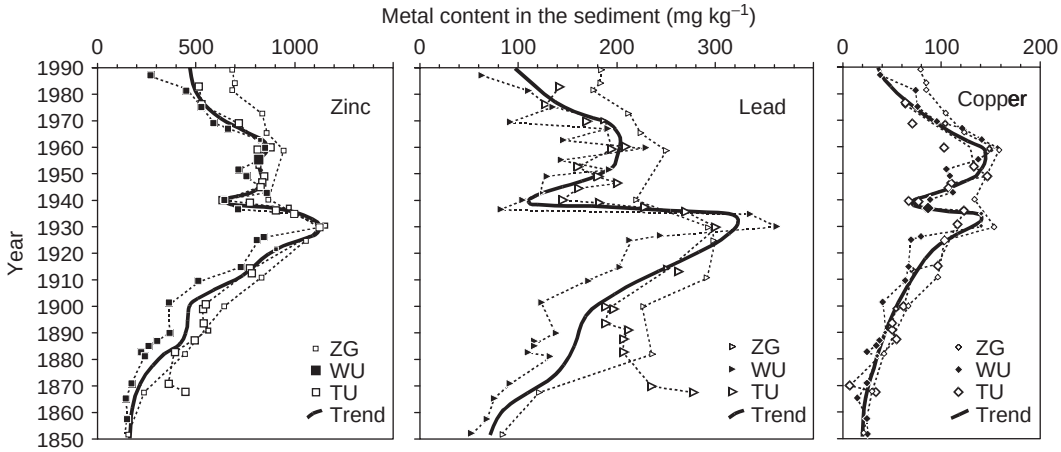

Figure 8 The temporal trend in pollution of the lower River Rhine over the past 150 years, reconstructed on the basis of metal concentrations in sediments from small ponds within the floodplain area

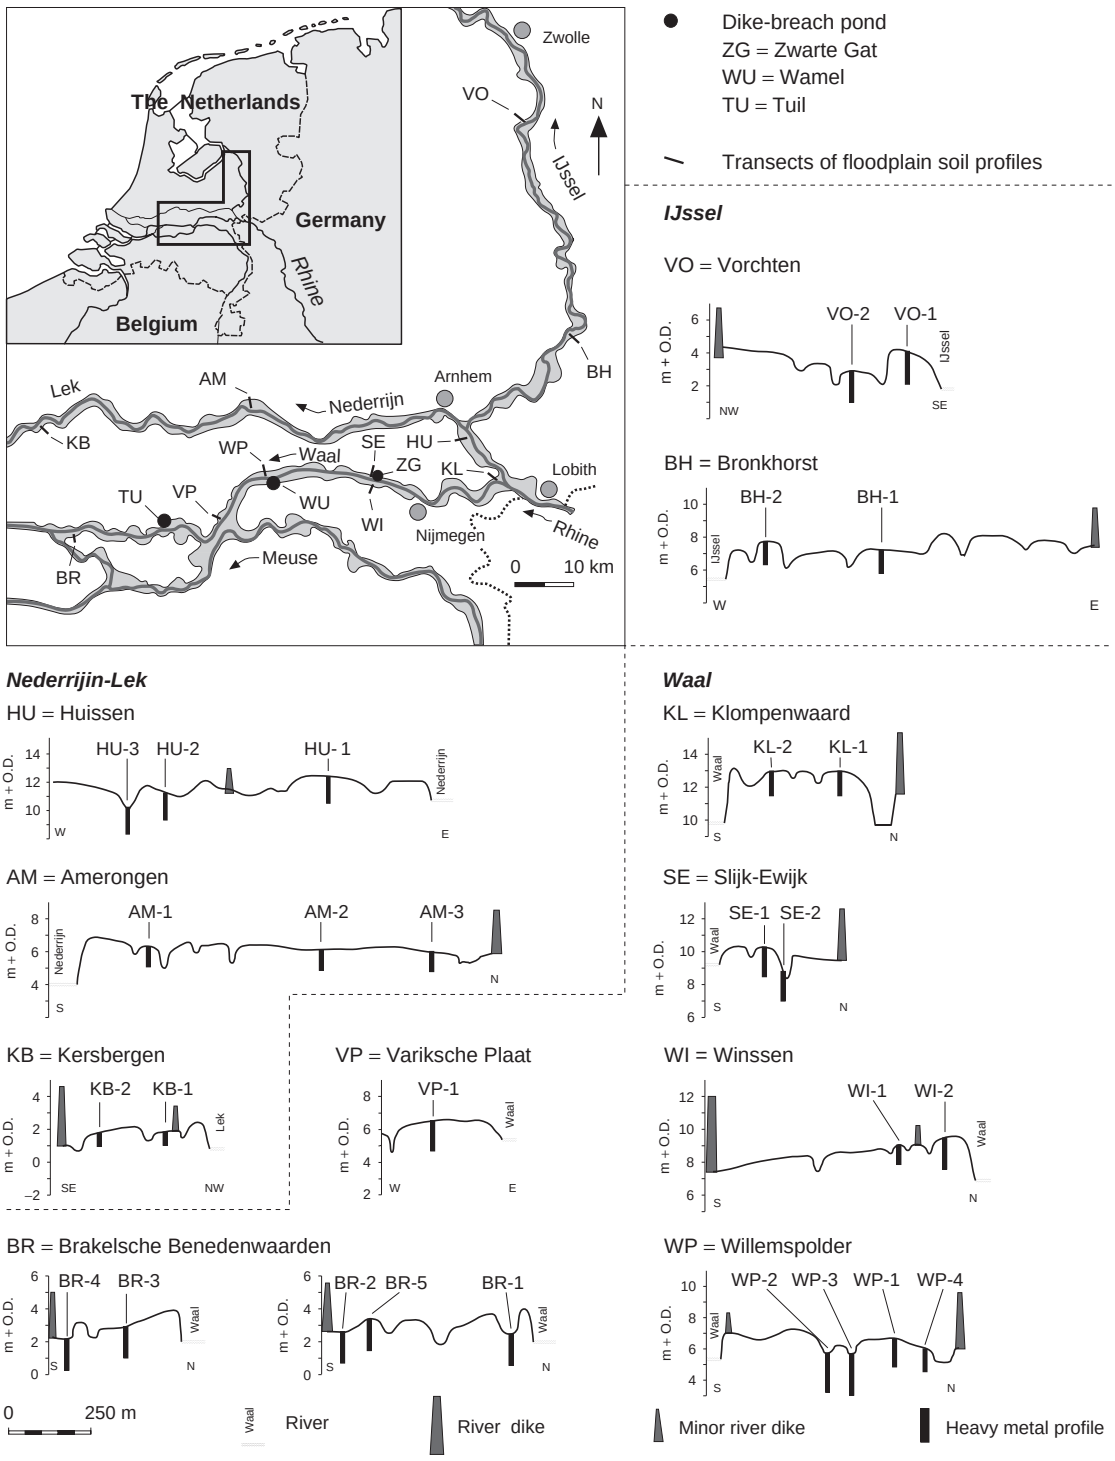

Figure 9 Location of the heavy metal profiles in the floodplain of the lower Rhine branches

floodplains. Within a floodplain section, sedimentation rates decrease with increasing distance from the river channel, but may be higher in local depressions, while a minor dike may reduce the sedimentation rate by a factor 2 to 3.

Contemporary Sedimentation Rates

Deposition During Flood Events

Contemporary floodplain sedimentation rates were studied using sediment traps placed during two low-magnitude

events (April 1994 and January 1993) and two high-magnitude events (December 1993 (Figure 11), January 1994). To document spatial patterns of the deposition as well as total deposition per section, the sampling results have been interpolated using universal block kriging to a 10×10-m grid (Middelkoop and Asselman, 1998).

The deposition during the 1993 flood was investigated in detail using about 800 sediment traps placed in different sections (Figure 12). Figures 13 and 14 show typical examples of deposition patterns that resulted from the flood. During the flood, two types of overbank sediment were formed: sandy bed load material and silt- and clay-sized wash-load material. Deposition of sand was highly variable, and formed locally as elongated sand sheets along the natural levees. Sediment deposition generally decreased with increasing distance from the river channel. In sections with a natural levee, such as the Klompenwaard, deposition amounts dropped rapidly with distance from the natural levee. At a distance of about 50 to 100 m from the levee, the deposition amounts level out to a constant

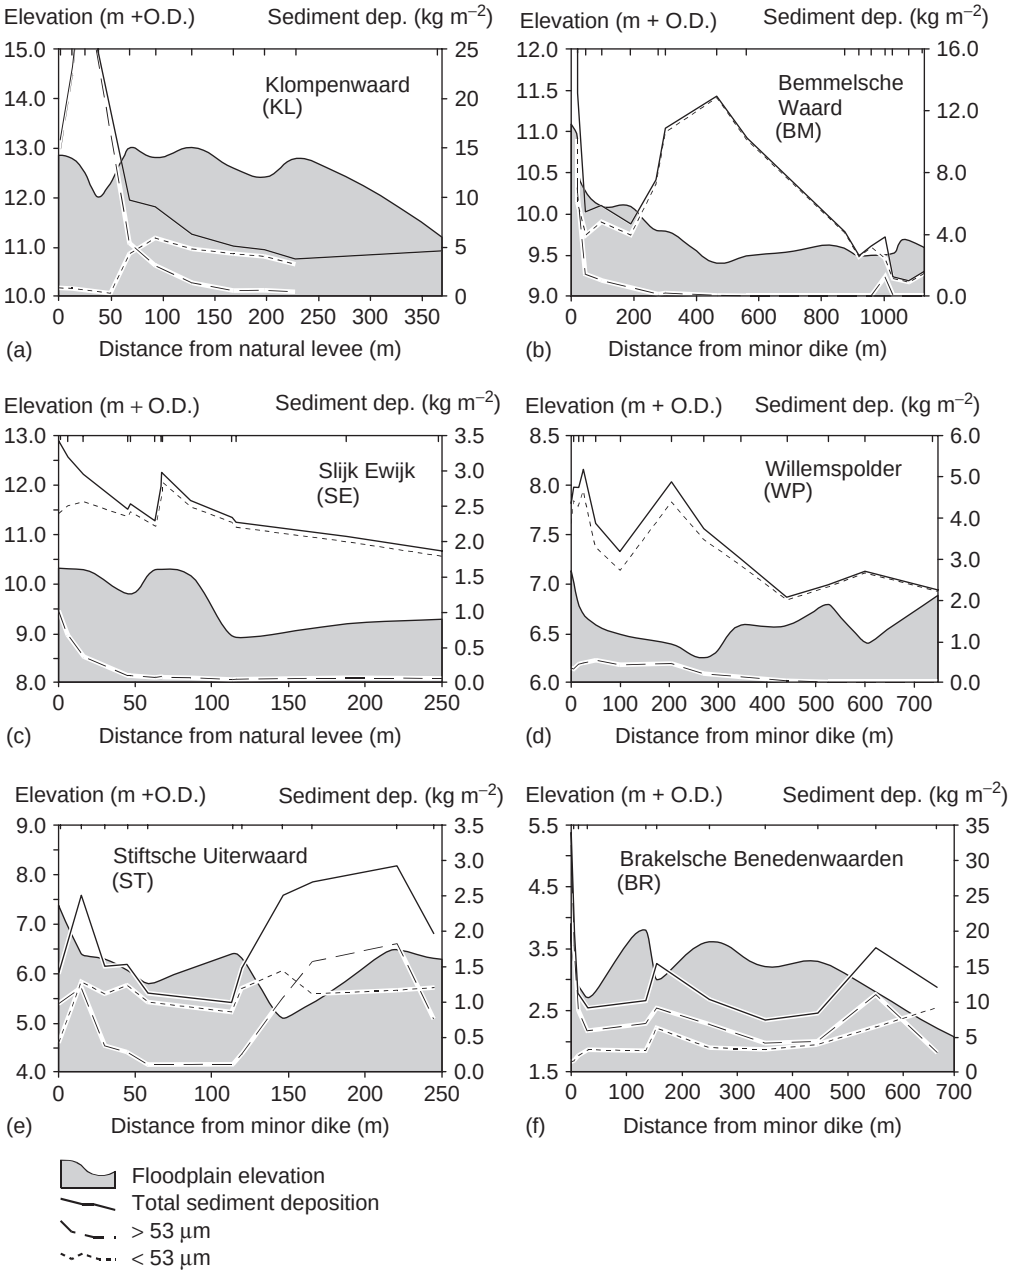

Figure 13 Floodplain elevation and overbank deposition in December 1993 on transects across different sections of the Waal floodplain. Total deposition, as well as sand and silt/clay-sized sediment deposition are shown

value. This trend mainly depends on the sand deposition, as the amounts of silt and clay remained almost constant with varying distance from the main channel when little relief is present. Percentages of sand decreased from about 90% at the levee to 15–5% in the central parts of the floodplain. Deposition amounts in depression were 50–100% larger than on more elevated locations, but varied within residual channels, depending on the prevailing current velocities. Minor embankments bordering several floodplain sections, such as the Bemmelsche Waard strongly influence the deposition pattern. Maximum sedimentation occurred at the location where the water flows over the minor river dike, while deposition amounts generally decreased with distance from the minor dike. After recession of the flood, an estimated additional amount on the order of 100–200 g m^{-2} sediment had settled from the ponded water behind the minor embankment. Local elevation differences are of minor importance when a minor dike isolates the floodplain from the main channel.

[a] = *without sediment from local source.*

For each floodplain section the average deposition of sand, and of silt and clay-sized material were determined separately (Table 2). Average deposition of silt and clay-sized overbank fines varied between 1.20 and 4.0 kg m^{-2} in the investigated sections. During the December 1993 flood the estimated total accumulation of suspended sediment on the entire Waal floodplain was 0.24 Mton, which is about 7.7% of the average annual load of suspended sediment transported by the river Rhine at Lobith. During the flood, the total trapping efficiency of the Waal floodplain for suspended sediment was about 19%.

Ten Brinke *et al.* (1998) independently quantified the deposition of sand on the channel banks of the lower Rhine distributaries during the same high-magnitude floods. Sand was deposited as sheets or oblong crevasse-like spays intermittently all along the entire branches, with average thickness of 4–7 cm and covering 1–4% of the floodplain area. The deposition pattern showed that convection had been the dominant transporting mechanism, while substantial deposition had occurred along the inner bends. Ten Brinke *et al.* (1998) mention helical current as an important mechanism, while locally stronger currents from the main channel onto the floodplain over lower parts of a levee also contributed to the overbank deposition. The total volume was on the order of 250 000 m^3, equivalent to an overall transfer of 1 m^3 channel-bed sediment per running meter bank onto the floodplain.

Influence of Flood Magnitude

Figures 15 and 16 show the deposition of sand and overbank fines on the Variksche Plaat floodplain section resulting from floods of different magnitudes (Asselman and Middelkoop, 1998). Deposition was determined on four parts within this section with different elevation and, hence, different inundation times per flood. Figure 16(a) shows total deposition per flood for each inundation zone within the floodplain and Figure 16(b) shows the corresponding deposition rates per day of inundation. During the low-magnitude floods (April 1994 and January 1993), total deposition was the highest in those parts that experienced deposition for a longer time. However, during the high-magnitude floods (December 1993 and January 1995), less sediment was deposited on the lower parts. Sedimentation (deposition amount per day of inundation, Figure 16(b)) is less efficient in low-lying areas than higher parts, in spite of the longer inundation. Also, when compared with

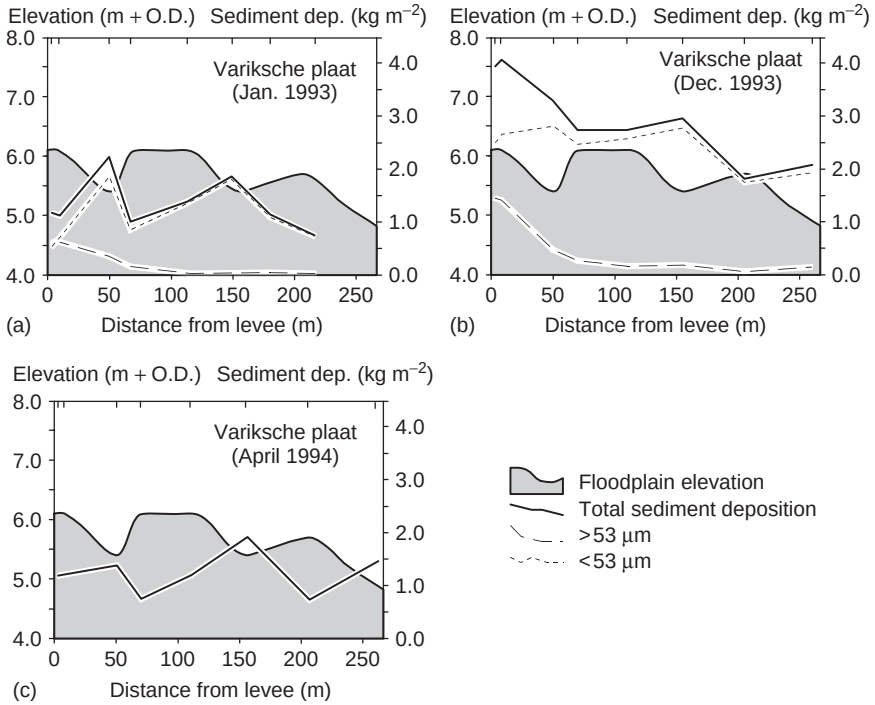

Figure 15 Floodplain elevation and overbank deposition on transects across the Variksche Plaat (VP) section of the Waal floodplain during different floods. Total deposition, as well as sand and silt/clay-sized sediment deposition are shown

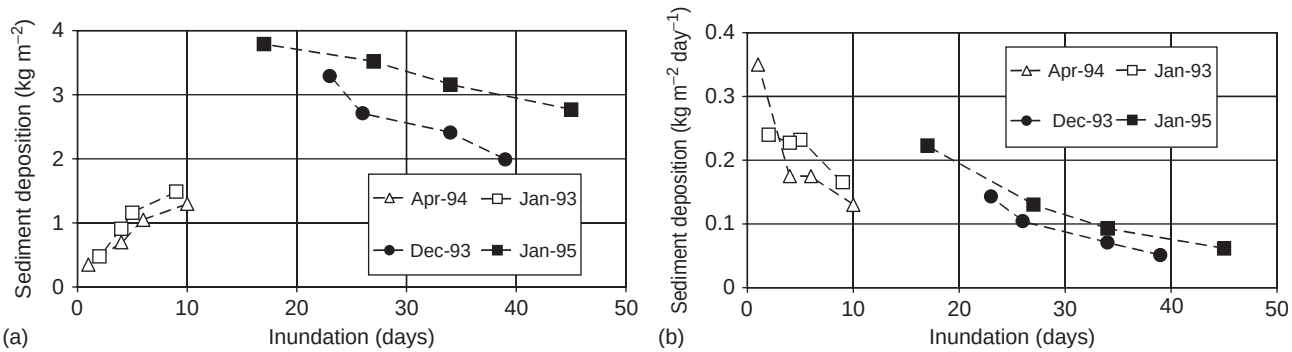

Figure 16 Overbank deposition on different parts of the Variksche Plaat (Waal floodplain) during four flood events of different magnitudes. Deposition was determined on four parts within this section with different elevation and, hence, different inundation times per flood. (a) shows total deposition per flood for each inundation zone within the floodplain, (b) shows the accordingly deposition rates per day of inundation

the amount of sediment transported through the river, the amount of sediment deposition increases less than proportionally for higher floods. The results demonstrate that *total sediment deposition* on this floodplain section increases with flood magnitude with the increase of sand deposition being considerably larger than for silt and clay. However, sediment-trapping efficiency in such a low-lying floodplain decreases at high discharge because flow velocities become too high for the sediment to settle. *Patterns* of sediment deposition also change with varying shape and magnitude of the flood wave. During minor floods, large accumulations of fine sediments occur in low areas and depressions. High-magnitude floods result in a pattern dominated by sand deposition along the main channel.

Annual Average Sediment Deposition Rates

As only a limited number of floods could be sampled, average annual sediment deposition was determined for two sections of the Waal floodplain using a sedimentation model, SEDIFLUX. This model uses water flow patterns calculated by a 2D hydrodynamic model as input. (Middelkoop and Van der Perk, 1998). As an example,

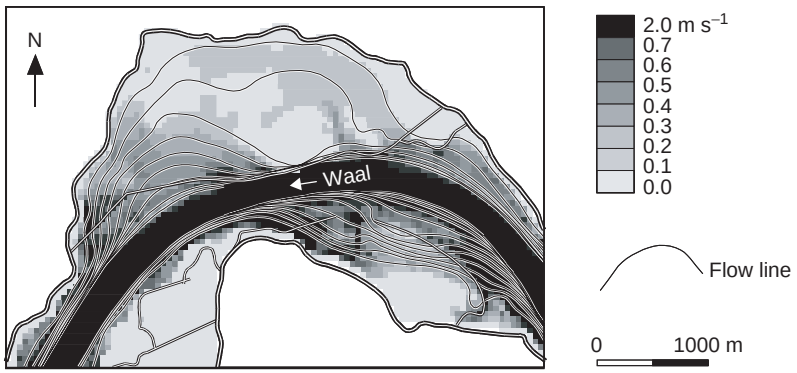

Figure 17 Flow pattern over the Bemmelsche Waard during maximum stage of overbank flooding

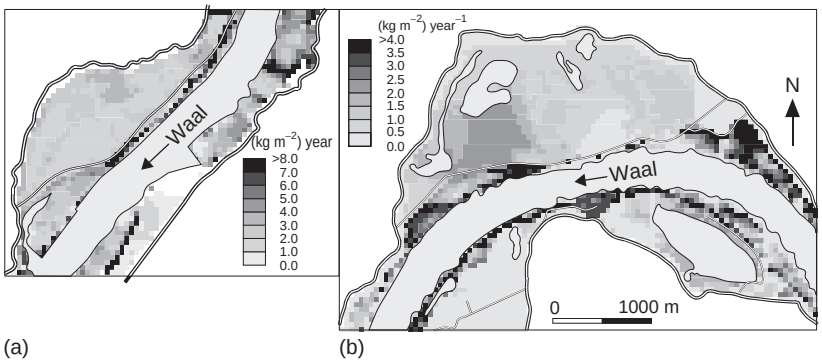

Figure 18 Annual average deposition rates on the Stiftsche Uiterwaard(a) and Bemmelsche Waard (b), calculated using the SEDIFLUX model (Middelkoop, 2002)

Figure 17 shows a typical flow pattern that occurs during inundation of the Bemmelsche Waard, which is bordered by a minor dike. Using this raster-based model, sediment deposition was calculated for a set of steady-state flow conditions resulting from a stepwise increasing river discharge, and using standardized concentrations of the suspension load in the main river channel. By multiplying the calculated deposition rates obtained for these different flow conditions in the river with the duration of each situation and with the associated suspended sediment concentration in the river, the total deposition during the high-magnitude, December 1993 flood event was obtained. The SEDIFLUX model was calibrated by varying the critical shear stress for settling and average settling velocity of the sediment particles. Calibration and validation was done by comparing calculated sediment deposition for the 1993 flood with raster maps of observed deposition, interpolated using universal block kriging. Subsequently, annual average overbank deposition was calculated using the average flow-duration curve of the Rhine and a rating curve to determine the corresponding suspended sediment concentrations.

The model results (Figure 18) show that annual average sedimentation rates in the Bemmelsche Waard are between 0.9 and 1.1 $kg\,m^{-2}\,year^{-1}$. In the zone behind the lowest part of the minor dike, the sedimentation rate is much higher: 2.2 to 2.4 $kg\,m^{-2}\,year^{-1}$. Sedimentation rates are lowest in the distal floodplain parts near the river dike: 0.6 to 0.7 $kg\,m^{-2}\,year^{-1}$. In the area between the minor dike and the river channel, the average sedimentation rate is more than 4 $kg\,m^{-2}\,year^{-1}$. The sediment deposition caused by ponding behind the minor dike may contribute about 25 to 50% to the total deposition during a minor flood. During high-magnitude floods, this contribution is less than 10%. Average annual sediment deposition within the Stiftsche Uiterwaard (Figure 18(a)) is generally larger than that within the Bemmelsche Waard (Figure 18(b)). Behind the natural levee, the sedimentation rate varies from 1.5 to 2.5 $kg\,m^{-2}\,year^{-1}$. In the central area, this is about 1.5 to 2.0 $kg\,m^{-2}\,year^{-1}$. In the upstream part of the Variksche Plaat, maximum average sedimentation rates are about 3.0 to 3.5 $kg\,m^{-2}\,year^{-1}$. In the downstream part, less sedimentation occurs (1.5 to 3.0 $kg\,m^{-2}\,year^{-1}$). In parts of this downstream area, however, sedimentation also results from back-ponding in depressions and it already occurs during lower discharges than those considered by the model.

Effective Discharge for Sedimentation

The local sediment deposition rate that occurs at a certain river discharge for a standard suspended sediment

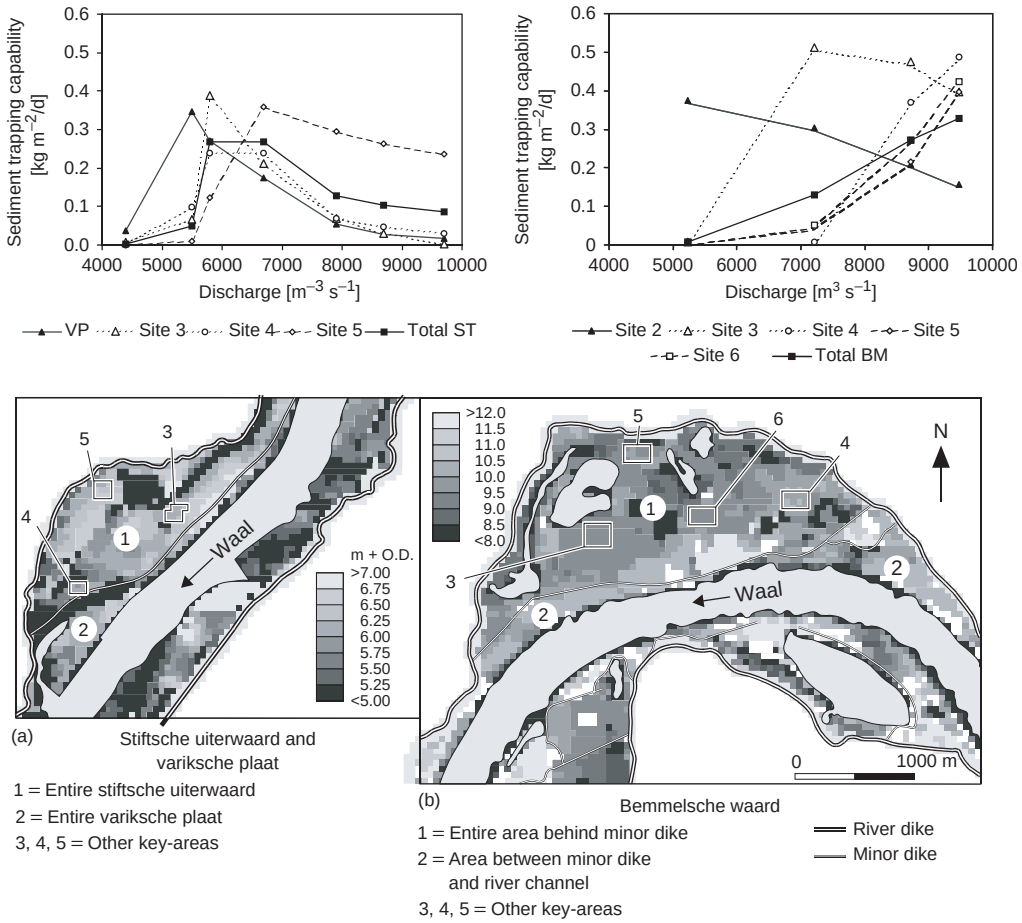

Figure 19 (a) and (b): Sediment trapping capability curves for different parts of the Bemmelsche Waard and Stiftsche Uiterwaard along the Waal river. The locations of the key areas are shown in the figure below the graphs

concentration in the river determines the sediment trapping capability (STC) of a floodplain section (Middelkoop *et al.*, 2002). The deposition rates plotted against river discharge makes up an STC curve that describes how deposition due to sediment trapping varies with river discharge, regardless of the frequency of occurrence of discharge or suspended sediment concentrations in the river. Thus, differences in STC curves are determined only by floodplain topography. STC curves were determined using the SEDIFLUX model after plotting for a site of interest, the calculated deposition rates for the standard sediment concentration in the river against increasing river discharge. The STC curves for the Bemmelsche Waard and Stiftsche Uiterwaard (Figure 19) show that the relative amounts of sediment deposited from the overbank flow on the floodplain are spatially variable, and that they also vary with discharge. After multiplication of these results with the suspended sediment concentrations associated with the varying discharge, the effective discharge for sedimentation is obtained, that is, the discharge at which in the long-term maximum sedimentation occurs (Asselman, 1999). Relatively low discharges are most effective for overbank deposition on the lower parts (i.e. Variksche Plaat, and between the main channel and minor embankment of the Bemmelsche Waard, sites VP and BM-1 in Figure 19). In contrast, high discharges contribute more to the long-term deposition in the distal floodplain parts, particularly behind the high minor dike of the Bemmelsche Waard (Figure 19b, site BM-5). These results confirm the observation that deposition amounts on the Variksche Plaat did not proportionally increase with flood magnitude.

Heavy Metal Deposition

Along with the overbank fines, particulate-bound heavy metals are transported through the Rhine and accumulate on the floodplain. Average heavy metal concentrations in Rhine sediment measured during the December 1993 flood at Lobith (German-Dutch border) were about 1.6 mg kg^{-1} for Cd, 64 mg kg^{-1} for Cu, 90 mg kg^{-1} for Pb and 400 mg kg^{-1} for Zn. These concentrations were lower than those during the preceding period of low discharge. By determining the metal concentrations in the overbank

deposits collected using sediment traps during the same flood, the spatial patterns of heavy metal deposition on the floodplain were analyzed. The results for two sections are discussed here.

In the Klompenwaard, metal concentrations in the overbank deposits strongly increase with increasing distance from the main channel (Figure 20). This trend coincides with increasing percentages of clay (% $<2\,\mu$m) and organic matter. This relationship clearly illustrates the preferential bonding of the trace metals to clay particles and organic matter. However, because of the large deposition along the channel banks, metal deposition was considerably higher at short distances from the river (about 5.0 g Zn per sq.m) than in the distal parts of the floodplain (about 1.5 g Zn per sq. m). A different pattern was found in the Bemmelsche Waard (Figure 21), which is bordered by a minor dike, where high metal concentrations occurred in the fine sediment deposited in the central parts (up to 5.0 g Zn per sq. m). Because of the large sediment deposition, metal deposition in the zone behind the overflow section of the minor dike is highest. These results demonstrate that the patterns of metal deposition during a flood event are strongly controlled by the patterns of sediment deposition, as well as by the *ultimate* grain sizes and organic matter contents in the deposited sediment. Both show major gradients within the floodplain, associated with the flow patterns from which settling of the sediment occurred.

Sensitivity to Future Changes in Upstream Catchment Conditions

Changes in climate and land use in the upstream basin may affect deposition rates on the floodplains of the lower river reaches. In a sensitivity study for the lower Rhine floodplains, the Rhine discharge regime and the suspended sediment rating curves were adapted according to different scenarios of climate change and land use development (i.e. reduction in arable land) in the Rhine basin (Asselman*et al.*, 2003), Table 3. These were used as inputs for the SEDIFLUX model to determine annual sedimentation rates under changed climatic and land use conditions. In this study, surface erosion due to rainfall and snowmelt was assumed the primary source of suspended load in the Rhine. The model results indicate that a reduction in the area of arable land leads to a considerable reduction in sediment supply from the upstream basin, resulting in a considerable reduction in annual sediment load in the lower Rhine. Consequently, floodplain deposition rates decrease by about 45%. Climate change and the associated higher winter precipitation and more intense summer rainfall is expected to cause an increased sediment yield due to rainfall erosion and an increase in peak flows of the Rhine. As a consequence, larger proportions of the annual sediment load are transported at higher discharges, when the sediment trapping efficiency of the floodplain becomes lower due to the higher current velocities. This causes only slightly increased floodplain sedimentation rates. The effects of reduced areas of sediment production, intensified erosion, and larger peak flows due to land use and climate change partly counterbalance one another. Depending on the areas of land use change involved and the assumed climate change, this may lead to a net decrease of floodplain deposition rates or (in case of the upper climate scenario) increased deposition rates (Table 3).

PATTERNS, PROCESSES, AND CONTROLS OF FLOODPLAIN SEDIMENTATION

Deposition Patterns

The average annual amount of overbank deposition on a floodplain is primarily determined by the average amount of sediment that is carried over the floodplain annually and the deposition rate from the overbank flow. The first factor depends on the average yearly floodplain inundation time controlled by the hydrological regime of the river, channel geometry, and floodplain elevation, on the amount of suspended sediment in the river, and on the flow patterns over the floodplain. Deposition rates on the floodplain are determined by the local sediment concentrations in the overbank flow, grain size characteristics and settling velocity of the entrained particles, and the hydraulic patterns of the overbank flow.

Overbank Flow

In the course of a flood event, complex flow patterns of the floodwaters occur over the floodplain, which may considerably change with the rising and falling floodwater stages. The following phases can be distinguished:

1. During the early stages of flooding, inundation patterns are largely the product of passive backwater ponding in drainage ditches and other low-lying areas near the river channel, as the levees still prevent the floodwaters to enter the floodplain.
2. With increasing discharge, inundation progresses via depressions of chutes, old channels, and ditches, from which the adjacent floodplain starts to inundate. Once out of bank, floodwaters are prevented from returning to the main channel by the natural levees, and they are diverted in a downstream direction over the floodplain, and concentrate in depressions or ditches along which they return to the main channel further downstream. Inundated areas become interconnected so that a number of distinct flow regions arise. Floodplain sections that are separated by minor embankments from the main channel do not inundate yet.
3. As the stage advances further, the flow overtops the natural levees almost entirely, while the lower sections of minor embankments are overtopped as well. The

Deposition on Waal floodplain (%)	−47	−36	−8	73

emergent areas between flow paths over the floodplain shrink, while sediment is conveyed over the inundated area. Embankments of roads or other minor dykes may strongly affect the flow patterns over the floodplain by obstructing or diverting the water flow.

4. At the highest flood stages, floodwater flow extends across the entire floodplain conveying large amounts of sediment. Flow directions are influenced less by local topographic structures and more by the overall geometry of the valley floor. However, flow velocities are strongly reduced in areas behind minor embankments.
5. After the recession of the flood, the inundated water drains through depressions and ditches to the main channel. Still, water may remain ponded for many days behind embankments or in enclosed depressions within the floodplain.

Sediment Deposition

The hydraulic patterns that develop during overbank flooding determine the spatial distribution of sediment deposition by controlling the frequency and duration of inundation, the amount of suspended sediment in the floodwaters, and the local current velocities. Overbank sediments deposited during a flood can be subdivided into two major components: (i) sand – originating from the channel bed – laid down as splays on the top and landward slope of the natural levee, and (ii) clay and silt-sized sediments – wash-load – deposited over the remaining part of the floodplain.

Sand The lee-side of natural and artificial levees are the zones where most deposition of sand may occur, although fine sand is present across the entire width of the floodplain. These sand deposits may refer to the influence of the zone with turbulent eddies where the channel and floodplain flows mix (Marriott, 1992, 1996). Large sand deposition occurs where the water flow from the channel enters the floodplain, since at this point sediment concentrations are high, while flow velocities are drastically reduced within a few meters' distance (Ten Brinke *et al.*, 1998; Middelkoop and Asselman, 1998). Sand deposition during the highest flood stages may particularly occur on the inside of meander bends, not only due to helicoidal flow, but also as a result of a general flow direction in the down-valley direction that tends to cut off meander bends. Sand deposition on levees is highly variable along the channel, depending on local elevation and overbank flow velocities. Sand splays therefore occur as a few cm to several dm thick natural levee deposits intermittently occurring along the entire riverbank. Where a levee fails, sand deposition may develop into local crevasse splays (Gomez *et al.*, 1997).

Silt and Clay-sized Sediment The settling of the finer sediment from the floodwater continues as it is conveyed over the floodplain. The deposition rate depends on the flow depth, flow velocity, local sediment concentration, and effective grain size of the sediment. Progressive sedimentation from the suspension results in a longitudinal decline in sediment concentration along the flow path and, hence, in decreasing deposition. The rate of the decline depends on the effective settling velocities as well as on the water flow velocities, and therefore, is not necessarily linear or exponential. Behind natural levees a steep depositional gradient occurs away from the channel edge, mainly due to sand deposition (Middelkoop and Asselman, 1998). Also, the mean particle size of the flood deposits decreases with increasing distance to the main channel, with a rapid fall within the first few tens of meters from the channel bank (Marriott, 1992, 1996; He and Walling, 1996; Walling *et al.*, 1998b). Farther away from the levee, the decline becomes more gradual and is largely determined by deposition of finer sediments. Lowest deposition rates occur within the distal parts of floodplains where the floodwater has become depleted from sediment due to settling in the proximal parts. Where a return flow from the floodplain to the main stream occurs, local suspended sediment concentrations are low due to settling in the upstream area, while flow velocities increase, preventing the remaining fines from settling. Consequently, deposition rates are low in spite of the proximity of the main channel. Enhanced deposition locally occurs where the flow velocity drops, due to lateral divergence or increasing water depth in depressions. Deposition may also be promoted in the lee of upstanding dense vegetation, reducing floodwater velocities and trapping sediment.

However, where flow velocities are high, such as on low floodplain parts adjacent to the main channel or where flow concentrates, turbulent eddies in the floodwater may hinder settling, reducing local deposition rates. Back-ponding results in enhanced deposition. This occurs in early flood stages of frequent low-magnitude floods, and is due to retention-ponding after the recession of large-magnitude floods. Minor dikes reduce the interaction between the floodplain and the flow in the river channel, causing lower current velocities over the floodplain, while only the fine suspended fraction present in the upper part of the water column will enter the floodplain. Although a minor dike decreases the effective time of sediment transport onto the floodplain, sedimentation rates per day of inundation are relatively high because the lower flow velocities, longer residence times, and retention-ponding lead to a more efficient sedimentation.

Thus, within the channel belt, suspended sediment transport processes are dominated by longitudinal and convective currents that promote high concentrations of suspended sediments and high rates of overbank deposition. The deposition pattern over the floodplain confirms this convective transport. Outside the channel belt, convective currents perpendicular to the main channel are weak, and suspended sediment is therefore strongly influenced by diffusive mechanisms. Here, patterns of sediment concentrations and deposition rates are controlled by both local and more distant floodplain topography, which determine the point in the channel from which suspended sediment is supplied, and the transport conditions in the intervening regions.

Relation to Flood Magnitude

In low floodplain areas in particular, the amount of sediment deposition may increase less than proportionally with the flood duration or magnitude. This effect can be, in the first place, attributed to decreasing sediment concentrations in the river in the course of a flood due to sediment depletion in the upstream basin (cf. Walling, 1974, 1978; Wood, 1976; Asselman, 1997). In addition, sedimentation on low floodplains becomes inefficient when the discharge is very high. In those situations, the sediment trapping capability (STC) of the floodplain is low: water flow velocities are so high that most sediment is conveyed over the floodplain without settling. In contrast, sedimentation rates behind minor embankments are high even during high flood stages due to the major reduction of flow velocities behind the embankment, rendering deposition efficient. Consequently, the effective discharge for floodplain sedimentation (calculated as the discharge where the product of the associated STC, suspended sediment concentration in the floodwater, and average frequency of occurrence reaches the maximum value) is spatially distributed. In low-lying floodplain sections, the more frequent moderate floods are in the long term more effective for floodplain sedimentation than high-magnitude floods. High-magnitude events are more effective for floodplain sedimentation in floodplain sections behind minor embankments, in spite of their lower frequency of occurrence (Middelkoop, 1997; Asselman and Middelkoop, 1998; Middelkoop *et al.*, 2003).

Medium-term Deposition Rates

Average floodplain sedimentation rates reconstructed using ^{137}Cs or heavy-metal profiles show spatially varying deposition rates where the patterns are similar to those observed at the flood event, and thus also reflect the processes and controls described earlier (Bradley, 1995; Owens *et al.*, 1999b; Van Wijngaarden *et al.*, 2002; Middelkoop, 2000). As sediment deposition increases the floodplain elevation over time, the overbank flooding frequency gradually reduces. When the deposition per flood or per day of flooding remains constant, this results in a decreasing growth rate of the floodplain (Moody and Troutman, 2000). Estimates of average contemporary floodplain sedimentation rates therefore, may expected to be lower than deposition rates decennia ago. For example, reconstructed average sedimentation rates on the lower Rhine floodplains over the past century are higher than estimates of contemporary deposition rates (Middelkoop, 1997). In other cases, however, sedimentation rates have been fairly constant over the past century (Owens *et al.*, 1999a).

Regional Controls of Sediment Deposition Rates

While within-reach patterns of sedimentation rates reflect small-scale topographic controls on flow characteristics and sedimentation, between-reach variations in total sediment storage are largely a product of downstream changes in cross-valley floor morphology and flood frequency (Sweet *et al.*, 2003). Valley width, through its control on flood hydraulics, has a strong influence on the amount of sediment deposited on the floodplain. In narrow valleys, floodwaters are laterally constricted, increasing flow velocity and depth, thereby favoring sediment transport. Conversely, in wide valleys, floodwaters are shallow and slow, promoting the deposition of sediment (Lecce, 1997). Also, downstream variations in specific stream power are seen as having an important control (Magilligan, 1992). Graf (1983) suggested that deposition occurs where specific stream power decreases in the downstream direction. Rumsby (2000) found that because of the changes in channel shape and capacity, associated with channel incision over centuries, overbank sedimentation rates on islands have varied considerably over the past centuries. Nevertheless, estimated *volumes* of sedimentation may remain more or less constant and consistent in time.

Floodplain aggradation may nonetheless show continuing nondecreasing rates with no change in bed height, when flood magnitudes or sediment availability tend to increase.

This may occur because of (i) a change in partitioning between in a multichannel system, or the abandonment and silting of secondary channels, causing flood stages in the river to increase; (ii) a reduction in channel width; or (iii) external factors including climate change or land use changes leading to higher peak flows and larger sediment yield from the upstream catchment (Brown, 1996).

Another control of the amounts of floodplain deposition may be the varying suspension load in the river in the course of a flood event. Because of extreme hysteresis effects in the discharge–sediment load relationship in the upper Mississippi, and after comparing the amounts of floodplain deposition after recent high-magnitude floods, Benedetti (2003) concluded that the magnitude and timing of suspended sediment concentration peaks are also important controls on deposition, because they determine the availability of suspended sediment for transport to the floodplain during peak flood stages.

These results demonstrate that caution is needed when attempting to identify causal linkages between changes in vertical floodplain sedimentation rates and catchment land cover and/or climate factors. Therefore, it is important to take into account the local geomorphological setting of the sampling site (Rumsby, 2000).

Sedimentation Rates and Conveyance Losses

A wide range of floodplain sedimentation rates and estimated conveyance losses due to overbank sedimentation has been reported from various rivers around the world, and obtained using different methods (see Table 4). Deposition rates may vary from about 0.1 mm year^{-1} to several centimeters per year. Highest floodplain sedimentation rates are reported from humid tropical regions, monsoon areas, and regions with high sediment yields due to massive upland erosion and deforestation. Examples include estimates of floodplain sedimentation in the Yamuna river basin, India, where Saxena *et al.* (2002) determined deposition rates between 24.8 and 59.9 mm year^{-1}. Terry *et al.* (2002) found extremely large sedimentation rates in a tropical island (Fiji) river system characterized by biannual cyclone-induced floods. Average rates up to 3.2 cm year^{-1} over the past ca. 45 years were reconstructed, which are due to excessively high suspended sediment concentrations in the river (200–500 g l^{-1}) that are attained during the biggest floods.

Overbank deposition may result in significant conveyance losses from the total suspension load in a river. Asselman and Van Wijngaarden (2002) estimated that the average annual sediment accumulation on the embanked floodplain of the river Rhine's lower distributaries in the Netherlands equals 1.72 kg m^{-2} year^{-1-1}, which is equivalent to 0.394 Mton year^{-1}. This is about 13% of the total annual suspended sediment load transported into The Netherlands at Lobith. Middelkoop and Asselman (1998) estimated that during the high-magnitude flood (70-year recurrence time) of the Rhine in 1993, about 0.24 Mton of overbank fines was deposited on the Waal floodplain, which is about 7.7% of the annual sediment load in the Waal and 19% of the sediment transported through the Waal during this flood. Reconstructed conveyance losses due to sediment storage by floodplain sedimentation along UK rivers (Culm, Ouse) during the past decennia vary from 10–40% (Lambert and Walling, 1987), to about 40–50% (Walling *et al.*, 1998a), and up to 50–60% (Sweet *et al.*, 2003) of the sediment delivered to these rivers). When compared to within-channel storage of fine sediments ($< 150\,\mu$m), floodplain trapping efficiency is higher, and causes a net loss from the river system. Because of the large residence time within the floodplain, these conveyance losses due to floodplain sedimentation thus constitute a major component of the sediment budget of the rivers (Owens *et al.*, 1999b).

Floodplain Deposition of Heavy Metals

In addition to suspended sediment, overbank floodplain deposits may be used to investigate sediment-associated contaminant sources and transport dynamics in river basins. While the contamination includes nutrients, trace metals, organic pollutants such as pesticides, Polychlorinated Biphenyls (PCBs), and Polycyclic Aromatic Hydrocarbons (PAHs), attention has been focused on heavy metals because of their relatively long pollution history with often huge releases, and their tendency to remain well bonded to sediment within the fluvial system. The amount and spatial patterns of heavy metal deposition on floodplains depend on a sequence of controls, including the amounts of pollutants released in the upstream basin over the past centuries, metal concentrations in the suspension load and preferential bonding of pollutants to finer particles and organic matter, and the patterns of floodplain deposition and the associated variation in grain sizes.

Contamination of the fluvial system originates from industrial and urban areas and associated point sources, from the diffuse release from industrial wastes, or from the reworking of historically contaminated floodplain deposits along the river. Often, a pronounced decrease in concentrations occurs in a downstream direction due to input of sediments from uncontaminated tributaries (Leenaers and Rang, 1989). Nevertheless, increased concentrations deposited further downstream indicate that remobilization of contaminants stored in upstream floodplains has occurred due to bank erosion, and was subsequently deposited on the downstream floodplain (Dennis *et al.*, 2003). The temporal trends of heavy-metal pollution resulting from nineteenth and twentieth century mining and industrial activities are reflected by variations in metal content (i.e. increased levels of Cd, Cu, Pb, and Zn) in floodplain soil profiles (Swennen *et al.*, 1994; Marron, 1986; Stam, 1999; Middelkoop, 2000; Walling and Owens, 2003). In the upper part of the

Table 4 Methods and vertical aggradation rates of floodplains (rates expressed in units used in the original paper)

Reference	River	Basin area (km^2)	Method	Time period	Sedimentation rate
Lambert and Walling (1987)	Culm, UK	276	Astro-tuf sediment traps (artificial grass)	1 year	0.49 mm $year^{-1}$
Brown (1987)	Severn, UK	10 000	Soil profile	10 000 (pre-settlement)	1.4 mm $year^{-1}$
Simm (1995)	Culm, UK	276	Astro-tuf sediment traps (artificial grass)	mean of 14 flood events	0.1–8.1 mm $year^{-1}$
Nicholas and Walling (1997a)	Culm, UK	274	Astro-tuf sediment traps, modeling, ^{137}Cs	flood events; 40 years	1–6 mm a^{-1}
Collins *et al.* (1997)	Severn, Exe, UK	4325 and 600	^{137}Cs	40–50 years	6.0–9.1 mm $year^{-1}$
Walling *et al.* (1998)	Ouse, Wharfe, UK	3315 and 818	^{137}Cs	40 years	0.010–0.554 g cm^{-2} $year^{-1}$
Walling and He (1998)	UK rivers	276–3713	^{137}Cs	40 years	0.08–0.16 g cm^{-2} $year^{-1}$ 0.7–1.6 mm $year^{-1}$
Walling and He (1997a)	Culm, UK	274	^{210}Pb, ^{137}Cs	40–100 years	0.4–9.5 mm $year^{-1}$
Owens *et al.* (1999a)	Ouse, UK	3520	^{210}Pb, ^{137}Cs	30–100 years	0.11–1.04 g cm^{-2} $year^{-1}$
Owens *et al.* (1999b)	Tweed, Scotland	4390	^{137}Cs	30–40 years	0.16–2.18 kg m^{-2} $year^{-1}$ 0.13–2.2 mm $year^{-1}$
Rumsby (2000)	Tyne, UK	1918	Soil profiles, heavy metals	400 years	12.5–73.6 mm $year^{-1}$ 547–1123 m^3 km^{-1} $year^{-1}$
Sweet *et al.* (2003)	Culm, UK	274	Modeling, ^{137}Cs	40 yr	$<$0.5 g cm^{-2} $year^{-1}$, locally 0.5–2 g cm^{-2} $year^{-1}$
Asselman and Middelkoop (1995)	Rhine, The Netherlands	165 000	Artificial grass sediment traps	Jan. 1993 flood event	mean = 0.82 mm

(*continued overleaf*)

Table 4 (*continued*)

Reference	River	Basin area (km^2)	Method	Time period	Sedimentation rate
Asselman and Middelkoop (1995)	Meuse, The Netherlands	33 000	Artificial grass sediment traps	Jan. 1993 flood event	mean = 0.47 mm
Middelkoop and Asselman (1998)	Rhine, The Netherlands	165 000	Artificial grass sediment traps	Dec. 1993 flood event	1.2–4.0 kg m^{-2} (clay-silt fraction)
Middelkoop and Asselman (1998)	Meuse, The Netherlands	33 000	Artificial grass sediment traps	Dec. 1993 flood event	1.0–2.0 kg m^{-2} 2.0 (clay-silt fraction)
Stam (1999)	Geul, The Netherlands	350	^{210}Pb, ^{137}Cs, heavy metals	since ca. 1800 A.D.	10–20 mm $year^{-1}$
Lecce (1997)	Blue river, Wisconsin – USA	208	Lithology		
Gomez *et al.* (1995)	Mississippi	308 000	Post-flood survey	1993 flood event	< 2–200 mm
Kesel *et al.* (1974)	Mississippi, USA	??	Thickness of flood deposits	1973 flood	5–840 mm
Magilligan (1985)	Galena, USA	526	Soil profiles	60 years	7.5 mm $year^{-1}$
Saxena *et al.* 2002	Yamuna, India	40.2% of Ganges	^{210}Pb, ^{137}Cs	50 years	25–60 mm $year^{-1}$
Terry *et al.* (2002)	Wainimala, Fiji	ca. 1000	^{137}Cs	45 years	up to 32 mm $year^{-1}$
Ormerod (1998)	Ironbark Creek, Australia	??	^{137}Cs	50 yr	2.6–27.6 mm $year^{-1}$
Campbell *et al.* (1982)	Maluna Creek, Australia	??	^{137}Cs	15 yr	5.7 mm $year^{-1}$
Goodbred and Kuehl (1998)	Brahmaputra, Bangladesh	??	^{210}Pb, ^{137}Cs	50–100 years	1.6 mm $year^{-1}$

profiles, there is a general trend of decreasing concentrations, reflecting changes in the nature of industrial activity in the last decennia and compliance with legislation and directives aimed at reducing the discharge of contaminants to water courses. Conversely, analysis of contaminants that have accumulated over the past centuries in floodplains or in floodplain lakes is an important means of assessing the degree of pollution in drainage areas (Middelkoop, 2000; Swennen *et al.*, 1998; Hutchinson, 2003).

The absolute concentrations associated with floodplain and channel-bed sediments are usually lower than corresponding values in the suspended sediment, which primarily reflects differences in particle size composition of the different sediments (Owens *et al.*, 2001). Furthermore, because of dilution with cleaner eroded sediment, metal concentrations in suspended sediment are lower during periods of increased discharge when overbank deposition occurs than during periods of low flow (Middelkoop *et al.*, 2002).

Mobile rivers with floodplains show a complex pattern of sediment pollution (Wolfenden and Lewin, 1977). Metal values reflect the timing of deposition of lateral accretions and point bar sediments in relation to the period of mining activity. Metal concentrations in low-energy environments are considerably higher than in the coarse point bars, complicating the age–contamination relationship in floodplain areas. Within the floodplains, metal contamination of floodplain sediments is spatially highly variable on account of the variation in deposition amounts and grain sizes of overbank sediments (Leenaers and Rang, 1989; Bradley, 1995; Middelkoop, 2000). Spatial variations in metal *concentrations* in overbank sediment deposited during a flood are influenced by differences in the clay and organic matter contents in the sediment, due to the strong preferential bonding of heavy metals to these components. Consequently, the highest metal concentrations generally occur in the finer sediments deposited in the distal parts of the floodplain and in ponded areas after settling of the finest sediments, while metal concentrations in the sand sheets are low. The patterns of metal *deposition*, however, are generally determined by the amounts of deposited sediment, which in turn are controlled by the flow patterns during overbank flooding. In the long term, the largest amounts of metals will accumulate nearby the natural levee due to the large sediment deposition, and in low-lying areas that inundate often and where large amounts of fine sediments are deposited.

Estimates of contemporary metal deposition as well as estimated deposition over the past century demonstrate that in polluted catchments, conveyance losses of particulate-associated contaminants due to floodplain deposition can be significant. Examples of metal supply onto floodplains are the deposition of 5–10 kg Cd, 75–150 kg Cu, 250–300 kg Pb, and 1000–1500 kg Zn per km^2 on the lower Rhine-Meuse floodplain measured during a high-magnitude event (Middelkoop, 2000), and a contemporary annual supply per square kilometer on the Derwent River floodplain (UK) equal to 10 kg Cd, 50 kg Cu, 1800 kg Pb, and 500 Zn, estimated by Bradley (1995) from the amounts of metals in floodplain soils. Walling and Owens (2003) estimated for polluted rivers in Yorkshire, UK, that up to 26–47% of the total flux of contaminants through the main channel has been stored on the floodplain. This is, in some cases, more than the conveyance losses of suspended sediment.

Given the amounts of sediments trapped by floodplain sedimentation and concentrations of contaminants in the sediments, floodplains may constitute important sinks for contaminants (Owens *et al.*, 2001). While the residence time of polluted sediment within channels may be in the order of less than a year, most of the sediment and pollutants stored in floodplains may have a residence time between 10^1 and 10^3 years. Where lateral channel migration is important, the pollutants will be reintroduced back into the river channel. This may make the floodplain a net source of contaminants even if primary inputs have ceased (Dennis *et al.*, 2003). If the frequency of high-magnitude floods increases in the forthcoming decades due to climate change as predicted by climate models, it is probable that historically mined areas will experience significant flood-related contamination as a result of enhanced channel bank erosion and subsequent reworking of metal-rich floodplain material (Macklin, 1996). Therefore, determination of the magnitudes and rates of contaminant accumulation on the floodplains, and the residence time of the sediment-associated contaminant storage on floodplains is essential for understanding, monitoring, and predicting the fate and release of sediment-associated contaminants in river systems.

Impact of Climate Change and Land Use and River Management

Two primary controls of floodplain sedimentation rates, that is, discharge and sediment yield in the upstream basin, depend on changes in climate and land use in the upstream catchment. Climate change firstly may affect the flooding frequency of a floodplain, as many climate models predict an increase of peak flows for temperate climate regions (Arnell, 1992; Middelkoop *et al.*, 2001; Asselman *et al.*, 2003). Furthermore, intensified summer precipitation and higher runoff will cause increased sediment yield in the upstream basin due to an increase in surface and bank erosion. Also, river training works and reservoirs may strongly affect the amounts of sediment transferred to downstream floodplains.

Owens and Walling (2002) found changes in sediment sources within a Scottish catchment, associated with changes in climate and land use over the past century. The extremely long record of sedimentation history of the lower Yellow river (Xu, 2003) demonstrated on a century scale that large-scale medieval deforestation of loess areas, followed by a period of increased precipitation has

increased sedimentation rates in the lower sedimentation zone from 2–4 mm year^{-1} to about 20 mm year^{-1}. The complete embankment of the river has further increased sedimentation rates on the remaining active floodplain to over 80 mm year^{-1} in recent years. Conversely, average sedimentation rates along the Upper Mississippi, Iowa, and Wisconsin, USA, over the past 50 years are in the order of about 100 mm year^{-1}, which is less than rates that prevailed in the twentieth century when agricultural land disturbance was at maximum, but they are an order of magnitude larger than long-term average rates for the Holocene (Benedetti, 2003). Magilligan (1985) demonstrated for a catchment in the United States that soil conservation measures may result in an overall reduction in bankfull channel capacity and bankfull width. While sediment yield and deposition rates were reduced, sediment transport relative to sediment storage has become more important. Valley width appeared a major control in determining the areas of transport and deposition along the river course. Stam (2002) showed that average floodplain sedimentation rates along the Geul river (The Netherlands) over 40–60 year time slices varied between 2 and 12 mm year^{-1} and attributed the higher sedimentation rates to more abundant low-magnitude floods that occurred due to deforestation and mining activities in the upstream catchment. Wyźga (2001) demonstrated that river training works and artificial bank protection have led to a dramatic reduction of the potential of the floodplains in the upper Vistula river basin to store sediment. Because of bank protection, the river vertically incises into its riverbed and the frequency of overbank flooding has reduced, while during floods, overbank flow velocities on the narrow floodplains are mostly too high for sediment deposition.

All these studies indicate the sensitivity of floodplain deposition rates to changes in climate, land use, and river training. These controls have not only changed in the past, but will do so in the forthcoming century as well, due to global warming, socioeconomic changes in agricultural land use (both causing intensified erosion by excessive land use and reduced sediment yield due to land conservation measures), and as a consequence of future river management.

CONCLUSIONS AND PROSPECTS

Floodplain sedimentation processes can be considered as a four-dimensional evolution process: spatially varying vertical accretion over time. Understanding floodplain development therefore requires not only analysis of two- or three-dimensional processes of channel-floodplain interaction, and of the spatially variable hydraulic patterns over the floodplain, but also the geomorphological development over time, and the controls of these. Consequently, identifying and understanding the factors that determine the complex discharge–sediment relationships are key steps in understanding the evolution of a floodplain over time and interpreting floodplain sedimentation as paleoenvironmental indicators.

The available data to document this evolution, however, do not fully represent these four dimensions at once, but are sparse in time and space and difficult to acquire (Anderson *et al.*, 1996). Analysis of floodplain evolution therefore relies on integrating time series of discharge and sediment transport from rivers, analysis of contemporary two-dimensional hydraulic patterns using remote sensing and sampling of the spatially variable overbank deposition, and reconstructions of past sedimentation rates, and relating these to the controls of the processes involved. While sediment traps have proven adequate tools for documenting spatial patterns of overbank deposition during single flood events, using radionuclides and heavy metals as tracers provides spatially distributed estimates of long-term sedimentation rates, avoiding representativeness problems associated with event-based sampling. Use of two- or three-dimensional models of floodplain hydraulics and sediment deposition is essential for quantifying the role of controls on the sedimentation processes, and for relating deposition at the event scale to longer-term floodplain development. However, this raises the demand for data to establish process models, to parameterize, and validate them.

Recent research has shown tremendous progress in documenting and quantifying floodplain sedimentation processes and their controls, and its role in sediment budgets of catchments.

Still, to improve the ability to predict changes in floodplain sedimentation rates in response to changes in climate and land use, to regulatory measures in upstream catchments, and to landscaping measures for flood prevention and river restoration, many research themes deserve further attention. Some key issues that are worth mentioning may be the following:

- Improvement of hydraulic modeling relies on a better representation of floodplain geometry (e.g. using high-resolution laser altimetry data; *see* **Chapter 58, Characterizing Forest Canopy Structure and Ground Topography Using Lidar, Volume 2**) and hydraulic processes, in particular, the role of hydraulic roughness of floodplain vegetation and the representation of turbulence. Improvement of sedimentation models requires additional information that allows parameter estimation, such as *in situ* measurement of effective grain size and aggregate settling velocity distributions under varying hydraulic conditions. Model validation requires field-scale observations of 2D or 3D water flow patterns and measurements of 2D patterns of sediment deposition resulting from various flood events of different magnitudes.

- In addition to the geomorphological implications, overbank deposition of sediment and contaminants may have considerable ecological impact. Therefore, the role of floodplain sedimentation as a control in spatial patterns of riparian ecology should be further explored.
- Improved understanding of catchment budgets requires better insight in the sources of the overbank deposits using various types of chemical and radiometric fingerprinting techniques.
- Finally, to fully understand the role of floodplains as sinks or storages of sediment and associated pollutants over a time period of 10^2–10^3 years, improved and quantified estimates of residence times of sediment and pollutants within floodplain areas are required. This demands research in which erosion and deposition processes within the floodplain area are considered together, which may be carried out by geomorphological reconstructions, contemporary process studies, and modeling exercises.

85: Sediment Yields and Sediment Budgets

DESMOND E WALLING

Department of Geography, University of Exeter, Exeter, UK

Measurements of sediment transport have been undertaken on many rivers throughout the world. Most of the available data relate to suspended sediment loads and the results provide a wealth of information on the variation of suspended sediment yields in both space and time. This contribution reviews current knowledge regarding land–ocean sediment transfer and sediment fluxes to the oceans, global patterns of sediment yield and their controls, and temporal variability of sediment yields in response to both natural controls and human activity and environmental change. In order to understand the sediment response of a drainage basin, it is important to take account of the complex linkages between sediment mobilisation and sediment output, and particularly the role of both short- and long-term storage. The sediment budget provides a useful conceptual framework for this purpose and current understanding of the structure of catchment sediment budgets is reviewed.

SEDIMENT YIELDS

The Context

Measurements of sediment transport or load (*see* **Chapter 86, Measuring Sediment Loads, Yields, and Source Tracing, Volume 2**) have been undertaken on many rivers throughout the world, either within the framework of national monitoring programmes or linked to specific research investigations or water resource assessment studies. The results provide a wealth of information on the sediment loads carried by rivers in different areas of the globe and their variation in both space and time. In reviewing this information, it is useful to distinguish between different components of the sediment or particulate load, and more particularly the suspended sediment load and the bed load (*see* **Chapter 140, Transport of Sediments, Volume 4**). Much less information is available for bed load transport, since this is far more difficult to measure, particularly in large rivers. However, in most environments, the suspended load dominates the sediment load and will provide a reasonable estimate of the total particulate flux. When comparing the sediment loads of different rivers, attention commonly focuses on the annual load, or more particularly the mean annual load, since this provides a useful index of the amount of sediment mobilized from the catchment surface or the mass of sediment entering a reservoir or lake or discharged to the ocean. The mean annual load of a river is frequently referred to as its sediment yield ($t\,year^{-1}$). Since the magnitude of the sediment yield from a catchment or river basin will be strongly influenced by its size, it is convenient to express the sediment yield in terms of the sediment yield per unit area (i.e. $t\,km^{-2}\,year^{-1}$) when making comparisons between different catchments. The sediment yield per unit area is termed the specific sediment yield, to distinguish it from the gross sediment yield, but in practice the term sediment yield is frequently used to denote the specific sediment yield. As indicated above, the suspended sediment load dominates the total particulate load of most rivers and much of the existing work on sediment yields has focused on suspended sediment yields.

Some Basic Facts

The current availability of suspended sediment yield data for the world's rivers affords a reasonable basis for establishing the global range of specific suspended sediment yields. Taking basins $>100\,km^2$ in size, in order to avoid local anomalies, documented global minima for mean annual specific suspended sediment yield lie around $1\,t\,km^{-2}\,year^{-1}$. Branski (1975), for example, reports values of $<1.0\,t\,km^{-2}\,year^{-1}$ for several rivers in northern Poland and Branski and Banasik (1996) indicate that specific sediment yields are less than $5\,t\,km^{-2}\,year^{-1}$ over much of

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

lowland Poland. Dedkov and Mozzherin (1984) cite similar low values ($<1.0\,t\,km^{-2}\,year^{-1}$) for rivers in several areas of the former Soviet Union, including the Kola Peninsula, the Yenesei and Dneiper basins, and the catchment of the Sea of Azov. In most cases, these basins are characterized by very low relief, the presence of lakes and marshes, dense vegetation or ground cover and surface materials that are either resistant to erosion (e.g. crystalline rocks) or which afford only a limited source of fine sediment for transport as suspended sediment (e.g. coarse glacial deposits). All these characteristics limit sediment mobilization and transport.

Maximum documented mean annual specific suspended sediment yields exceed $10\,000\,t\,km^{-2}\,year^{-1}$ and Table 1 lists a number of rivers for which such extreme values have been reported. The highest value listed in Table 1 is a mean annual specific suspended sediment yield of $53\,500\,t\,km^{-2}\,year^{-1}$ for the Huangfuchuan River ($3199\,km^2$) in the People's Republic of China. This river is a tributary of the Middle reaches of the Yellow River (Huanghe), which drain the highly eroded gullied loess region. Here, the semiarid climate with high intensity rainfall in summer, the lack of vegetation cover, the highly erodible loess, and the densely dissected and gullied terrain combine to produce some of the highest rates of soil loss in the world. The dense gully networks and the high suspended sediment concentrations (hyperconcentrations), which may exceed $1000\,kg\,m^{-3}$ and which limit sediment deposition, also combine to produce a highly efficient sediment delivery system, such that most of the sediment mobilized by erosion is transported to the catchment outlet. A range of factors reflecting the topography, the erosivity of the local hydrometeorological regime, the erodibility of the terrain, tectonic instability, and surface disturbance by human activity can be invoked to account for the other examples of high suspended sediment yields noted in Table 1. The semiarid climate is again a key causal factor in the Kenyan example, but the impact of severe overgrazing is also important. For Taiwan, Java, and New Guinea, the steep mountainous relief, tectonic activity, high rainfall totals, and intense agricultural activity are key controls. In North Island, New Zealand, soft sedimentary rocks and tectonic activity account for the high specific sediment yields of rivers such as the Waiapu, and in South Island, New Zealand, the steep relief, tectonic uplift, and the very high rainfall (up to $9000\,mm\,year^{-1}$) are again key controls.

Table 1 Maximum reported values of mean annual specific suspended sediment yield for world rivers

Country Area	River sediment yield	Drainage (km^2)	Mean annual ($t\,km^{-2}\,year^{-1}$)
China	Huangfuchuan	3199	53 500
	Dali	187	21 700
China (Taiwan)	Erjenhsi	350	28 911
	Tsengwen	1000	28 000
Kenya	Perkerra	1310	19 520
Java	Cilutung	600	12 000
	Cikeruh	250	11 200
New Guinea	Aure	4360	11 126
North Island New Zealand	Waiapu	1378	19 970
	Waingaromia	175	17 340
	Hikuwai	307	13 890
South Island New Zealand	Hokitika	352	17 070
	Cleddau	155	13 300
	Haast	1020	12 736

Based on data presented by Walling and Webb (1996).

Although suspended sediment will, by definition, comprise only particles of fine sediment, information on the grain size composition of the suspended sediment transported by a number of rivers in different areas of the world reported by Walling and Moorehead (1989) and presented in Figure 1 serves to emphasize the potential range of size distributions that may exist. Thus, for example, the situation in the Barwon River in Australia, where the majority of the suspended sediment is clay-sized and $<0.002\,mm$ in diameter may be contrasted with the situation in the Huangfu River, a tributary of the Middle Yellow River in China, where up to 60% of the suspended sediment load is sand-sized (i.e. $>0.062\,mm$ in diameter) and clay-sized particles comprise only a small proportion of the total load. Such contrasts in the grain size composition of the suspended sediment load will have important implications for sediment chemistry and for the sediment-associated transport of nutrients and contaminants (cf. Horowitz, 1991), since the specific surface area of the sediment ($m^2\,g^{-1}$), which exerts a fundamental control on its capacity to adsorb nutrients and contaminants, increases markedly with decreasing particle size. Typical values for clay (e.g. $20–800\,m^2\,g^{-1}$) are, for example, several orders of magnitude greater than those for silt and sand. The contrasts in the grain size composition of suspended sediment evident in Figure 1 reflect both the granulometry of the source materials within a catchment and their degree of weathering, and the physiographic conditions. In the latter case, both low relief and low drainage density could be expected to promote the preferential deposition of coarser particles during transfer of mobilized sediment to the channel network, thereby increasing the proportion of finer particles. The relatively coarse nature of the loess deposits underlying the catchment of the Huangfu River, is clearly reflected by the grain size composition of the sediment, whereas the very fine suspended sediment found in the Barwon river reflects, at least in part, the very low relief of its catchment area.

The limited availability of reliable information regarding annual bed load transport by the world's rivers precludes a detailed assessment of the relative magnitude of the two load components, but some indication of the likely situation is provided by the data assembled by Dedkov

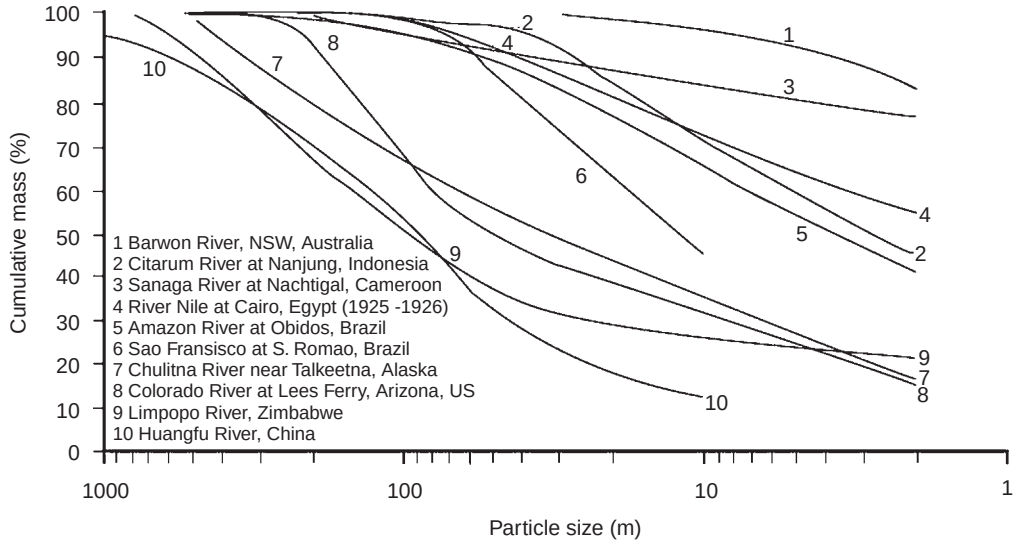

Figure 1 The grain size composition of suspended sediment transported by a range of world rivers (based on data presented by Walling and Moorehead, 1989)

and Mozzherin (1984) for a number of the worlds larger ($>5000\,km^2$) rivers, although the majority of these were located in the former Soviet Union. The estimates of bed load discharge were derived using a variety of methods, including both direct measurements and assessments of reservoir siltation and the use of empirical formulae, either for estimating bed load transport or for estimating the relative magnitude of the bed load component from measurements of the grain size composition of the suspended load and the bed material. These data indicated that bed load was on average ca. 8% of the suspended sediment load for "Plains" rivers and ca. 23% for "Mountain" rivers. Bed load was shown to reach its maximum importance, relative to the suspended sediment load, in glacierized mountains, for which an average value of 36% was reported.

Sediment Flux to the Oceans

Linked to the magnitude considerations outlined above, it is also useful to consider the total sediment flux from the land surface of the globe to the oceans. In the absence of information on bed load fluxes for most rivers, and accepting that the suspended load will dominate the global flux, attention will focus on suspended sediment loads. Since the 1950s, a number of workers have attempted to establish the magnitude of this flux (see Table 2), but it must be recognized that any such attempt faces several important problems. Leaving aside the question of the reliability of sediment load data, which represents a major source of uncertainty (see Walling and Webb, 1981), the problems include the lack of information on suspended sediment loads for many areas of the world, particularly large areas of Africa and South America, the location of measuring stations above the tidal limit, such that the measured loads may overestimate the flux to the ocean, where significant deposition occurs in the lower reaches of a river basin, and the temporal variation of annual sediment loads. In the latter context, the high interannual variability of annual sediment loads means that a short period of record may not provide a reliable estimate of the mean annual flux. The coefficient of variation of the annual suspended sediment load from a river basin will commonly exceed that of the annual water discharge and values in excess of 100%

Table 2 Existing estimates of total suspended sediment transport to the oceans

Author	Estimated mean annual load (10^9 t)
Fournier (1960)	51.1
Kuenen (1950)	32.5
Gilluly (1955)	31.7
Jansen and Painter (1974)	26.7
Pechinov (1959)	24.2
Syvitski (2003)	24.0
Schumm (1963)	20.5
Milliman and Syvitski (1992)	20.0
Holeman (1968)	18.3
Goldberg (1976)	18.6

Sundborg (1973), Walling and Webb (1983)	15.0
Ludwig and Probst (1996)	14.8
Ludwig and Probst (1996)	14.7
Milliman and Meade (1983)	13.5
Lopatin (1952)	12.7
Mackenzie and Garrels (1966)	8.3

are not uncommon (Walling and Kleo, 1979). A lengthy period of record (e.g. 20 years) is therefore needed to characterize reliably the mean annual suspended sediment load of a river. Furthermore, it must be recognized that the records of suspended sediment flux available for many rivers cannot be regarded as stationary, since sediment yields are likely to be sensitive to climate change, changing land use and the construction of reservoirs. The latter will trap sediment (*see* **Chapter 88, Reservoir Sedimentation, Volume 2**) and therefore reduce land–ocean transfers. The global land–ocean flux cannot therefore be viewed as a static quantity, but rather one that is continually changing. As a result, use of data from different periods can introduce further uncertainty into the final result. The potential significance of the latter problem is well demonstrated by the sediment load data available for the Yellow River in China. Before 1985, the mean annual suspended sediment load for Lijin on the lower Yellow River averaged about 1×10^9 t, but this load declined markedly after 1985, as a result of climate change (lower annual rainfall), increased water abstraction for both irrigation and industrial use and the implementation of soil conservation and sediment control programmes in the upstream catchment, so that since 1985 it has averaged less than 0.5×10^9 t and in 1997 it fell to a record low of 0.03×10^9 t (Yang, 1998; Wang, 2003).

Table 2 presents some existing estimates of the total suspended sediment flux to the oceans. The values evidence considerable variability and range between 8.3 and 51.1 billion tons. Much of the variability reflects the limited data available to early workers and the need to extrapolate these data to large areas of the globe with no measurements. More recent studies have been able to take advantage of the increasing number of rivers for which sediment load data are available and values in the range 15 to 20×10^9 t year^{-1} have been most frequently cited. However, although data are now available for an increasing number of the major rivers of the world, which in turn account for a substantial proportion of the total land surface draining to the oceans, uncertainties still exist regarding the sediment flux from the smaller river basins draining to the oceans. Milliman and Syvitski (1992) have, for example, estimated that, whereas the world's 100 largest rivers drain ca. 60% of the land surface draining to the oceans, data from more than 10 000 rivers would be required to produce a definitive value for the total land–ocean flux. Any attempt to extrapolate existing data from large rivers to these smaller river basins faces substantial problems, since the specific sediment yields of smaller river basins are typically much greater than those of large basins. Furthermore, many smaller rivers drain areas of high relief, which are commonly characterized by high specific sediment yields. In particular, Milliman and Syvitski (1992) highlighted the need for more information on the sediment yields of the islands of Pacific Asia, where steep topography, tectonic instability, and land use pressure combine to produce very high sediment yields.

The most rigorous attempt to estimate the global suspended sediment flux to the oceans available to date is probably the work of Milliman and Meade (1983), which was further refined by Milliman and Syvitski (1992). Based on summation of the available river load data and extrapolation of this information to ungauged areas, Milliman and Meade (1983) produced an estimate of the mean annual suspended sediment flux to the oceans of 13.5×10^9 t year^{-1}. This value excluded sediment deposited in major reservoirs which would previously have reached the oceans and Milliman and Meade (1983) suggested that it should be increased to ca. 14 billion t year^{-1}, to represent the "natural" flux. A reassessment of the values used by Milliman and Meade (1983) when extrapolating to ungauged areas led Milliman and Syvitski (1992) to suggest that yields from many areas had been underestimated and that the total flux was likely to be ca. 20 billion t year^{-1}. Further refinement of the extrapolation to ungauged areas undertaken by Syvitski and Vorosmarty using digital elevation data for the global landmass and reported by Syvitski (2003) has increased the estimate to 24×10^9 t year^{-1}. Whereas the estimates produced by Milliman and Meade (1983), Milliman and Syvitski (1992) and Syvitski (2003) were based on summation of available load data and extrapolation of these data to ungauged areas, a different approach was adopted by Ludwig and Probst (1996), who used a database comprising sediment yield data for 58 rivers and information on climate and land surface characteristics for the land surface of the globe, extracted from available data sets at a resolution of $0.5° \times 0.5°$ latitude/longitude, to develop simple predictive models relating specific sediment yield to the product of several variables, including mean annual runoff, average basin slope, an index of the magnitude and seasonality of the annual precipitation and basin lithology. Both a single model for the entire globe and separate models for four different climate zones were developed and these were used to estimate the mean annual specific sediment yield for the total land surface of the globe and for the individual climate zones. The products of these specific sediment yields and the respective exoreic continental areas provided estimates of the total suspended sediment flux to the oceans of 14.8×10^9 t year^{-1} using the global model and 14.7×10^9 t year^{-1} using the models for the individual climate zones. These values are less than those proposed by Milliman and Syvitski (1992) and Syvitski (2003), but might arguably be expected to underestimate the total flux, since a number of river basins with high specific sediment yields were excluded from the global database.

In both the approaches outlined above, and indeed for most of the estimates listed in Table 1, at least some of the specific sediment yield data employed in deriving the

estimate of land–ocean flux will have been influenced by trapping of sediment in reservoirs and will thus underestimate what might be seen as the "natural" flux. In this respect, the estimates presented in Table 1 could be seen as underestimates. However, it is important to recognize that any attempt to establish the "natural" flux should also take account of the effects of land clearance, agricultural activity, and related activities in increasing sediment fluxes. It is possible that these opposing effects could be of a similar magnitude and thus cancel each out, but it would seem likely that the increased sediment flux associated with accelerated erosion caused by human activity would exceed any reduction caused by reservoir trapping. A wide range of estimates of the magnitude of the increase in the contemporary land–ocean sediment flux relative to the "pristine" situation prior to significant human impact have appeared in the literature. For example, Panin (2004) used evidence from past geological periods to estimate that contemporary sediment transport to the oceans is about 1.2 times the natural or pristine level. However, other authors have based their estimates on comparison of sediment yields from areas impacted by human activity with those from areas less influenced by anthropogenic impacts to suggest greater increases. Milliman and Syvitski (1992) and McLennan (1993) suggested a twofold increase, whereas Farnsworth and Milliman (2003) estimated that human activity may be directly or indirectly responsible for 80–90% of the delivery of fluvial sediment to the coastal ocean and thus that the flux has increased between five and tenfold.

Turning to the opposite effect, namely, the trapping of sediment in reservoirs, Vorosmarty *et al.* (2003) have undertaken a detailed analysis of the global distribution of reservoirs and their role in intercepting sediment transport. They have estimated that more than 40% of the water discharge of the world's rivers is currently intercepted by large ($\geq 0.5\,km^3$ maximum storage capacity) impoundments and that as much as 16% of the contemporary sediment flux from the land to the oceans is currently being trapped behind such dams. If the impact of the >44 000 smaller registered reservoirs is also considered, the proportion trapped increases to 28%, representing $4–5 \times 10^9\,t\,year^{-1}$. This trapping is clearly focused within those river basins of the world where the flow is regulated by dams and in these regulated basins the proportion of the total sediment flux that is trapped is as high as 53%. However, these values take no account of the ca. 8 00 000 smaller unregistered impoundments which can be expected to further increase the proportion of the global land–ocean sediment flux that is now trapped by dams. It is also important to recognize that the growth of dam construction on the world's rivers has been relatively recent. Vorosmarty *et al.* (2003) suggest that for the first half of the twentieth century, sediment retention in regulated basins was relatively modest, accounting for less than 5% of the global flux. However, after 1950, with the great expansion of dam building worldwide, the value tripled to 15% by 1968 and doubled again to nearly 30% by 1985 when it essentially stabilized. The values reported above suggest that, whilst significant, the trapping of sediment by reservoirs is likely to be significantly less than any increase in the land–ocean sediment flux caused by land use activities and that the latter can be expected to have caused a substantial increase in the contemporary land-ocean sediment flux relative to the "pristine" condition.

The Global Pattern of Sediment Yield and Its Controls

The literature provides examples of a number of attempts to generate maps of the global pattern of suspended sediment yield. Such attempts have inevitably faced a number of problems relating to the lack of data for many areas of the world, the extrapolation or interpolation procedures used, the nonstationary nature of sediment load data in many areas of the world, and the scale-dependent nature of sediment yield data. In the latter context, it is important to recognize that whilst information on the sediment yield at the outlets of major river basins may be a key requirement for assessing sediment flux to the oceans, the associated values of specific suspended sediment yield provide no information on the spatial variability of sediment yield within the upstream basin and indeed serve to mask such variability. Furthermore, the magnitude of specific suspended sediment yields has also been shown by many workers to be influenced by drainage area (e.g. Walling, 1983; Milliman and Syvitski, 1992) so that a map depicting the specific sediment yields of drainage basins of one size (e.g. $10^3\,km^2$) would present a different range of values from a map based on the sediment yields of much larger basins (e.g. $10^5\,km^2$).

Although the early attempts to produce maps of the global pattern of sediment yield by Fournier (1960) and by the Soviet scientist Lopatin (see Strakhov, 1967) have been frequently cited in attempts to describe the global denudation system, these maps were necessarily based on very limited data (96 rivers in the case of Fournier and 60 rivers for Lopatin) and must therefore be viewed as unreliable (see Walling and Webb, 1983). More recent improvements in data availability have permitted the production of more meaningful maps, although these still possess many uncertainties due to the lack of sediment yield data for many areas of the world. Those concerned primarily with fluxes to the oceans (i.e. Milliman and Meade, 1983) are, as noted above, of limited value for establishing the detail of the global pattern involved and in some cases only those areas of the globe for which data were available were mapped (e.g. Jansson, 1988). However, more explicit

attempts to map these patterns have been documented by Walling and Webb (1983, 1987), Walling (1987), Dedkov and Mozzherin (1984), and Lvovich *et al.* (1991). The maps produced by Walling and Webb (1983) and by Lvovich *et al.* (1991) are presented as Figures 2 and 3. Both relate to intermediate sized drainage basins and, although the procedures used to derive the maps were somewhat different (the former map is based primarily on spatial interpolation of available river load data, whereas the latter is based on extrapolation of available data using regional relationships between specific sediment yield and mean annual runoff), the patterns depicted evidence clear similarities. Maximum sediment yields are associated with the loess region of China and the young Cenozoic mountain areas around the Pacific margin. High values are also found in other mountain areas and in regions with Mediterranean and semiarid climates and in the seasonally humid tropics. Low values are associated with desert regions and with the low relief, glaciated regions of the Canadian Shield and northern Eurasia. In both cases, these maps must be seen as only tentative representations of the detailed global patterns involved, and further work is required to extend the sediment load databases employed, to assess and take account of the reliability of those data, to standardize the resulting estimates of sediment yield to a common drainage basin area, and to refine the interpolation and extrapolation procedures employed, particularly for those areas where data are totally absent. Recent advances in the development of detailed global databases for land surface and climate and hydrological characteristics (e.g. Vorosmarty *et al.*, 2000), coupled with GIS techniques, clearly offer potential to produce a new generation of maps.

Attempts to account for the broad trends encompassed by maps such as Figures 2 and 3 and the data used in their development have involved a number of different approaches. Whilst not aiming explicitly to identify specific controls, the work of Dedkov and Mozzherin (1984) is worthy of mention as one of the few attempts to develop a global zonation of sediment yield based on morphoclimatic zones. These authors assembled sediment load data from more than 3000 measuring stations on world rivers and firstly subdivided these data into *Plains* rivers and *Mountain* rivers. Specific suspended sediment yields associated with the latter were on average more than three times greater than those for the former. They subsequently attempted to characterize each of the morphoclimatic zones within these two broad categories by typical suspended sediment yields. Yield values were given for both small ($<5000\,km^2$) and large ($>5000\,km^2$) rivers, in order to take account of the scale problem identified above. The results of this analysis presented in Figure 4 are highly dependent on the representativeness of the sediment yield data available for the different morphoclimatic zones, since the values depicted are simply mean values for the available data. Figure 4 should therefore not be viewed as a definitive representation of the global zonation of suspended sediment yields, but it affords a useful indication of the patterns involved. In the case of plains rivers,

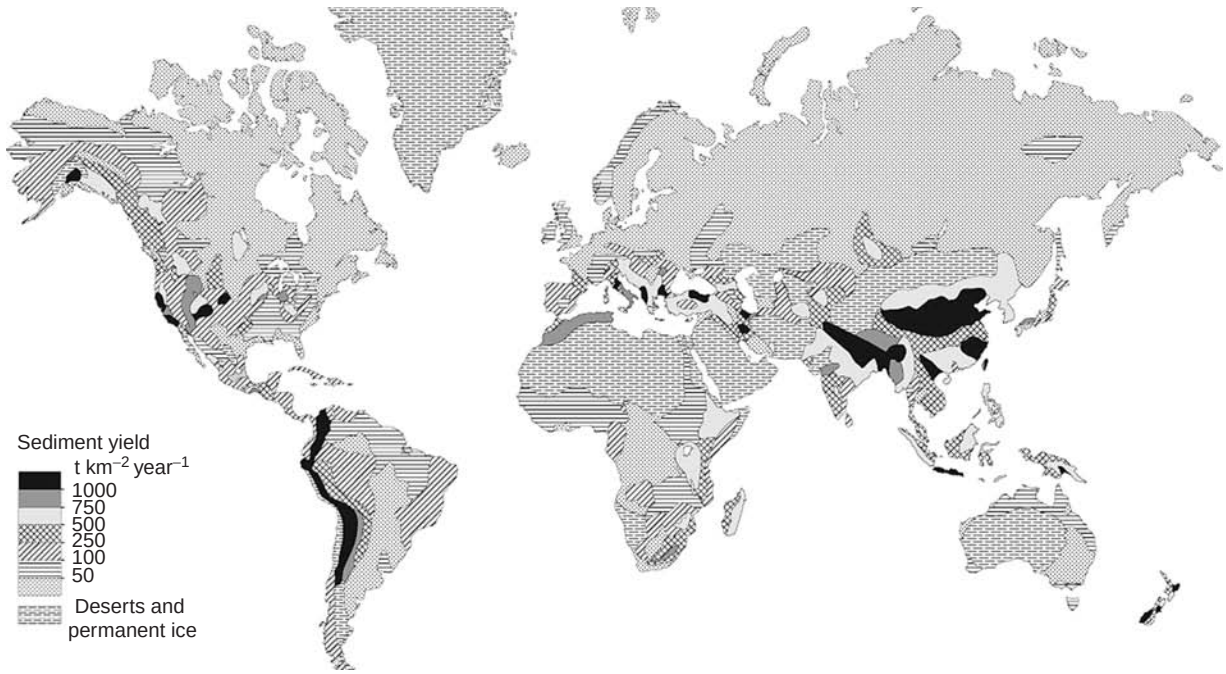

Figure 2 The world map of suspended sediment yield (Reproduced from Walling and Webb, 1983 by permission of John Wiley & Sons Ltd)

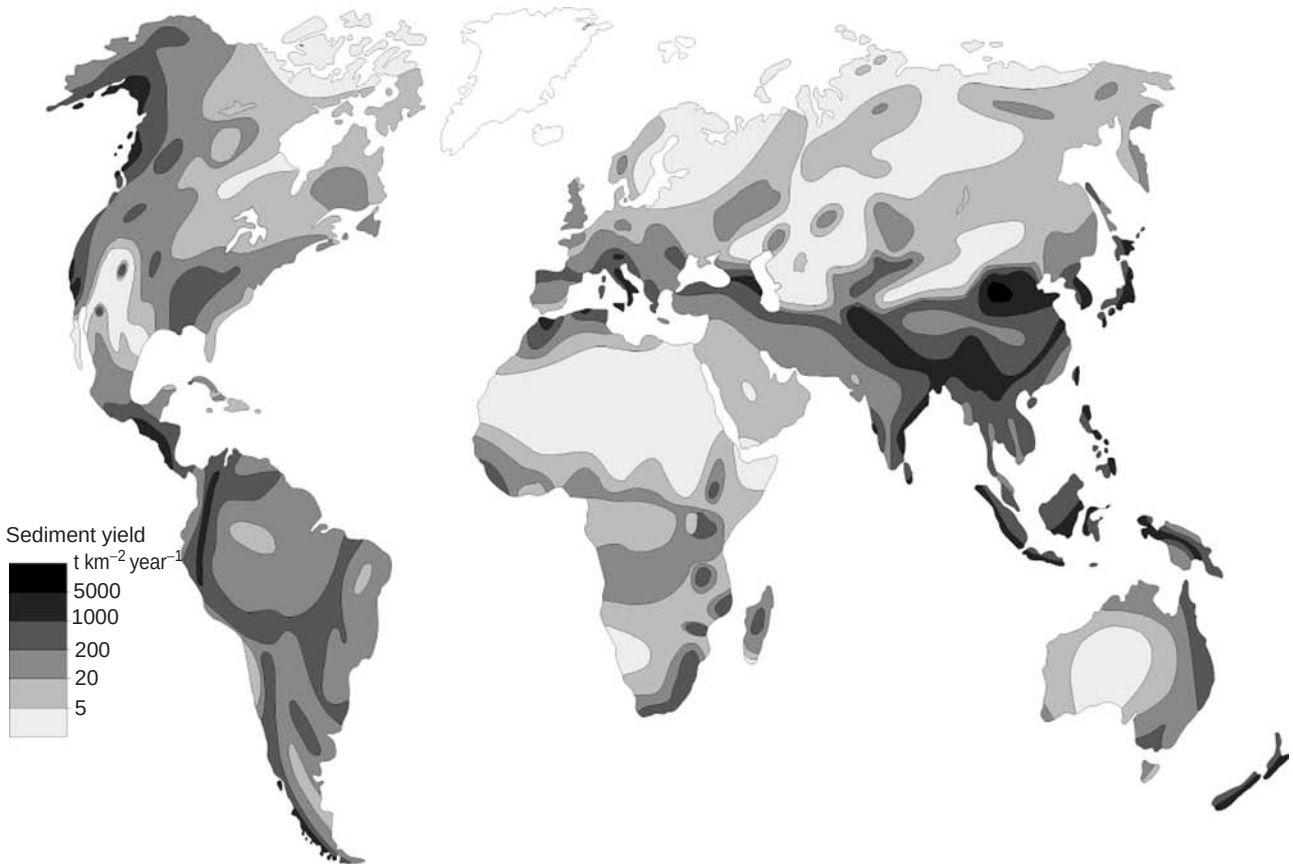

Figure 3 The world map of suspended sediment yield produced by Lvovich *et al.* (1991)

it emphasizes the relatively low specific suspended sediment yields encountered in the temperate and equatorial belts and the existence of much higher values in subtropical and tropical regions. A similar pattern is shown by mountain rivers, but in this case the rivers in the glacial zone produce the highest specific suspended sediment yields.

Attempts to identify the key controls responsible for the global patterns evident in Figures 2 and 3 and in the global zonation documented in Figure 4 have frequently focused on climatic controls and, more particularly, the relationship between specific suspended sediment yield and mean annual precipitation and runoff and measures of precipitation seasonality (e.g. Langbein and Schumm, 1958; Fournier, 1960; Douglas, 1967; Wilson, 1969; Walling and Webb, 1983; Jansson, 1988). However, the availability of larger and more representative databases has demonstrated that there is no simple and well-defined relationship between specific sediment yield and annual rainfall and runoff (cf. Walling and Webb, 1983). The relationships between mean annual specific sediment yield and effective precipitation (defined as the annual precipitation required to generate the given annual runoff, assuming an annual mean temperature of 50°F) and mean annual runoff proposed by Langbein and Schumm (1958) and Douglas (1967), respectively, are, nevertheless, presented in Figure 5, since they have been widely cited in the literature. The relationship reported by Langbein and Schumm (1958) has been referred to as the "Langbein–Schumm Rule". This "rule", which provides a convincing explanation of the trend shown in Figure 5(a), highlights the interaction of changes in erosive energy and vegetation cover density associated with changing annual precipitation. Maximum suspended sediment yields occur in areas with an annual effective precipitation of approximately 300 mm (i.e. semiarid areas). In areas with increased precipitation, the vegetation cover density increases, causing reduced erosion and sediment yield. In drier areas, the available energy for water erosion is also limited, resulting in reduced sediment yields. The relationship reported by Douglas (1967) (Figure 5a) evidences a similar peak for semiarid areas (i.e. for a mean annual runoff of ca. 60 mm), but in this case sediment yields increase again when mean annual runoff exceeds ca. 500 mm, suggesting that the increased erosive energy overrides the effect of any increase in vegetation cover density for higher values of mean annual runoff.

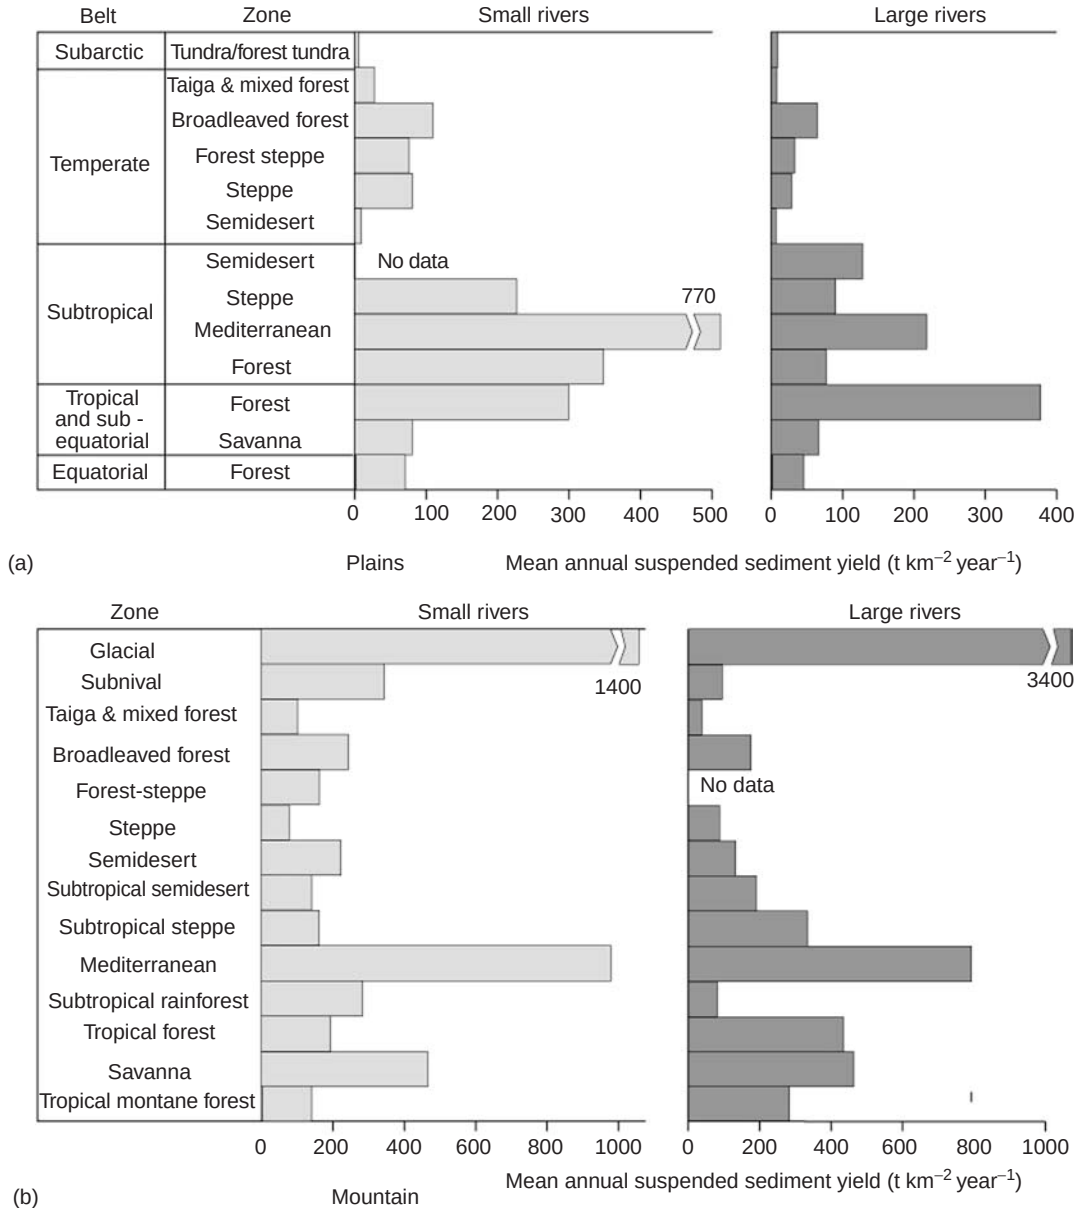

Figure 4 The global zonation of suspended sediment yield proposed by Dedkov and Mozzherin (1984)

The lack of a clear relationship between specific suspended sediment yield and annual precipitation or runoff demonstrated by Walling and Webb (1983) reflects the important role of many other factors in controlling global variations in sediment yield. Pinet and Souriau (1988), Milliman and Syvitski (1992), and Summerfield and Hulton (1994) have, for example, emphasized the role of relief in accounting for global variations in sediment yield. Based on a dataset comprising the suspended sediment loads of 33 major world rivers, Summerfield and Hulton (1994) demonstrated that the highest degree of statistical explanation was provided by variables reflecting catchment relief, as represented by the basin relief and relief ratio. Whereas basin relief accounted for 64% of the total variance of the dataset, mean annual runoff accounted for only 20% of the variance. Lvovich *et al.* (1991) further demonstrated the important role of variables other than annual precipitation or runoff by analyzing a very much larger database of sediment loads for world rivers. They found a positive log/log relationship between specific sediment yield and mean annual runoff, but showed that the intercept of this relationship varied markedly between different regions, thereby masking any general global relationship.

A useful demonstration of the complex set of controls influencing the global pattern of suspended sediment yield is provided by the work of Ludwig and Probst (1996). These

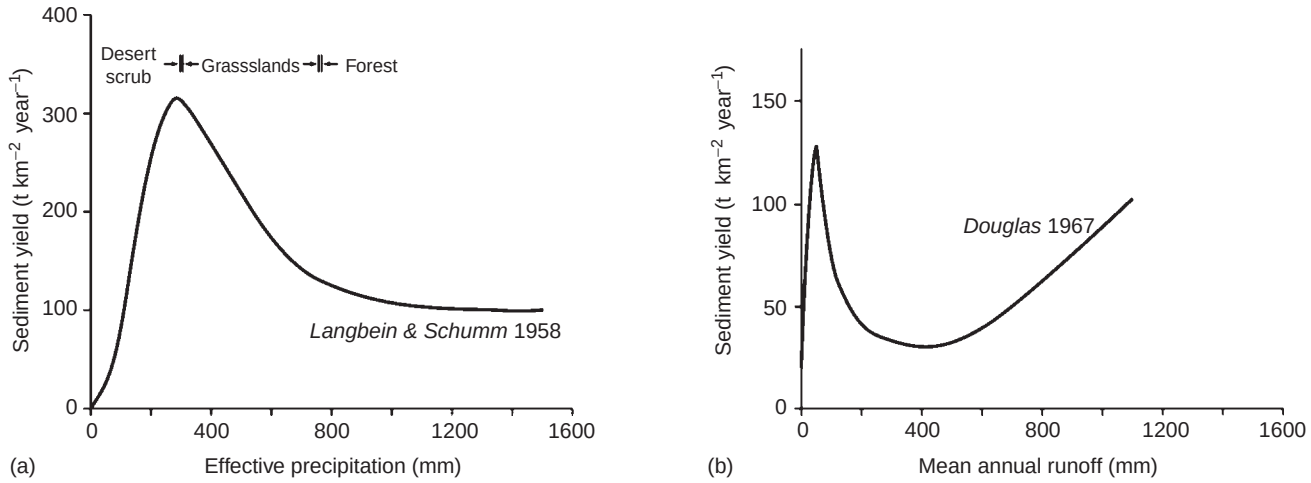

Figure 5 The relationships between mean annual suspended sediment yield and mean annual effective precipitation and mean annual runoff proposed by Langbein and Schumm (1958) and Douglas (1967) (Reproduced from Langbein and Schumm (1958) by permission of American Geophysical Union)

authors assembled specific sediment yield data for 60 major world river basins which accounted for about 50% of the total exoreic continental area and were representative of the major ecosystems of the land surface of the globe. Environmental data, including variables such as mean annual precipitation and runoff, the seasonal variability of precipitation, basin slope, lithology, biomass density, and percentage cultivated area were extracted from a range of global data sets at a grid point resolution of $0.5° \times 0.5°$ longitude/latitude and area-weighted values were obtained for each river basin. The significant correlations between the values of specific suspended sediment yield for the 60 river basins and the different environmental variables are summarized in Figure 6. Figure 6 indicates that mean annual runoff has the strongest (positive) correlation with specific sediment yield and the next strongest correlations, which again are all positive, are with mean annual precipitation, precipitation variability, biomass density, lithology (erodibility) and basin slope. These results are, however, sensitive to multicollinearity or interdependence between the variables, so that the positive relationship between mean annual suspended sediment yield and biomass density, which runs counter to what might be intuitively expected in terms of the influence of vegetation cover density on erosion rates, probably reflects the close association between biomass density and mean annual runoff. This and other significant intercorrelations between the independent variables are also shown on Figure 6. There is clearly scope to extend the analysis reported by Ludwig and Probst (1996) to include more river basins and to incorporate more rigorous multivariate analysis, in order to identify the "real" effect of the individual variables. Furthermore, since most of the river basins represented were relatively large (between $5903 \times 10^3\,km^2$ and $9 \times 10^3\,km^2$) there is again scope to include smaller basins which are more representative of global variability in the key controlling variables. However, the analysis does serve to emphasize the multiple controls on the patterns evident in Figures 2 and 3.

Further evidence of the relative importance of controls such as mean annual rainfall or runoff and basin geology can be gleaned from the large number of regional and national studies documented in the literature, which have attempted to develop predictive relationships. The results from two such studies undertaken in New Zealand (Hicks *et al.*, 1996) and the Maghreb region of North Africa (Heusch and Milliés-Lacroix, 1971) are shown in Figure 7(a) and 7(b). The results from New Zealand clearly demonstrate the role of mean annual rainfall and rock type in controlling suspended sediment yields in that country, since variation in either of these controls can cause sediment yields to vary over three orders of magnitude. A similar, albeit slightly less marked trend, is evident for the Maghreb region of North Africa. In their study of the spatial variability of suspended sediment yields in New Zealand, Hicks *et al.* (1996) suggest that the influence of mean annual rainfall and rock type, with the latter reflecting both lithology and tectonic instability, explains the broad pattern of sediment yields, and that other variables such as catchment slope and secondary climatic parameters that index the seasonality operate to cause further local variation within the broad pattern produced by variations in mean annual precipitation and rock type. In some areas, land use will also exert a key control over the pattern of suspended sediment yield, since, if other controls are held constant, the contrasts between, for example, forest areas and areas with intensive cultivation could be reflected by differences in sediment yield involving several orders of magnitude. This situation is well illustrated by the general analysis of land

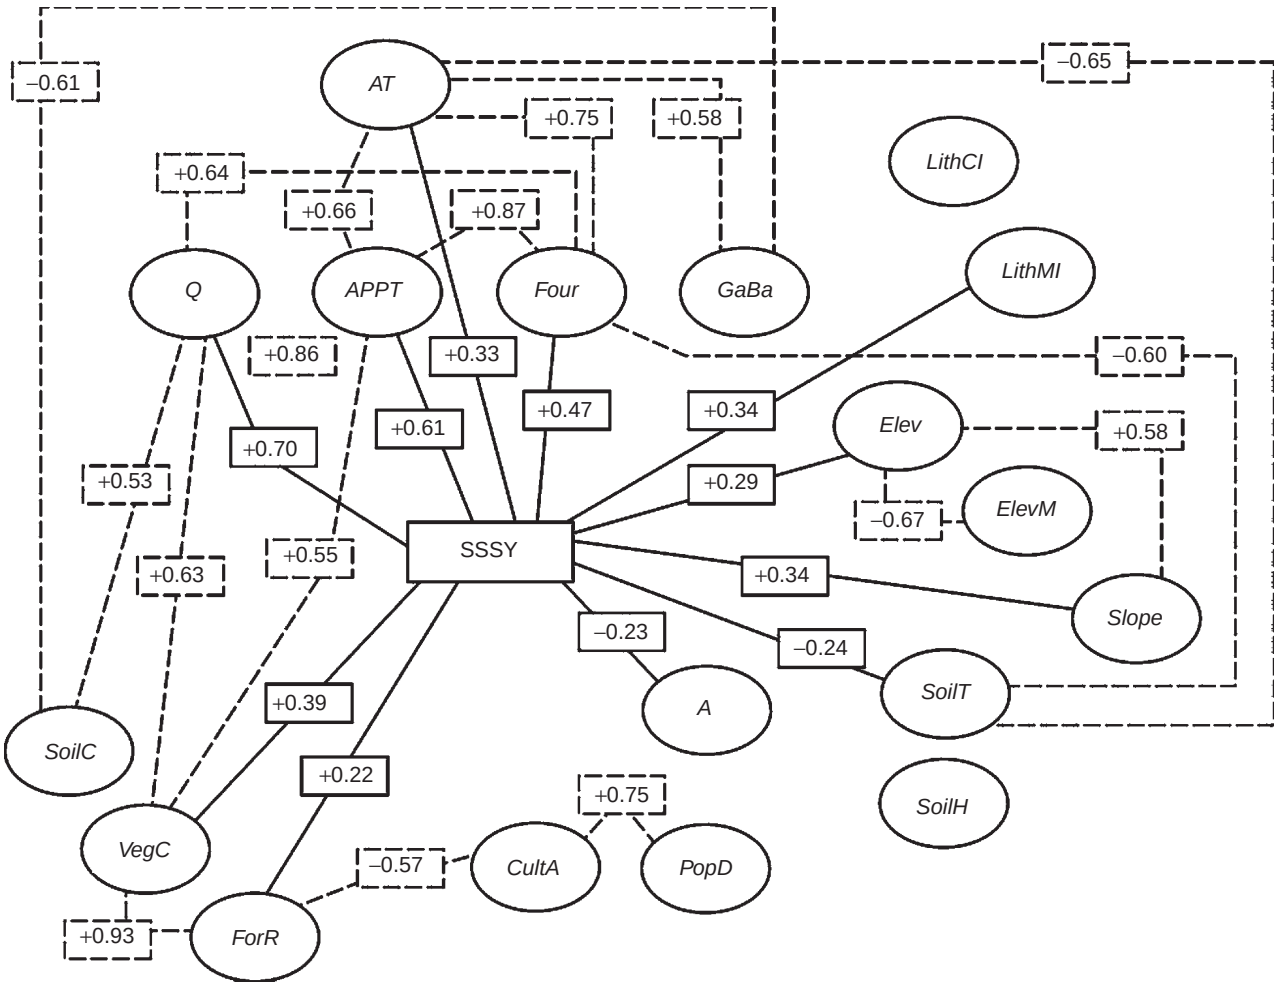

Figure 6 The correlation (r values) between mean annual specific suspended sediment yield (SSSY) and a range of catchment characteristics for 60 major world river basins (the solid lines show correlations significant at $P < 0.1$). Correlations between the catchment characteristics are shown by dashed lines, with only correlations with r values < -0.5 and $> +0.5$ depicted. *Q* is mean annual runoff depth; *AT* and *APPT* are the mean annual temperature and mean annual precipitation, respectively; *Four* is a modified form of the Fournier index of intra-annual variability of precipitation: *GaBa* is an aridity index based on monthly precipitation and temperature data; *LithMl* and *LithCl* are measures of the erodibility of the dominant basin lithology, with respect to mechanical and chemical erosion, respectively; *Elev* is the mean modal basin elevation and *ElevM* is the maximum basin elevation; *Slope* is the average basin slope; *SoilT* is a measure of soil erodibility based on soil texture; *SoilH* is the average soil depth; *A* is the basin area; *SoilC* is the average organic carbon content of the soil; *VegC* is the average biomass density; *ForR* is the proportion of forest in the basin; *CultA* is the proportion of cultivated land in the basin and *PopD* is the mean population density in the basin (Based on Ludwig and Probst, 1996, with permission from IAHS Press)

use effects on sediment yields in Kenya reported by Dunne (1979), which is presented as Figure 7(c). In this region, contrasts in land use can be seen to induce a two- to three-fold variation in specific sediment yield, for a given value of mean annual runoff.

The Role of Drainage Basin Area

As indicated above, there is a general expectation that specific suspended sediment yield will decrease as catchment area increases (see Walling, 1983; Milliman and Syvitski, 1992). This inverse trend is commonly accounted for in terms of the increased opportunity for deposition and storage as travel distances increase and the sediment is transported into areas with reduced slope gradients and well-developed floodplains. Thus the probability that a sediment particle will be deposited increases with increasing transport distance and therefore catchment area. This effect is frequently paralleled by a general decrease in specific sediment yield from downstream areas, due to reduced relief and slope gradients and reduced precipitation and runoff, such that the average sediment yield per unit area also decreases as catchment area increases. Figure 8(a)

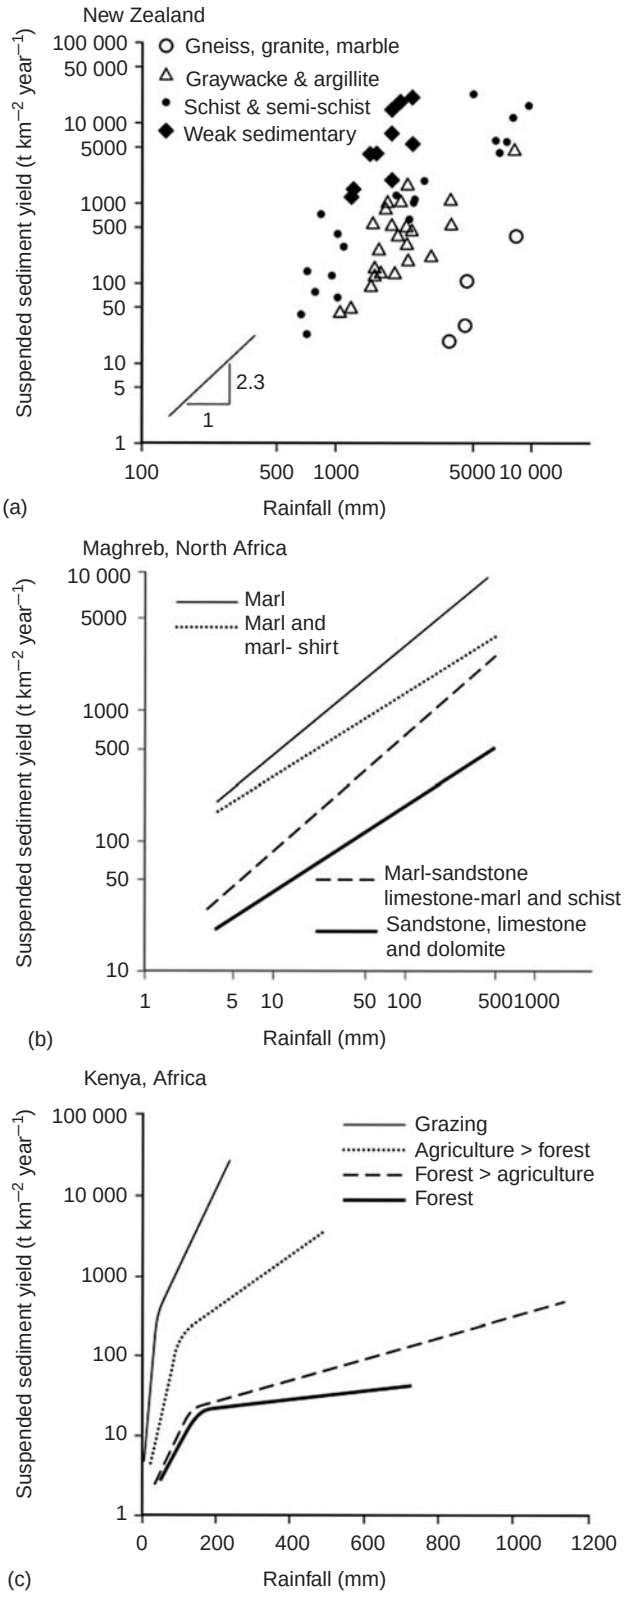

Figure 7 Regional relationships between mean annual suspended sediment yield and controlling factors reported (a) by Hicks *et al.* (1996), (b) by Heusch and Milliés-Lacroix (1971), and (c) by Dunne (1979)

presents a selection of the typical inverse relationships between specific suspended sediment yield and catchment area that have been widely reported in the literature.

The simple inverse relationship between specific sediment yield and catchment area has, however, been questioned by a number of recent studies. Church and Slaymaker (1989), for example, suggest that in British Columbia, Canada, specific sediment yield frequently increase downstream up to a catchment area of c. 3×10^4 km^2, as a result of remobilization of Quaternary sediments stored in the valley and channel systems. It is also relatively easy to conceive of situations where deviations for the "standard" inverse relationship could be accounted for by specific local conditions. For example, sediment yields in headwater areas characterized by resistant rocks and good vegetation cover could be much lower than in downstream areas developed on softer, more erodible rocks and characterized by more intensive land use, and in such circumstances specific sediment yields could increase downstream.

A more fundamental questioning of the traditional view is, however, provided by Dedkov and Mozzherin (1992) and Dedkov (2004), who have suggested that river systems will be characterized by either positive or negative relationships between specific sediment yield and catchment area, according to the relative importance of channel and slope erosion. Where slope erosion (i.e. sheet, rill, and gully erosion) represents the dominant sediment source, most of the erosion will be concentrated in the headwater areas and conveyance losses associated with transfer of the sediment through the basin will result in an inverse relationship between specific sediment yield and basin area. However, where channel erosion is dominant, as for example in forested areas with dense vegetation cover, which protects the surrounding slopes, erosion rates are likely to increase downstream in response to increasing entrainment and transport of sediment associated with increased water discharge. Specific sediment yield will therefore increase downstream, resulting in a positive relationship between specific sediment yield and basin area. Examples of both situations are presented in Figure 8(b) which plots the relationship between the downstream change in total suspended sediment yield (i.e. downstream/upstream) and the equivalent change in catchment area, for a number of river basins where there are several measuring stations along the main river. For those basins with limited cultivation (i.e. where channel erosion is likely to be dominant), the total sediment load increases more rapidly than the catchment area, whereas the reverse situation exists for intensively cultivated catchments (where sheet, rill and gully erosion are likely to be dominant). Dedkov and Mozzherin (1992) and Dedkov (2004) based their conclusions on a study of sediment yield data from a range of morphoclimatic zones and suggested that the positive relationship, indicative of the dominance of channel erosion, was typical of forested areas

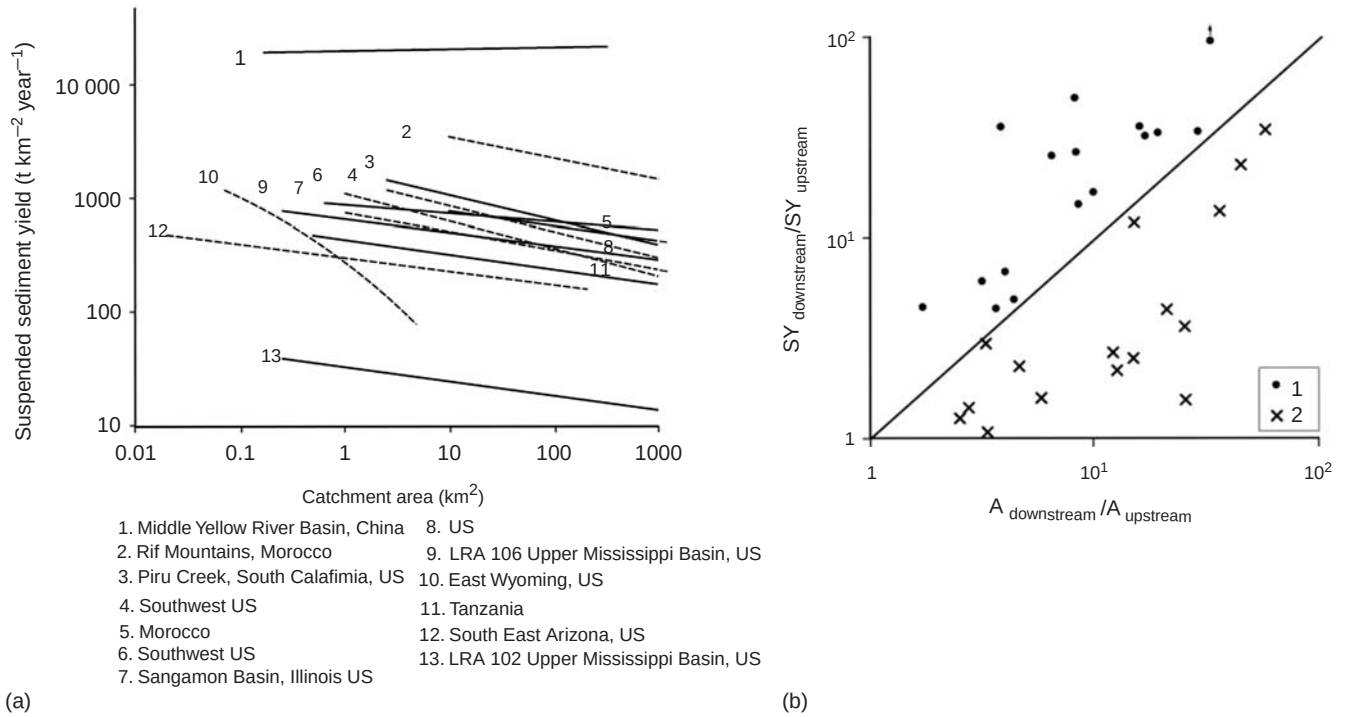

Figure 8 Relationships between mean annual specific suspended sediment yield and catchment area reported by Walling (1983) and the relationship between the downstream increase in total suspended sediment yield and the downstream increase in catchment area for catchments where cultivated land is limited (1) and where it predominates (2) (Based on Dedkov, 2004, with permission from IAHS Press)

with an undisturbed vegetation, whereas the inverse relationship is more characteristic of natural zones with poor vegetation cover and strong surface erosion (e.g. glacial, subnival, and semiarid zones) and of areas disturbed by human activity (e.g. agriculture). The traditional emphasis on an inverse relationship between specific sediment yield and catchment area may therefore reflect the preponderance of results derived from areas such as the United States, which are heavily impacted by human activity, rather than a more universal principle.

Temporal Variability in Suspended Sediment Yields

The suspended sediment loads of most rivers will exhibit considerable variation through time, in response, for example, to individual flood events, discharge magnitude, and the overall seasonal regime. Meybeck *et al.* (2003) assembled records of daily suspended sediment loads from 60 monitoring stations in different areas of the globe and used the ratio of the mean daily specific flux to the median daily specific flux to characterize such variability. The values obtained ranged from 1–2 in the case of large river basins such as the Loire, Mississippi, Rio Grande, and Seine, to >50 for the Eel, the Walla Walla and the Matanuska in the United States and the Red Deer in Canada. The daily load data were also used to establish the percentage of time needed to transport 50% of the total sediment flux and the values obtained ranged from <16.5% for the Middle Rhine, Mississippi, St Lawrence, and Somme, to <0.4% for the Bermejo and Elvira in Bolivia and the Walla Walla in the United States. These results indicate that temporal variability decreases with increasing basin size and that the most variable flux regimes are associated with small- to medium-sized basins in steep mountainous terrain. Such analysis emphasizes the short-term variability of suspended sediment transport, but this should be seen as reflecting the transport regime, rather than the longer-term pattern of sediment yield, where the variability of annual sediment yields is of greater interest.

In considering the temporal variability of annual suspended sediment fluxes or yields, it is necessary to consider both the natural variability and their response to anthropogenic influences, such as land use change and reservoir construction. As indicated above, the coefficient of variation of the annual sediment yields from a given river basin commonly exceeds that of the annual runoff or discharge and values >100% are not uncommon. Walling and Kleo (1979) report a study in which the coefficient of variation was calculated for the records of annual sediment yield available for more than 250 rivers located in

different parts of the world. The analysis was limited by the short period of record available for many of the stations, but the results suggest that a coefficient of variation of 70% is typical of annual sediment yield data, although the values ranged between 20% and 214%. No clear relationship was found between the coefficient of variation and mean annual precipitation, although there was some evidence to suggest that CV values were higher in semi-arid areas. For many rivers, interannual variability will reflect an essentially regular pattern of variability about the mean, whereas in others low frequency, high magnitude events, such as those associated with hurricanes or cyclones, can represent a key component of the variability. Figure 9 presents two examples of such situations, highlighted by the work of Meade *et al.* (1990). In the case of the 8700 km^2 Juniata River in Pennsylvania, USA (Figure 9a), the extreme flood associated with Hurricane Agnes in 1972 transported more sediment in a few days than would normally be transported in three or four years and the annual sediment yield for 1972 is very considerably higher than in any other year during the 33 year record. Another example is provided in Figure 9(b) for the Eel River in California (8100 km^2), where an intense Pacific storm, occurring in December, 1964 (1965 water year) transported more sediment in three days than would normally be transported in 10 average years and introduced a major perturbation into the time series of annual suspended sediment yields. Although it falls outside the direct evidence provided by river monitoring, another even more striking example of the potential for extreme events to distort the pattern of annual sediment yield from a river basin is provided by a study reported by Milliman *et al.* (1996) that used offshore sediment deposits to reconstruct the sediment discharges associated with Jøkulhaup floods from the Alsek River, which drains a 28 000 km^2 basin in Alaska and Yukon Territory. Based on the offshore sediment deposits, the average sediment yield from the Alsek River over the past 3000–4000 years was estimated to be $6–8 \times 10^6$ t year^{-1}. However the loads associated with individual Jøkulhaup events were estimated to be more than two orders of magnitude higher at 2.5×10^9 t year^{-1}. In such events, the sediment load transported by this relatively small river would be equivalent to ca. 10% of the current mean annual land–ocean sediment flux.

Land clearance, land use change and other human activities, including reservoir construction, can also result in major perturbations in longer-term records of suspended sediment flux. The potential impact of land clearance and associated population growth and use change on suspended sediment yields is clearly demonstrated by an analysis of reservoir sedimentation data for a number of reservoir catchments in Southeast Asia reported by Abernethy (1990) and presented in Figure 10. In this case, annual rates of increase of sediment yield were estimated to lie within the range 2.48–6.02% year^{-1} and Abernethy (1990) suggested that these increases closely paralleled the rate of population increase in the catchment, although the ratio of the rate of increase of sediment yield to that for population was significantly greater than unity and about 1.7 : 1 (Figure 10). Based on this evidence, he suggested that annual sediment yields in some developing countries could be expected to double in about 20 years. Whilst this example provides

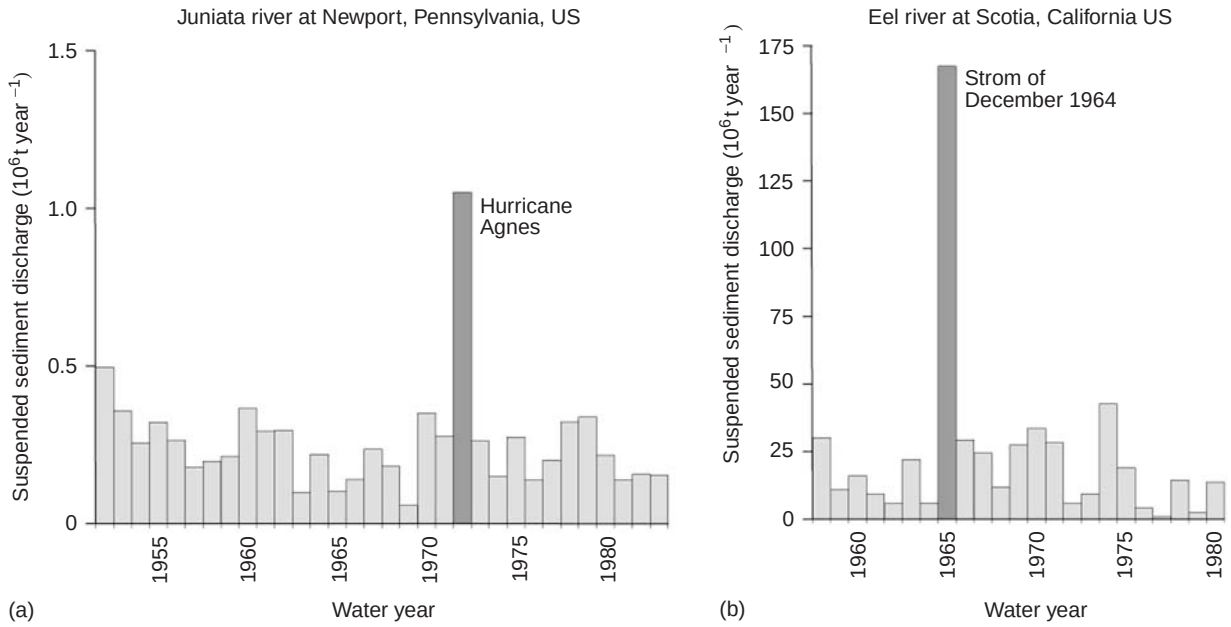

Figure 9 The impact of extreme events on annual suspended sediment yields (Based on Meade *et al.*, 1990)

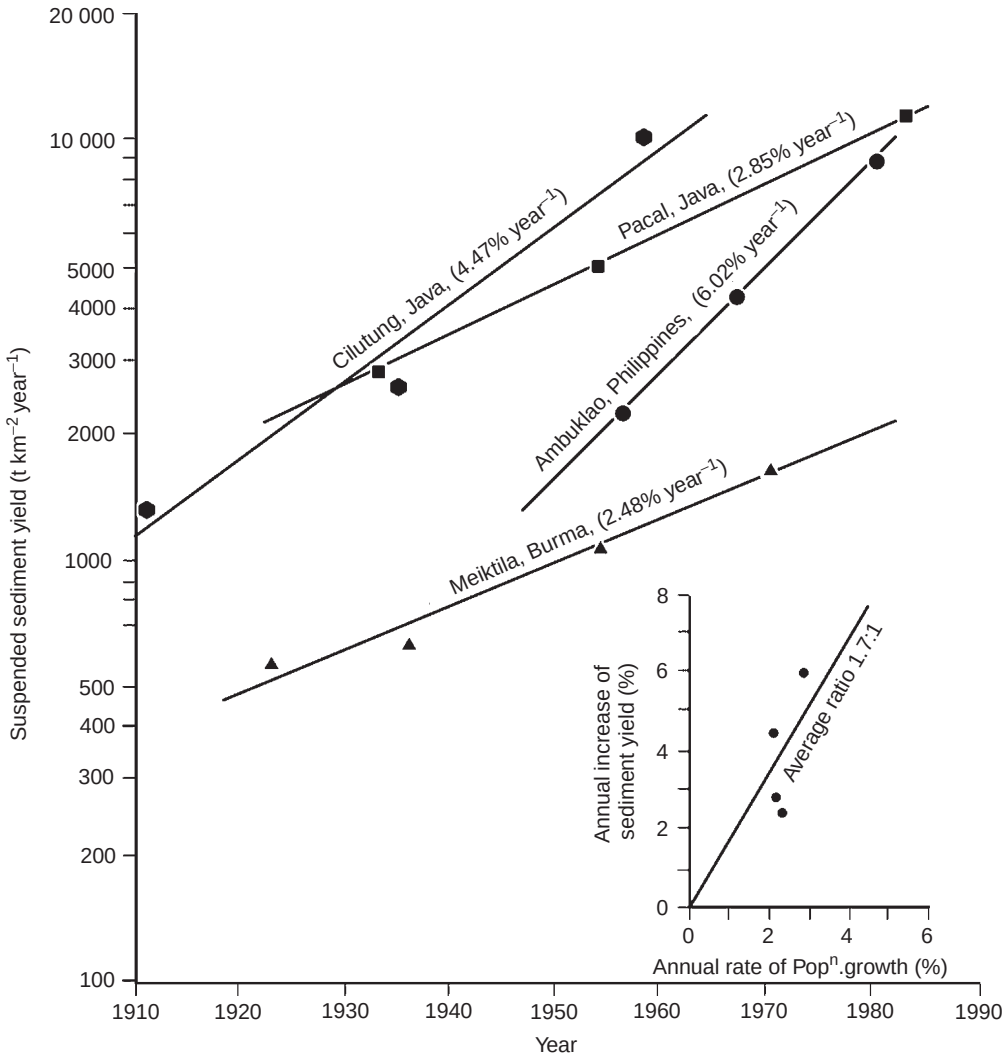

Figure 10 Increases in sediment yield during the twentieth century in selected reservoir catchments in Southeast Asia. (Figure drawn by Dr C. Abernethy)

clear evidence of an increase in sediment yield caused by land clearance and population growth, it is important to note that such trends are absent from other larger rivers where they might have been expected. One example of this situation is provided by the 14 028 km^2 Chao Phraya basin draining the highlands of northern Thailand, for which Alford (1992) found no evidence of an increase in sediment yield during the period extending from the late 1950s to the mid-1980s, despite substantial deforestation and extensive land clearance by swidden agriculture within the catchment. A similar situation is provided by the Upper Yangtze River at Yichang, China, which drains an area of 1005×10^3 km^2 in central and western China (cf. Dai and Tan, 1996; Walling and Fang, 2003). Although the population of this area has more than doubled since the early 1950s and there has been an major expansion of agricultural activity within the basin, the time series of annual sediment yields for the period 1950–1991 is essentially stationary and shows no evidence of change. Walling (2000) has suggested that the absence of a significant change in sediment yield from these and other large river basins could reflect the influence of "buffering", whereby any increases in sediment mobilization are attenuated by storage within the fluvial system.

An analysis of available longer-term records of annual sediment yield from more than 140 rivers in different areas of the world reported by Walling and Fang (2003), nevertheless, provides clear evidence of significant temporal trends in the sediment yields of many river basins, as a result of human activity. In some cases, such as the River Danube in Central Europe (Figure 11a), reservoir

construction has caused a significant reduction in the annual sediment flux. In this case, the annual suspended sediment load has decreased by about 70% over the period extending from the mid-1960s to the 1990s, although the annual runoff has remained essentially stable. The progressive flattening of the double mass plots presented in Figure 11(a) suggests that the decrease in the sediment flux has continued to intensify through to the mid-1990s. Examples of rivers where annual sediment yields show a significant increase in recent decades, despite annual runoff totals remaining

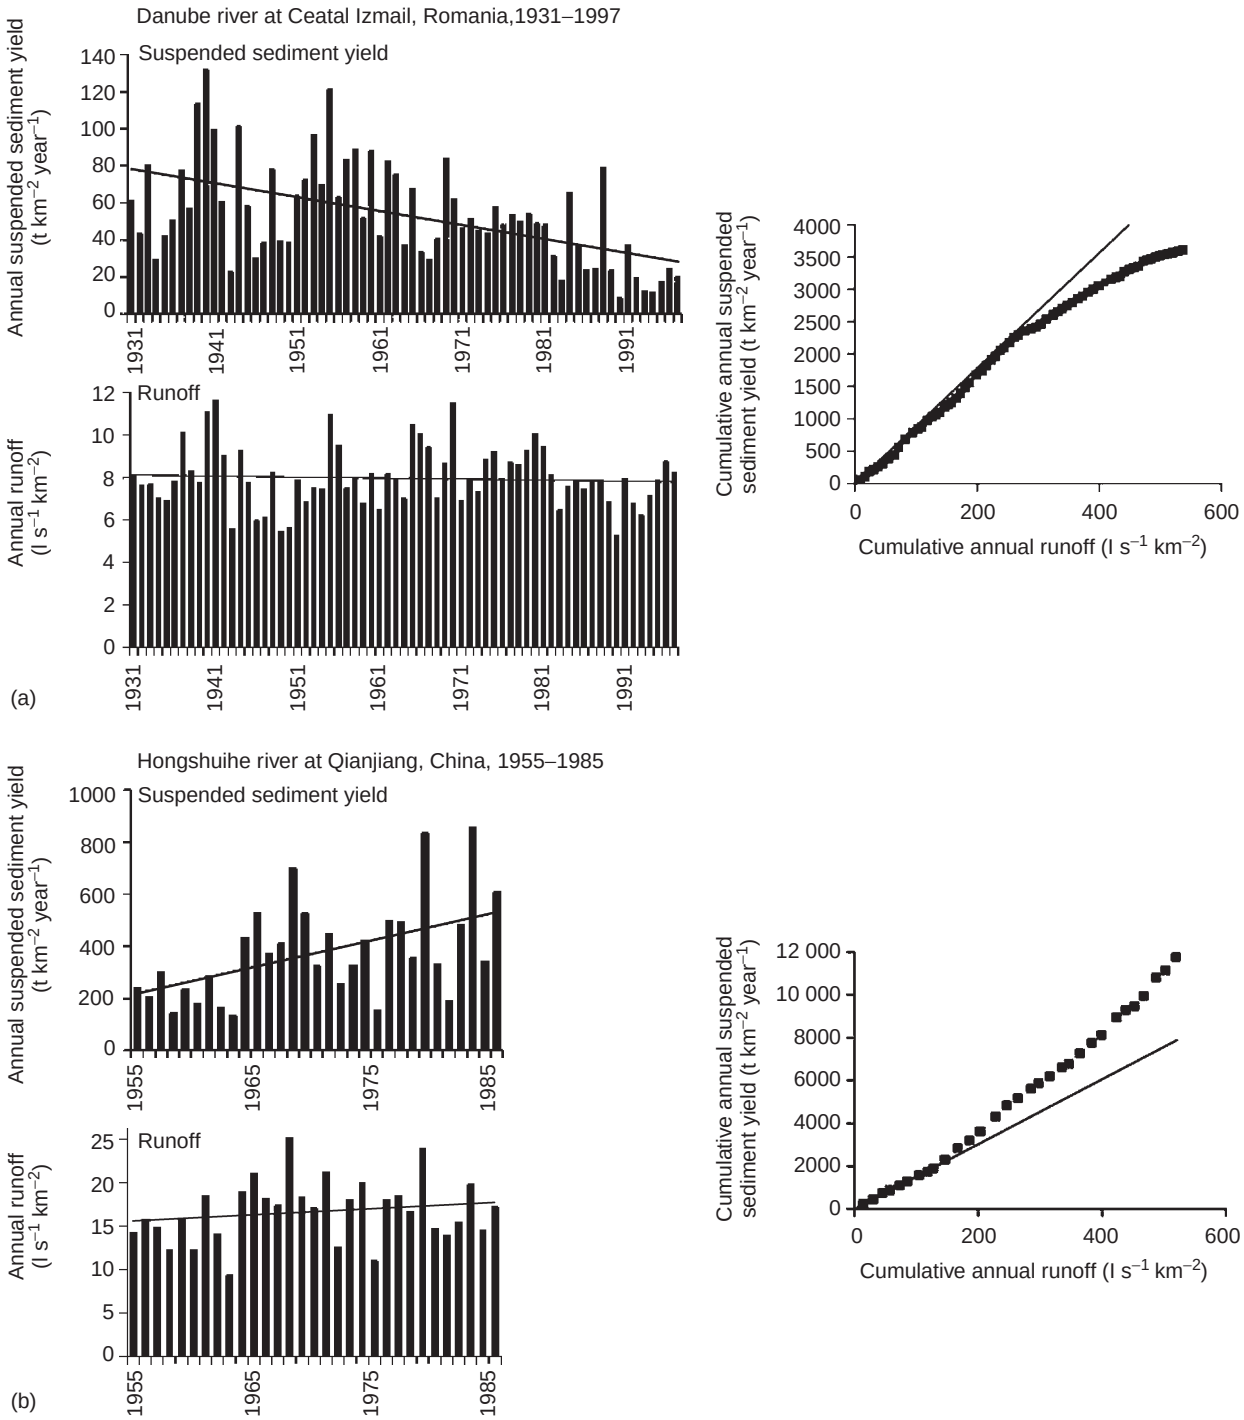

Figure 11 Recent trends in annual suspended sediment yield and runoff for the River Danube, Romania, the Hongshuihe River, China, and the Kolyma River in Western Siberia (Based on data presented by Walling and Fang, 2003)

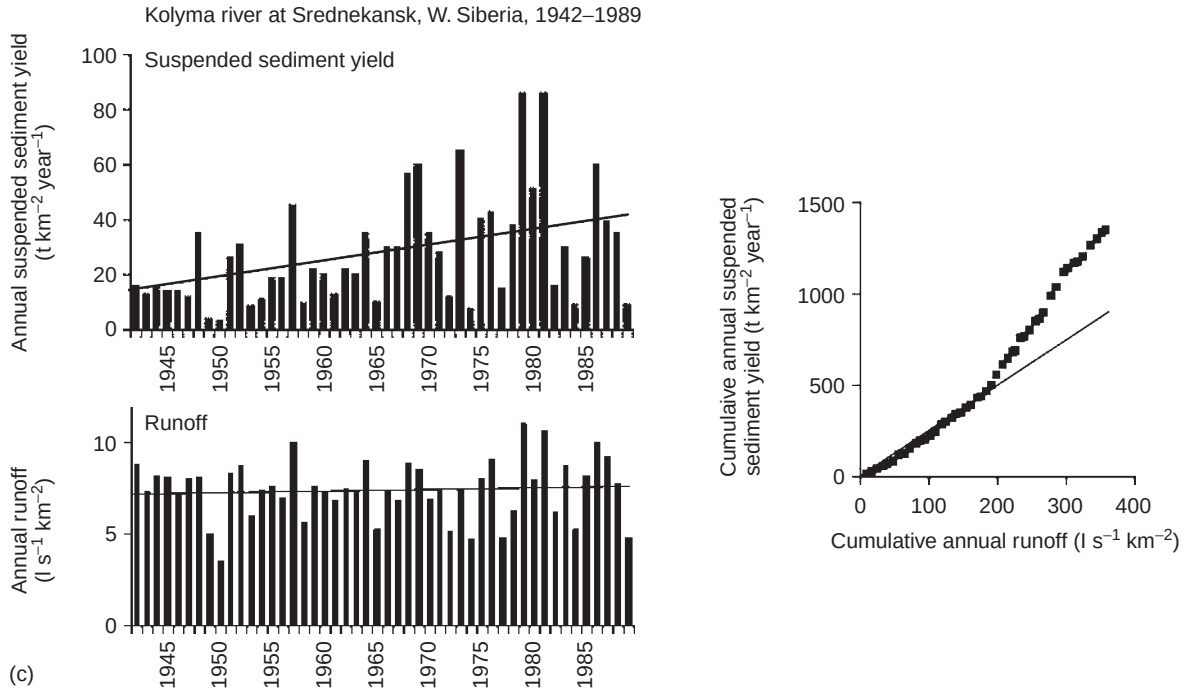

Figure 11 (*continued*)

essentially stationary, are shown in Figures 11(b) and 11(c). The Hongshuihe River, a tributary of the Pearl River in Guangxi Province, China, which drains a catchment of 1 28 165 km^2, shown in Figure 11(b) provides clear evidence of increasing sediment yields, with loads increasing by ca. 75% over the period of record. In this case, population growth can be linked to both an expansion of the area of agricultural land and intensification of land use activities over the period of record, which in turn have resulted in increased rates of soil loss and sediment yield. The double mass plot suggests that the increase in sediment flux commenced in the mid-1960s and its progressive steepening further suggests that the impact of land use intensification has continued through to the present. The other example shown in Figure 11(c) relates to the Kolyma River, which drains a 99 400 km^2 catchment in western Siberia. The runoff record for this river again shows no significant trend over the 50 year period, but the sediment yields show a significant increase and the double mass plot indicates that sediment yields have more than doubled since the mid-1960s. This increase has been attributed to widespread gold mining in the catchment, which disturbs the catchment surface and greatly increases sediment mobilization by erosion (cf. Bobrovitskaya, 1996). The specific suspended sediment yield of this basin under "natural" conditions was relatively low (ca. 20 t km^{-2} year^{-1}) and the disturbance caused by mining activity has caused a substantial relative increase in the total sediment load.

Other rivers can be expected to show evidence of changes in both runoff and sediment yield and Walling and Fang (2003) cite the example of the Dnestr River in the Ukraine (850 km^2) where both runoff and sediment yield have shown a significant upward trend since the 1960 s in response to forest clearance and the expansion of agriculture as well as a shift to wetter conditions. Conversely, the Yellow River at Sanmenxia (667 948 km^2), the gauging station located close to where the river leaves the loess region and enters the North China Plain, shows a statistically significant decline in both runoff (ca. 13%) and sediment yield (ca. 50%) since the 1960s, in response to drier conditions, increased water abstraction and a comprehensive soil and water conservation and sediment control programme in the loess region, the main source of the high sediment load transported by the river. In the case of the sediment load, the shift to drier conditions accounted for ca. 50% of the decrease and the remaining ca. 50% of the decrease was attributed to the impact of soil and water conservation and sediment control works. Land use change can result in reduced sediment yields as well as the more commonly cited increase.

SEDIMENT BUDGETS

The Context

Although the sediment yield from a river basin will reflect the rates of sediment mobilization or soil loss within the

basin, it is important to recognize that only a proportion, and probably only a small proportion, of the mobilized sediment will reach the catchment outlet. Much of the sediment mobilized within the basin will be deposited and stored at the foot of slopes, in depressions and valley floors, in channels, on floodplains and in backswamps, as well as in ponds, wetlands, lakes, and reservoirs. The inverse relationships between specific sediment yield and catchment area presented in Figure 8(a) have already been identified as reflecting the increasing significance of conveyance losses and sediment storage as catchment area increases. Such conveyance losses and sediment storage must clearly be taken into account when attempting to use measurements of sediment yield to provide an indication of rates of soil loss or soil degradation within a drainage basin or to predict the impact of climate or land use change or other causes of changing catchment response on sediment yields. Equally, where there is a need to develop a sediment management strategy for a catchment, aimed at reducing downstream sediment fluxes, it is necessary to recognize that reducing erosion rates may not result in an equivalent reduction in sediment flux at the catchment outlet, due to storage effects. Furthermore, it is possible that a reduction in sediment input to the channel system could result in increased transport capacity and therefore remobilization of stored sediment, such that the sediment flux at the catchment outlet remains essentially unchanged. An integrated view of sediment mobilization, transfer and output is necessary when interpreting sediment yields in terms of sediment mobilization and delivery within the upstream basin and assessing the potential for reducing the sediment output from a river basin. In addition, it will frequently be necessary to recognize that the sediment output from a catchment can be derived from different sources, for example, erosion of the catchment surface by sheet and rill erosion, gully erosion, channel erosion, and mass movements transporting sediment directly to the channel system. The different pathways followed by sediment mobilized from the different sources are likely to offer different opportunities for sediment storage and associated flux attenuation, such that control of certain sources may have a greater impact on the downstream flux than control of others.

The Sediment Delivery Ratio

Early attempts to take account of the importance of storage in influencing the relationship between sediment mobilization and sediment output from a catchment focused on the simple concept of a sediment delivery ratio (SDR), which expresses the relationship between gross erosion within a drainage basin and the sediment output from that basin (see e.g. Glymph, 1954; Maner, 1958; Walling, 1983). Since the SDR will, by definition, be <1, it implicitly takes account of storage. The magnitude of the SDR for a particular basin will be influenced by a wide range of catchment characteristics, including the nature and location of the sediment sources, relief, and slope characteristics, the drainage pattern and channel conditions, vegetation cover, land use, and soil texture. A number of authors have attempted to establish predictive relationships that can be used to estimate the SDR for a drainage basin, and an inverse relationship between SDR and catchment area has been widely proposed (cf ASCE, 1975; Walling, 1983), such that the SDR for a small $0.1\,km^2$ basin might be as high as 0.5, whereas it could decrease to about 0.1 for a $1000\,km^2$ basin. However, many uncertainties surround any attempt to establish the SDR for a catchment, not least the difficulty of establishing the magnitude of the gross erosion, which must be compared with the measured sediment yield, in order to calculate the SDR. In many studies, the gross erosion has been quantified by using the Universal Soil Loss Equation (USLE) or a similar predictive tool to estimate sheet and rill erosion and correcting (increasing) this value to take account of additional contributions from channel and gully erosion. Uncertainties associated with the resulting values of gross erosion will be propagated through to the estimates of SDR. In addition, the SDR must be seen as a lumped black box concept, which fails to take account of both spatial and temporal variability in sediment delivery (see Walling, 1983). Attempts to provide a more explicit representation of storage, as well as contributions from different sources and different transfer pathways, have resulted in the concept of a sediment budget. This links sources, sinks, and output by a mass balance equation, namely,

$$\text{Output} = \text{Input(from sources)} \pm \Delta\text{Storage} \qquad (1)$$

and, equally importantly, provides a schematic representation of the transfer of sediment between sources and sinks and the catchment outlet (see Figures 12 and 13).

Sediment Budgets

Although it has been suggested that the concept of a sediment budget can be traced back to the early work of G K Gilbert, when investigating the impact of mining activity on the Sacramento River in California (cf. Gilbert, 1917), the credit for this concept is commonly accorded to Jackli (1957) and Rapp (1960), who were amongst the first to attempt to document rates of sediment mobilization and transfer within small catchments. Their work was extended by many subsequent workers, and particularly by Dietrich and Dunne (1978), who produced a comprehensive representation of the sediment budget of the $16.2\,km^2$ Rock Creek catchment in the Oregon Coast Range. Interestingly, all three of these studies were undertaken in mountain environments and their perspective was primarily geomorphological, aimed at understanding rates

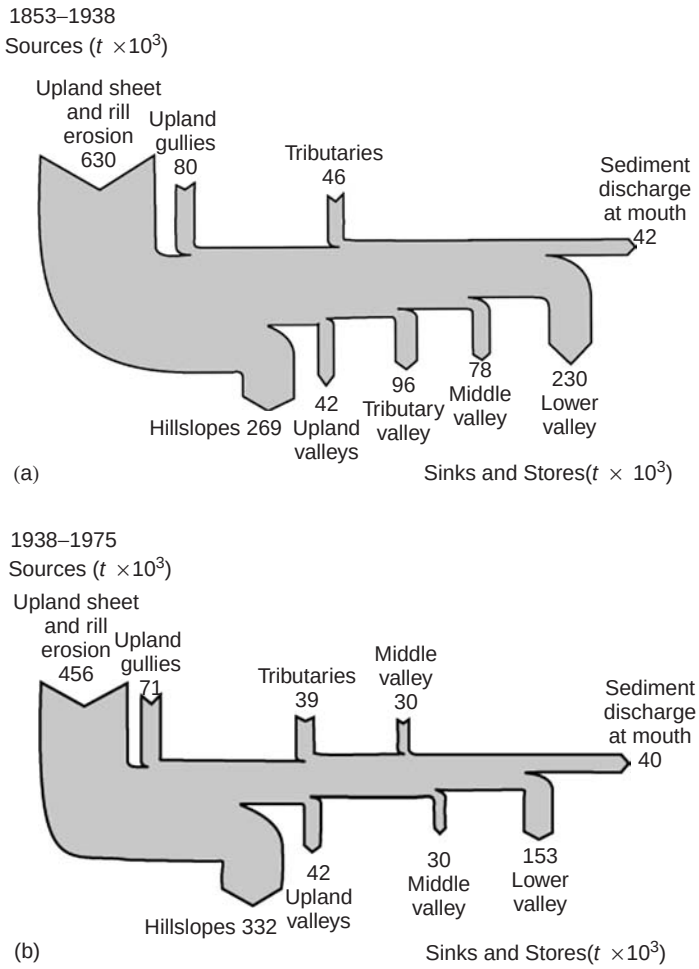

Figure 12 The sediment budgets for Coon Creek, Wisconsin, USA, for the periods 1853–1938 and 1938–1975 produced by Trimble (1983). The fluxes indicated represent mean annual values

of landscape development. As such they included chemical weathering and solute transport as well as the mobilization, transfer, and storage of both coarse (bed load) and fine (suspended load) clastic sediments. Arguably, it was the work of Meade and Trimble (e.g. Meade and Trimble, 1974; Meade, 1982; Trimble, 1976, 1983) and others in demonstrating the important role of alluvial storage within the channel and floodplain systems of drainage basins in eastern and central United States, that focused attention on the important role of such storage in influencing suspended sediment yields and promoted the wider application of the sediment budget concept to hydrological investigations of erosion and sediment delivery in drainage basins.

Figure 12 presents results from the classic work of Trimble (1983) in establishing a sediment budget for the 360 km^2 basin of Coon Creek, Wisconsin, USA, for both the period of intensive agriculture and severe soil erosion that followed the expansion of agriculture into the area and the subsequent period when soil conservation measures were introduced. A key feature of the sediment budget for the first period (1853–1938) is the relatively small proportion of the sediment mobilized within the catchment by erosion that reached the catchment outlet (i.e. ca. 5%). Large amounts of sediment were stored in colluvial deposits, upland, and tributary valleys and the main valley and did not reach the catchment outlet. The sediment budget for the subsequent period indicates that, although the introduction of soil conservation measures reduced erosion rates from the slopes of the catchments by ca. 25%, the sediment output was little changed due to the increased efficiency of sediment transfer through the channel network and remobilization of sediment stored within the middle valley, during the phase of accelerated soil loss. This example clearly demonstrates the significant improvement in understanding of the linkage between erosion and sediment mobilization, sediment delivery, and conveyance losses and sediment yield afforded by the sediment budget when compared with the sediment delivery ratio concept.

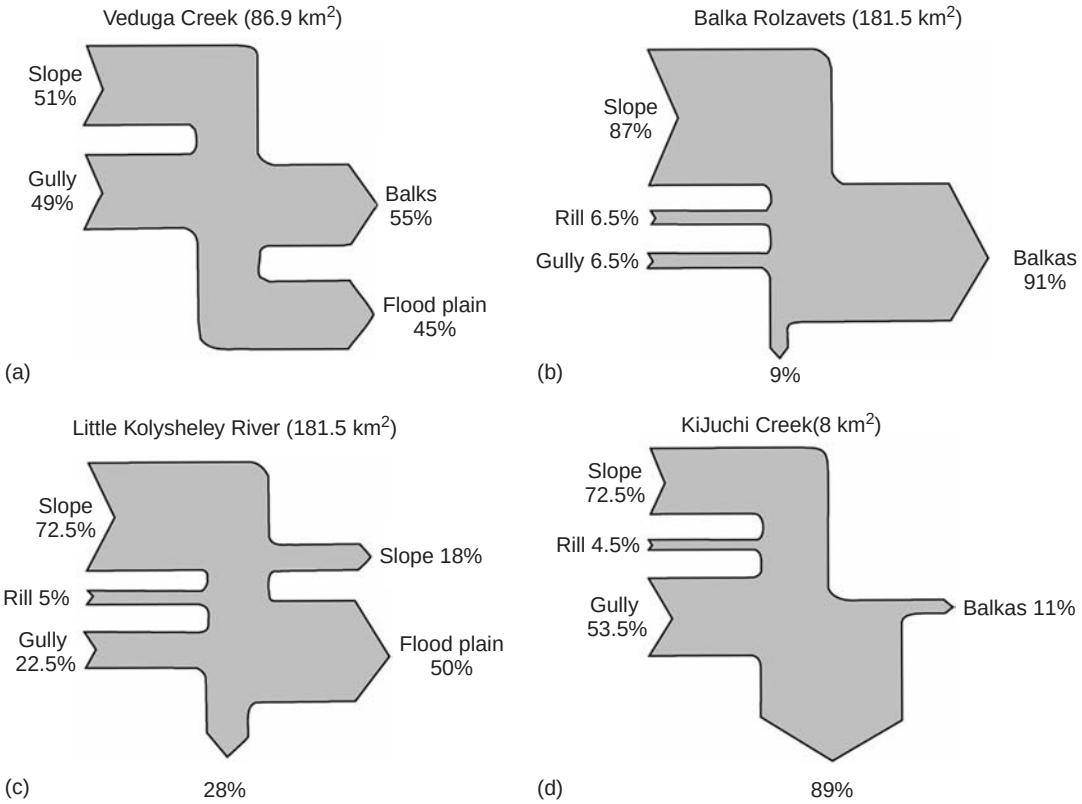

Figure 13 The sediment budgets for four drainage basins on the Russian Plain, documented by Golosov *et al.* (1992)

Furthermore, it usefully emphasizes why an understanding of the overall sediment budget of a river basin is essential when assessing the likely impact of changes in land use on sediment yields and the potential for implementing soil conservation and other sediment control measures to reduce downstream sediment yields. In this case, a reduction in rates of soil loss in the upstream areas by ca. 25% and a ca. 25% increase in the amount of sediment trapped in colluvial stores on or below the slopes resulted in a negligible decrease in sediment yield at the catchment outlet.

Although the greatest utility of the sediment budget concept is arguably at the basinwide scale, it can also be applied to individual components of the overall sediment budget. Figure 13 focuses on the sediment budget structure of small tributary basins on the Russian Plain, a region which is heavily impacted by land use activities and soil erosion. In these examples, based on the work of Golosov *et al.* (1992) the proportion of the sediment mobilized within the catchments that reached the basin outlet ranged between zero and 89%. This substantial range emphasizes the considerable diversity in sediment budget structure to be found within even a relatively homogeneous region, as well as potential contrasts in the sensitivity of the basins to changing land use or soil conservation measures. In the former case, changes in land use and erosion rates would be unlikely to exert a significant influence on the downstream sediment yield, whereas in the latter case sediment yields could be expected to be highly sensitive to such changes. Sediment budgets have also been constructed for floodplain systems, to assess their role in trapping and storing sediment moving through the main channel system of a drainage basin. Work on the catchments of the River Ouse (3315 km^2) and the River Wharfe (818 km^2) in Yorkshire, UK, reported by Walling *et al.* (1999a), for example, demonstrated that 30–40% of the sediment delivered to the main channel system was deposited on the adjacent river floodplains, and did not reach the catchment outlets (see Figure 14).

Establishing Sediment Budgets

Although the sediment budget concept affords an invaluable basis for interpreting the linkages between erosion and sediment mobilization, sediment delivery, and conveyance losses and sediment yield, it introduces something of a dilemma in that it is difficult to establish a detailed sediment budget for a drainage basin, and particularly for anything other than a relatively small basin. It is clearly difficult to obtain a detailed assessment of rates of sediment mobilization and deposition over a large heterogeneous

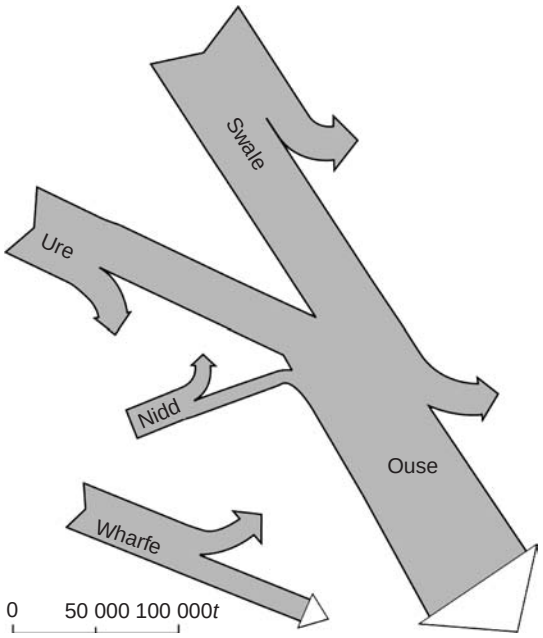

Figure 14 The role of overbank floodplain sedimentation in the sediment budget of the main channel systems of the River Ouse and its major tributaries and the River Wharfe, Yorkshire, UK (based on Walling *et al.*, 1998)

catchment and even studies of the conveyance losses associated with floodplain deposition face significant problems in assessing depositional fluxes along extensive floodplain reaches, where deposition rates can be expected to be highly variable spatially. Furthermore, temporal (e.g. interannual) variability in sediment generation and transfer introduces additional problems in establishing a representative budget. Thus the utility of the concept could be seen more in terms of providing a conceptual framework than as a practical tool. However, recent advances in sediment source fingerprinting afford a means of obtaining a spatially integrated assessment of sediment sources within a drainage basin (e.g. Walling and Woodward, 1995; Walling *et al.*, 1999b) and the use of environmental radionuclides as sediment tracers provides a means of assessing erosion and deposition rates both on the slopes of a catchment and on river floodplains (see Owens *et al.*, 1997; Walling and He, 1997; Walling, 1998, 2002; Zapata, 2002). Walling *et al.* (2001) have attempted to combine these novel approaches with more traditional measurement techniques, to provide an integrated framework for establishing catchment sediment budgets (cf. Walling *et al.*, 2001, 2002), although this approach is primarily suited to smaller drainage basins.

86: Measuring Sediment Loads, Yields, and Source Tracing

GRAHAM LEEKS

Centre for Ecology and Hydrology, Wallingford, Oxfordshire, UK

The sediment load of rivers is, for both practical purposes and field research, usually divided into the finer suspended load and coarser bed load. A range of instruments can be used, depending on the mode of sediment transport. Measurements of the bed load can be made using fixed and portable traps, samplers and tagging methods, and electronic detection systems. Suspended sediment load is usually measured with both manual and automatic samplers. Continuous measurements are made possible by using turbidity as a surrogate measure of suspended sediment concentrations. An advantage in the use of the manual and automatic samplers is to provide samples which can be subjected to further analysis (e.g. of particle size distributions or chemistry). One of the opportunities this can provide is to identify up-catchment sediment sources, including channel, gully, sheet/rill, and surface erosion under different land uses. Source "fingerprints" are identified from combinations of sediment properties. Multivariate analysis and mixing models can then be used to quantify the relative contributions from individual sources.

INTRODUCTION

The physical dynamics of sediments on catchment surfaces and within river channels, including erosion, transport, and deposition, is one of the fundamental drivers of the movement of materials (physical, chemical, and biological) through river basins. From sediment transport theory, and laboratory flume experiments, it is anticipated that the sediment load in rivers could be divided into three components or modes of transport – the suspended load, saltation load, and bed (or traction) load. In practice, for field research in rivers and streams, it is not possible to measure the saltation load separately from the bed- and suspended load. A fourth mode of transport, floatation load, can also be observed. This is mainly organic debris which may vary in scale from small leaf and invertebrate fragments up to whole trees. A consensus on the methodologies for measurement of the floatation load in rivers has not been developed, and quantification has been rare. Most of the following descriptions are based upon the bed load and suspended load modes of transport. However, it is also worth making a brief reference to another overlapping classification of sediment load, which is sometimes applied. This is a two-fold division based upon a differentiation between sediment source and size characteristics. This is between the fine material from catchment surfaces known as the *wash load* and coarser channel-derived *bed-material load*. The former is transported in suspension, whereas the latter is transported both in suspension and as bed load.

The rest of this article focuses on methods which have been commonly used in river sediment load, monitoring, and source tracing, in terms of manual and automated systems of measurement and analysis, with accompanying references which describe the methodologies in more detail or provide examples of case study applications.

BED-LOAD MEASUREMENT

The bed load or traction load comprises sediment that moves whilst remaining in contact with the channel bed. This is mostly in the size ranges between sands, gravels, cobbles, and boulders. Bed-load monitoring can present greater difficulty, in terms of determining appropriate sampling strategies, relative to suspended load. The movement of the bed load tends to be more intermittent and erratic than the suspended load. Critical flow thresholds for movement

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

are higher than for suspended load and are complicated by particle shape, the range in particle sizes, and packing of the bed material. The relationships with water discharge rates and its distribution through the stream channel cross section are also more complicated than is generally the case for suspended load. In some cases, pulsing effects have been observed (e.g. Bathurst *et al.*, 1985; Reid *et al.*, 1985; Tacconi and Billi, 1987). Hubbell (1987) noted that the bed-load transport rate can vary in a cyclic manner even during steady flow conditions. This was observed whether pronounced bedforms(such as dunes) were present or absent.

Assessment of the volume of sediment which has been transported, its weight, and size distribution are most conveniently carried out after flood events. Therefore, in many cases, traps are used to catch the total bed load generated by a flood. Traps of this sort can consist of excavated chambers lined with concrete or simple flow barriers formed with timber, steel girders, boulders, concrete, or gabion baskets. In each case, the purpose is to slow the flow of water and sediment sufficiently for the coarse sediment to be deposited. By assessing catchment yields over several years and dividing by catchment area, comparisons of annual loss with other catchments can be made. Links to catchment management including land use cover and practices have been inferred. Examples of the use of this type of measurement and data are described in Leeks and Marks (1997) and Newson (1980) in relation to forest and grassland paired catchment experiments in mid Wales, UK (see Figure 3).

More sophisticated versions of bed-load traps have also been developed. Reid *et al.* (1985) used pressure pads to monitor continuously the accumulation of bed load in a trap in Turkey Brook, UK (see also Sear *et al.*, 2000 and Habersack *et al.*, 2001). In the United States, a conveyor belt system was installed beneath a slot excavated in the bed of the East Fork River (Leopold and Emmett, 1976; Leopold, 1992). Bed-load material falling in to the slots was then conveyed to the bank side for analysis. A vortex sampler has also been developed in the United States which takes bed-load material and part of the water discharged from a flow-gauging structure to a work pit where the amounts of bed load can be continuously monitored (Klingeman and Emmett, 1982). A further example of a vortex trap has been installed on Virginio Creek in Tuscany, Italy. Details of the design and the data obtained are provided by Tacconi and Billi (1987).

In addition to permanent structures built into the stream bed, a number of portable samplers are also available. These can be lowered into the channel to capture and filter out the bed-load material over short sampling periods. Portable samplers can be used in detailed investigations of the critical flow thresholds for bed-load movement and of changes in bed-load sediment discharges and associated particle properties (e.g. size distributions), within high flow events. Such instruments include the VUV sampler developed by Novak (1957) and the sampler developed by Helley and Smith (1971) shown in Figure 1.

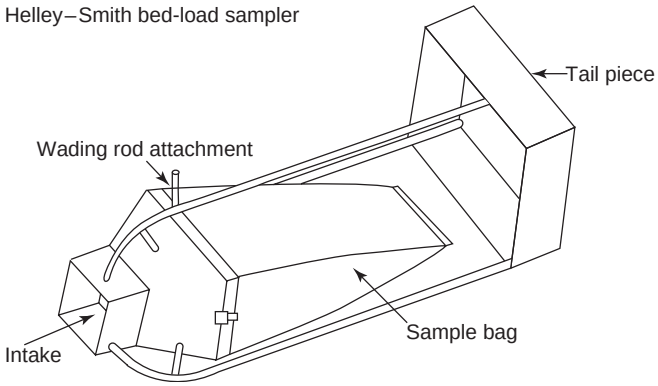

Figure 1 Diagram showing a modified Helley–Smith sampler used for sampling of bed load

Portable samplers can be used at a number of points across the channel to produce sediment discharge values representative of the cross section. Obtaining detailed data through the full cross section can be very time consuming and unless the stage levels remain static, this may be of limited value. Bed-load movement usually occurs in a number of flow threads across the channel. Where these are limited in number, for example, either side of a protruding boulder, sampling may be restricted to a much smaller number of points along the cross section. Detailed cross-sectional information obtained from many verticals can therefore be used to reduce the number of verticals which are repeatedly sampled and the time required to obtain sediment data to represent the cross section.

Another important consideration is that investigations of the efficiency of the Helley–Smith sampler indicate that it over-samples by a factor of 1.5 (Hubbell *et al.*, 1985). Pitlick (1988) highlighted the potential for additional scour as the sampler is placed in the channel because of its high hydraulic efficiency. Sediment catch efficiency may also vary across the flow range. Bunte and Abt (2003) found higher rates of transport during lower flows, and lower transport rates at high flows, using Helley–Smith samplers in four gravel-bedded mountain streams relative to the rates measured using bed-load traps. A variety of modifications have been made to Helley–Smith samplers, which may reduce over-sampling (Kuhnle, 1992) and increase stability on the bed (Figure 4) (Bathurst *et al.*, 1985).

There are also a number of methodologies for indirect measurement of bed-load movement. These include acoustic detectors, which sense the sounds produced as particles collide in the flow and with the river bed, to give indications of particle mobilization thresholds (Ergenzinger and De Jong, 2003) and variations in rates of transport over time (e.g. Bogen and Møen, 2003). It is also possible to

label sediment particles by attaching magnetic materials or coils, radio transmitters, or luminescent coatings to particles and to detect transport using electromagnetic, video, or photographic detection systems. In addition to documenting thresholds of movement and variations in transport through flow events, these methods can also provide useful data on distances of travel. Manipulation of the data collected using these novel methodologies to derive estimates of overall rates of bed-load transport has proved both promising and very difficult. There have been some successes (e.g. Sear *et al.*, 2003), but further work on both the technical and numerical methodologies is required.

SUSPENDED SEDIMENT LOAD MEASUREMENT

The suspended load comprises sediment which is buoyed up by the flow of water, varying in size mainly from clay through to fine sand. Although bed load is predominantly inorganic, suspended sediment can be almost entirely organic (e.g. down stream of a point discharge of effluent). In most instances, however, it is a mixture of both inorganic and organic material. Droppo (2001) emphasizes that suspended sediment is not made up of discrete particles, but is a "composite matrix of water, inorganic and organic particles" forming a "complex microecosystem". The fundamentals of quantifying instantaneous suspended sediment load or flux are through the combination of measurements of both sediment concentration and water discharge. The approaches used to monitor suspended concentration range from instantaneous spot sampling to continuous turbidity recording.

Manual Sampling

The simplest technique used to provide a sample for laboratory analysis of sediment concentration is to take a "gulp" sample (i.e. fill a wide-necked container directly from a stream). However, if sand-sized particles are likely to be in suspension, then, to prevent under- or over-representation, an isokinetic sampler should be used (Edwards and Glysson, 1999). The manual instantaneous point sampling method is most effective where suspended sediment is distributed uniformly through the cross section (as in some upland streams which have a rough bed and high turbulence during high flows), or where it has been possible to establish a relationship between the spot value and concentrations within the overall cross section.

Where there is variation in concentrations within the channel cross section, depth -integrating samplers, which are lowered slowly through a number of vertical profiles, can permit collection of more representative samples. At high flows within a large river cross section, vertical and horizontal velocity gradients will exist. Variations in suspended sediment concentration are directly related to velocity (Ingram *et al.*, 1991). In order to take account of such variations, depth-integrated sampling at several vertical sections across a channel is recommended. Detailed depth-integrated and point sampling of six North American rivers by Horowitz *et al.* (1990), revealed that although there was considerable variation in suspended sediment concentration in the sections studied, this was mostly accounted for by the $>63\,\mu m$ fraction.

The most widely used manual suspended-load samplers are the depth-integrating suite of instruments developed by the US Geological Survey (USGS) (Guy and Norman, 1970). These samplers have the advantage of being highly portable and can be used quickly at a large number of sites during periods of high flow rates, either in handheld versions or by use on cableways. The use of cableways and larger, heavier samplers are particularly useful as flow depth, river width, and velocities make wading less convenient and/or hazardous. The main disadvantages in the use of these and other manual samplers are the requirements for dedicated and very flexible field teams. In addition, a large number of samples are usually generated, which require analysis for concentration using vacuum filtration techniques. However, these techniques also produce physical samples which can then be subjected to other types of analyses (e.g. for geochemical properties). This will be further considered in Section "Investigating suspended sediment properties and sediment source tracing".

Automatic Sampling

Equipment that is designed to automatically extract water from the stream and place it in a sequence of containers can reduce the labor input in the field. Those systems which incorporate stage triggers or are driven by information from sensors through programmed loggers can initiate sampling at preset flow, water quality, or sediment concentration thresholds (e.g. Lewis and Eads, 2001). Series of samples linked to patterns of variation in the river (e.g. rates of rise or fall in river stage) may also be produced. These methods are particularly useful in upland (Leeks, 1992) and urbanized catchments, which may respond rapidly to rainfall (see Figure 2 and Old *et al.*, 2003), or in extended monitoring networks, where it is difficult to deploy other instruments and staff resources to many sites with sufficient speed to catch peaks in flow and sediment (Evans *et al.*, 1997). Although automatic samplers can reduce response times, there remains the need for simple, but time-consuming laboratory analysis to derive sediment concentration data. The efficiency of the autosampler in extracting a representative water sample through its inlet is a further source of uncertainty. Comparisons between methods of obtaining river water samples and their effect on suspended sediment concentration have been carried out (Evans *et al.*, 1997; Tai *et al.*, 1991 and Horowitz *et al.*,

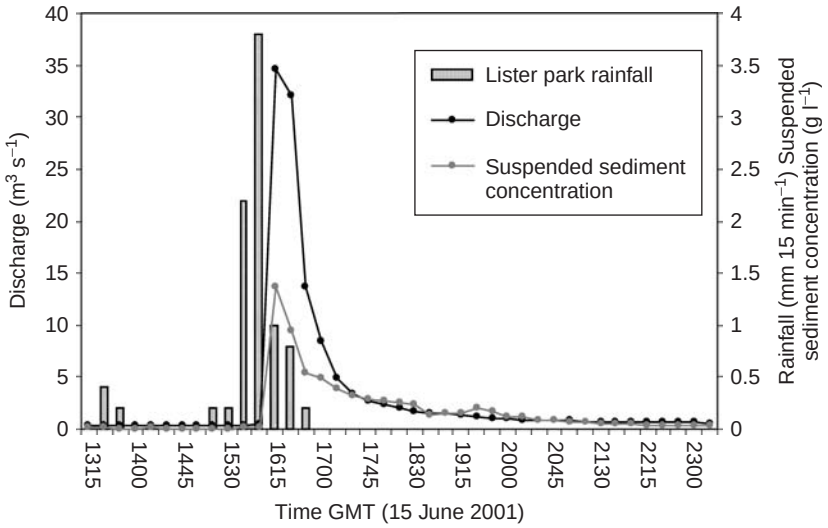

Figure 2 Rainfall, river flow and suspended sediment concentration time series in an highly urbanized catchment, at a downstream river monitoring station, Bradford Beck, UK (after Old *et al.*, 2004). This diagram illustrates the rapid suspended sediment response in the Beck river to a short and intense storm rainfall event

Figure 3 Emptying of a bed-load trap at the CEH upland experimental catchments, Plynlimon, Mid Wales, UK. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Figure 4 Use of a modified Helley–Smith sampler on a mountain stream (Roaring River, Colorado). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

1989). Such comparative work is of considerable value in giving additional confidence in the quality and appropriate use of field sediment load data. For example, Evans *et al.*, 1997 carried out several field tests on the River Swale, UK. In a sequence of 10 successive automatic samples taken every 3 min in parallel with a manual USGS sampler, it was found that sample sediment concentrations were initially more than 35% higher in the automatic sampler (despite a complete purging cycle before sampling). The second samples showed concentrations within 2% of each other, whilst the following eight automatic samples all exhibited concentrations 10–14% lower than those from the USGS sampler.

It is also possible to programme samplers to fill single containers with multiple samples taken at regular intervals (or weighted by flow or stage) to represent sediment concentrations over extended periods, that is, time-integrated samples (see Section "Investigating suspended sediment properties and sediment source tracing").

Turbidity Monitoring

An alternative to the collection of large numbers of bulk samples is the use of turbidity monitors (Eden, 1965 and Thorn and Burt, 1975) to provide instantaneous point

measurements. Experience from a range of studies (e.g. Gippel, 1995; Foster *et al.*, 1992, Glysson and Gray, 2002; Gray *et al.*, 2002) using turbidity as a surrogate for suspended sediment concentration, and monitoring this property along with water discharge at high frequencies, often provides the most practical means of estimating suspended sediment fluxes in rivers. The basic sensor technologies involve the beaming of visible or infrared light along single or dual light paths through water sediment mixtures directly towards photoelectric sensors (absorptiometric methods) or by measuring the scatter of light away from a light path (nephelometric methods).

Instruments based upon nephelometric or absorptiometric principles can be used to provide semicontinuous in-river turbidity measurements. These systems have also been used as laboratory-based instruments to speed up analysis (Ward and Chikwanha, 1980). They do not, however, provide suspended load concentration values which are representative of the whole water flow cross section and it must be emphasized that the turbidity of waters is not only a function of suspended sediment concentration. For this reason, cross-calibration with automated samplers and isokinetic USGS depth-integrating samplers is recommended (Figure 5). Wass and Leeks (1999) found that point samples, represented by turbidity sensors, consistently underestimated the load by between 2% and 12% for two rivers in northern England (the Ure and Aire respectively), relative to the values obtained using the depth-integrated method as described by Guy and Norman (1970).

Scatter in the relationship between turbidity and suspended sediment concentration is also partly a function of measurement error. Sensors are sensitive to changes in temperature, aging of light sources, fouling by debris and algae, variations in incident light, and vandalism. A more detailed account of some these problems can be found in Wass *et al.* (1997), Gippel (1995) and Old *et al.* (2002). The errors introduced by such problems are difficult to quantify, but calibration checks are carried out to monitor any instrument drift. Instrument drift and total failures are not uncommon, so regular calibration against a standard calibration in Formazin Turbidity Units (FTU) is recommended. In the past, Formazin and Fullers Earth have been used. However, there are possible Health and Safety issues involved in use of Formazin. The US Environmental Protection Agency has now endorsed an alternative method using a suspension of polymer beads.

Turbidity has a linear relationship with suspended sediment concentration only when the particle properties are constant (Foster *et al.*, 1992). For example, if the particle size distribution or mineralogy of the suspension changes, then so does the turbidity. Across natural catchments, variations in geology, soils, and land cover (and effluent inputs) mean that the sediment delivered to a river is usually heterogeneous, and represents a mixture of materials derived from different sources (Walling *et al.*, 1999). By comparing the suspended sediment concentrations of many samples with the measured turbidity, an assessment of the impact of this heterogeneity on the accuracy of load calculations can be made. Schoellhamer and Wright (2003) maintain that the suitability of optical sensors should be evaluated on a site-specific basis. When used for continuous stream monitoring, there is a need for regular cleaning of sensor heads and calibration under a variety of flow conditions. Some turbidity sensors incorporate self cleansing cycles (e.g. mechanical wipers which clean sensor lenses). It may also be necessary to establish laboratory analysis protocols to exclude (or include) larger particles (e.g. those above 6 mm diameter), which can have significant impact upon calculations of concentrations.

Figure 5 Use of a handheld depth-integrating USGS suspended-load sampler at a downstream flow gauging station during a high flow event (following a test release from Llyn Clywedog Reservoir, Mid Wales, UK). Please note: when rivers are hazardous and/or there is significant cross-sectional variation in sediment concentrations, cable systems or safe bridging points are used. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

As mentioned earlier, maintaining a good turbidity record can be difficult because of a range of factors, including sensor blockage and drift. Where instantaneous turbidity peaks are known to be spurious, manual manipulation and

interpolation are needed to correct or infill the data. In the event of larger sections of data being lost, a rating curve can be developed between sampled suspended sediment concentrations and flow for adjacent storm events. This relationship is then used to develop a synthetic suspended sediment record for the missing sections as described in Wass and Leeks (1999). However in all cases, it is recommended that the original data (including raw outputs from turbidity monitors) should be archived, in parallel with modified and derived data, in the event that subsequent revisions are required.

More advanced technologies have also been used in more limited applications, such as Acoustic Doppler Velocimeters (ADV) as described by Nicholas (2003). Laser technologies have also been used (Agrawal and Pottsmith, 2001; Melis and Topping, 2003), whilst at very high concentrations in which optical sensors do not work well, nuclear techniques have been applied (e.g. at concentrations above $5000\,\mathrm{mg\,l^{-1}}$).

Estimating Suspended Sediment Yields

To calculate the longer-term flux, needed to establish the sediment yield from a catchment, the derived record of suspended sediment concentration is combined with the flow and summed over the desired period of record as described by the formula below:

$$L = \sum_{i=1}^{n} (C_i Q_i) \tag{1}$$

Where L is the suspended sediment load [kg], C_i is the suspended sediment concentration [$\mathrm{g\,l^{-1}}$], and Q is the flow [$\mathrm{m^3\,s^{-1}}$] summed over the period of record, n.

Estimates of the longer-term (e.g. annual) amount of suspended load can be derived using equation (1) from the continuous records provided by turbidity sensors (e.g. Truhlar, 1978; Brabben, 1981; Grobler and Weaver, 1981; Wass and Leeks, 1999 and Old *et al.*, 2002). A second method is to use a rating curve technique relating sediment concentrations, derived from spot or depth-integrated sampling, to water discharge. The rating curve, derived by regression analysis, is combined with the flow series or a flow duration curve to calculate the quantity of suspended sediment transported during given periods of time. A detailed review of the errors inherent in the rating technique has been presented by Walling (1977). Errors in estimates can be reduced by partitioning data in relation to other factors such as season and hysteretic effects. Furthermore, if data are log-transformed to define rating relationships, a bias correction methodology (as described by Ferguson, 1986) is desirable when back-transforming data.

Both methods of estimating suspended sediment load are generally less successful in upland streams than in downstream reaches for several reasons. Seasonal changes in the composition of suspended sediment are more marked in some upland channels, making estimation of suspended sediment concentration from turbidity measurement less reliable. Concentrations of suspended matter tend to be lowest in rural upland streams and therefore more sensitive sensors are required. In the case of the rating curve technique, correlation between water discharge rate and sediment concentration is usually much poorer in smaller headwater subcatchments than in larger catchments.

It is possible to combine suspended and bed-load sediment methods to estimate total sediment yield or to use other techniques which directly measure total loads. In small catchments, devices such as the Coshocton Wheel samplers, which are designed to obtain a composite proportional samples of runoff, have been used to measure runoff and sediment outputs. This sampler collects a composited representative sample of runoff from each storm event at sites where flow is measured using weir structures. The sample can be used to determine average concentrations and total transport of the water and suspended sediment in runoff events. Proportionality is maintained by a revolving vane and movable outfall that collect a consistent fraction of all runoff above a threshold or base flow level (Bonta, 2002; Bonta and Pierson, 2003). Surveys of alluvial fans and deltaic deposits at the mouths of rivers and repeated topographic surveys and dating of sediments in lakes and reservoirs (e.g. Foster and Lees, 1999) have also been used to estimate total sediment yields from upstream catchments.

INVESTIGATING SUSPENDED SEDIMENT PROPERTIES AND SEDIMENT SOURCE TRACING

As indicated previously, the main focus of measuring suspended sediment transport in rivers is commonly establishing the instantaneous load or the longer-term sediment yield, by obtaining measurements of sediment concentration that can be combined with water discharge data to estimate the sediment flux. In some instances, however, information on the physical and chemical properties of the sediment, rather than the suspended sediment concentration, may be required. These situations could include investigations of sediment-associated nutrient and contaminant fluxes (e.g. Walling *et al.*, 2001) and sediment source tracing investigations (e.g. Walling and Woodward, 1995). In this case, there is a need to collect a representative sample of the suspended sediment transported by a river for further physical or chemical analysis. In some situations, the small amounts of sediment that can be recovered from the small samples collected by a depth-integrating suspended sediment sampler or an automatic sampler may meet this requirement, but more commonly a larger sample will be required. In upland catchments, for example, where sediment concentrations are relatively low, a 500-ml sample may only yield less

than 100 mg of sediment. If standard sampling equipment is used, this may need to be constructed of special materials to avoid contamination of the sediment sampler prior to analysis. Where larger samples are required, pump samplers may be used to collect bulk water samples in special containers and the sediment can be recovered from these samples by centrifugation or settling. An alternative approach involves the use of a portable, continuous-flow centrifuge, with water being pumped directly from the river into the centrifuge which recovers the fine sediment (e.g. Owens *et al.*, 2001; Ongley and Thomas, 1989). In both cases, however, the sample will effectively be an instantaneous sample of the sediment flux and numerous samples may be required to document the temporal variability of the suspended sediment properties and its controls.

The time-integrating trap sampler described by Phillips *et al.* (2000) affords a means of collecting a more temporally representative sample of suspended sediment. This device comprises a cylindrical chamber, with a small diameter inlet and outlet tube, which is orientated into the flow and deployed in the river for an extended period (e.g. several weeks). A representative sample of the suspended sediment transported by the river or stream during the period of deployment collects within the chamber and this can be recovered by emptying the chamber. In small streams the trap sampler can be fixed above the bed using metal supports driven into the bed, but in larger rivers the chamber may need to be suspended from a fixed structure within the channel or at the edge of the channel. Although this type of time-integrating trap sampler affords an effective means of overcoming problems associated with the temporal representativeness of instantaneous samples, it is clearly important to recognize that a sample withdrawn from a single point within the channel may not be representative of the overall suspended sediment flux.

Measurements of the particle size distribution will frequently be made on sediment samples collected for subsequent analysis, and a wide range of devices and methods have been used for such analysis. It is, however, important to recognize that most of such analyses provide information on the *absolute* grain-size composition of the sample, which reflects the size distribution of the discrete mineral grains after removal of the organic component of the sample and chemical or ultrasonic dispersion. It is now well known that the suspended sediment particles transported by a river will commonly comprise a substantial proportion of composite particles (i.e. flocs or aggregates), which are larger and differ in both density and shape from the discrete particles of which they are formed (*see* **Chapter 83, Suspended Sediment Transport – Flocculation and Particle Characteristics, Volume 2**). The grain-size distribution of the actual particles transported by the river may therefore be significantly different from the absolute grain-size composition of the constituent mineral particles, and this is commonly referred to as the *effective* or *in situ* size distribution. Since the latter size distribution will change immediately after the sample is withdrawn from the river, it is best measured *in situ*. Laser probes provide a means of undertaking such measurements (e.g. Phillips and Walling, 1995a; Melis and Topping, 2003). However, results presented by Phillips and Walling (1995b) suggest that a meaningful indication of the *in situ* grain-size distribution can be obtained from samples returned to the laboratory for measurement using a laser granulometer, without further processing, provided care is taken in agitating and resuspending the sediment.

Another context in which suspended sediment sampling is undertaken is for sediment source tracing or "fingerprinting". Although the traditional focus of sediment measurement programmes has been in quantifying the *amount* of sediment transported by a river, there is an increasing need to obtain information on the *source* of that sediment. Information on source could relate to the relative contributions of different parts of a catchment to the suspended sediment flux at the catchment outlet, but more commonly the emphasis will be placed on quantifying the relative importance of different source types within a catchment. Source types could include channel erosion, gully erosion, and sheet/rill, or surface erosion of the slopes of the catchment under different land use (e.g. cultivated land or pasture / rangeland). Information on source type is of particular importance for the design of effective sediment control or management strategies, since it is necessary to target the control measures at those sources which are of most importance for producing sediment. Thus, for example, it could prove of little value to implement a programme for controlling channel erosion in a catchment if the main sediment source was erosion of the catchment surface.

In many environments where specific sediment yields are relatively low, it may prove difficult to identify the key sources of sediment within a catchment by field observation. Furthermore, it is important to recognize the key importance of slope-channel connectivity in influencing the importance of a source to the sediment flux at the catchment outlet. Thus, for example, areas of severely eroding slopes within a catchment could be of limited importance as a sediment source if they were not well connected to the channel network and most of the mobilized sediment was deposited at the bottom of the slope or in ephemeral valleys, prior to reaching the permanent channel system. A means of establishing the source of the sediment actually transported by the river could therefore prove of great value in many situations. Source "fingerprinting" procedures provide such a means. In essence, this approach is founded on a comparison of the "fingerprints" of transported sediment with those of potential sources and involves, firstly, the selection of one or more physical or chemical properties which clearly differentiate potential source materials and, secondly, the

comparison of measurements of the same property obtained from suspended sediment with equivalent values for potential sources, in order to identify the likely source of that sediment. By using composite fingerprints involving a variety of fingerprint properties, multivariate statistical techniques to test source discrimination, and quantitative mixing (or unmixing) models, the fingerprinting approach can provide reliable quantitative information on the sources of the sediment transported by a river or stream, and their relative contributions.

Further details of the source fingerprinting approach can be found in reports of its application provided by Walling and Woodward (1995), Walling *et al.* (1999), and Russell *et al.* (2001) for both small catchments and larger river basins in the United Kingdom, by Collins *et al.* (2001) for a catchment in Zambia, as well as by others. Following the outline of the methodology provided previously, the first stage of a source fingerprinting investigation commonly involves collecting representative samples of the various potential sources in a catchment or river basin (i.e. source types or spatial units), analyzing those samples for a range of fingerprint properties, and selecting a set of properties which together clearly discriminate the potential sources. This set of properties is used as the composite fingerprint in the subsequent fingerprinting exercise. Statistical procedures, such as the Kruskal–Wallis test and multiple discriminant analysis, provide a means of confirming which properties are best able to assist in discriminating between the sources and selecting the optimum set for use as the composite fingerprint. Once the composite fingerprint has been identified, it is necessary to collect samples of the suspended sediment transported by the river and to analyze these for the properties comprising the composite fingerprint. To facilitate direct comparison between the properties of the potential sources and the suspended sediment samples, only the $<63\,\mu m$ fraction of both groups of samples is commonly analyzed.

Once the information on the fingerprint property values has been obtained for both the suspended sediment sample and the potential sources, a linear mixing model can be used to establish the relative contributions of the individual sources to the sediment sample. Further corrections for contrasts in particle size composition and organic matter content between the sediment and the source materials can be introduced at this stage. It is important to recognize that the results obtained from the mixing model will relate solely to the particular sediment sample used in the mixing model and it will generally be necessary to analyze a substantial number of suspended sediment samples for use with the mixing model, in order to obtain representative information on the relative importance of the different potential sources. Their contributions can be expected to vary both within and between individual storm events and seasonally. A load-weighted average is frequently used to estimate the overall relative contributions of the individual sources. Where a time-integrated sampler, such as that described by Phillips *et al.* (2000) and mentioned previously, is used to collect the suspended sediment samples, these samples should prove more representative of the overall sediment flux.

A wide range of sediment properties have been successfully used as fingerprint properties, although fallout radionuclides, including ^{137}Cs and excess ^{210}Pb, have proved particularly useful for discriminating between surface and channel sources and between cultivated and non-cultivated surface sources. However, until more generic guidelines become available, it will rarely be possible to define the set of fingerprint properties to be used without empirical tests, and the use of statistical procedures to identify properties that afford good discrimination between potential sources and to select the optimum set of properties as the composite fingerprint currently remains a key component of the methodology (Collins and Walling, 2002).

Acknowledgments

Thanks are extended to Gareth Old for commenting on the text and Prof. D.E. Walling for providing many useful suggestions, particularly with regard to the Section "Investigating suspended sediment properties and sediment source tracing".

87: Sediment Yield Prediction and Modeling

SUE WHITE

Institute of Water and Environment, Cranfield University, Silsoe, Bedfordshire, UK

The estimation of sediment yield – the amount of sediment reaching or passing a point of interest in a given period of time – is an inherently complex and uncertain science as it is the integrated outcome of erosion, sediment transport, and deposition processes through an often complex landscape. Thus, sediment yield can vary greatly from year to year with variation in climate, land use, and land management. A range of estimation techniques have been developed ranging from simple empirical relationships between sediment yield and river flow or basin characteristics, through methods to scale soil erosion estimates or measurements using delivery ratios, to physically based distributed models. Descriptions of the various approaches, together with advantages and shortcomings of these methods, are given. For prediction of future sediment yields, the uncertainties are even greater as climate and land-use pressures are not easily defined for hypothetical situations. Here, recommendations are made to incorporate uncertainty into the prediction and decision-making process.

INTRODUCTION

Sediment yield can be defined as the amount of sediment reaching or passing a point of interest in a given period of time. Sediment yield estimates are normally given as tons per year or kilograms per year. Specific sediment yield, as with specific flow, brings the catchment area into the equation and here yields are defined as tons per square kilometer per year or kilograms per hectare per year. By definition, in estimating sediment yield, we are taking a snapshot of a part of the sediment cycle. With any modeling exercise, we are trying to take a look at a particular point of interest to see how the variability in the sediment cycle upstream of this point presents itself in terms of sediment delivery over time. This also differentiates between sediment transport modeling, where we are looking solely at in-stream processes, and sediment yield modeling, where we are attempting to make an integrated assessment of both supply and transport. Traditionally, sediment yield estimates were required as part of the feasibility study for a proposed dam or barrage. In these cases, an average annual sediment yield was often considered to be sufficient. Even this apparently simple output has proved to be difficult to achieve, and a number of well-publicized cases have seen reservoirs losing capacity at a rate far exceeding that estimated before construction of the dam (Table 1). Today, sediment yield estimates are also required as part of our assessment of sediment budgets and delivery of sediments and contaminants to the estuarine or ocean system.

A large part of the failure to achieve reasonable estimates of average annual sediment yield lies in the practice of extrapolating relationships derived from field data with no consideration of how appropriate they might be for future conditions. The impact of changing land use on sediment yield has been extensively documented (e.g. Lu and Higgitt, 1998; Harden, 1993; García-Ruiz *et al.*, 1995). Similarly, there are frequent reported changes in sediment deposition or yield related to climate and flow variability (e.g. Valero-Garcés *et al.*, 1999; Bathurst *et al.*, 1996). Yet other papers detail both influences (e.g. Xu, 2003; Asselman *et al.*, 2003; Lang *et al.*, 2003). Reservoir catchments in developing countries are particularly prone to act as concentrators of human activity postconstruction. Such activity will mean dramatic changes to land use and, potentially, to water as well as sediment yields. Other factors have played their part in the frequent underestimation of sediment yield. Another major contributor to error is the use of sediment concentration – water discharge relationships based on sparse data, often monitored at low river flow rates. We will see later on that extreme nonlinearity and nonstationarity in these relationships make their use a high-risk strategy.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Table 1 Predicted and actual sediment yields for reservoirs

Reservoir	Sedimentation rate $m^3 \times 10^6$ $year^{-1}$		Source
	Preconstruction estimate	Postconstruction actual	
Karangkates, East Java	0.33	2.04	Brabben (1982)
Wlingi, East Java	0.38	1.42	Fish (1983)
Bhakra, Punjab, India	28.4	41.6	Patnaik (1975)
Panchet, Bihar, India	2.5	11.8	Patnaik (1975)
Tungabhadra, Karnataka, India	12.1	50.6	Patnaik (1975)
Nizam Sagar, Andhra Pradesh, India	0.66	10.8	Patnaik (1975)
Ukai, Gujarat, India	9.2	26.8	Patnaik (1975)
Magat, Luzon, Philippines	5.5	11.0	Wooldridge (1986)
Kamburu, Kenya	0.3	2.3	Wooldridge (1984)
Ambuklao, Luzon, Philippines			Abernethy, (1984, Personal Communication).
1956–1967	2.72	2.45	
1967–1980	2.72	4.98	

The processes involved in sediment supply, transport, and deposition are generally not linearly dependent on the causal factors, nor do they relate to one another in a linear manner. Rather, at any scale from the field to a large river basin, there will be a cycle of supply-transport-deposition (Figure 1), which will repeat in both space and time. Thus, sediments that are deposited at a point in a river basin may become part of the supply chain for sites further downstream or may remain deposited for long time periods. This sediment erosion-transport-deposition cycle is summarized in the concept of a sediment delivery ratio (SDR) (Walling, 1983; Walling, 1988).

There may be large time lags built into the sediment supply-transport-deposition system as is the case for man-made structures such as dams or estuarine barrages, although natural barriers, such as hedgerows or topographic depressions may also store sediments for periods of months to centuries. Sediment release from such stores may happen in extreme or catastrophic events, or may be as a result of human intervention. Similar sediment release occurs as a result of mass movements or river bank collapses, which may be associated with very wet conditions, or occurrences such as earthquakes. Such sudden high inputs of sediment would mean that supply is likely to exceed the capacity of water to move these sediments either locally or further through the system. Thus, in our modeling, we need to consider the concepts of supply and transport limitations on sediment yield as well as including the capability to model extreme events.

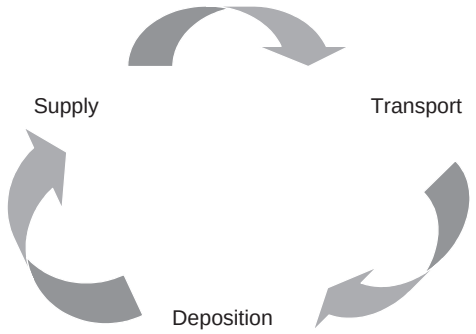

Figure 1 The sediment cycle. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

As has been demonstrated in previous articles (*see* **Chapter 80, Erosion and Sediment Transport by Water on Hillslopes, Volume 2**; **Chapter 81, Erosion Monitoring, Volume 2**; **Chapter 82, Erosion Prediction and Modeling, Volume 2**; **Chapter 84, Floodplain Sedimentation – Methods, Patterns, and Processes: A Review with Examples from the Lower Rhine, the Netherlands, Volume 2**; **Chapter 88, Reservoir Sedimentation, Volume 2**; **Chapter 85, Sediment Yields and Sediment Budgets, Volume 2**; **Chapter 86, Measuring Sediment Loads, Yields, and Source Tracing, Volume 2**), soil erosion, sediment transport, and deposition processes are highly variable in both time and space. Monitoring is therefore complex and expensive. Modeling provides an alternative approach to improved estimation and understanding of sediment movement and delivery and, in addition, can be used to investigate possible future land-use and climate scenarios. However, it should be stated early in this discussion that sediment yield modeling is not a complete substitute for monitoring. Any mathematical representation of a complex system requires validation against real-world data. Once validated, a model can be a powerful tool for investigating various possible natural and/or anthropogenic scenarios to provide a range of possible sediment yield futures, that is, sediment yield prediction. Validation should not simply be a comparison of predicted and measured sediment yields,

but should also evaluate the adequacy of the model to represent processes. This could be done in a variety of ways depending on the complexity of the model, from considering sediment yield estimates at various subbasin scales, to comparing model performance in wet versus dry conditions (here a cross-calibration exercise might be useful), to comparing the shapes of sediment flux curves and sediment size distributions at detailed timescales and validating their behavior with respect to water discharge curves (e.g. comparing times of sediment and water flow peaks).

Recently, studies have become much more concerned with the dynamic nature of sediment yield, both within river systems and at sink points such as natural or artificial water and sediment storage bodies. For rivers and estuaries, sediment yield dynamics are important in terms of ecosystem health and for planning and management of dredging for navigation or flood protection. Sediments may also have contaminants bound to them and any assessment of contaminant delivery may also need an estimate of sediment yield. For impounded water bodies, such information can be used to manage the impoundment in a way that minimizes sediment trapping or water quality problems, and this maximizes the useful life of the structure. Thus, the interest in and demand for sediment yield prediction and modeling has grown rapidly.

For most rivers in the world, the amount of sediment transported by water is limited by the amount of sediment available for transport, rather than the capacity of the river to carry sediment. The most extreme sediment concentrations are seen in rivers in China, where the combination of fine-grained soil, erosive rainfall, and overland flow and extensive land disturbance for agricultural production produce high rates of sediment supply to the river system. In other locations, sediment supply limitations occur both long-term and at the event level as demonstrated through the hysteretic nature of sediment concentration versus water discharge loops. Any apparent relationship between instantaneous sediment concentration and water flow, or between sediment load and water discharge at the event level, is because both supply and transport mechanisms involve many of the same causal factors. An example is precipitation, which both erodes soil and contributes to river flow: more intense rainfall has more erosive power and is likely to result in more rapid and higher peak river flows.

Sediment sources have conventionally been thought of as fields, hillsides, forests, construction sites, and so on: a range of spatially distributed sources around the river basin whose capacity to supply sediment varies with both climate inputs and the way in which these areas are managed. It is here that much of the monitoring and research effort has been focused. However, many recent studies have shown that riverbanks and roads also play a very important role in supplying sediment to the river (Walling and Woodward, 1995; Walling *et al.*, 1999; Carter *et al.*, 2003; Gruszowski *et al.*, 2003), and, in some cases, this input dominates over other sediment sources. Activation of these sources may be infrequent and the material supplied from riverbank sources may have been previously deposited by the river system – the timescale of sediment yield prediction therefore needs to be long. The linkage between river morphology and sediment yield is often not addressed in sediment yield modeling and yet may prove to be fundamental to ensuring better yield assessment or prediction.

There is a further complication in the task of sediment yield modeling and this is because sediments occur in a range of shapes, sizes, and densities. In general, this variability is determined by the soils of the river basin upstream of a point of interest, although there are actions taken by humans that can change particle structure and/or the accessibility of parts of the sediment size range to transport. Thus, when we cut down forests, plough up rangeland, dump mine waste, or lay concrete over a new urban area, we are changing the balance between supply and transport that nature would find for itself, and in so doing we also change the proportions of different sediment particles available for transport. Human activity also adds a range of particulate matter to the equation through industrial and sewage discharges to rivers and to the atmosphere, through automobile exhausts and through a range of other activities. The role of flocculation in altering sediment transport characteristics has been discussed in **Chapter 83, Suspended Sediment Transport – Flocculation and Particle Characteristics, Volume 2**. A good sediment yield model should be capable of representing or reproducing the effects of such complexity, either explicitly through mathematical relationships or implicitly through process understanding.

APPROACHES TO SEDIMENT YIELD MODELING

Historically, there have been a number of attempts to estimate sediment yield using modeling, but these can be broken down into four main groups:

1. Empirical models based on broad catchment and climate descriptors, where sediment yield equations are derived from known basin characteristics.
2. Soil erosion and sediment delivery approaches in which measured or estimated soil erosion rates are factored by an SDR, which is often based on catchment characteristics.
3. Physically based and/or distributed basin modeling approaches in which movement of water and soil is estimated in a distributed way throughout a catchment.
4. Models relating sediment concentration or load to river flow where measured sediment concentration data is related to river flow characteristics.

1. Empirical models based on broad catchment and climate descriptors

Some of the earliest attempts to model basin sediment yield were those based on relationships developed between basin landscape, soil and vegetation characteristics, and basin precipitation. Notable amongst these simple models are those developed by Langbein and Schumm (1958) who related sediment yield to effective rainfall in small basins, Fournier (1960) who related rainfall to sediment yield for a series of 78 river basins around the world, and Fleming (1969) who used data from 240 basins worldwide to produce a range of formulae relating sediment load to catchment area, mean annual flow discharge, and land use. Similar thinking is seen in the soil erosion versus average annual precipitation relationship proposed by Hudson (1971), where erosion rates with natural vegetative cover peak at around 750-mm annual precipitation, although greatly increased erosion rates are possible at higher rainfalls once natural vegetative cover is disturbed. However, such models do not account for variability within a basin or changes that may take place. In addition, relationships change around the globe as precipitation patterns, soil types, topography, land use and management, and underlying geology change. A method to address such shortcomings was introduced by Al Kadhimi (1980) where an attempt was made to improve on the Fournier and Fleming models by including factors describing the catchment and its rainfall. A range of global sediment yield maps have been produced using the same general concepts as described above (Walling and Webb, 1983; Fournier, 1960; Strakhov, 1967). These show areas of high sediment yield in southeast Asia, west Africa, the western side of South America, New Zealand, and some Mediterranean areas.

More sophisticated versions of this approach include regression models in which explanatory variables may include water discharge, precipitation, parameters representing vegetative cover, soil type, soil moisture, and so on. These parameters may be spatially distributed and/or weighted. In a study in Malawi White *et al.*, (1988) reported explanation of some 69% of variability in sediment yield from four small basins using precipitation, flow at the basin outlet, total event rainfall (mm), total event runoff (mm), peak 30-minute rainfall intensity ($mm\,h^{-1}$), and runoff coefficient as explanatory variables. Figure 2 shows predicted versus observed event sediment yields for the four basins. The four basins were similar in all aspects apart from their land use and management, resulting in sediment yields differing by 100 times between the lowest (forested (Mphezo) and complete land-use plan (Bvumbwe)) and highest (traditional agriculture (Mindawo I)) sediment yields. An intermediate basin (physical conservation only (Mindawo II)) had annual sediment yields 10 times higher than the forested site and 10 times less than the traditional agricultural site.

Recent work has investigated the use of neural networks rather than multiple regression models to fit the best relationships between causal and resultant values. For the same Malawian data set, Abrahart and White (2001) developed a neural network model which outperformed the multiple linear regression technique, and also offered transferability to other sites. Figure 3 gives the same predicted to observed relationships for the neural network model as seen above for the multiple linear regression approach.

However, there are still major shortcomings with such empirical approaches:

- Such generalized modeling or mapping cannot be used to give reliable estimates of sediment yield for engineering purposes.

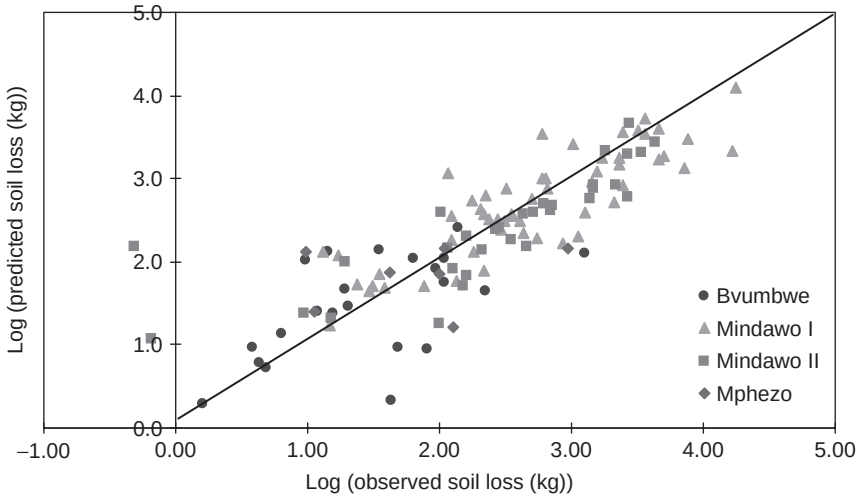

Figure 2 Predicted and observed sediment yield for runoff events in four small basins in Malawi derived from multiple linear regression relationship. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

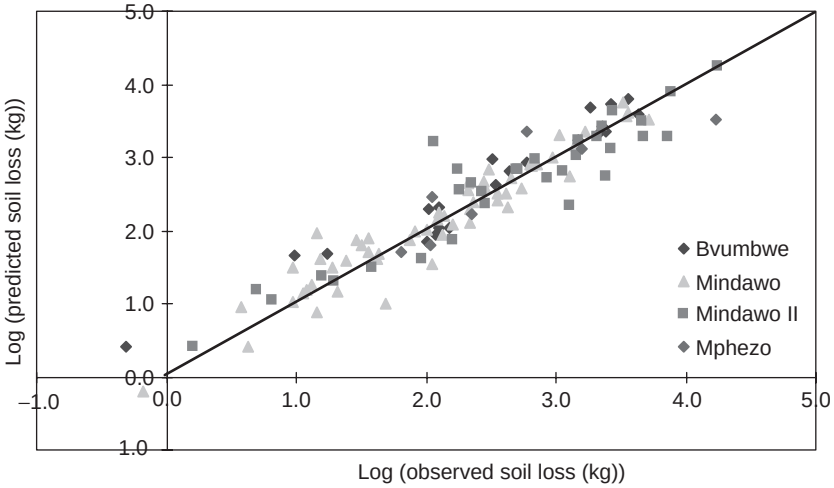

Figure 3 Predicted and observed sediment yield for runoff events in four small basins in Malawi derived from a neural network model using the same inputs as for multiple linear regression relationship. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

- Where these approaches have been tested on a range of basins, the fact that monitored sediment yield for similar catchments can vary by orders of magnitude means that there is little hope of accurate yield assessment.
- The presence of man-made structures such as dams, or natural lakes or swamps, also complicates the application of such general models and means that beyond a broad estimate of potential yield under natural conditions their usefulness is limited.
- These approaches provide limited capability for modeling changed situations.

2. Soil erosion and sediment delivery approaches

As suggested by the title, two parallel strands of research contributed to these approaches. The first was the development of empirical soil erosion models such as the Universal Soil Loss Equation (USLE) (Wischmeier and Smith, 1978) or the Soil Loss Estimator for Southern Africa (SLEMSA) (Elwell, 1980). These were succeeded by modifications such as RUSLE (Revised Universal Soil Loss Equation) (Renard *et al.*, 1997) and MUSLE (Modified Universal Soil Loss Equation) (Williams, 1975) and subsequently by more physically based models such as WEPP (Water Erosion Prediction Project) (Flanagan *et al.*, 2001), KINEROS2 (Kinematic Runoff and Erosion 2 Model) (Smith *et al.*, 1995) and EUROSEM (European Soil Erosion Model) (Morgan *et al.*, 1998). Such models allow estimation of actual or potential annual soil loss – or sediment yield – at the field scale. By summing up soil loss estimates across space to cover a complete river basin, an estimate of total soil loss could be made. However, not all of this eroded soil will be supplied to the river network: some will be trapped for very long periods behind obstacles, some will be double accounted as previously deposited sediment is reeroded. Thus was born the concept of the SDR, which relates the amount of sediment leaving a river basin to the total eroded sediment supply within it. There is a wide range of formulae for the SDR, most of them relating SDR to basin area, basin relief, basin shape, annual runoff, stream network characteristics, and gully density (e.g. Maner, 1958; Roehl, 1962; Williams and Berndt, 1972; Williams, 1977; Mutchler and Bowie, 1975; Mou and Meng, 1980). Many authors include in their SDR investigations the formula suggested by ASCE (American Society of Civil Engineers) (1975):

$$\mathrm{SDR} = kA^n$$

where A = basin area, and k and n are numerical constants for a particular basin. Reported values of n vary from -0.01 to -0.7, with some of this range being explained by regional differences and some by differences in sediment characteristics. Intuitively, one would expect an inverse relationship between SDR and basin area, as the smaller, steeper headwaters provide more efficient transfer of material than larger, flatter basins.

Application of the erosion + SDR methodology was considerably facilitated by the development of Geographical Information Systems (GIS), which allow automated application of a range of erosion models for a regular grid covering an entire river basin. A major shortcoming was the definition of a lumped SDR value for an entire river basin, meaning that in practice one normally required monitored sediment yield in order to calculate the SDR as the ratio of total yield to total erosion.

Ferro and Minacapilli (1995) addressed the problem of the lumped SDR approach by introducing a spatially distributed SDR at the level of morphological units.

Their SEDD model uses an empirical travel time concept, based on slope length and steepness, to investigate the effectiveness of sediment transport through morphological units. The model assumes that rivers can transport all supplied sediment. Mashriqui and Cruise (1997) have developed a methodology based on "grouped response units" defined by topography and soil characteristics. Kothyari *et al.* (1994) used a similar approach, but here the basin was subdivided into time–area segments for routing of sediment overland. Other approaches have continued to use USLE but have calculated delivery to the stream network as a function of slope, distance to the stream, or aspect (e.g. Lea, 1991).

The WaTEM/SEDEM (Van Oost *et al.*, 2000; Van Rompaey *et al.*, 2001) models provide a slightly different approach using a grid-based model to estimate annual soil erosion using RUSLE and then calculating annual transport capacity for individual cells. The models allow calculation of annual sediment delivery to rivers from hillslopes. Eroded sediment is routed across the land surface to rivers in a topographically driven manner, restricted by the annual transport capacity of flow. Original claims that the SEDEM (Sediment delivery model) model could be applied to basins up to 10 000 km^2 have since been questioned (Verstraeten *et al.*, 2003). However, SEDEM has been used to look at the impact of land-use change in the Czech Republic (Van Rompaey *et al.*, 2003), for defining catchment management priorities in Belgium (Verstraeten *et al.*, 2002), and for looking at the erosion and sediment delivery implications of historic and possible future land-use changes in Belgium (Van Rompaey *et al.*, 2002).

Although many combinations of erosion and sediment delivery modeling are available, they all still require calibration and thus cannot be transferred to other catchments and environments. Other shortcomings include:

- USLE (and its derivatives) and SLEMSA are not easily applied to nonagricultural land uses or to areas outside the range of original development and application.
- The approach ignores the fact that fields are often not the dominant sediment sources – gullies, mass movements, avalanches, and river banks are all major contributors to sediment supply, and one or a combination of them often far exceed field-scale sheet and rill erosion as modeled by soil erosion models.
- The error in the sediment supply term can be compensated for in the sediment delivery term where data exist to determine the SDR empirically. More often, SDR is calculated as a function of catchment characteristics such as slope length and steepness, and no allowance is made for other landscape complexity.

3. Physically based and/or distributed basin modeling approaches

A different modeling approach is taken by Arnold *et al.* (1995), in which soil–water balance models generate boundary conditions for a sediment generation and routing model called ROTO (Routing outputs to outlets). This model was developed for use at the river basin scale where capability to represent change in land use and agricultural management is required.

As discussed in the article on erosion modeling (*see* **Chapter 82, Erosion Prediction and Modeling, Volume 2**), models such as the EUROSEM (Morgan *et al.*, 1998) and WEPP (Flanagan *et al.*, 2001) were an attempt to bring more physically realistic components into erosion modeling at a small catchment scale. Again, these are dealing with erosion from fields rather than sediment yield in its totality. In order to incorporate the ability to model supply, and transport of sediment into larger catchment-scale models, it is necessary to have a realistic representation of water movement through the catchment with correctly defined components of total river flow moving to the river by their correct routes, that is, models should have the ability to model surface, through flow and groundwater contributions to streams in a spatially distributed and dynamic manner. This demands a higher level of both complexity in the model structure and sophistication in model validation than that used for straightforward hydrological modeling. Models that have the ability to model surface flow as a separate component include those that are predominantly physically based (e.g. SHE-TRAN, Ewen *et al.*, 2000; Wicks, 1988; Wicks and Bathurst, 1996; Areal Nonpoint Source Watershed Environmental Response Simulation (ANSWERS), Bouraoui and Dillaha, 1996; Bouraoui and Dillaha, 2000) and those that are more conceptual in approach (e.g. Soil and Water Assessment Tool (SWAT), Neitsch *et al.*, 2001; Arnold *et al.*, 1998; a development from the CREAMS (Chemicals Runoff and Erosion from Agricultural Management Systems) approach discussed in the erosion modeling article (*see* **Chapter 82, Erosion Prediction and Modeling, Volume 2**), Williams and Arnold, 1997) and AGNPS (Agricultural Nonpoint Source) (Young *et al.*, 1989). Both approaches may explicitly include components for modeling of erosion and transfer of sediment; however, even in the most advanced physically based models, there are still some aspects of sediment behavior that are represented by empirical relationships.

More recently, a range of erosion and overland sediment transport approaches based on overland flow transport capacity have been developed. Notable amongst these is the Limburg Soil Erosion Model, LISEM (De Roo *et al.*, 1996a,b; Jetten and De Roo, 2001). LISEM is a physically based single-event erosion model that works on a raster-grid basis. It has been tested, with varying success, in a range of

environments (e.g. Hessel *et al.*, 2003; Jetten *et al.*, 2003) with limitations sometimes due to unmet data requirements and sometimes due to physical limitations in the model equations or grid size used. LISEM calculates infiltration using a finite difference version of the Richard's equation and then calculates the transport capacity of the resulting overland flow using stream power approaches. The model is very sensitive to the parameters controlling infiltration (saturated conductivity and initial moisture content) and to the slope angle, where the stream power concept is only valid for slopes of up to 20%.

None of the currently available distributed modeling approaches at river basin scale includes all potential sediment source mechanisms in a physically realistic manner. It is indeed arguable that if such complete physically based models were developed, available data would not be sufficient to provide a full spatial and temporal representation of all causal factors. Possible future developments in this area include the use of remote sensing and Internet databases to address some of the spatiotemporal data acquisition issues implicit in physically based modeling. In their defence, these models do provide the possibility of investigating future climate or land-use scenarios (Bathurst *et al.*, 1996; Bathurst *et al.*, 2002), and if used with care and thoroughly validated should prove to be robust.

- Although these models are of use in modeling the dynamics of sediment and associated contaminants, they are very data hungry and still rely on empirical relationships for many of the sediment detachment and transfer processes.
- Some of these large basin models use USLE to estimate erosion rates, and thus the same caveats apply as detailed above.
- These models do not provide quick answers. Setting up, calibrating, and modeling a river basin model will typically require a time input of several man-months.
- However, such a modeling approach does provide a way to investigate possible future scenarios in climate or land use and management, and can include repeated application to account for uncertainty.

4. Models relating sediment concentration or load to river flow

This is the most commonly used approach for sediment yield assessment in practice, and assumes that river flow is the dominant factor in sediment yield, rather than sediment supply, or that these two controlling factors vary in parallel. It is important to remember that the concentration of the finest material in transport, the wash load, is explicitly defined as being independent of water discharge, although here the relationship between supply and transport means that peaks in wash load are often seen at times of high flow. A relationship between suspended bed material sediment concentration or sediment load and water discharge – a sediment-rating curve (American Society of Civil Engineers. Task Committee for the Preparation of the Manual on Sedimentation, 1975) – can be derived. Such rating curves always demonstrate a wide scatter of points in part due to hysteresis effects at the event scale. These occur because of sediment exhaustion as sediment supplies are transported down the river system or sediment "bunching" as material that is mobilized at the subcatchment scale in spatially limited events is then moved through the system in events affecting larger areas. Such an effect was reported in the Philippines (White, 1995) where localized thunderstorm events prepared sediments at the subcatchment scale, but did not cause high transporting capacity (flow) throughout the river system. Once larger cyclone events occurred, these previously mobilized sediments were rapidly transported through the system.

Increases in sediment concentration for a particular water flow rate have also been seen for the River Tees in the United Kingdom, following severe flooding in the winter of 2000–2001. Here, a rating curve between mean event sediment concentration and peak event flow has been derived for the period before the flood event. This showed relatively little scatter and had performed well over a range of river discharges. After the flood events, when a considerable amount of sediment was released from riverbanks as a result of bank collapse, the relationship between sediment concentration and peak flow moved upwards on the graph (Figure 4). The two lines are significantly different by a factor of up to 2 in mean sediment concentration for a particular size of event. This new relationship persisted over several months while sediment stocks in the river were exhausted. By March 2003, the rating curve had still not completely returned to, but was approaching, the pre-flood line. The Tees river is unusual in having an estuarine barrage close to its outlet to the North Sea. Before this barrage was built, a feasibility assessment had estimated sediment yield to the barrage at 35 630 t year^{-1}. In the water year 2000–2001, monitored sediment yield was in excess of 85 000 t, and yield per unit flow (tons per millimeter of specific flow) had increased from 78 in the initial feasibility study to 111 in the post-flood period. In this particular situation, the increased sediment yield has little influence on the viability of the barrage impoundment, as high sediment loads occur with high river flows, which have the ability both to transport material through and out of the system and to scour out previously deposited sediments. For the Tees, 80% of sediment yield is delivered by the top 10% of the river flows, thus emphasizing the need for both data and models that address such events.

Extreme examples of high sediment yield events are seen in mountain basins where events that may occur only once in a decade or longer can dominate sediment yield patterns

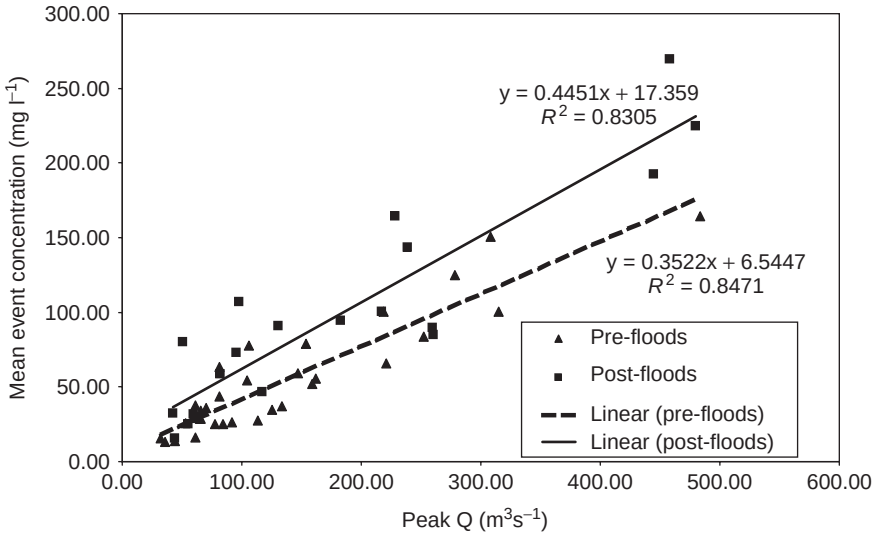

Figure 4 Sediment-rating curves for the Tees river, UK, pre- and post-floods in winter 2000–2001

for years to come (Alvera and García-Ruiz, 2000; White and García-Ruiz, 1998; White *et al.*, 1997b). A single event in a 30-ha basin in the high Pyrenees transported more sediment than the total seen in the following 5 years, in part because of sediment exhaustion following the event, in part because of the extreme nature of the event and the high flows associated with it (White *et al.*, 1997a). Hence, extreme care is required in interpreting data and extrapolating relationships derived for such areas.

- Although these approaches are based on real sediment flux data, they still require a large amount of data gathering to give realistic estimates of a long-term average annual sediment yield.
- It is important that data gathering is carried out across a range of flow and sediment supply conditions. Special attention should be paid to extreme, high flow, and storm events.
- These approaches are based on what has happened in the past rather than what may happen in the future. Understanding of sediment supply and transport processes is therefore required to extrapolate to unmonitored future climate and/or land-use scenarios.
- Models can be transferred only to situations that have been seen before in the data set. The large difference between apparently similar basins in Malawi demonstrates the scale of error that can be made for relatively minor land management changes.

SEDIMENT YIELD PREDICTION

Prediction is by definition a forward-looking activity and thus has a large number of unknowns and uncertainties attached to it. These undefined aspects have rarely been addressed in conventional feasibility studies for dams, where one may be predicting sediment yields forward for the next 100 or more years. Most prediction of this type has been done assuming stability in the driving processes, clearly not a reasonable assumption in today's world where climate change is widely accepted to be influencing river flows and hydrological behavior of river basins. Given the major changes in land use that have been seen worldwide over the last century, such an assumption becomes completely unrealistic and unsupportable. **Chapter 88, Reservoir Sedimentation, Volume 2** suggests a changed approach to reservoir design and management, based on life-cycle concepts (Palmieri *et al.*, 2003) rather than the design life approach traditionally used. In the latter, sedimentation was accepted as given, and reservoirs were designed to fulfil their purpose over a limited number of years, often based on very poor preconstruction sediment yield estimates (see Table 1). One of the outcomes of this lack of sediment yield estimation capability is the annual reduction in water storage capacity in reservoirs, now being seen internationally (World Commission on Dams, 2000).

In a feasibility study for a proposed new dam in the Philippines, (White, 1987; White, 1993) sediment yield estimates were made using an uncertainty approach in which model inputs such as the slope and intercept of a sediment-rating curve, the water level in the reservoir at the time of sediment delivery, and the frequency and impact of cyclone events were varied over reasonable ranges. A daily time-step model based on different statistical flow distributions and rating curves for wet and dry season conditions was used as the basis for sediment yield estimation. Cyclone events, which fall outside the standard frequency distribution patterns, were then superimposed on more "normal" flow patterns as additional intermittent

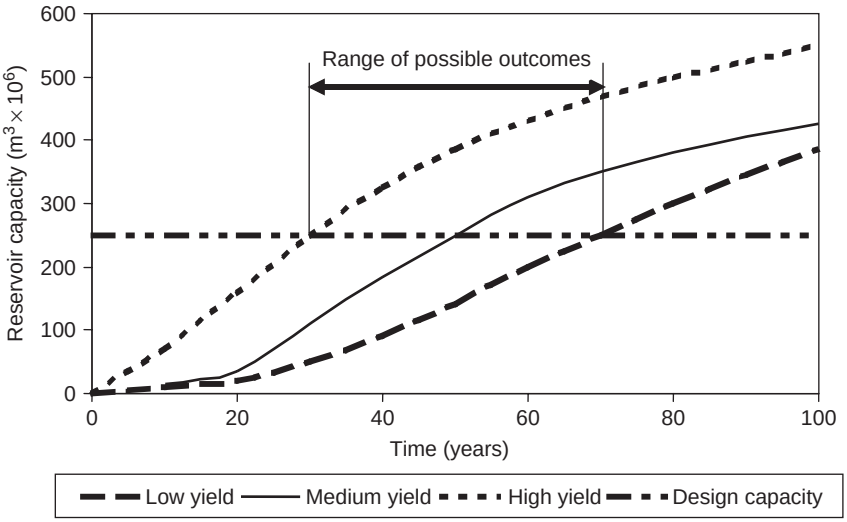

Figure 5 Idealized approach to prediction of a range of sediment yield rates and their relation to viable reservoir life

sediment pulses. Sediment inputs to the reservoir were then deposited in locations related to current water level, and sediment deposits were thus built up in a spatially varying manner. Failure of this reservoir was determined by sedimentation threatening a water transfer tunnel located along the reservoir profile. Parameters within this modeling framework were then subject to variation, providing a range of predictions of effective reservoir life (Figure 5). These different scenarios could then be tested against the required economically operational life of the reservoir. Such an approach was novel, as previous studies only provided an average annual sediment yield with no definition of deposition locations or possible changes in sediment supply regime or river flows. By investigating the range of possible outcomes for the proposed reservoir, a much more robust assessment of viability could be made.

Since this study, other authors have looked at the inclusion of uncertainty in sediment yield prediction. Work in Europe, using SHE-TRAN, has looked at model application to future land-use and climate scenarios in order to assess a range of possible outcomes, including sediment yield (e.g. Bathurst *et al.*, 1996; Bathurst *et al.*, 2002) using a varying model parameterization to investigate the range of outcomes. Tattari and Barlund (2001) used their ICECREAM model, a field–scale mathematical simulation model for prediction of water transport, soil and nutrient losses, to investigate the uncertainty in model output arising from parameter uncertainty. The uncertainty analysis was carried out using a Monte Carlo simulation package. A similar Monte Carlo approach was used by Salas and Shin (1999) to look at error in reservoir sedimentation rates in Colorado. They concluded that annual streamflow and sediment load were the two most important factors determining sedimentation rate, emphasizing again the need for robust sediment yield modeling and a realistic consideration of error. Moving on still further, Tate and Farquharson (2000) used varying sediment yield and flow inputs to the Tarbela dam to study different management scenarios and economic consequences. Such uncertainty in sediment yield estimation will continue to exist and should always be taken into account when assessing the viability, operation, or future development of an impoundment or other sediment delivery zone.

RECOMMENDATIONS

To conclude, a number of recommendations can be made about the way in which sediment yield is modeled, in order that a robust estimate or prediction can be made:

1. Understand what is controlling sediment yield in the basin of interest.
2. Be realistic about how things – land-use, land management, climate – have changed and how they are likely to change.
3. Never make a single number prediction of sediment yield – at least include some error bars or a distribution of likely yields.
4. All estimates require some sediment yield data – for model development, calibration, and validation.
5. Available data must be put into a longer term context.
6. Extreme events must be included in the assessment as they often control sediment yield over the long term.

88: Reservoir Sedimentation

GEORGE W ANNANDALE

Engineering and Hydrosystems Inc., Denver, CO, US

The storage loss due to reservoir sedimentation has been found to exceed the storage added worldwide by the mid 1990s. Recovery of this lost storage is estimated to range between US$ 10 billion and US$ 20 billion per year, not accounting for the growth in world population. Reservoir sedimentation does not only impact water supply and power supply reliability, but also has significant impacts on the environment, including downstream river degradation, and impacts on recreation, flood management, infrastructure, and the economy. The article illustrates how sediment is trapped in reservoirs, provides empirical techniques for calculating the volume of sediment that can be trapped by reservoirs, outlines sediment management techniques, which includes flushing, dredging, dry excavation, hydrosuction, and bypassing, and introduces the life-cycle management approach. This approach to reservoir sedimentation management is in contrast to the conventional design life approach, which is inappropriate for the design, construction, and management of dams and their reservoirs. Numerous references for further reading are listed.

INTRODUCTION

Reservoir sedimentation occurs when sediment conveyed by river flow into a reservoir settles. Sediment transported by rivers originates from riverbeds and banks, and from eroding surfaces in catchments. This sediment is carried in suspension, as bedload, or as washload as long as the sediment transport capacity of the water flowing in the river is high enough to convey it. When a river flows into a reservoir, the flow velocity of the water reduces, which leads to a reduction in sediment transport capacity and concurrent deposition of the sediment. Large particles settle first, followed by smaller particles further downstream in the reservoir. The larger particles form a delta at the upstream end of the reservoir, and the finer particles settle downstream closer to the dam. The water closer to the dam could become clearer as sediment settles out, but in some cases remains turbid. The level of turbidity in the quiescent water closer to the dam depends on the physical and chemical properties of the colloidal-sized suspended particles and the physical and chemical properties of the water. The upper, mild slope of the delta is *known as* the *topset* slope, and the steeper slope at the end of the delta as the frontset slope (Figure 1).

Sediment can also be conveyed into reservoirs by means of density currents, although the occurrence of density currents is not common (Figure 2). The density of these currents is higher than that of the water in a reservoir, resulting from high sediment concentrations in the inflowing water and temperature differences between the inflowing water and the water in the reservoir. The presence of density currents can often be detected by floating debris that remains at the point of subsidence at the upstream end of the reservoir. The higher density of a density current causes it to dive below the surface of the water in the reservoir and move along its bed towards the dam. A density current can move up the dam wall and recirculate in the reservoir. One of the management techniques used to manage sediment deposition in reservoirs that are subject to density currents is to install low-level venting gates that are opened during such events. By timing the opening of the gates correctly, it is possible to vent the high sediment load carried by a density current and discharge it downstream of the dam. Density current venting makes it possible to reduce the volume of sediment depositing in a reservoir, although this is not common.

As sediment is deposited in reservoirs, it reduces the useful capacity of these facilities, which, in turn, reduces the reliability of water and power supply, especially during

periods of drought. It is, therefore, important to consider the worldwide reduction in water storage due to reservoir sedimentation, consider its impacts, and stress the importance of reservoir sustainability and reservoir sedimentation management.

WORLDWIDE STORAGE REDUCTION RESULTING FROM RESERVOIR SEDIMENTATION

A comparison between the reservoir storage added internationally each year due to construction of new dams and the volume lost due to sedimentation is shown in Figure 3. This figure shows that the incremental storage added annually has been reducing since about 1970 and that the cumulative storage lost to reservoir sedimentation exceeded the incremental addition of storage in about 1995. If this trend is maintained, the loss in reservoir storage will continue to exceed its addition, leading to a continued reduction in the reliability of water supply as the world population grows. A clear need for sustainable management of reservoirs and water resource infrastructure exists. Reservoirs are valuable community resources requiring sustainable management and protection.

The International Commission on Large Dams (ICOLD) (1998) estimates the total current storage volume contained in man-made reservoirs worldwide amounts to about

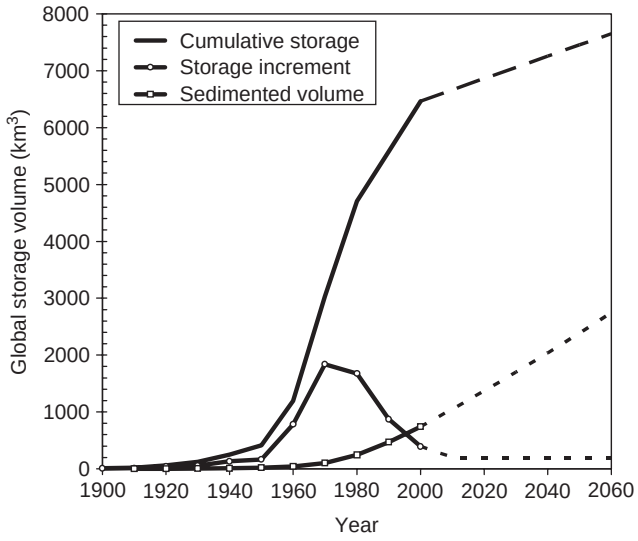

Figure 3 Cumulative reservoir storage constructed, incremental storage constructed, and storage lost due to reservoir sedimentation (Morris, 2003)

7000 km^3. This includes storage for water supply, irrigation, power generation, and flood protection. Estimates of average reservoir storage loss due to sediment deposition throughout the world vary, but are generally considered to range between 0.5 and 1% annually (White, 2001). This means that between 35 km^3 and 70 km^3 of reservoir storage is lost every year due to reservoir sedimentation. In order to maintain the reservoir storage that currently exists in the world, it is necessary to invest significant sums of money to develop new water supply infrastructure. Should the water supply infrastructure be replaced by other man-made reservoirs, it is estimated that the investment required to replace the lost storage capacity would range between US$ 10 billion and US$ 20 billion annually (2003 value), a substantial investment. This estimate of required investment only covers replacement of lost storage, and does not include creation of additional storage to maintain and improve reliable water supply to a growing world population.

The rate of reservoir sedimentation varies internationally, and is dependent on regional factors. The largest losses in storage due to reservoir sedimentation generally occur in China, followed by North America, the rest of Asia and the Pacific Rim, Europe, the Middle East, Africa, and South America (Figure 4).

IMPACTS

The consequences resulting from reservoir sedimentation are varied and include reduction in the reliability of water supply and impacts on the environment, infrastructure,

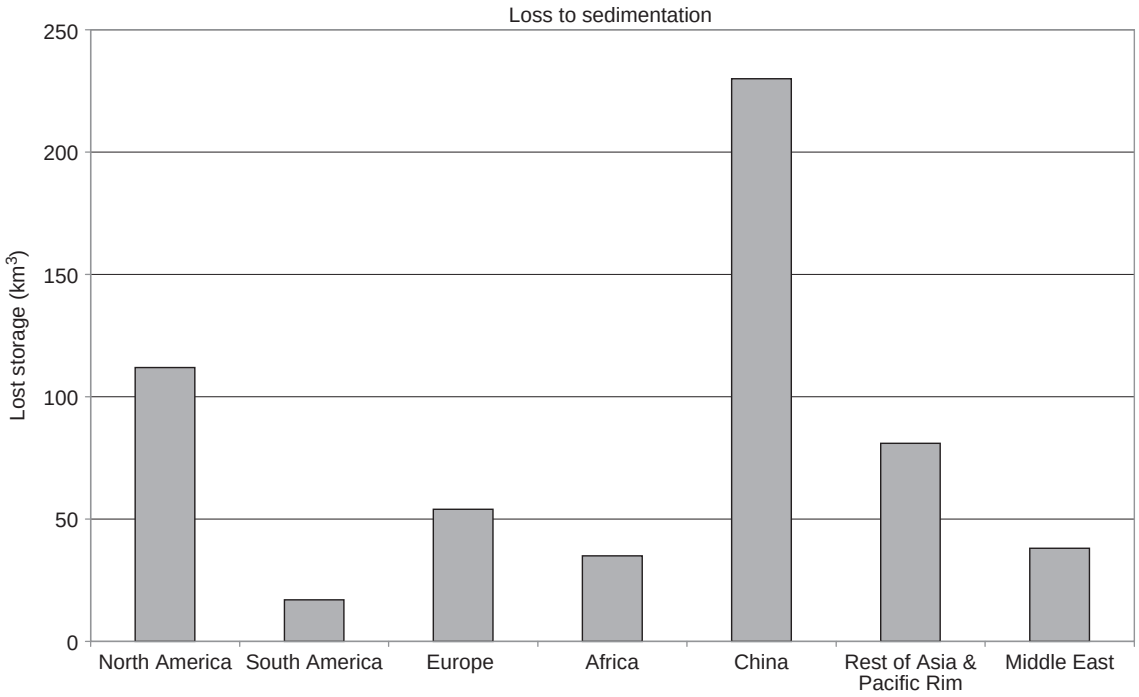

Figure 4 Reservoir storage lost due to sedimentation (data source: White, 2001). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

economy, life, and property. Although reservoir sedimentation leads to multiple negative impacts, it can also, in some cases, lead to more favorable environmental, social, and economic conditions as indicated further on in this article.

Impact on Water Supply Reliability

The effects of reservoir sedimentation on the reliability of water supply are not obvious during the early stages of reservoir sedimentation. Figures 5 and 6 relate the reliability of water supply to reservoir size and draft from a reservoir. The reservoir size is expressed in dimensionless form as the ratio between reservoir volume and the mean annual runoff (MAR), and dimensionless draft is expressed as the ratio between draft and MAR. Draft in this article is defined as the volume of water that a user wishes to withdraw from a reservoir. Figure 5 illustrates how the reliability of water supply varies with draft and reservoir volume for a river with an annual coefficient of variation (C_v) of 0.3 flowing into the reservoir, and Figure 6 shows it for an annual coefficient of variation of 1.2. C_v is a dimensionless variable that is defined as the standard deviation divided by the mean. Therefore, the annual coefficient of variation for river flow is the standard deviation of annual flows divided by the mean annual flow in a river. Small values of C_v (say 0.3) are indicative of river flows that do not vary much from year to year. A value of 1.2 is characteristic of annual river flows that can

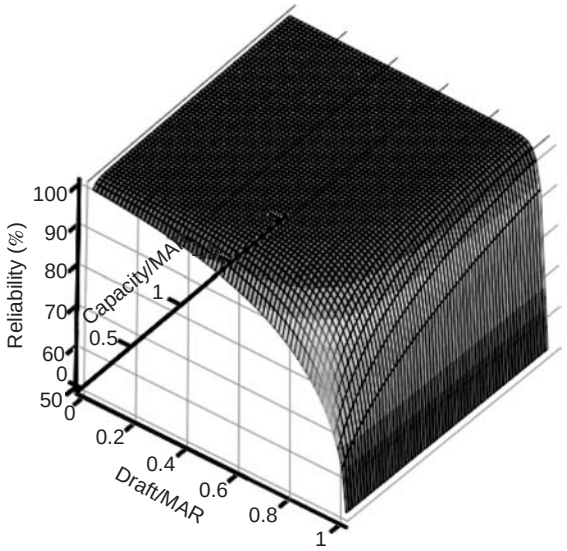

Figure 5 Reliability of water supply as a function of dimensionless reservoir capacity and dimensionless draft for an annual coefficient of variation of inflow equal to 0.3 (temperate regions). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

vary quite considerably on an annual basis, and represent flow in rivers located in arid and semiarid regions.

These two figures indicate the sensitivity of water supply reliability to storage capacity (volume) and draft, and

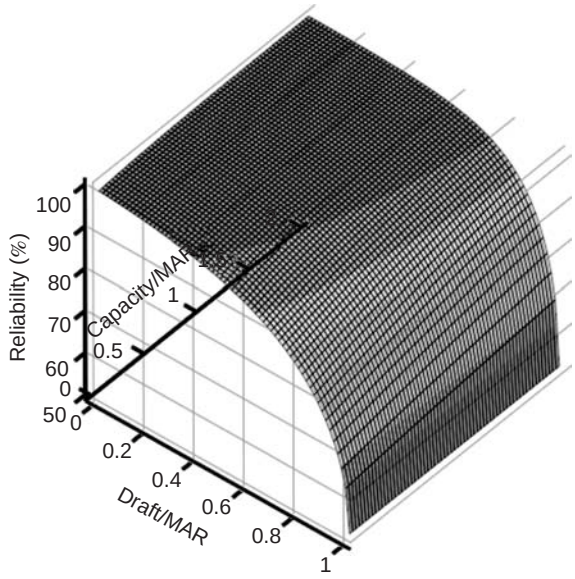

Figure 6 Reliability of water supply as a function of dimensionless reservoir capacity and draft for a coefficient of variation of inflow equal to 1.2 (arid/semiarid regions). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

provide insight into the impact of reservoir sedimentation on the reliability of water supply to growing communities. Such impacts are more noticeable in fast-growing communities located in arid and semiarid regions. The trend in both cases indicates a sudden drop in water supply reliability as the dimensionless draft increases to values that are on the order of 90% and higher. However, the change is more abrupt when the draft becomes very high in the case of a reservoir in a temperate climate (Figure 5) than what it is in the case of one in a semiarid region (Figure 6). For example, in the case of storage reduction due to reservoir sedimentation in temperate climates (Figure 5), if the reservoir capacity reduces by 50% by changing from twice the MAR to one time the MAR, and the draft concurrently changes from 50% of the MAR to, say, 80% of the MAR, the change in reliability of water supply is insignificant (it changes from a theoretical value of close to 100% to 99.9%). However, in the case of a reservoir in a semiarid region (Figure 6), the same change in storage due to reservoir sedimentation and the same growth in water demand will have a significant impact on the reliability of water supply (it changes from 98.7% to 88.5%).

When assessing the impact of reservoir sedimentation, it is therefore important to take account of the hydrologic characteristics of inflow, specifically its mean and variability (expressed in terms of C_v), and the changes in capacity and draft, which can be expressed in terms of the MAR. A set percentage reduction in storage due to reservoir sedimentation combined with a concurrent set increase in percentage draft does not have the same impact on reliability of water supply in temperate and semiarid regions. The adverse impact of storage loss due to reservoir sedimentation on water supply reliability in semiarid regions with high sediment yield and fast-growing populations is greater than in temperate regions.

Environmental Impacts

The environmental impacts of reservoir sedimentation, either positive or negative, occur within upstream and downstream of reservoirs. The delta region of sedimentation in a reservoir (in the upstream reaches) can change the morphology of the inflowing rivers, leading to marshy environments.

Within a reservoir, continued sedimentation can lead to changes in the properties of the lake bed, which in turn leads to changes in the food chain and reproductive environments for fish and other aquatic species. However, the environmental impacts from reservoir sedimentation are often most noticeable in the river reaches downstream of dams.

As sediment deposits in a reservoir upstream of a dam, the amount of sediment that is available for transport in the river reach downstream of the dam is reduced. The water discharged downstream of the dam, therefore, has a greater ability to entrain sediment from the riverbed and banks, which generally leads to degradation of downstream river reaches. In cases where the riverbed material is easily eroded, such degradation can lead to deepening of the river and general degradation of the riverbed and banks. In cases where the river bed contains gravel, cobbles, and boulders that are resistant to the erosive power of the discharged water, the river often widens as the preferred source of sediment shifts to the river banks, which might be more vulnerable to erosion.

Additionally, degradation of riverbeds downstream of dams often leads to deterioration in spawning habitat for fish. For example, some fish like trout require pea-sized gravel to lay their eggs. Reservoir sedimentation results in a reduction in the amount of pea-sized gravel in the river reach downstream of a dam, and consequent poorer conditions for spawning. However, some consequences of reservoir sedimentation can have a positive impact on the environment.

Examples of positive effects of reservoir sedimentation on the environment include the effects on Chesapeake Bay and the positive effect on trout fishing downstream of dams in the upper portions of the South Platte River in Colorado. In the case of Chesapeake Bay, reservoir sedimentation in upstream reservoirs prevents sedimentation of the bay. Trout fishing streams in Colorado are ranked, with Gold Medal trout fishing streams considered prime fishing spots. The Gold Medal trout fishing streams in the upper reaches of the South Platte River are generally located downstream

of dams. The reason for this is that the sediment generated in these Rocky Mountain catchments are generally very young, granitic sediments with rough sharp edges. By depositing these sediments upstream of the dams by the process of reservoir sedimentation provides improvement to the habitat for fish downstream of dams.

Hydropower

Hydropower plants are generally used to provide peaking power, contrary to thermal power plants that are more effective in providing base load power. Peaking power demand is the power that develops in a power grid due to sudden increases in the need for power. Hydropower plants have the flexibility to provide in this sudden increase in power demand. However, some hydropower plants do provide base load, which is the power that is used on average in a power grid.

Hydropower plants that mainly supply base load require storage to ensure enough water for long term power generation and can be adversely affected by storage loss due to reservoir sedimentation. This is not necessarily the case for power plants that are used to generate peaking power. In the latter case, less water is usually needed, and the impact of storage loss is less important.

However, sedimentation in reservoirs could result in sediment being discharged through the turbines should the deposited sediment move closer to the forebay of the hydroelectric plant. When sediment is discharged through turbines, it leads to erosion of the turbine blades, and deterioration.

Recreational Impacts

Reservoir sedimentation adversely impacts boating and fishing on lakes, but can have a positive impact on other sports, like duck hunting. As the volume of sediment deposited in a reservoir or lake increases, it decreases its depth, which can adversely affect boating. The changes in bed sediments can also lead to changes in the aquatic habitat of lakes, which affects the food chain and the type and abundance of fish.

Flood Management

The impact of reservoir sedimentation on flood management is twofold. If a reservoir is specifically constructed to reduce flood peaks downstream of the dam, reservoir sedimentation adversely impacts the effectiveness of such measures once the reservoir volume has been significantly reduced.

Reservoir sedimentation can also adversely impact flooding in reaches upstream of the reservoir. During delta formation, some of the sediment is deposited upstream of the normal pool level in a reservoir. This changes the fluvial geomorphology of the river in the reaches upstream of the dam, which generally results in higher flood levels than what have been experienced prior to reservoir sedimentation.

Infrastructure

Infrastructure built in rivers, like intakes, and bridges, are affected by reservoir sedimentation. Intakes are adversely affected in river reaches upstream of reservoirs when the river aggrades due to reservoir sedimentation. When the riverbed aggrades enough, it is possible for the sediment to block the intakes and prevent water from flowing into it. Degradation of the riverbed and banks downstream of a dam can also adversely affect intakes. As the riverbed elevation decreases, intakes on the river banks can be left high and dry.

In the case of bridges, the effects are different on the upstream and downstream sides of the reservoir and dam. On the upstream side of a reservoir subject to sedimentation, aggradation of the riverbed can lead to a reduction in the size of the bridge opening, which in turn could lead to the bridge being overtopped by flood waters on a more frequent basis than prior to the impacts of reservoir sedimentation taking effect. On the downstream side of a dam, degradation of the riverbed can in turn lead to excessive scour at bridges. As the riverbed elevation decreases, the foundations of bridge piers and abutments can be undermined and lead to failure.

Economic

The economic impacts of reservoir sedimentation can be significant. As reservoir sedimentation reduces the reliability of water and power supply and impacts the effectiveness of flood management, it affects public health, economic production, property value, and the general standard of living. For example, the value of property on lakeshores is adversely impacted if sedimentation moves the shoreline away from the property and results in aquatic vegetation taking up the water front. Property values are also affected if floods occur on a more regular basis due to the effects of reservoir sedimentation, than what has previously been experienced. When the reliability of water and power supply reduces, the effectiveness of industrial production is reduced, which can have significant effects on the economy of a region if economic multiplier effects are taken into account.

PREDICTION OF RESERVOIR SEDIMENTATION

Good planning of water resource development requires, amongst other things, the ability to predict the anticipated

effects of reservoir sedimentation. This is done by estimating the sediment yield from a river and estimating the amount of this sediment that will be deposited in a reservoir. Once it is known how much sediment could potentially deposit in a planned reservoir, it is then possible to assess its impacts and decide how it could be managed.

Estimating sediment yield for catchments is presented in other articles in this encyclopedia and is not repeated here. However, once it is known how much sediment could flow into a reservoir, the amount that could deposit can be estimated by making use of empirical relationships like the Brune (1953) and Churchill (1948) curves. The Brune curve (Figure 7) relates the percentage of sediment that is likely to be retained in a reservoir to the ratio of the reservoir capacity to the MAR. This figure indicates that small reservoirs (in terms of their capacity relative to the MAR) can trap large proportions of the sediment flowing into them. For example, the graph indicates that approximately 80 to close to 100% of the sediment flowing into a reservoir can be trapped if the reservoir capacity is only about 10% as large as the MAR.

The version of the Churchill curve presented in Figure 8 was modified by Roberts (1982) to relate the percentage of sediment that can pass through a reservoir to a dimensionless index, known as the "*sedimentation index*". The sedimentation index is a function of the reservoir capacity, discharge, and reservoir length, and is made dimensionless by multiplying it with the acceleration due to gravity (g). As long as the units that are used when inserting the different variables into the equation are consistent, the index will be dimensionless and can be used to enter the graph on the abscissa. Once it is known that reservoir sedimentation could be a potential problem in the long-term operation of a reservoir, management techniques should be considered.

DENSITY OF DEPOSITED SEDIMENT

As sediment is deposited in reservoirs, its density depends on the type of sediment. In the case of coarse, noncohesive sediment, the water between the individual sediment particles escape relatively easily as the sediment deposits and the grains essentially touch each other. As additional sediment is deposited on top of that already in place, the increase in sediment density over time is not that significant. However, if silt- and clay-sized material is deposited, it initially forms a very porous mass with a significant volume of water within its matrix. The initial dry density of deposited sediment consisting principally of silt and clay is often lower and at times only slightly higher than that of water. Typically, the initial dry density of deposited fine sediment can range from 950 kg m^{-3} to 1100 kg m^{-3}. After about 50 years, the density of such fine deposits gradually increases up to a maximum value of about 1300 kg m^{-3}. An empirical method to predict the density of deposited sediment and how it might change with time can be found in Lane and Koelzer (1943).

RESERVOIR SEDIMENTATION MANAGEMENT

Reservoirs are valuable community resources and should be managed as such by making use of a life-cycle management approach (Palmieri *et al.*, 2003). The life-cycle approach to sustainable development and management of reservoirs

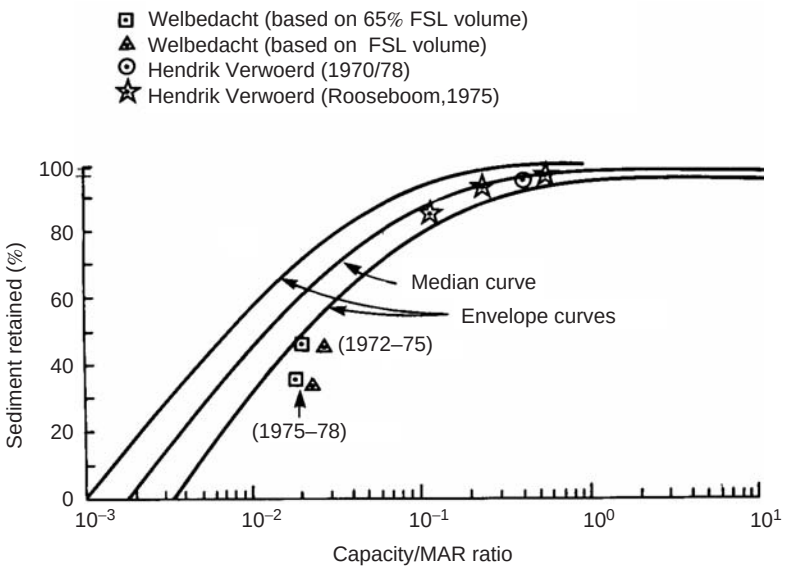

Figure 7 Brune (1953) Curve for determining sediment trap efficiency of reservoirs

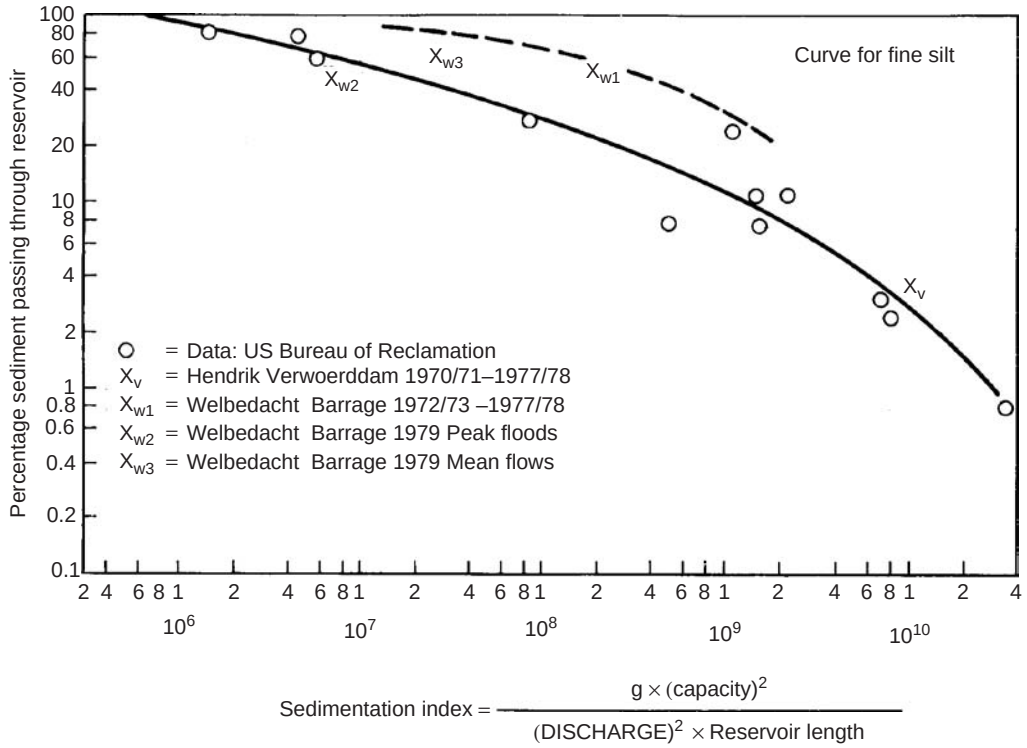

Figure 8 Churchill (1948) curve, as modified by Roberts (1982) for determining sediment trap efficiency of reservoirs

was developed because of the unique nature of these facilities. Reservoirs, contrary to most other infrastructure, are not easily refurbished once they have lost their utility due to storage loss resulting from reservoir sedimentation. Whereas other infrastructure, such as roads or buildings, can be refurbished once they have reached the end of their design life, making their continued use possible, the utility of reservoirs subject to sedimentation can generally not be recovered as easily. The approach to designing, constructing, and operating reservoirs can, therefore, not follow the conventional "design life" approach generally implemented by engineers, but adoption of a life-cycle management approach is required.

There is a marked difference between the conventional design life approach that pays scant attention to sustainability and regards environmental effects as residuals that may be recognized and are not accounted for as project liabilities, and the life-cycle management approach that focuses on sustainability. The process of life-cycle management contains many of the same elements as the design life approach but arranged in a circular fashion, indicating perpetual use of the infrastructure. Consequently, the opportunity exists to incorporate changing environmental and societal concerns that are often associated with direct impacts of a dam. Operation and maintenance, as well as sediment management, are conducted in a way that will encourage sustainable use. Figure 9 shows the differences between the design life approach and the life-cycle management approach.

Principal differences between the two approaches are that the design life approach is linear, and no allowance is made for care of the dam and reservoir at the end of its "life", with residual concerns pertaining to a variety of safety, social, and environmental issues remaining. On the other hand, the life-cycle management approach, with its circular progression, is principally aimed at continued, indefinite use of the facility with decommissioning only an option if no other management options for perpetual use are available. Economic analysis, which incorporates the cost of dam decommissioning, usually indicates that it is more economical to manage the dam and reservoir in a sustainable manner than to abandon it by decommissioning once it is completely filled with sediment (Palmieri *et al.*, 2003).

In order to implement the life-cycle management approach, it is preferred to consider operation and maintenance issues for sustainable management and use during the planning and design phases of the facility. This ensures that sediment management can be implemented in the most economical way. In existing facilities, where such provisions were not made during the original planning, design, and construction of the dam and reservoir, it is often possible to make modifications to the facility to implement sediment management. Several techniques are available to remove or prevent sediment from accumulating

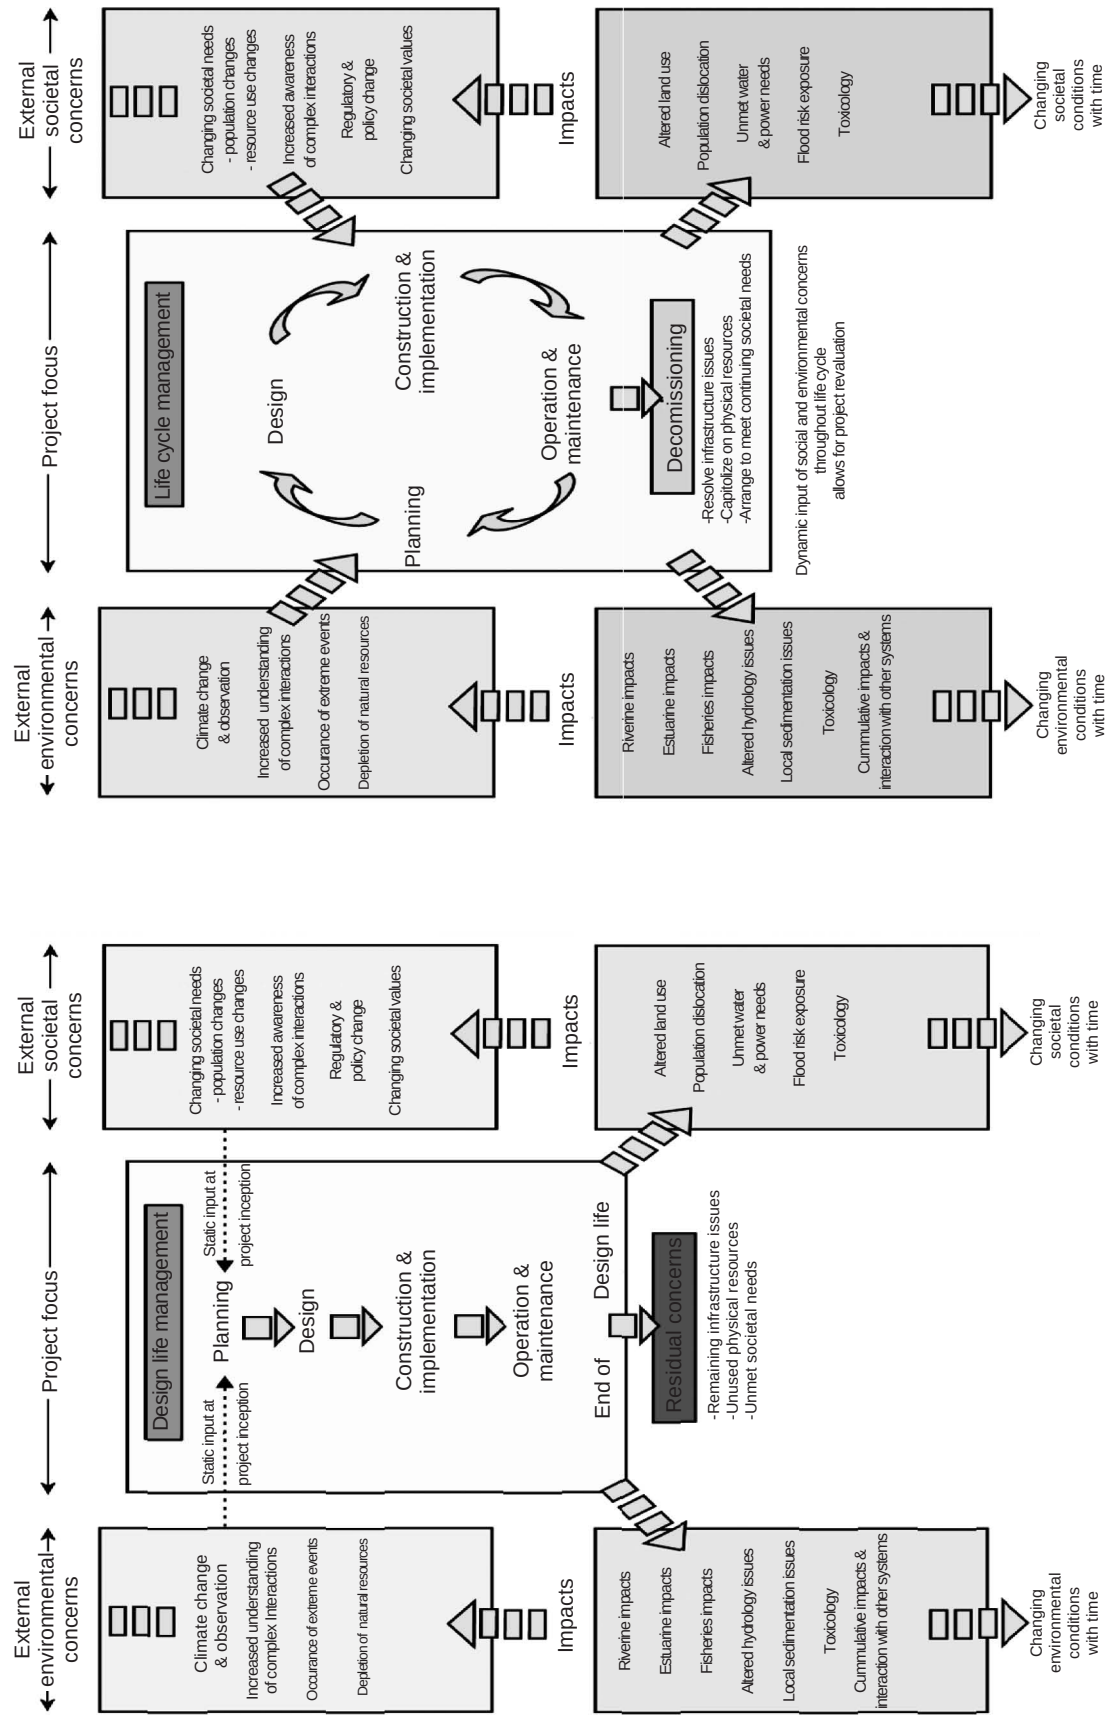

Figure 9 Comparison of the design life and life-cycle management approaches (Palmieri *et al.*, 2003). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

in a reservoir (Morris and Fan, 1997). The ones commonly used are: (i) flushing, (ii) sluicing, (iii) density current venting, (iv) mechanical removal (traditional dredging, hydrosuction removal system (HSRS), trucking) and bypassing. Catchment management to reduce sediment yield is an ideal that should be considered.

Flushing

Flushing is a technique whereby the flow velocities in a reservoir are increased to such an extent that deposited sediments are remobilized and transported through low-level outlets in the dam. *Sluicing* and *density current* venting also use the flow of the water, but their purpose is to pass a substantial portion of the incoming sediment load through the reservoir before the sediment particles can settle.

Dredging

Traditional dredging mechanically removes sediment from under the water by making use of suction pumps and pipelines. Disposal may be downstream in the river or at an off-site location.

Hydro-suction

The *HSRS* is a variation of conventional suction pipe dredging that uses the hydraulic head available at the dam as the energy for dredging instead of pumps powered by electricity or diesel (Hotchkiss and Huang, 1995). As such, where there is sufficient head available and the reservoir length is relatively short (usually not more than about 3000 m), the operating costs are substantially lower than those of traditional dredging.

Dry Excavation

Trucking (also *known as dry excavation*) requires the lowering of the reservoir water level during the dry season when the reduced river flows can be adequately controlled without interference with the excavation works. The sediments are excavated and transported for disposal using traditional earth moving equipment.

Bypassing

Bypassing is a technique that is used to prevent, or at least reduce, the amount of sediment entering a reservoir. This can be accomplished by constructing off-channel storage reservoirs or by creating channels or tunnels that bypasses sediment flows around a reservoir under high flow conditions.
