given mostly to estimation of the evaporative demand of crops, especially in irrigated areas. For this purpose, many countries have established pan evaporation networks that use somewhat standardized procedures, for instance, in the United States, measurements are taken using what is termed the National Oceanic and Atmospheric Administration (NOAA) Class A pan, which is accompanied by wind speed measurements, typically at a height of 2 m above the pan. The main complication with evaporation pan measurements is that they are related more closely to potential than to actual evaporation, where potential evaporation is defined as the evaporation that would occur from a fully wetted surface. Even as an index of potential evaporation, however, interpretation of pan measurements is complicated by the facts that (i) the pan surface is open water, as opposed to a" freely evaporating" land surface consisting of wet bare soil or vegetation that is fully wetted and (ii) there are aerodynamic and thermodynamic effects associated with the physical characteristics and area surrounding the pan.

Weighing lysimeters are a more accurate (but costly) method of measuring evapotranspiration (actual, as opposed to potential). Weighing lysimeters monitor the weight of a soil column, including plants. By monitoring rainfall, evapotranspiration can be computed by difference. If carefully installed, measurements can be quite accurate, although weighing lysimeters are generally most appropriate for agricultural conditions, where the physical setting (minimal lateral moisture flux, for instance) is more faithfully replicated. Dingman (1994; Chapter 7) contains a more detailed discussion of weighing lysimeters.

An indirect method of estimating evapotranspiration over short vegetation is the Bowen ratio method. In this method, gradients of near-surface temperature and specific humidity are measured, and the Bowen ratio (ratio of sensible to latent heat flux, which is proportional to the ratio of the near-surface temperature and specific humidity gradients, assuming equal eddy diffusivities for mass and heat) is used to partition the available energy, Rn – G (where Rn is the net radiation, and G is the ground heat flux, both of which are measured directly), into latent and sensible heat. While neither the latent nor the sensible heat flux is measured directly, the Bowen ratio allows the available energy to be

partitioned into these terms. Standard Bowen ratio systems are available commercially and generally perform best for short vegetation.

An alternate approach that provides direct measurements of evapotranspiration is the eddy correlation method. In the eddy correlation method, high frequency measurements of air temperature, specific humidity, and the vertical component of wind are made near the surface. Averaged overtime, the product of the vertical component of wind and specific humidity represents the transport of moisture from the surface (evapotranspiration). Similarly, when high frequency measurements of carbon dioxide are made, eddy correlation estimates of CO_2 flux can be produced, and in fact many, if not most, eddy correlation systems are installed primarily for that purpose. Among these are regional and global networks such as AmeriFlux, EuroFlux, and Fluxnet (Gu and Baldocchi, 2002). Eddy correlation measurements are usually made from towers, the height of which is proportional to vegetation height, and for forests typically yield "footprints" (the area that affects the measurements) of one to several square kilometers. Over short vegetation, tower heights may be only a few meters, while over forests, tower heights of several tens of meters or more are typical. In any event, while the number of flux towers globally is increasing, routine measurements are probably made at considerably fewer than 1000 sites globally, which is inadequate to provide a coherent spatial picture of evapotranspiration at any scale. The most common use of these towers is to validate model estimates, which then can be applied more widely (see e.g. Betts *et al.*, 1998).

Streamflow

Streamflow is usually measured by continuous recorders of river stage that are converted to discharge via stage–discharge relationships constructed using limited coincident measurements of stage and discharge. Depending on the hydraulic characteristics of the stream cross section and the stability of the rating curve, instantaneous discharge estimates can be accurate to within 5% (larger errors are typical at extreme low and high flows), and considerably lower errors are possible for (e.g. monthly or annual) time averages (Winter, 1981). Because stream discharge provides an areally integrated measurement, for time averages it is one of the most (if not the most) accurately measured of the terms in the water cycle.

Most developed countries have networks of stream gauges that are operated for a variety of purposes, including water management, flood forecasting, and scientific purposes. In the United States, the US Geological Survey maintains a stream gauging network with over 7000 currently active gauges, most of which are telemetered to a central archiving facility. In lesser-developed countries, however, gauge networks are much sparser. The Global Runoff Data Centre in Koblenz, Germany maintains an archive of stream discharge measurements globally. Participation is voluntary, however, and time lags of 10 years or longer are not uncommon for receipt of the data. Furthermore, many countries impose restrictions on release of the data, especially for river basins where there is perceived proprietary interest in the data. In addition to the time lag in acquiring data, many countries (including developed nations like the United States) have reduced support for stream gauging networks over the last two decades.

The result of the time lag and reduction in network support is shown in Figure 2. As shown in the figure, the location of stations globally is highly nonuniform. Also, as shown in the inset, there has been a dramatic reduction in station availability in the last decade. This is of particular concern for studies that make use of remote sensing data, as the period of overlap for many sensors with globally available stream gauge information is minimal.

Lake and Reservoir Storage

Measurement of storage in lakes and reservoirs (and hence storage change, the term of interest for water balance purposes) is straightforward – storage is simply the integral of elevation times the elevation-dependent surface area. Even in the United States, however, there is no integrated network for measurement of lake and reservoir storage. The US Geological Survey maintains some reservoir and lake stage gauges from which storage is estimated, but this is primarily for purposes of water management on a cost reimbursable basis. Other agencies, like the US Army Corps of Engineers, and the US Bureau of Reclamation, observe reservoir storage for water management purposes. There is, however, no central location where these data are archived. Globally, the situation is even more difficult – there is no central archive for lake and reservoir storage data, and even if there were, there are few sources from which the data might be drawn. Lake and reservoir storage is, however, a variable that is amenable to satellite observation as indicated in the Section "Lake and reservoir storage", and as indicated in that section, even now some satellite-based archives are beginning to appear.

Wetlands

At present there is no global observation system for water stored in wetlands, nor are there good estimates of this term in the water budget. In some cases, for instance, the Sud Swamps of Africa, and the Pantanal of South America, the amount of water stored and its seasonal variability can be large. In the Section "Wetlands", options for remote sensing of lake, reservoir, and wetland storage are discussed.

Groundwater

Many countries have groundwater observation networks, although most are associated closely with groundwater

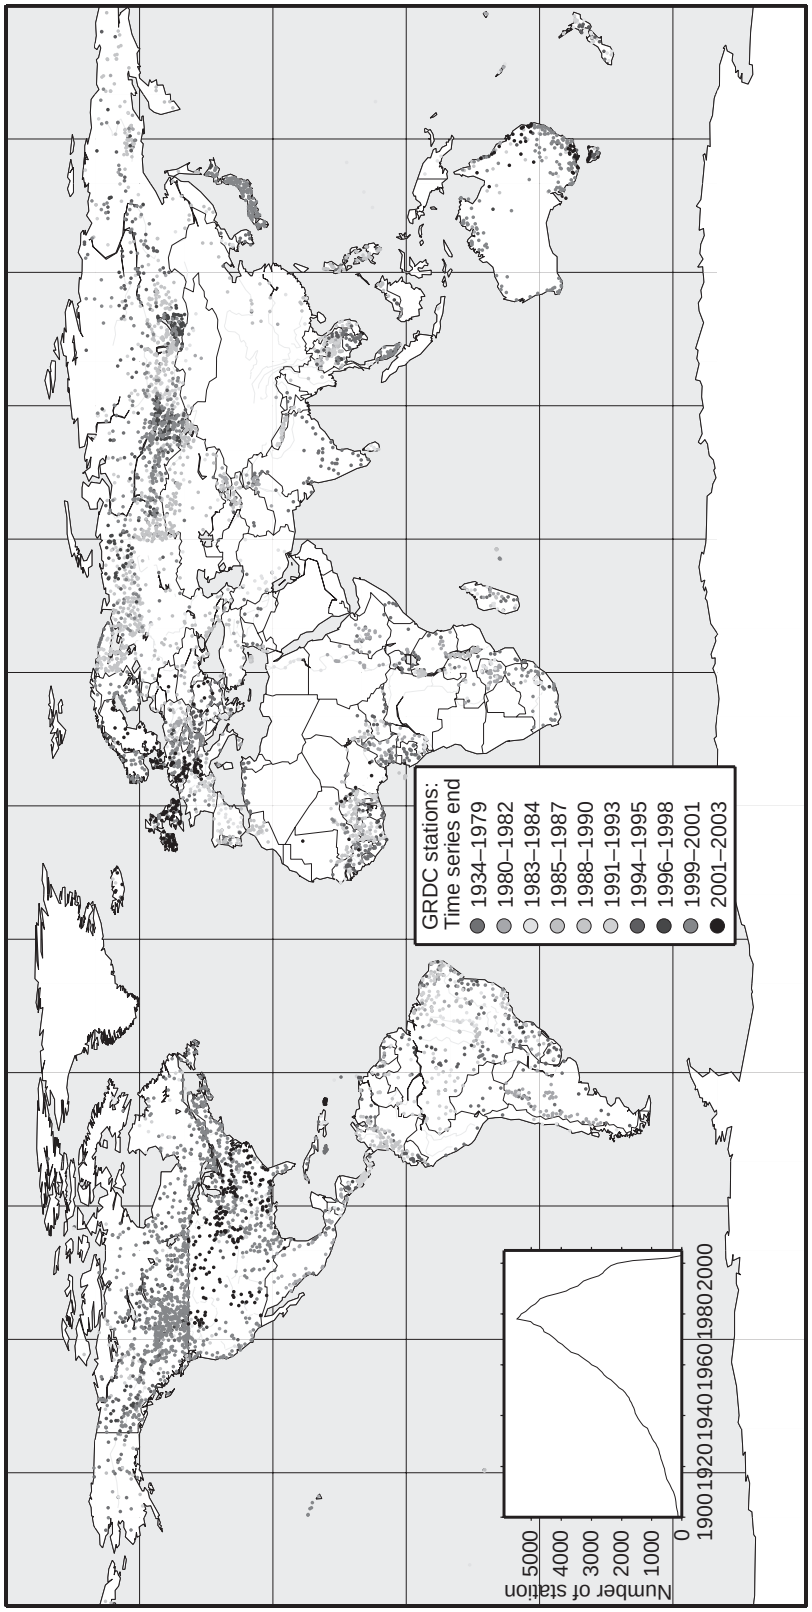

Figure 2 Location and length of period of record of stream discharge records archived by the Global Runoff Data Centre. Inset shows the number of stations archived per year; rapid drop off after about 1990 is due to combination of loss of stations and time lags in data acquisition and archiving. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

management efforts. A significant difficulty in constructing estimates of changes in subsurface storage from well level data is that pumped wells (or wells close to wells that are pumped) are not well suited to providing regional groundwater storage estimates. Unlike precipitation, streamflow, and other surface variables, there is no international archive center for groundwater data, and global data sets are generally sparse.

Soil Moisture

Soil moisture has historically been monitored primarily in association with agricultural concerns, so observations are poorly distributed in time and space. For water balance applications, it is important to monitor changes in soil moisture over a column, typically to a depth of one to several meters. This is most accurately done with weighing lysimeters that are constructed to weigh the soil column to a given depth. However, weighing lysimeters are fairly costly and exist mainly at research sites. Other methods that have been used include neutron probes and time domain reflectometry (TDR), as well as methods based on differential electrical resistance and thermal signatures of soil moisture. Neutron probes generally involve manual readings and hence do not produce time-continuous data, and for that reason have been less used recently. New methods, like TDR, require installation of probes at multiple depths if depth profiles are desired. Neutron probe measurements form the basis for a network of about 20 stations distributed over the state of Illinois, where weekly soil moisture observations have been collected for about 20 years. TDR is used in the Oklahoma Mesonet, which provides, for a shorter period, observations across Oklahoma.

Globally, soil moisture measurements have been collected in a number of countries, notably the Former Soviet Union and Mongolia. These observations, and others from many countries around the globe, have been archived in the Global Soil Moisture Data Bank (**`http://climate.envsci.rutgers.edu/soil_moisture`**; see Robock *et al.*, 2000 for a description). As in the United States, observations are generally poorly distributed in time and space, but nonetheless have proved useful for evaluation of model predictions of soil moisture temporal variability (see e.g. Nijssen *et al.*, 2001, who constructed a transect across Eurasia from the Global Soil Moisture Data Bank for comparison with model simulations). Recently, the United States has installed a skeletal network of soil moisture sensors (Soil Climate Analysis Network, SCAN) that use a frequency-shift dielectric measuring device at multiple depths of 1 m to provide column soil moisture profiles. These sensors provide time-continuous measurements.

A major concern with point measurements of soil moisture is that soil moisture is highly variable in space due to heterogeneity in soil properties at sub-meter spatial scales. However, point observations have nonetheless been shown to have some value for evaluation of temporal variability of area-average soil moistures, primarily because soil moisture is an integrator of precipitation, and therefore its temporal evolution (especially when integrated over depth) tends to respond to long-term (e.g. monthly to seasonal scale) variations in precipitation that usually have relatively long (spatial) correlation lengths. Although networks like SCAN are much too coarse to provide useful information about the continental water balance (other than for local evaluation of models intended for use at continental scales), it does appear that useful information can be provided about larger scales from networks with station separations of 100 km or greater, like those of the Oklahoma network (Vinnikov *et al.*, 1996).

Snow

Snow depth is a relatively easily made measurement, and many precipitation observations networks (e.g. the Cooperative Observer network in the United States) also make routine measurements of snow depth. In Canada, snow depth measurements are made in many parts of the country in lieu of direct measurement of solid precipitation to avoid difficulties with wind catch deficiencies in gauge observations of solid precipitation. The water equivalent of falling (or accumulated) snow is the variable of primary interest for water balance estimates, however, and is more difficult to measure. The most widely used approach has been the use of snow coring devices that are then weighed to estimate the water content of the snowpack. Snow course observations (that usually consist of multiple cores taken in a fixed location) have been widely used to estimate snowpacks in the western United States and are the basis for estimates of spring snowmelt runoff. Because snow course observations are labor intensive, they usually are only made a few times a year, typically near the time of maximum snow accumulation (usually early spring in mountainous areas). In areas with thin snowpacks, high spatial variability of snow depth makes accurate measurement of snow water equivalent difficult.

Over the last 20 years, automated weighing devices have replaced most manual snow courses in the United States. The device used by the Natural Resources Conservation Service in its SNOpack TELemetry (SNOTEL) network monitors pressure in a glycometh-filled bladder ("snow pillow") that reflects the weight, and hence water equivalent, of the overlying snowpack. These devices provide a near-continuous measurement of snow water equivalent (that is telemetered from the usually remote sites to a central data archiving facility). Problems with snow pillows include the influence of local effects that may not be averaged as well as by snow courses, and differential snow accumulation and ablation on and around the pillow due to thermal and other effects. Also, "bridging" of snow across the pillow to the surrounding snowpack, which reduces the snow load on

the pillow and leads to spurious measurements, can occur in some cases. Nonetheless, the US SNOTEL network has been fairly successful and provides the best time-continuous data available on the current status of snowpack in the western United States. Similar networks are used elsewhere, for example, in the mountainous areas of Canada.

Other approaches to measuring snow properties are available as well. Commercially available sonic sensors can provide continuous measurements of the distance from the sensor (that typically is suspended so as to look downward from a fixed measurement point) to the snow surface. Such measurement devices are well suited to remote installations from which the data may be telemetered to a central location. Snow water equivalent can be estimated by measuring the attenuation of naturally emitted gamma radiation through the snowpack. This requires a background measurement (typically performed shortly before the onset of the snow season) to which the measurements over snow are compared. The US National Weather Service operates an aircraft-based gamma system that is routinely flown over the upper Midwest and elsewhere. Their system provides transect estimates of snow water equivalent throughout the winter. There are some limitations to this method in deep snowpacks, where the signal can be too attenuated to provide accurate estimates, and over mountain topography where high spatial variability complicates the interpretation of measurements.

Glaciers and Ice Sheets

Estimates of global frozen water storage as alpine glaciers are based on glacier inventories of glacier (number and area of glaciers) and area-volume scaling methods to estimate total volume. Estimates of the increase or decrease in glacier storage rely on site-specific mass balance studies that make use of direct measurements of snow accumulation, ice and melt loss, and measurements of changes in glacier extent. The World Glacier Monitoring Service (WGMS) publishes estimates of changes of individual glaciers over time, as well as glacier inventories (Haeberli, 1998). WGMS maintains two data sets: a World Glacier Inventory (WGI) that documents the spatial variability of glaciers over the entire globe and the Fluctuations of Glaciers data set that provides a history of a larger number of glaciers, including changes in length, area, elevation, and mass. These data are especially useful for reconstructing the history of "indicator" glaciers that ideally represent the glacial changes in the surrounding region. Unfortunately, these indicator glaciers constitute only a very small fraction of all glaciers globally and their locations are not well distributed. Global monitoring of glacier change is arguably better accomplished by satellite observations (see Section "Glaciers and ice sheets"), and are the only feasible way to measure changes in ice storage in the two great global ice sheets, Greenland and Antarctica.

Atmospheric Moisture Storage and Fluxes

The two terms on the right-hand side of equation 2 are the atmospheric moisture storage and transport respectively. Radiosondes provide a means of directly estimating both of these terms. They consist of a small instrument pack that records and transmits atmospheric pressure, temperature, and humidity from a weather balloon (usually manually launched from a surface observing station) to a receiver at the observing station. The radio signal also allows the position of the balloon to be tracked, and hence its velocity. Usually, profiles of atmospheric moisture are reported at fixed pressure heights, which are specified through knowledge of the atmospheric pressure observations. Integration over the balloon profile provides an estimate of the total column moisture. By tracking the position of the balloon, it is also possible to estimate wind velocity profiles, and hence moisture transport, as well as the total column moisture content, which is the first term on the right-hand side of equation 2. Radiosondes observe moisture as vapor only, and not cloud liquid water or precipitation. Hence radiosonde-based estimates of both atmospheric moisture content and transport are most accurate during nonprecipitating periods (however, Ropelewski and Yarosh (1998) show that the contribution of cloud liquid water to seasonal variations in continental scale moisture budgets is small). Radiosondes are fairly costly (around $200 each), and hence operational launches are usually made 2–4 times per day (twice per day is the United States standard). Station separation is typically several hundred kilometers in parts of the globe that are well observed (e.g. the most populous parts of North American and Europe) and can be much larger elsewhere (e.g. the operational radiosonde network in South America has about 20 stations). Because there can be strong diurnal variations in atmospheric moisture content and low level winds, especially in the interior of the continents in summer, infrequent radiosonde launches can lead to considerable errors in estimates of the atmospheric moisture budget. For instance, Yarosh *et al.* (1999) found that long-term estimates of mean atmospheric convergence from twice-daily radiosondes over central United States resulted in underestimates of as much as 60% when compared with mean river discharge, and in general atmospheric water budget estimates based on radiosonde data alone are not as accurate as those based on atmospheric model analysis fields that are effectively used in the merger of models and observations, both *in situ* and satellite (see e.g. Roads *et al.* (2003)).

SATELLITE METHODS

Precipitation

Satellite estimation of precipitation is based on one or more of several general approaches. The first uses infrared

sensing of cloud-top temperatures to infer precipitation rates. A desirable aspect of these approaches is that the infrared channels on geostationary satellites provide relatively high-resolution (several km spatial resolution) continuous measurements of cloud-top temperatures. Among the most widely used infrared methods is the GOES Precipitation Index (GPI) of Arkin and Meisner (1987), which is based on the number of GOES pixels within a larger area (typically of order 50 km × 50 km) for which the cloud-top temperature is less than a threshold. In general, the GPI method is most successful for deep convection in the tropics. Numerous refinements of this approach have been reported, but all suffer from the disadvantage that the measurement is indirect and is only applicable to convective storms. Furthermore, even for convective storms, rain rates can vary widely for the same cloud-top temperature.

The primary current satellite-based alternative to infrared methods is based on passive microwave remote sensing, and utilizes the principle that the combined microwave emission signature of a precipitating atmosphere and the surface background differs from that of a dry atmosphere. The advantage of this method is that it is more closely related to the precipitation process than are methods based on cloud-top temperature. However, these methods suffer from the fact that all of the candidate sensors are flown in low earth orbit (LEO), and even so, spatial resolutions of the retrievals are quite coarse, typically several tens of kilometers. Furthermore, LEO implies instantaneous "snapshots", rather than continuous observations, and hence relatively large sampling errors. For this reason, most passive microwave products are only usable when aggregated to relatively long time intervals, unless some additional information source (e.g. *in situ* observations) are used to create a merged product. Recent work by Joyce *et al.* (2004) has attempted to combine passive microwave and infrared measurements so as to take advantage of the superior accuracy of passive microwave with the superior spatial resolution and temporal sampling of infrared algorithms.

The Tropical Rainfall Measurement Mission (TRMM) satellite includes three instruments that are targeted toward rainfall estimation: a precipitation radar, a microwave imager, and a near-infrared visible scanner. The precipitation radar provides valuable information about precipitation microphysics, and hence better rainfall rate information, than is possible from either infrared or passive microwave sensors alone. The main disadvantages of TRMM-based products are that the overpass is only roughly once per day, so sampling errors are severe, and the orbit goes only as far north and south of the equator as 35°. The planned Global Precipitation Measurement mission (GPM) is expected to alleviate both of these problems by providing, via a set of "drone" satellites with passive microwave sensors, three-hourly passive microwave signatures and daily radar overpasses. The orbit is expected to extend to roughly 60–65°. Nonetheless, sampling errors will remain a significant issue (Nijssen and Lettenmaier, 2004), as will errors associated with information transfer from the precipitation radar to the microwave drones.

Evapotranspiration

All satellite-based methods of estimating evapotranspiration are indirect. Most of them are based loosely on the principle that over an area, there will be some mixture of vegetation and bare soil, and that the evaporating vegetation will have a different thermal signature than bare soil. Hence, the most successful algorithms use visible and near-infrared sensors to extract a vegetation index (VI), and from the surface radiative temperature to an inference about the corresponding surface temperature T_s (Jiang and Islam, 2003). The MODIS algorithm, for instance, (Nishida *et al.*, 2003) is based on estimation of the evaporative fraction of a mixture of bare soil and vegetated surfaces, via isolation of end members of a vegetation index over a scene with a large enough number of pixels to allow estimation of the endpoint surface temperature signature. Most of these so-called VI–Ts (vegetation index–surface temperature) methods work best when they are used in combination with some *in situ* data (typically including one or more of surface wind, vapor pressure deficit, and net radiation and ground heat flux), although Nishida *et al.* show how some of the requirements for *in situ* data can be relaxed via various assumptions. Satellite evapotranspiration algorithms generally require some calibration and are susceptible to instrument change. On the other hand, they work with visible and near-IR data, of which there are a number of current (and past) candidate sensors.

Streamflow

Birkett *et al.* (2002) have demonstrated the capability to measure the stage of very large (width $>\sim$1–2 km) rivers using an existing radar altimeter (TOPEX/Poseidon) designed primarily for ocean altimetry. Figure 3, for example, taken from Birkett *et al.* (2002) shows that the observed river stage at selected locations along the Amazon River could be reproduced to within several tens of centimeters under most conditions. Alsdorf and Lettenmaier (2003) argue that the potential exists using current technology to provide stage estimates with accuracy well under 10 cm and for rivers with widths of order 100 m (vs. several kilometers for the Amazon cross sections analyzed by Birkett *et al.*). The main "weak link" in satellite estimation of river discharge is the inability to measure river velocity remotely. However, Birkett *et al.* (2002) show that surface slope is potentially measurable, which offers some hope that discharge might be derived via a combination

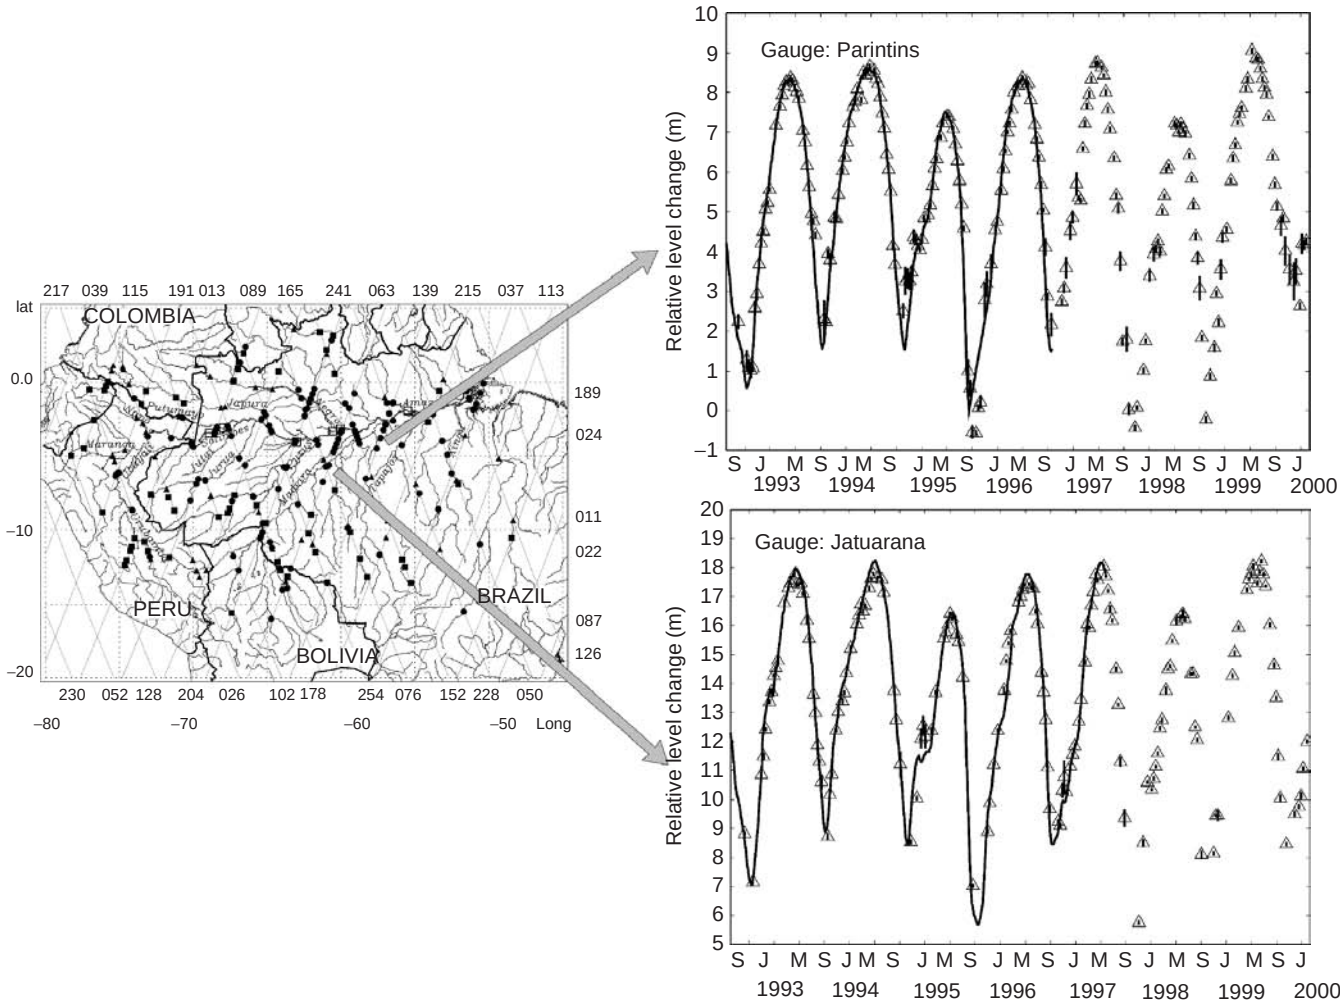

Figure 3 Remotely sensed (from TOPEX-POSEIDON; triangles) and *in situ* (solid black) measurements of river stage at two locations in the Amazon basin (Reproduced from Birkett *et al.* (2002) by permission of American Geophysical Union (AGU))

of stage measurements and hydraulic calculations for discharge, although complications remain in determining the channel cross section and its hydraulic characteristics (e.g. roughness).

Lake and Reservoir Storage

Radar altimeters have the capability to measure the stage of very large lakes and wetlands. Birkett (1995) have shown the capability to observe the stage of large water bodies such as large lakes in Africa to accuracies of about 10 cm using existing satellite radar altimetry. Existing radar altimeters (TOPEX/Poseidon and Jason-1) are designed to provide accurate measurements of the ocean surface, but over relatively large footprints. However, technology exists via hardware and signal processing to provide estimates of water surface elevation for much smaller (e.g. inland) water bodies, with spatial dimensions well less than 1 km (Alsdorf *et al.*, 2003). The potential also exists to provide sub-1 cm accuracy altimetry over relatively small footprints using laser altimetry (e.g. ICESAT).

Absent vegetation, lake, and reservoir extent can be measured by a variety of visible band sensors, or in the presence of flooded vegetation, Synthetic Aperture Radar (SAR) with relatively long wavelength (L band) has been demonstrated. While open water extent of large water bodies is measurable using operational satellites (LandSat, AVHRR), the accuracy of horizontal extent measurements is determined by sensor spatial resolution, and detection of storage change for shallow water bodies is generally less accurate than for deep ones.

Wetlands

Satellite-based methods for detection of change of storage in wetlands are essentially the same as those that are

applicable to lakes and reservoirs. Radar altimeters are sensitive to flooded vegetation, so an adequate open water footprint (currently order of 10 km) is essential, although there is the potential to reduce this considerably. Feasibility of detecting changes in storage in the Sud Swamps, for instance, has been demonstrated by Birkett (1995). The same complications noted in Section "Lake and reservoir storage" for lakes and reservoirs pertain to the estimation of the extent of wetlands, which usually involve determination of the extent of flooding of vegetation, which is best accomplished by L-band radar.

Groundwater

There is no existing remote sensing method that is able to measure directly (or indirectly for that matter) groundwater levels. However, the microgravity sensor onboard the Gravity Recovery and Climate Experiment (GRACE) has the potential to provide indirect large area ($o(10^6\ km^2)$) estimates of subsurface moisture variations in time. The microgravity sensor records variations in the total gravity field "felt" by the satellite. Over relatively short time intervals (order of a month or so), these result primarily from variations in moisture content of the atmosphere, the land surface (lakes, wetlands, snow), and the subsurface (soil moisture, groundwater). Atmospheric moisture is relatively well observed (or estimated by weather prediction models that combine observations and model predictions via data assimilation) to the accuracies required to adjust for the atmospheric influence. The other terms – snow, surface water, and soil moisture – can be estimated to varying accuracy via land surface modeling and land data assimilation, although the supporting models and observations are only now evolving. Swenson *et al.* (2003) have performed synthetic experiments to estimate the accuracy with which GRACE data will be able to estimate variations in total (surface plus subsurface) water storage at seasonal time intervals and at the scale of large continental river basins. Discussions have begun on a "next generation" microgravity sensor that might have an effective footprint of the order of $10^4\ km^2$. At this spatial resolution, the estimation of the dynamics of regional groundwater systems will become possible.

Soil Moisture

The microwave emission brightness temperature from the land surface varies strongly with soil moisture content to a depth of approximately one-quarter of the wavelength. Thus passive microwave measurements at lower frequencies (longer wavelengths) provide better estimates of the near-surface soil moisture and are less influenced by overlaying vegetation. Additionally, the sensitivity of the microwave brightness temperature to soil moisture is larger at lower frequencies. Collectively, these factors dictate that sensors that measure brightness temperatures at low microwave frequencies are preferred for estimating surface soil moisture. This desire to measure at the lowest possible frequency is countered by the fact that the antenna size (e.g. diameter) increases with wavelength for a fixed spatial resolution. Because of technological limitations of antenna size (and hence spatial resolution with which soil moisture variations can be inferred), the lowest frequency passive microwave sensor that has reasonable spatial resolution is L-band (~1.4 GHz). At this frequency, soil moisture can be retrieved reliably from vegetated surfaces with a vegetation water content of roughly $5\ kg\ m^2$ (corresponding approximately to dense cropland or shrubs, but not to forests).

Several passive microwave instruments have been flown with somewhat shorter wavelengths that have facilitated proof of concept studies targeted at areas with relatively sparse vegetation. For instance, the Scanning Multichannel Microwave Radiometer (SMMR) instrument was flown on the SeaSat and Nimbus-7 satellites from the 1970s to mid-1987. Its lowest frequency was 6.8 GHz at which the footprint was about 150 km. Owe *et al.* (1992) evaluated the feasibility of estimating surface soil moisture over a relatively sparsely vegetated (shrub/grass savannah) area of southern Africa. Some attempts have been made to use the higher frequency 19 GHz channel of the operational Defense Meteorological Satellite Program (DMSP) Special Sensor Microwave/Imager (SSM/I) instruments. While the footprint at this frequency is about 25 km, the frequency is so high that except in areas of very sparse vegetation, soil moisture products derived from SSM/I primarily reflect vegetation moisture. An intermediate frequency (10.7 GHz) is available from the (TRMM) microwave imager (TMI). Although the TRMM orbital inclination of about 35° precludes observations over temperate and high latitudes, some success has been demonstrated with TMI-based soil moisture products in areas of sparse vegetation, like the US Southern Great Plains (Gao *et al.*, 2004). The Advanced Microwave Sounding Radiometer (AMSR) was launched on the NASA EOS Earth Observing System Aqua satellite in mid-2002. Its lowest frequency (6.9 GHz) is close to that as SSMR, but the spatial resolution is considerably higher due to a larger antenna. However, early attempts to derive soil moisture products from the AMSR-E 6.9 GHz channel have been confounded by radio interference, especially over North American and northern Europe.

Both the European Space Agency and NASA have now planned launches of L-band passive radiometers designed specifically for soil moisture measurement. The European Soil Moisture and Ocean Salinity (SMOS) instrument will most likely be launched first. It is a two-dimensional instrument and will use a Y-shaped antenna that will support a product spatial resolution of about 50 km. The NASA Earth System Pathfinder HYDROS mission uses a somewhat different approach. It will consist of a multipolarization L-band radiometer capable of producing a 40-km spatial

resolution product, and an unfocused L-band Synthetic Aperture Radar that will allow disaggregation of the passive microwave product to a spatial resolution of 1–3 km. It will have a revisit time of 2–3 days over all global land areas. It is expected to be launched in about 2010.

Snow

Snow areal extent can be observed via visible sensors and a variety of algorithms have been developed. In the United States, the NOAA Operational Hydrologic Remote Sensing Center produces an operational product on the basis of daily GOES and AVHRR data at approximately 1 km spatial resolution. Coarser resolution global products that use both AVHRR and SSM/I passive microwave sensors are produced for operational use by the National Environmental Satellite Data Service (NESDIS). Higher resolution products based on LandSat TM and other high-resolution sensors have also been developed. These high-resolution products are better able to resolve partial area coverage of snow. Among the key problems with satellite snow areal extent from visible band sensors are discrimination of clouds from snow and detection of snow under forest cover. More recent MODIS-based products at 500 m resolution are available daily in near real time, and are better able to discriminate snow from clouds and to detect snow under forest canopies than AVHRR-based products (Maurer *et al.*, 2002).

Passive microwave algorithms can be used to estimate snow water equivalent (SWE). An operational product based on SSM/I 37 and 85 GHz channels developed by the Meteorological Service of Canada is used operationally in Canada over areas with thin, cold snowpacks (prairies and tundra). The spatial resolution of this product is relatively coarse (approximately 25 km). AMSR-based SWE products are currently becoming available. Problems with all passive microwave SWE products include dependence of brightness temperature, and hence SWE estimates, on grain size, saturation of the signal from deep snowpacks, and inability to provide measurements for wet snow (although wet and dry snow can be discriminated). Radar-based algorithms have also been researched and show some promise, although they generally require more surface information (e.g. surface roughness) than passive microwave methods.

Glaciers and Ice Sheets

The Glacier Land Ice Measurements from Space (GLIMS) program is an effort to estimate changes in glacier extent and storage using satellite remote sensing such as interferometric SAR (various instruments) and lidar altimetry (ICESAT). However, this effort has been underway for only a few years. Use of older visible band satellite data (covering the last three decades) has facilitated estimates of change of glacier extent, but these data are not able to provide the surface topographic measurements that are needed to estimate changes in glacier mass storage accurately. For the two great ice sheets, Antarctica and Greenland, satellite measurements are the only feasible ways to measure change in storage. Although changes in ice sheet volume and area are increasingly easier to obtain, changes in mass continue to be a problem due to a lack of information on density over the ice sheet and submarine mass loss though bottom melting of the ice shelves.

Atmospheric Moisture Storage and Fluxes

Because of the high cost of radiosonde launches (around $200 per instrument package, not including labor costs) and the sparseness of the global network, there has long been an interest in remote sensing alternatives. Passive microwave sounders have been used since the 1970s and are able to retrieve profiles of atmospheric moisture and temperature at horizontal resolutions that have improved to less than 1° latitude–longitude, and vertical resolutions that now approach 1 km. The most recent series of operational instruments are the Advanced Microwave Sounding Unit (AMSU) that flies on the NOAA operational satellites. These data are assimilated into the global weather prediction models run by most major weather centers. Microwave sounding units do not supply information about the atmospheric wind profile, which is a major source of error in atmospheric moisture flux estimates (second term on the right-hand side of equation 2) globally. Furthermore, estimates of moisture flux and total column moisture content based on microwave soundings are impeded by the lack of detailed information in the lower troposphere. On the other hand, analysis fields of moisture profiles and fluxes produced via data assimilation in global models are considerably more accurate than estimates derived directly from observations, which implies that despite the absence of wind information, there is considerable information content in the satellite profiles.

Recently, options for retrieving atmospheric moisture information from global positioning satellites have been pursued. The basis of the method is that the deformation in the signal path (hence time delay) through the atmosphere between two GPS satellites is a function primarily of the moisture content of the atmosphere along the path. Hence, it is possible to infer an effective moisture content along the path. Furthermore, because many pairs of satellites are available, it is possible at any time to retrieve moisture information along many paths at a range of heights in the atmosphere. This information is fundamentally different from that obtained from sounding units, though it does not produce a consistent profile, but rather information for a series of nearly random paths. On the other hand, there is no constraint on vertical resolution; the path depends only on the location of the two satellites at the time the signal was sent and received. Like sounding data, the power of these observations will lie in the development

of data assimilation methods that can effectively exploit the information. In common with microwave soundings, no information is provided about wind.

SUMMARY

Understanding the global water cycle demands measurements that allow estimation of the dominant hydrologic storages and fluxes at spatial scales from local to continental and global, and at temporal scales sufficient to resolve the diurnal variations that are driven by Earth's ultimate source of energy, the Sun. The arrival of the satellite era over 30 years ago has lead to an earth system science approach to observations that is perhaps most apparent in the genesis of NASA's EOS satellites. Nonetheless, satellites are unable to measure, or to measure accurately, a number of the key water cycle storage and flux terms globally. For instance, while great strides have been made in satellite estimation of precipitation, and atmospheric moisture and moisture fluxes, key land surface terms like streamflow and lake and wetland storage, soil moisture, and groundwater are poorly observed, or not at all, via remote sensing. The global networks of *in situ* observations that are needed to provide estimates of these water cycle terms generally are unable to do so – in some cases because the observations are so sparse as to provide adequate global coverage (as in the case of soil moisture), and in others because of data access problems and/or lack of coordination among nations (as in the case of streamflow data), or due to a combination of these and other limitations (as in the case of groundwater data).

Generally, *in situ* networks of water cycle and other climate-related data have been in the decline over the last several decades, due in large part to cost, especially in remote areas, but for other reasons that are more difficult to ascertain as well. It appears that the trend with respect to global observations is toward greater reliance on satellite remote sensing, and in some cases, improved technology (e.g. as in the case of soil moisture) will doubtless lead to global observations with characteristics that cannot reasonable be matched by *in situ* networks. In others, it is less likely that the needs for global observations can be met from remote sensing. Furthermore, even in cases where remote sensing can eventually provide good estimates of water cycle variables, there will remain a need for high quality *in situ* data for algorithm testing and evaluation, and for evaluation of differences between historic *in situ*-based and satellite-based observations.

176: Observations of the Global Water Cycle – Satellites

FRANKLIN R ROBERTSON

NASA/Marshall Space Flight Center, Huntsville, AL, US

Satellite observations of Earth's climate system have evolved dramatically since the first crude video images of cloud cover taken over 40 years ago. Today, spaceborne measurements of precipitation, cloud attributes, radiative fluxes, and surface properties make crucial contributions to monitoring key processes and the evolving state of the planet's hydrologic cycle. We illustrate how this maturing capability has enabled study of the hydrologic cycle in a global context that goes beyond consideration of local or regional water balance. Remote sensing has become a key technology for addressing such interdisciplinary questions as whether the global hydrologic cycle is changing and if so how? What key processes linking the atmosphere, biosphere, and hydrosphere are at play, and what are the prospects for predicting extreme hydrologic events of significant societal impact? The discussion is motivated first by considering these key science problems. Following a brief overview of key remote sensing concepts, we then survey existing capabilities to determine various quantities such as precipitation, evaporation, soil moisture, turbulent fluxes, cloud cover, water vapor, and the links to radiative fluxes. Both successes and persisting challenges are discussed. An assessment of where we stand in developing an integrated picture of the hydrologic cycle and climate is presented, along with anticipated improvements in the future measurements.

In the context of climate, we demonstrate that in spite of substantial improvements in determining hydrologic variables and processes from space, some key challenges remain. Our examination here of signals in precipitation, evaporation, and radiative fluxes suggests that at present we can detect regional patterns of interannual variability with considerable skill; we can resolve globally integrated signals with only modest certainty; and for the most part, we have little confidence yet in decadal changes or trends. Nevertheless, the situation is encouraging because in many cases these retrievals have been done without regard to intercalibration of sensor data streams, and in the case of operational retrievals, algorithm modifications which result in spurious trends. Careful reprocessing is likely to yield substantial benefits. Future planned missions with active remote sensing at 94 GHz (CloudSat) and interferometric measurements at 1.4 GHz promise to expand our knowledge of hydrologic processes of crucial importance to climate.

INTRODUCTION: WHY A REMOTE SENSING APPROACH?

In 2003, the National Aeronautics and Space Administration (NASA) launched the Aqua spacecraft with the mission of monitoring the global hydrologic cycle. The diverse sensors aboard, spanning the visible to microwave portion of the spectrum, represent an amazing evolution of remote sensing from 1960, when the first grainy video pictures of clouds were beamed back to Earth from the weather satellite Television Infrared Operational Satellite (TIROS) I. (See IEEE Transactions on Geoscience and Remote Sensing, February 2003, for a Special Issue on the EOS Aqua mission). Aqua joins Terra, TRMM (Tropical Rainfall Measuring Mission), Envisat and satellite platforms from various other international efforts that now provide monitoring and research capability for the global water cycle. Motivation for this impressive expansion of measurement capabilities for viewing our planet from space has come from the challenge of developing a globally extensive yet locally resolved description of the planet's water cycle, as well as its connections to Earth's radiative balance and

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

biogeochemical processes. Water is dispersed over atmosphere, ocean, and land/biosphere. It exists in three phases: in the atmosphere and ocean, as fluid parts of the earth system, as life-sustaining liquid in the biosphere, and as seasonal and "permanent" ice in the cryosphere. For various cost and technological reasons, comprehensive *in situ* measurements of these reservoirs and the fluxes of water and energy between them are not feasible. A prominent deficiency is the lack of measurements in the vast, uninhabited regions of the globe such as the oceans, polar regions, deserts, and tropical rainforests. Aside from the existence of large data-void areas, even existing available point measurements of rainfall, snow accumulation, and turbulent heat fluxes are often difficult to interpret. Sampling biases and representativeness of point measurements (especially for rainfall) are difficult to contend with, when correlation length and timescales of hydrologic processes are far smaller than instrument spacing.

Remote sensing advances have allowed us to relax some of these sampling uncertainties and obtain a more complete picture of the distribution of water over the planet, documenting, for example, how exchanges of water between the atmosphere and surface are related to radiative, chemical, and biological processes. Global mapping of cloud properties, precipitation, water vapor, sea ice, snowcover, ocean topography and heat content, and other variables is now routinely done on a daily basis. Much progress has been made in determining the optical and microphysical properties of clouds, their bulk mass of liquid and ice water, some coarse vertical structure of water substance, and how winds redistribute water (and heat) on scales as small as individual storm systems that affect our weather. At the same time, satellite platforms have provided the ability to relate these atmospheric properties to sea-surface temperature and near-surface soil-moisture variations during the past two decades and thereby improved our understanding of year-to-year climate disruptions (e.g. *El Nino*) and even trends in certain variables (sea-ice distributions, surface temperature).

To be sure, there are significant remaining challenges for improving remote sensing of the global water cycle. The error properties of current sensors and their algorithms are far larger and less well understood than desirable. Historically, remote sensing has been done primarily with passive instruments, interpreting Earth's emitted radiation in terms of geophysical variables. Passive systems have certain limitations, most notably, the inability to provide detailed atmospheric vertical profiling. The inability to directly sense soil moisture several centimeters below the surface even with today's advanced passive microwave systems is another example. Technological considerations also currently restrict geostationary satellite measurements to visible and infrared (IR) wavelengths, which provide only cloud-top temperature and brightness information. This renders monitoring the life cycle of rainfall and the evolution of cloud systems from space problematic. Even the stability of satellite orbits over time induces diurnal sampling biases that, over time, may contribute substantially to retrieval uncertainties. However, these technology challenges are not insurmountable and are currently being addressed. Active systems that emit and capture reflected radiation are the promise of the future. Radar measurements from TRMM have provided unprecedented surveys of vertical profiling of precipitation.

As we begin this survey, we need to clarify just what we mean by the global water cycle. The most inclusive description of the hydrologic cycle of the planet encompasses not only the mass cycling of water but also connections to heat and radiation balance, as well as the role of water in biological processes like net primary productivity. In a sense, the water cycle is a key signature of the "metabolic rate" of the planet. While this integrated view is extremely important, we will, for the purposes of a tractable discussion, limit our focus to the physical components of the global water cycle and to some key connections to radiation and the planetary energy balance. Consider, for example, that although the climate system is very near radiative balance at the top of atmosphere (TOA), the atmosphere itself and remaining land/ocean/ice complex are not. Balancing the global mean $168\,W\,m^{-2}$ of solar energy absorbed at the earth's surface are a net cooling of $66\,W\,m^{-2}$ from net long-wave radiative flux, $24\,W\,m^{-2}$ by sensible heat flux, and $78\,W\,m^{-2}$ by latent heat flux (Kiehl and Trenberth, 1997). Realization of evaporation as latent heat of condensation in the atmosphere has major consequences and, in fact, determines, in complex fashion, how radiative fluxes are partitioned through the earth's climate system. Paradoxically, while only a miniscule amount of water on this planet resides in the atmosphere, its controlling effect on habitability of the planet through impacts on the heat budget is prominent. Our discussion focuses primarily on remote sensing capabilities from space that are most relevant to the perspective of climate. We shall emphasize certain science questions that drive observational requirements and examine the current capabilities and weaknesses of the observational strategy. We conclude with some comments on expected future observational systems.

MOTIVATING/DRIVING QUESTIONS

Improved satellite observations have stimulated research on interdisciplinary science topics that span meteorology and climate, hydrology, oceanography, and other Earth sciences. In part, this has been because space-based remote sensing requires that algorithms and retrieval methodologies contend simultaneously with atmospheric and surface effects on upwelling radiation. Solving this issue physically yields information about the surface geophysical and biophysical

properties and, to a large extent, the turbulent and radiative energy fluxes that link the atmosphere to the varied underlying surface. So besides the added benefit of global coverage, an improved determination of the physical processes that link water and energy reservoirs is now available to complement the historical point flux measurements gathered during field campaigns. With the growing length of these data sets, we are now able to ask questions about the climate system as a whole – its natural modes of variability and possible signatures of anthropogenic impacts. The global hydrologic cycle is at the center of many of these issues that ultimately have great practical concern in agriculture, land use practices, transportation, health and public policy. These scientific issues have been articulated by a number of intergovernmental agencies and panels [the Global Water and Energy Cycle Experiment (GEWEX) and the Climate Variability and Predictability Programme (CLIVAR), both supported under the World Climate Research Program (WCRP), the Intergovernmental Panel on Climate Change (IPCC), and national space agencies (NASA), the European Space Agency (ESA), and the Japan Aerospace Exploration Agency (JAXA)]. We briefly examine some of these questions here in order to provide context to subsequent discussion of remote sensing challenges.

- *What is magnitude of hydrologic cycle and is it changing with time?* How do fluxes of water and energy and their stores change in response to natural interannual to decadal variations, and are there signals of anthropogenic change? How, if at all, are rainfall and evaporation changing with time? While measurements of rainfall for many decades and even longer exist at specific points around the world, the variability of rainfall is poorly sampled even in densely populated countries, and conventional measurements are virtually absent over the ocean and other data-sparse regions. Evaporation measurements are even less robust in coverage, particularly outside agricultural regions. Satellite estimates, though not as mature as those for precipitation, hold significant promise here.
- *How do clouds and surface processes control mass cycling of water and associated energy exchanges?* Clouds affect surface radiative fluxes directly but, at the same time, respond to surface energy fluxes. Water and energy availability controls evaporation and transpiration in determining the surface energy balance and thermodynamic energy in the boundary layer. Atmospheric transients tap and release this energy, producing clouds that have systematic organization reflecting atmospheric dynamical scales. These processes are so complex over land that even from space not all the components are adequately observed. Land data assimilation techniques to merge observations with physical models are a fundamental strategy to help answer this question.
- *How are extreme hydrologic events related to climate variability?* Atmospheric transients that induce local hydrologic events (either droughts or floods) are organized by, and, in turn, influence, large-scale atmospheric flow features (e.g. jet streams). Anomalous atmospheric planetary wave configurations and circulation changes may arise from internal atmospheric instabilities, from SST forcing associated with the *El Nino*-Southern Oscillation (ENSO) or perhaps in response to low frequency ocean circulations (e.g. Atlantic meridional overturning). Remote sensing helps monitor the energy exchanges between the atmosphere and surface, thereby sorting out precursors to hydrologic events. Over longer periods, this information aids in developing statistical models of how extreme events are associated with disruptions or anomalies in average climatic conditions. The extent to which anthropogenic changes to the atmosphere and land surface might influence the frequency and intensity of extreme events is also an important issue.
- *What potential exists for predictability and what do we need to realize it?* If we can understand and quantify these processes, can we then determine their predictability, and can the physics in our numerical models and the forcing observations from space be used to realize this predictability to its inherent deterministic and stochastic limits? Because the capacity to store heat energy in the oceans, and, to a lesser extent, in soil, is far greater than in the atmosphere, these reservoirs of energy are thought to contain "memory" or boundary conditions that are useful beyond the theoretical two-week limit to deterministic weather forecasting. The slow evolution of SSTs or soil moisture and snowcover may, in a sense, "load the dice" such that seasonal or multiyear predictions may be statistically much more useful than climatology for many applications. Use of remote sensing to build a quantitative picture of covariability of the atmosphere, land surface, and oceans is central to this capability.

This list is clearly not exhaustive but represents the intersection of the water cycle with weather, hydrology, and the physical climate system. These questions require that in studying the water cycle we maintain focus on the associated radiative processes, on transports of energy by the atmosphere and ocean, and on energy exchanges between the atmosphere and underlying ocean, land/ocean, and cryosphere. Not only is it important to resolve and retrieve the physical attributes of processes and variables (e.g. cloud microphysical and radiative properties and soil-moisture availability) but we must also construct and maintain sufficiently long records to understand variability on interannual to decadal scales. Many of our evolving data sets are just beginning to meet this last criterion, making observational study of these questions now accessible.

A BRIEF BACKGROUND OF THE REMOTE SENSING PROBLEM

Remote sensing is a classic inverse problem in that measurements are collected, say, of upwelling radiation at different frequencies, representing the convolved effects of many geophysical signals. These measurements do not by themselves define a unique solution to the retrieval of a given variable and typically are supplemented by *a priori* constraining "guesses". However, one key concept to be noted is that remote sensing of water using different regions of the electromagnetic spectrum reveals different physical attributes of clouds, water vapor or surface water, and energy states. Visible and IR measurements from space provide key measurements for two reasons. First, it is in these wavelengths that most of the Sun's energy is intercepted by the earth system and then reradiated to space. Thus, we are measuring the direct effects of clouds and moisture on radiant energy exchanges that drive weather, climate, and the hydrologic cycle. Because these wavelengths are shorter than or nearly the same as the characteristic dimensions of cloud particles, they are strongly reflected and absorbed. Therefore, when viewing cloudy atmospheres, we are typically only seeing into the top portions of clouds – in a sense we are seeing the optical and thermal morphology of the cloud tops. But it is these very energy fluxes that help connect the global radiation budget to the earth's hydrologic cycle and heat budget. Second, because of the wavelength, visible/IR spaceborne detectors can provide very high spatial resolution for imaging and sounding – typically footprints of a few kilometers or less. Cloud fields and surface vegetation have much fine structure so that if we wish to monitor precipitating clouds, soil-moisture gradients, or snow cover in elevated terrain, these measurements provide a unique way of sampling these features globally.

In contrast, microwave remote sensing measures radiation at wavelengths of several millimeters to centimeters, which is larger than characteristic sizes of cloud droplets and even most precipitating raindrops or frozen particles. Consequently, there is a weaker response to condensate in the atmosphere that allows microwave sensors to sense upwelling radiation from much deeper in clouds and frequently from the surface below. Instead of just seeing the hydrometeors at cloud top, the entire mass of condensate in the clouds affects the upwelling radiation, either absorbing and re-emitting energy or scattering it from the field of view depending on the wavelength and size of the particles. Wavelength-dependent sensitivity to the *entire mass of hydrometeors* by upwelling radiation from the ocean or land-surface backgrounds gives radiative flux measurements that are much more closely related to bulk cloud water and ice mass and surface precipitation rate.

One might gain the impression that with these two classes of measurements – visible/IR and microwave – quantifying the hydrologic cycle is relatively straightforward. Unfortunately, there are key uncertainties that limit us. Size, shape, and density of hydrometeor populations are each important to varying degrees, as are the atmospheric thermodynamic profiles. Surface characteristics of emissivity and roughness respond to soil moisture, vegetative cover, sea roughness, and wind speed in a dramatic fashion. This provides both problems and opportunities. Some additional *a priori* information is needed about these factors if one is trying to produce retrievals of atmospheric variables. On the other hand, by viewing the surface through an undisturbed (cloud free) atmosphere, the frequency dependence, in the way these geophysical characteristics present themselves, can yield much information about soil moisture, surface temperature, emissivity, ocean surface wind stress, and other factors important to surface hydrologic processes.

CURRENT CAPABILITIES

We examine now the major components of the hydrologic cycle, beginning with precipitation and evaporation. As primary source and sink terms of the global water balance, these variables are treated in some depth. Evapotranspiration and soil moisture are also discussed in the overall context of land-surface data assimilation strategies. Clouds and water vapor are treated largely in relation to their important effects on radiative fluxes. Finally, we turn our focus on the cryosphere, noting some of the challenges in this more slowly evolving component of the global water cycle.

Precipitation

Attempts to estimate precipitation from spaceborne remote sensing have a long history. Most early studies were indirect methods that inferred rain accumulation on the basis of the presence of cloud cover alone (Woodley and Sancho, 1971; Martin and Suomi, 1972; Griffith *et al.*, 1978). The physics behind these approaches was that cold IR and bright (visible) clouds were deep and thick and so offered the most probable location of rainfall. The IR technique was investigated systematically by Arkin (1979) and Richards and Arkin (1981) in studies of tropical rainfall in the GATE (Global Atmospheric Research Program Atlantic Tropical Experiment) region. They showed that under appropriate time- and space-averaging, precipitation estimates useful for climate diagnostics studies could be achieved using geostationary IR imagery. This approach, applied to the global suite of geostationary imagers, eventually became the basis for the initial Global Precipitation Climatology Project (GPCP) on rainfall climatology. While these cloud-top temperature statistics do not measure rainfall *per se*, their statistical relationship to rainfall and their high temporal availability (as frequently as every hour) have

made them an integral component to the mix of information used to monitor global rainfall even today. The historical record of these observations stretches back to the mid-1970s, making these measurements a valuable complement to microwave data, which have poor sampling before late 1987.

The sensing of actual precipitating hydrometeors from space began with the Nimbus-5 Electrically Scanning Microwave Radiometer (ESMR), a passive microwave imaging sensor (Wilheit *et al.*, 1977). These measurements clearly demonstrated the radiometrically warm signature of raindrops (and cloud water droplets) over cold ocean backgrounds. Because the ocean surface is highly polarized, its emissivity is small and the ocean looks "cold" radiometrically. In contrast, liquid water in the atmosphere emits unpolarized microwave radiation and the liquid hydrometeors appear as "warm" regions against the cold ocean background. Over land, surface emissivity is much larger and more variable, so the liquid water emission signature is largely indistinguishable against the land background. However, in a series of papers (Wilheit *et al.*, 1982; Spencer *et al.*, 1983; Spencer *et al.*, 1989) it was shown that an alternative technique that recognizes the scattering of upwelling radiation by large raindrops and precipitating ice hydrometeors present above the freezing level can be effective in detecting rainfall.

Over the past two decades these complementary methodologies of passive microwave emission and scattering and cloud-top temperature and optical brightness have been expanded, refined, and verified for the purposes of climate and weather studies. In various forms, they presently constitute the basis for international efforts to systematically monitor rainfall from space. The most significant recent advance, however, has come with active radar remote sensing from TRMM, (Simpson *et al.*, 1988) jointly developed by the NASA and JAXA. Using a single frequency radar at 13.8 GHz, this joint US/Japanese mission has yielded unprecedented vertical structure of precipitation reflectivity and rainfall. Range-gating the energy returned from precipitating clouds allows vertical resolution of better than 250 m. Instantaneous spatial resolution of about 4 km exceeds that of conventional passive microwave sensors. For a more extensive discussion of remote sensing techniques and data set production the reader is referred to **Chapter 64, Satellite-based Estimation of Precipitation Using Microwave Sensors, Volume 2**. In what follows here, we focus more on how these methodologies have provided signals of climate variability.

Regime Dependencies in Tropical Precipitation

One of the major illuminating results from the TRMM precipitation radar (PR) has been the confirmation of differing precipitation regimes over the tropical regions. From studies combining TRMM PR reflectivities, TRMM Microwave Imager (TMI) 85-GHz-deep convective ice scattering, and Lightning Imaging Sensor (LIS) lightning flash densities (Boccippio *et al.*, 2000; Toracinta and Zipser, 2001; Petersen and Rutledge, 2001), there has emerged confirmation of distinct variations in vertical structure and intensity of convection, particularly over tropical "continental" locations. On a seasonal mean basis, distinct differences over the Amazon basin are noted with a more "maritime-like" weak reflectivity regime during the wet season and more strongly electrified, strong ice-scattering regime during the dry season (Petersen and Rutledge, 2001). There is also evidence of differing relationships between deep convective ice frequency and surface rain rate in the Amazon as compared to equatorial Africa (McCollum *et al.*, 2000). Although convection over tropical land tends to have higher vertical penetrations of a given reflectivity intensity (e.g. 30 dBZ), much higher lightning density (10 to $10^2 \times$ frequency) and more intense 85-GHzice scattering (Toracinta *et al.*, 2002), there frequently exist transitions to periods of "maritime-like" character in precipitation (e.g. low reflectivities above the freezing level, reduced lightning, and ice scattering), which seem to have variability on intraseasonal timescales. These variations contrast with precipitation systems over oceanic convergence zones, which are generally more muted in variability because boundary-layer moisture and temperature are typically nearer equilibrium with the ocean surface. Here, large accumulations of convective, available potential energy to fuel strong updrafts and produce hail or large graupel are quite rare. Even for these regimes, however, there is evidence that intraseasonal modulation of low-level moisture can serve as an agent to alter the hydrometeor characteristics within organized, deep precipitating systems.

Vertical profiles of hydrometeors (raindrops, graupel, cloud, water, and ice) are closely linked to atmospheric condensational heating profiles. One TRMM algorithm, the Goddard Profiling Algorithm, GPROF (Kummerow *et al.*, 2001), derives hydrometeor profiles by statistically associating TMI-measured brightness temperatures with *a priori* information from cloud model predictions of hydrometeors and associated modeled brightness temperatures. These estimates also take into account cloud water and ice and thus complement the direct measurements of precipitation from PR. Along with maturing TRMM algorithms for diabatic heating, (e.g. Tao *et al.*, 2001) these global, tropical retrievals will be useful in studies of how atmospheric heating affects atmospheric dynamics and how precipitation is organized on regional and global scales. Follow-on missions to measure precipitation and vertical profile information at higher latitudes are expected in the future.

Climate Variations (ENSO Signals)

It is well documented that El Nino/Southern Oscillation (ENSO) events, with marked SST changes over the tropical

oceans, produce significant regional changes in precipitation, water vapor, and radiative fluxes in the tropics (e.g. Ropelewski and Halpert, 1987; Sun and Trenberth, 1998; Curtis and Adler, 2000). Berg *et al.* (2002) have recently documented the distinct differences between precipitation structure over the eastern and western Pacific ITCZ and noted how various satellite precipitation algorithms may respond quite differently to ENSO modulations of these precipitation regimes. However, quantifying the associated *net integrated changes* to water and heat balance over the entire tropical oceanic or land sectors remains an observational challenge.

The GPCP data set (Huffman *et al.*, 1997; Adler *et al.*, 2003) shows consistent increases (decreases) in precipitation associated with ENSO warm events when integrated over tropical ocean (land) regions. The reverse tends to occur during ENSO cold SST events. These variations are typically of order 0.30 mm per day, less than 10% of climatological mean values. Over the tropics as a whole, these perturbations in rainfall essentially vanish.

Why should we be interested in these large regional averages? ENSO events offer a natural experiment in terms of perturbations to the tropical heat balance. Changes in fluxes averaged over this system or its land and ocean components thus represent restoring mechanisms and involve many of the same feedback processes relevant to climate change – changes in evaporation, cloud and water vapor forcing, and energy transport. It is important to remember that since ENSO is a natural climate variation the internal responses or feedbacks are different from those related to anthropogenic forcing (Bony *et al.*, 1997). Nevertheless, the ENSO 2–7 year periodicity offers an accessible "experiment" involving changes in air–sea interaction processes, precipitation, radiative fluxes, and surface temperature – changes in water and energy fluxes that are highly coupled (Sun and Trenberth, 1998). These changes constitute a necessary test that climate models must successfully navigate.

Precipitation Accuracies

Estimating error in precipitation retrievals is sensitive to the density of rain gauges, the character of the precipitation, the topography, and spatial scale of the satellite and gauge averaging. Adler *et al.* (2003) estimate, overall, the errors for the monthly GPCP product to range between 10% and 30% at rain amounts above 100 mm per month (3 mm per day). This percentage error is for a 2.5° latitude × 2.5° longitude square, and time- and space-averaging will significantly reduce the random error. Over land, comparison to independent gauge data over the Oklahoma Mesonet indicates that GPCP monthly amounts correlate to the observations at 0.74 (0.94) before (after) global adjustments of the satellite estimates to rain gauges. Globally, the GPCP data set has similar magnitudes and zonal mean distributions as the historical Jaeger (1976) and Legates and Willmott (1990) values. In the tropics, values are systematically smaller than Legates and Willmott values due to reliance by the latter on Pacific atoll data whose magnitude is still in question.

For interannual and longer signals, error inferences are complicated by the stability of the satellite sensors and subtleties in retrieval physics assumptions and how they respond to precipitation physics. In a paper that documented the uncertainties in detecting interannual variations of precipitation, Robertson *et al.* (2001) critically examined six satellite-derived precipitation data sets over the tropical oceans. When averaged over the domain 30° N/S, only two of these, the Wentz and Spencer (1998) Special Sensor Microwave Imager (SSM/I) algorithm and a deep convective index (DCI) from Microwave Sounding Unit Channel 2 (MSU2) showed strong correlations between each other and with tropically averaged SST variations. The implication of these results was that for the purposes of climate diagnostics work and model validation, the precipitation data sets commonly used in the research community have significant observational uncertainties. The expectation was that measurements from TRMM PR and TMI would reveal the physical and quantitative reliability of these algorithms.

Interestingly enough, a definitive statement regarding interannual variability of oceanic precipitation has not yet been provided by TRMM, even though it sampled perhaps the largest warm SST event in decades. Figure 1 shows differences between the PR and various passive algorithms from TMI in both the sense and magnitude of interannual precipitation variations averaged over the tropical oceans.

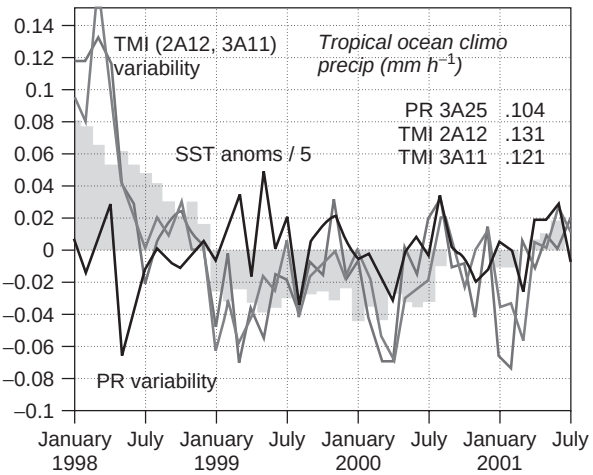

Figure 1 Time series of precipitation anomalies averaged over the tropical oceans from the TRMM Version 5 PR 2A25 and TMI passive microwave algorithms 2A12 and 3A11. Time series have been normalized by their respective climatological values to yield fractional variability. SST anomalies (°C) over the tropical oceans scaled by 1/5 are shaded. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

The two TRMM TMI algorithms, in agreement with the previous DCI and Wentz/Spencer results, indicate a positive correlation with SST. The TRMM PR time series is notably different, exhibiting correlations with the TMI algorithms of only 0.12. At first blush, one might regard the TRMM PR result as definitive because the reflectivity measurements respond directly to precipitation size hydrometeors. However, the TRMM PR operates with a single frequency (13.8 GHz), an attribute necessitating significant microphysical assumptions regarding drop-size distributions and parameterizations of reflectivity/attenuation/rainfall relationships. In a recent paper, Robertson *et al.* (2003) found evidence that it is the uncertainties in these microphysical assumptions needed for the primary TRMM algorithm (2A25) that are problematic in trying to isolate interannual variations integrated over the tropical oceans. They found that a direct rainfall attenuation measurement made from the return signal of the TRMM PR (the so-called Surface Reference Technique) in fact shows strong similarities to those interannual variations detected from passive microwave estimates from TMI. This is consistent with the agreement found by Robertson *et al.* (2001) between the MSU precipitating ice and SSM/I depictions of rainfall variations. It is also consistent with the results of Adler *et al.* (2003). New versions of the TRMM algorithms are encouraging for the reconciliation of active and passive precipitation estimates for climate work over the tropical oceans.

We note in passing that a number of satellite precipitation estimates (GPCP, TRMM, TMI, and PR) seem to agree somewhat better over land areas. Whether this has to do with the influence of rain gauges on the GPCP product or the dominance of rainfall by stronger, deeper rain systems more easily and reliably detected by precipitating ice-scattering algorithms used over land has yet to be determined. Finally, in understanding the differences between passive and active results, it is important to keep in mind that both approaches measure only the physical attributes of hydrometeors – neither is a direct measurement of rain flux at the earth's surface.

Oceanic Turbulent Heat Fluxes

The counterpart of precipitation in the hydrologic cycle is, of course, surface latent heat flux or evaporation. In this section we consider processes over the global oceans. Because it is impractical with *in situ* eddy correlation techniques to measure latent (and sensible) heat fluxes over large regions, the complexities of this process are typically approached from bulk aerodynamic methods to which conventional data can be applied. Efforts to infer surface turbulent fluxes from space have also followed this tack. The availability of global observations of wind stress with the Seasat and Nimbus 7 (Scanning Microchannel Microwave Radiometer (SMMR)) instruments inspired the development of techniques over oceans using bulk formulae of the form

$$E = \rho C_{\mathrm{E}} U (q_{\mathrm{s}} - q) \tag{1}$$

where E is evaporation, U is surface wind speed at 10m, q is 2m specific humidity and q_{s} is the saturation q of the ocean surface SST, ρ is air density, and C_{E} is the transfer coefficient for the reference height. Estimates of SST from *in situ* and satellite (e.g. Reynolds and Smith, 1994) provide a means of obtaining q_{s}. For many applications, C_{E} for a neutral atmosphere over the oceans is a reasonable first estimate. Situations such as cold, dry air outbreaks over warm middle latitude waters are a typical exception. Liu *et al.* (1979) provided a methodology for estimating variations in exchange coefficients. The other remaining unknown, near-surface humidity, q, was estimated by Liu (1984) and Liu and Niiler (1984) on the basis of its statistical relationship with column-integrated water vapor, W, which is also retrieved from microwave satellites.

This basic approach, with variations and improvements, has formed the cornerstone of virtually all succeeding efforts to develop latent heat-flux data sets. Validation and improvement of bulk flux models are receiving considerable emphasis in recent years (Chou, 1993; Fairall *et al.*, 1996b, 2003; Clayson *et al.*, 1996; Zeng *et al.*, 1998; Brunke *et al.*, 2003). As in the case of precipitation, the growing archive of SSM/I data has provided the extensive data set needed to produce global evaporation estimates. Several near-global data sets of retrieved evaporation and other air–sea flux parameters have been derived. The Hamburg Ocean–Atmosphere Parameters and Fluxes from Satellite Data, HOAPS dataset, (Schulz *et al.*, 1997; Grassl *et al.*, 2000) provides gridded fluxes on various scales (0.5 to 2.5 degrees, daily to monthly averaging). In attempting to improve upon Liu's methodology, HOAPS uses estimates of the integrated water vapor content of the lowest 500 m of the atmosphere, W_{b} (Schulz *et al.*, 1993; Schlüssel, 1996) and relates this statistically to specific humidity near the oceans surface. The atmospheric stability to compute the transfer coefficient is estimated with a fairly simple technique. Following Smith (1988) it is assumed that the atmosphere has a relative humidity (RH) of 80% at any time. Thus, the near-surface air temperature can be computed from the measured q. The errors in the transfer coefficient that occur if this assumption is wrong are small at high wind speeds and unstable conditions ($\sim$2%) but can approach 50% at low wind speeds and strong stable conditions (Schulz *et al.*, 1997).

An alternative but similar methodology is the Goddard Satellite-based Surface Turbulent Fluxes data set, Version 2, GSSTF2, (Chou *et al.*, 2003). These flux retrievals use Wentz (1997) Version-4 SSM/I surface (10-m) wind speeds and total precipitable water, and SSM/I antenna temperatures, as well as the SST, 2-m air temperature and sea-level

pressure of the National Centers for Environmental Prediction (NCEP)–National Center for Atmospheric Research (NCEP/NCAR) reanalysis. The methods for deriving the GSSTF2 daily turbulent fluxes and input parameters essentially follow those of Chou *et al.* (1997). A fairly sophisticated bulk flux model is used. The methodology for retrieving daily q at 10 m height, q10 m, (Chou *et al.*, 1995, 1997) also uses the Schulz *et al.* (1993) method to estimate W_b but applies a vertical empirical orthogonal function methodology (Wagner *et al.*, 1990) to aid in inferring q10 m. Daily W_b is derived from SSM/I following Schulz *et al.* (1993), while daily precipitable water is taken from that of Wentz (1997) for the GSSTF2.

Turbulent Flux Accuracies

There is no doubt that satellite techniques are able to produce reasonable flux fields on a climatological basis. Annual climatological evaporation estimates for the Chou *et al.* (2003), da Silva *et al.* (1994) and NCEP/NCAR Reanalysis each show similar regional patterns of broad, elevated latent heat flux over subtropical oceans and maxima off the east coasts of continents in winter. Nevertheless, each of these estimates has significant uncertainties. For example, Gleckler and Weare (1997) estimated that monthly mean latent heat fluxes had uncertainties of approximately 35 $\mathrm{W m^{-2}}$. Estimates are that reanalysis evaporation also has a similar uncertainty. Aside from random error, regional biases are of particular concern. It has also been noted that in subtropical regions the satellite evaporation estimates are significantly larger than either the reanalysis or da Silva values. This type of bias was originally pointed out by Esbensen *et al.* (1993) and linked to biases in estimates of q inferred from column-integrated water. Varying scale heights of water depending on large-scale vertical motion can significantly affect near-surface q. For example, in subtropical regions sinking motion produces a drier-than-average atmosphere; however, in the planetary boundary layer, turbulent mixing still moistens the overlying air. Thus, estimates of q inferred from the column-integrated water vapor will systematically indicate a smaller q value and hence a larger bulk estimate of evaporation.

Wind speed accuracy is also a question. Mears *et al.* (2001) and Meissner *et al.* (2001) have shown generally very good correspondence with buoy winds and suggest rms errors of order 1.0 $\mathrm{m\,s^{-1}}$ and overall biases of order several tenths $\mathrm{m\,s^{-1}}$. There are also known wind speed biases along coastal areas where ocean currents and wave geometry relative to spacecraft orbital track produce systematic biases also of order 1.0 $\mathrm{m\,s^{-1}}$ or more.

What are the implications of these uncertainties for monitoring evaporation changes on interannual and longer timescales? Some idea of current capabilities is seen in Figure 2 in which tropical ocean evaporation estimates from two different SSM/I-based estimates and the NCEP/NCAR reanalysis are presented. Long-term trends in each of the three estimates are seen, but the two SSM/I estimates are significantly larger. On interannual timescales, the SSM/I estimates clearly show the influence of ENSO warm and cold events with time-lagged responses to SST, with reanalysis estimates being much weaker and noisy. Part of the large evaporation changes in the satellite estimates can be related to the effects of the q biases. But it is also true that the NCEP reanalysis, like any model, is driven strongly by model physical parameterizations in the tropical regions.

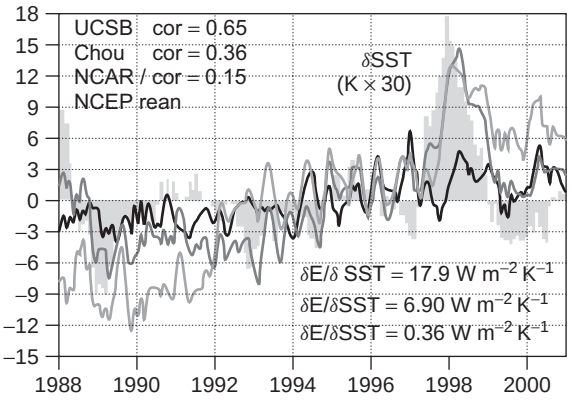

Figure 2 Bulk aerodynamic evaporation anomalies (30 °N/S average) from two different SSM/I passive microwave algorithms [University of CA Santa Barbara (Jones *et al.,* 1999) and GSSTF (Chou *et al.,* 2003)] show large flux trends and δE/δSST sensitivities compared to NCAR/NCEP Reanalysis. SST anomalies (°C) over the tropical oceans scaled by 30 are shaded. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Global coverage of ocean evaporative fluxes is steadily improving with clearer insight into bulk formula approaches and detection and understanding of systematic biases in satellite input data. A collaborative project, SEAFLUX, (Curry *et al.*, 2004) is serving as a forum for improving algorithms and recommending best practices for improving remotely sensed ocean fluxes. This includes moisture, heat, and momentum. It is expected that continued efforts will fulfill the need for high-resolution, accurate surface turbulent fluxes (heat, water vapor, and momentum) over the global ocean that has been articulated by numerous advocacy groups within the global climate community, including the WCRP Joint Steering Committee/Scientific Committee on Ocean Research (SCOR), Joint Working Group on Air/Sea Fluxes (JWGASF), the GEWEX Radiation Panel, and the CLIVAR Science Steering Group.

Land-surface Hydrology

Water and energy balance obviously differs fundamentally over land compared to ocean regions. Because mixing and dynamical transport can facilitate heat storage from solar

radiation in the ocean (Levitus *et al.*, 2000; Sun, 2003), timescales of near-surface temperature change can extend past seasons to interannual and decadal scales. Over land, the capacity for subsurface energy storage is diminished and so radiative, latent, and sensible heat fluxes can have strong variability on shorter timescales. The diurnal cycle in surface fluxes is a prominent example of this, as are frequent subseasonal anomalies associated with regional droughts or wet periods. The availability of near-surface water in soil and vegetation is of critical importance to the partitioning of energy flux among these three processes. In middle and higher latitudes where solar forcing is weak, soil-moisture anomalies can extend to seasonal and even interannual or decadal timescales (Delworth and Manabe, 1988). Further complicating the water balance and energy exchange, in comparison to oceans, is the extreme heterogeneity in vegetative cover, soil characteristics, topography, and drainage characteristics. Surface emissivities are constantly changing owing to soil-moisture changes. The diurnal growth and collapse of planetary boundary-layer structure and sharp vertical gradients in thermodynamic quantities and wind shear also present extreme challenges for passive remote sensing, which is not adept at capturing vertical structure. All these distinguishing attributes of the water cycle over land make remote sensing of hydrologic processes more problematic.

Given these challenges, how do we best use the remotely sensed data to determine the water and energy balance over the varied terrestrial regions of the globe? Beginning with GEWEX in the early 1990s, a scientific consensus emerged for evolving hydrologic models into systems that can assimilate, or be constrained by, observations from space in such away that *a priori* knowledge on soils characteristics, vegetation, drainage, and so on are optimally combined with observed radiative fluxes and atmospheric retrievals of near-surface meteorology. This assimilation process allows the information we gain from space-based observations to build physical consistency into inferences of surface water, heat, and radiative fluxes.

Added degrees of freedom due to inclusion of such land-surface schemes require the specification of additional parameters within the model system such as vegetative resistances, green vegetation fraction, leaf area index, soil physical and hydraulic characteristics, stream flow, runoff, and the vertical distribution of soil moisture, all of which are difficult to measure over large regions. This issue is even more problematic in areas where the land-surface characteristics are extremely heterogeneous. Consequently, some attempts to use remotely sensed data have emphasized simplified treatments of surface energy balance. For example, McNider *et al.* (1994) developed a procedure based on the work of Wetzel (1984) and Carlson (1986), which takes a practical approach toward assimilating space-based observations of land-surface temperature (LST) by recognizing that adjustments in this parameter must be consistent with other components of the surface energy budget. The technique requires the use of Geostationary Operational Environmental Satellite (GOES) derived IR LST *tendencies* and GOES-derived net solar radiation over the time period of interest. It is based upon adjusting the model's bulk moisture availability so that the model's *rate of change* of LST agrees more closely with that observed from the satellite. Therefore, the simulated latent heat flux, which is highly correlated with surface moisture availability during this time period, is adjusted based upon differences between the modeled and satellite-derived LST tendencies.

Lapenta *et al.* (1999) tested the technique over the southeastern US where the vegetation is highly variable. Twenty-five case days were initialized at 12 UTC from the NCEP Early Eta and run through 12 h.A 25-km nested grid centered over the southeastern US was employed, and satellite data were assimilated between 1400 and 1700 UTC (forecast time of 2–5 h). The remainder of the model run was executed in a free forecast mode. Verification statistics for the 2-m air temperature were computed and are displayed in Figure 3. The control run (marked SLAB) was performed with no assimilation and a second run (marked ASSIM) assimilated the satellite data. The results demonstrate that short-term simulations of near-surface temperature were generally improved on a daily basis. Another nonassimilation run was made with the Oregon

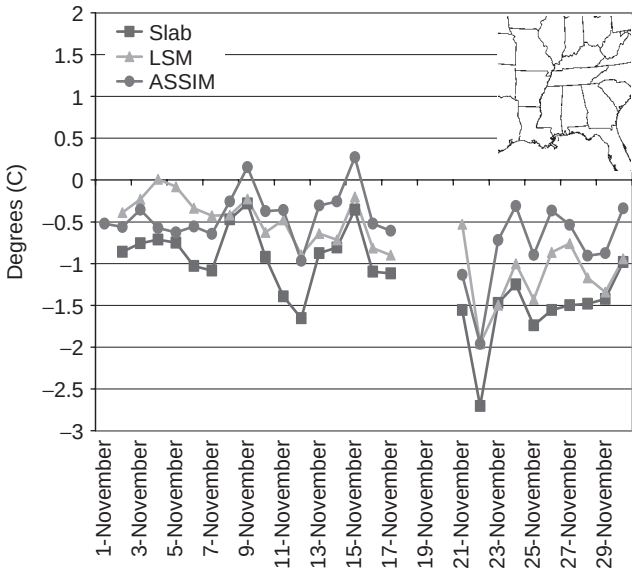

Figure 3 Mean absolute error (°C) of simulated 2-m air temperature for the control (SLAB), assimilation (ASSIM), and land-surface model (LSM) runs for November 1998. Hourly error statistics were averaged over the 12-h forecast period. The geographic coverage of the model domain is shown in the inset. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

State University Land-surface Model, LSM, (marked LSM in Figure 3), to determine how the assimilation technique performs relative to a more sophisticated approach. Early in the month, the LSM performs better than control and assimilation runs. However, this pattern is reversed from the 9th to the end of the month. Examination of satellite data revealed that the poor performance of the assimilation run occurred during a cloudy period. The later half of the month when the assimilation had the most positive impact was mostly cloud free.

In addressing the more complex task of driving fully functional hydrologic models with space observations, a number of internationally coordinated efforts have arisen. For example, the International Satellite Land Surface Climatology Project (ISLSCP) has served as a pathfinder effort to determine just what types of surface and near-surface satellite measurements are relevant to climate and global change studies. It facilitated improvements in algorithms for the interpretation of satellite measurements of land-surface features and developed methods to validate area-averaged quantities derived from satellite measurements for climate simulation models. The First ISLSCP Field Experiment (FIFE) and Boreal Ecosystem–Atmosphere Study (BOREAS) field programs were middle- and high-latitude field studies for addressing these problems.

Under the ISLSCP Initiative I, the first global land cover, hydrometeorology, radiation, and soils data sets regridded to a common 1×1-degree format for 1987–1988 were produced. The Global Soil Wetness Project-1, GSWP-1, (Dirmeyer *et al.*, 1999) has used these data sets in conjunction with an international suite of land-surface models to produce state-of-the-art global data sets of land-surface fluxes, surface state variables, and related hydrologic quantities. Key components of the forcing data have been derived from satellite. Among these are the surface radiation budget components from the NASA/GEWEX Surface Radiation Budget Project. In this effort, thermodynamic soundings and satellite measurements of surface properties have been combined with the International Satellite Cloud Climatology Project (ISCCP) cloud data to constrain radiative models and yield surface radiative fluxes. Precipitation forcing to drive soil moisture has been taken from the GPCP merged gauge/satellite product with temporal disaggregation estimated from 6h resolution rainfall from the European Centre for Medium-Range Weather Forecasts (ECMWF) analysis. These products are being extended with ISLSCP-2 forcing, which now covers the period from late 1987 through 1995.

In support of first GEWEX Continental-Scale Experiment, the North American Land Data Assimilation System (NLDAS) (; see Mitchell *et al.*, 1999) has provided a useful regional focus for extending GSWP capabilities to finer scales in an operational setting and provided impetus for development of ground-based radar estimates of precipitation as well. A Global Land Data Assimilation System (GLDAS) that uses various new satellite- and ground-based observation systems within a land data assimilation framework is being developed by NASA and various collaborators (Houser *et al.*, 2001; Rodell *et al.*, 2004) and provides an extension of GSWP products to near real time. This integrated system assimilates land-surface and diverse satellite observations (including precipitation, solar radiation, snow cover, surface temperature, and soil moisture) globally at 1/4 degree resolution in near real time. This real-time aspect is crucial if the hydrologic state variables and fluxes are to be used for global weather forecast models and for initializing ensemble model experiments for seasonal prediction. Figure 4 depicts representative fields of evapotranspiration and soil-moisture content produced from this system.

Accuracy of Hydrologic Quantities

Determining the accuracy and sources of errors in surface water and energy balance components is at present very difficult. There are uncertainties in the model physics, the accuracy of forcing data, the specified fields (e.g. root zone properties, leaf area index, soil properties, vegetation type etc.), and in verifying field data. In fact, the whole question of how to compare point measurements to retrievals of fluxes and surface state supposedly representative of model grid points or entire watersheds is far from settled. Some perspectives on the accuracy and physical realism of satellite-constrained surface retrievals are emerging nonetheless.

The GSWP-1 intercomparison effort (Dirmeyer *et al.*, 1999) showed significant spread among the participating land-surface schemes in terms of their partitioning of surface energy between latent and sensible heat flux, and of water between runoff and evapotranspiration. When averaged globally, the ensemble mean Bowen ratio was 0.95 with a standard deviation of 0.18. The runoff mean of 228.6 mm underestimated basin-scale measurements, possibly due to the GSWP specification of the treatment of convective precipitation. The standard deviation of 39.6 mm suggests that subgrid-scale variability in infiltration due to heterogeneity in soil properties and the uncertainties in distribution of rainfall within a grid box have significant impacts on the simulation of runoff. Most notably, the comparison of the LSM simulations against point data showed poor and inconsistent performance, raising the question of whether the model physics is adequate or simultaneously appropriate at both point and grid scales.

Robock *et al.* (2003) studied the performance of four state-of-the-art land-surface models participating in the NLDAS Project (Mitchell *et al.*, 2003). The models were forced by observed precipitation and solar insolation for the periods May–September of 1998 and 1999 and validated with observations taken at Oklahoma Mesonet and

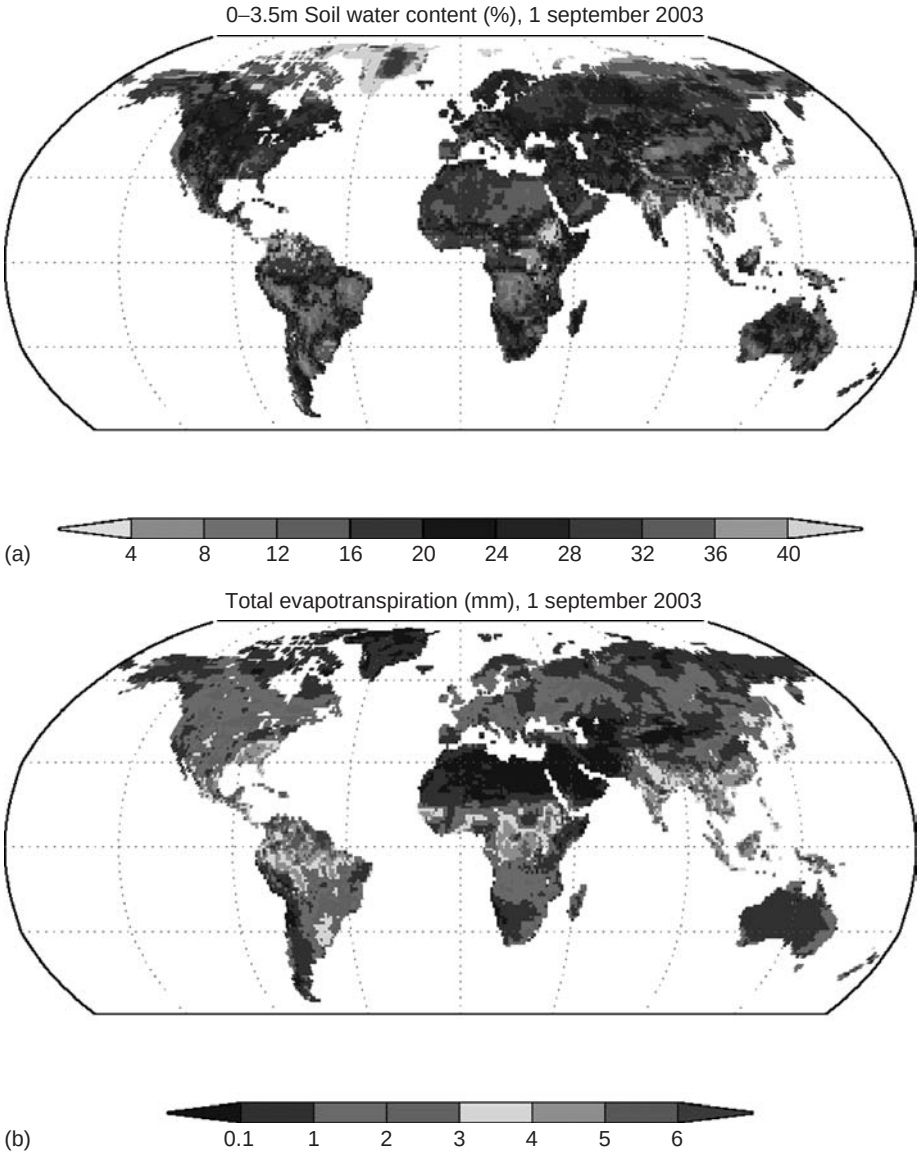

Figure 4 Total evapotranspiration (a) and soil water content in the top-most 3.5 m (b) for September 2003 produced by the NASA global land data assimilation system. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

the Department of Energy Atmospheric Radiation Measurement (ARM)/Cloud and Radiation Testbed (CART) site in the southern Great Plains region. While the NLDAS models captured broad features of soil-moisture variations in the top 40 cm and detected interannual differences, intermodel variability was still substantial. Monthly departures of turbulent fluxes were typically several tens of $W\,m^{-2}$ from the sensible and latent heat-flux observations of 35 and 70 $W\,m^{-2}$, respectively. These systematic biases also varied with season and between years.

These early comparisons suggest that physically based land-surface models do respond to atmospheric forcing in realistic fashion, though the quantitative accuracy remains to be increased across regional to global scales. The transition from statistical modeling of hydrologic processes to a physically based methodology means that, while substantial work remains, the linking of surface states to the atmosphere and the derivation of associated energy fluxes is rapidly being put on a sound physical basis needed for coupled global prediction.

Clouds and Water Vapor

Traditional studies of the hydrologic cycle have tended to emphasize the mass balance of water yet, as noted in the Introduction, clouds and water vapor are tightly coupled

to the surface temperature and the overall heat balance of the planet. Monitoring the radiative aspects of this coupling and the effect of clouds and water vapor on TOA fluxes are particularly amenable to remote sensing by satellite.

A detailed compilation of cloud fractional cover and morphology in both the visible and IR regions has been sustained under the ISCCP since 1983 (Rossow and Schiffer, 1991; 1999). Available at 280 km resolution, these cloud statistics derived from combined geostationary and polar-orbiting satellites have provided diurnally resolved, monthly mean statistics on cloud type, frequency, cloud-top temperature and pressure, optical depth, cloud water content, and other physical attributes. Because ISCCP cloud properties are derived from a downward looking perspective, this data set is complementary to historical ground-based climatologies (e.g. Warren and Hahn, 1986; Warren *et al.*, 1988). These data have been instrumental in evaluating and improving the representation of clouds in global models (Yu *et al.*, 1996; Webb *et al.*, 2001). The ISCCP clouds have also served as input to a global data set of radiative flux retrievals, ISCCP-FD, (Zhang *et al.*, 1995, 2004) and to the GEWEX Surface Radiation Budget products (Gupta, *et al.*, 1999).

Subsequent to the start of ISCCP, more sensitive methods for detecting upper-tropospheric clouds have been demonstrated using IR channels on atmospheric sounding instruments (Susskind *et al.*, 1987). The IR channels from 13–15 μm, which are operational on all polar-orbiting National Oceanic and Atmospheric Administration (NOAA) satellites provide a means of detecting optically thin cloud that the visible and IR window channels used by ISCCP may misinterpret. These measurements, though unable to resolve the diurnal cycle since they are made from polar-orbiting platforms, provide an independent and complementary set of data regarding cloud frequency (Wylie and Menzel, 1999; Stubenrauch *et al.*, 1999). With the recent availability of data from the Moderate Resolution Imaging Spectroradiometer (MODIS) on Terra and Aqua (Platnick *et al.*, 2003), significant improvements to cloud detection and retrieval of microphysical retrievals are possible. MODIS is a 36-channel whiskbroom scanning radiometer with bands distributed between 0.415 and 14.235 μm and nadir spatial resolutions of 250 m to 1 km. The products consist of a cloud mask for detection of clear skies, cloud-top properties (temperature, pressure, effective emissivity), cloud thermodynamic phase, and cloud optical thickness and microphysical properties (effective radius, water path).

Microwave remote sensing offers yet another measurement of cloud properties (e.g. Ferraro *et al.*, 1996; Wentz, 1997). Over oceans, these frequencies can retrieve column-integrated cloud water, which, with visible and IR methods, can only be done reliably for thin clouds. Aside from snow and graupel, ice clouds are largely transparent to most microwave frequencies flying on current sensors. Imaging and sounding at submillimeter wavelengths are needed. The cloud radar on CloudSat (Stephens *et al.*, 2002) operating at 94 GHz will offer an opportunity to directly determine cloud vertical structure, a measurement that is largely lacking today except for limited nadir views from the lidar flying on ICESat.

Atmospheric water vapor obviously plays a direct role in the global water cycle since it is maintained by surface evapotranspiration and provides a source for precipitation as air parcels are lifted and cooled. However, far from being a passive constituent, atmospheric moisture is intertwined with dynamics and radiation. Convective available potential energy depends crucially on the amount of water vapor in the planetary boundary layer and has a strong control on the occurrence and intensity of atmospheric convection. Because of its IR opacity, water vapor modulates atmospheric long-wave radiation and enables a far warmer surface temperature than would be possible if Earth were a dry planet.

Despite considerable focus on how water vapor would change radiative fluxes and climate in a CO_2-enriched world, we are still constructing an observational framework for understanding the full effects. Long-term satellite retrievals of water vapor over the globe date back to the NOAA Operational Polar-Orbiting Satellite Sounders, beginning with TIROS-N in 1978. Geostationary sensors (e.g. GOES and Meteosat) have provided complementary high time resolution of this quantity beginning in the early 1980s. These IR measurements have provided insight on the variations of atmospheric moisture on regional to global scales unavailable from widely spaced radiosonde reports. IR retrievals cannot however be made in cloudy regions, so sampling bias is a factor in using these data. Beginning with SSM/I microwave imager data in late 1987, the ability to retrieve column-integrated water vapor over oceans under most cloudy conditions has been a critical supplementary source of water vapor data, especially in providing information of the bulk of water vapor in the lower troposphere where IR methods are most suspect. The NASA/GEWEX Water Vapor Project, NVap, (Randel *et al.*, 1996; Vonder Haar *et al.*, 2003) has been instrumental in merging these varied satellite measurements, along with radiosonde data, to provide global gridded time series of water vapor needed to study atmospheric hydrologic processes.

While it is generally agreed that water vapor in the lower troposphere varies approximately at constant RH in response to surface temperatures, there exists continuing debate as to whether this is true in the mid- to upper troposphere where the radiative effects of water vapor are strongest. The importance of humidity variations in modulating OLR over the dry subtropical "oceanic deserts" has been pointed out by Spencer and Braswell (1997). Using RH estimates from the HIRS-2 6.7 μm channel, Soden *et al.* (2002) found a roughly constant RH response

to global atmospheric cooling produced in the two years following the eruption of Mount Pinatubo. Stratospheric aerosol from this event reduced solar insolation at the surface, surface temperature, and atmospheric convection intensity. Bates *et al.* (2001) have used a longer time series of HIRS data to show that interannual variations of upper-tropospheric humidity (UTH) are strongly modulated by the dynamical flow changes during ENSO events and that the relationship between UTH and SSTs involves both seasonal and interannual timescales. On the other hand, findings by Minschwaner and Dessler (2004), using Microwave Limb Sounder (MLS) data, have suggested that UTH variations with SST over the tropics are significant, but with water vapor changing at a rate somewhat smaller than that of constant RH.

Accuracy of Cloud and Water Vapor Retrievals

In part, our current ability to determine many attributes of clouds stems from the need to account for their effects on retrieving temperature soundings whose accuracy is crucial for numerical weather prediction. Inversion techniques have followed the philosophy that accounting for the effects of clouds across channels with varying sensitivity to moisture and temperature yields more physically based, accurate retrievals (Susskind *et al.*, 1987). Limiting temperature retrievals to purely clear scenes would be much less productive. However, like other hydrologic quantities, clouds vary greatly over a broad range of scales, diurnal to interannual, and from small fair weather cumulus to extensive multilayered clouds in baroclinic zones, thus making validation efforts exceedingly difficult. Virtually all clouds have significant spatial variability below the resolution of the High-resolution Infrared Sounder (HIRS) and even of the new Atmospheric Infrared Sounder (AIRS) instrument flying on Aqua. Geostationary visible and IR techniques used by ISCCP have higher spatial resolution, but at the expense of spectral diversity that is needed to accurately determine cloud microphysical attributes.

Since no single current strategy is optimum, our assessment of cloud cover, height, and optical properties has significant sensor dependence. Cloud overlap issues from satellite are a significant uncertainty, particularly for maritime stratocumulus. Weare (2000) has estimated that the magnitudes of annual-mean low cloud amount in the ISCCP and Hahn *et al.* (1994) climatologies differ by up to about 0.4 for a number of locations. Surface-based observations have the inverse problem that satellites have, recording low clouds well but missing overlapping middle and high clouds. Surface cloud observations are scarce over oceanic regions and cannot adequately monitor interannual variability. High clouds are more readily measured by satellite, but the pervasiveness of optically thin cirrus is a challenge. Stubenrauch *et al.* (1999) have shown that nighttime thin cirrus detection with the HIRS multispectral information is substantially improved over infrared window methods of ISCCP.

One of the principal challenges in retrieving water vapor concerns the small-scale height (several km) that results from the strong combined effects the atmospheric lapse rate and the Clausius-Clapeyron constraint on saturation vapor pressure. Since passive remote sensing has very poor vertical resolution, accuracies in RH retrievals at specific pressure levels can often be 30–50% for operational soundings. The inability of IR techniques to deal effectively with cloud contamination is another source of error. For climate studies, a more tenable approach has been to interpret water vapor sounding channel brightness temperatures (either the 6.7 μm or 183.3 GHZ regions) as proportional to log(RH) weighted over the effective width of the channel response function; typically, pressure layers several hundred hPa thick (Soden and Bretherton, 1996; Spencer and Braswell, 1997). On the basis of the work of Escoffier *et al.* (2001), one can estimate biases among different satellite sensors to be of order 20 to 30%. These disparities are traceable in large part to processing differences. Despite these biases space/time correlations for 5-day mean RH estimates between sensors are quite high (order of 0.80 to 0.90) indicating that the variability in humidity retrieved by this approach is quite accurate for climate variability studies.

Cryospheric Issues

Our examination of remote sensing and the hydrologic cycle has focused so far on tropical and middle latitude regions. Many of the greatest challenges lie in fact with detecting ice mass balance trends of the polar regions, changes in sea-ice extent, seasonal snowcover amount, and trends in alpine glaciers. Issues of climate change have strong intersections here since climate models tend to project largest CO_2-related warmings to occur in the cryosphere due to ice-albedo feedback. This process, in which melting ice from a CO_2-warmed planet lowers albedos in the cold regions and results in even more solar absorption, is an important yet poorly quantified feedback. Sea-level rise with melting in polar regions is one possible, yet still highly speculative, outcome of anthropogenic effects. In general, remote sensing uncertainties over ice surfaces are some of the most difficult challenges.

Perhaps the most straightforward measurements in the cryosphere are simple ice-extent estimates. Both visible band data from NOAA polar-orbiting satellites and microwave measurements from SMMR and SSM/I instruments have been used to track changes in snowcover over the past 20+ years (Armstrong and Brodzik, 2001). Interannual variations have been found to be as large as long-term trends. The latter show a decrease in snow extent of approximately 0.2% per year, which is consistent with recent surface warming. Determining snow water equivalent is

much more difficult since ice age strongly affects this variable. New estimates of this quantity from the Advanced Multichannel Scanning Radiometer for the Earth Observing System (AMSR-E) on Aqua are expected to be greatly improved over historical estimates from SMMR and SSM/I.

Sea ice is important because it regulates energy exchanges and ocean salinity in the polar oceans. The extent of cracks or leads in the sea ice is important because these are the only regions where cold, dry polar air can gain access to the underlying seawater. Tremendous latent and sensible heat fluxes here affect the production of atmospheric clouds and affect precipitation. Charting sea-ice variations has led to the present understanding that, whereas Arctic sea ice has been decreasing over the past three decades, Antarctic ice has increased after previous decreases (Zwally *et al.*, 2002). Trends estimated from these data suggest a net decrease in Arctic ice extent of about 2.9% per decade while Antarctic ice extent increased by 1.3% per decade. Again, the SMMR and SSM/I estimates of sea-ice coverage have been crucial to making these estimates. A variety of remote sensing instruments have been used successfully to map sea-ice conditions. However, because of frequent cloud cover in the polar regions and the fact that the sun remains below the horizon for continuous periods in winter, microwave sensors are the most commonly used instruments for ice-cover mapping.

Global sea level is currently rising, mainly because of ocean thermal expansion and glacier melt, both thought to result from recent increases in global surface temperature. Will ice sheet melting contribute to this significantly in the future? By far, most of ice water is contained in the Antarctic and Greenland ice sheets. Current estimates, however, indicate that mass balance for these ice sheets is in approximate equilibrium and therefore they are not currently affecting sea level to any significant extent. The NASA ICESat (Ice, Cloud, and land Elevation Satellite) launched in early 2003 is using a laser altimeter to precisely map global ice sheet topography. Repeated flights of this type of sensor in the decades to come will enable accurate measurements of how these huge stores of freshwater are changing.

SYNTHESIS AND ASSESSMENT

The inventory of remote sensing accomplishments and data set generation over recent years represents an impressive advance in observational capability and understanding of water on this planet. We now possess global records of precipitation, evaporation, clouds, and radiative fluxes extending over more than two decades. These time series have delineated regional ENSO responses to SST fluctuations and ocean heat content. Methodologies have been developed to assimilate surface soil and vegetative state, skin temperature, and precipitation with physically based models, an achievement that, in parallel with ocean modeling advances, has laid the groundwork for true Earth system models. Cloud, water vapor, and radiative measurements have provided a basis for understanding connections between convection, radiation and atmospheric dynamics. These data sets have also guided the improvement of atmospheric hydrologic processes in regional and global models. Now these models typically carry conservation equations for all three phases of water as opposed to statistically inferring cloud and precipitation from water vapor amounts alone.

At this point we return to the science questions posed in the Section "Motivating/driving questions" and ask how these pieces now fit into the overall goal of understanding the global hydrologic cycle. What can we say about the nature of the water and energy cycles as viewed from space, and do there seem to be changes afoot? What have we learned about variability in the climate system as viewed from space? It is here, when we consider integrated signals and lower frequency signals, that the remaining challenges become more obvious. The precipitation and evaporation uncertainties related to ENSO suggest that natural variations in the water and heat balance of the tropics are clearly present, but their amplitude remains in question. We know that tropical and global SST signals may reach nearly 0.5 K for a large ENSO event. Signatures of increased (decreased) precipitation over ocean (land) emerge from GPCP. Suggestions of increased evaporation over oceans are also in evidence from microwave measurements. Yet these results are not yet definitive. Uncertainties and artifacts in the time series are significant compared to the signals of hydrologic processes averaged over large global regions.

In considering decadal scale signals we appeal to the TOA radiative flux record that is sensitive to cloud and water vapor distributions. The series of global satellite measurements begun by the Earth Radiation Budget Experiment has been continued under NASA's Clouds and Earth's Radiant Energy System (CERES) sensors on TRMM, Aqua, and Terra and has provided a stable, precise monitoring capability. From a TOA perspective the net radiative flux appears nearly invariant with net shortwave and outgoing long-wave fluxes of approximately 235 $\mathrm{Wm^{-2}}$ globally; clouds provide a small net cooling effect of about 20 $\mathrm{Wm^{-2}}$ (Ramanathan *et al.*, 1989; Kiehl and Trenberth, 1997). However, the ERBE/CERES measurement stream suggests the emergence during the 1990s of decreased shortwave reflection of several $\mathrm{W\,m^{-2}}$ over the tropical region 20° N/S and nearly offsetting increases in outgoing long-wave radiation (OLR) (Wielicki *et al.*, 2002a). Chen *et al.* (2002) have interpreted these radiative signatures as indications of strengthened tropical convection and vertical Hadley and Walker circulations. The net effect of these flux changes

is small, about 1.5 W m^{-2} increased radiation to the tropical earth/atmosphere system, and the quantitative accuracy of these changes is still under debate (Trenberth, 2002; Wielicki *et al.*, 2002b) with data set revisions in progress. These changes are of the same amplitude as higher frequency responses signatures associated with ENSO events but substantially smaller than the effects of the eruption of Mt. Pinatubo in June 1991.

Independent ISCCP cloud cover retrievals show a reduction in cloud cover of 3–5% over the 1983–2001 period and the trends in calculated fluxes from the ISCCP-FD data set match the ERBE/CERES quite well, yet mid- and high level cloud cover from the HIRS data set (Wylie and Menzel, 1999) gives little indication of the trend so these results remain to be reconciled. From the uncertainties discussed in the Section "Current capabilities", it is clear that our ability to detect changes (or confirm the lack thereof) in precipitation, evaporation, surface radiation, and land-surface signals is not yet at a stage where regional to global variations of order 1.0 W m^{-2} can be isolated.

Observational verification of water vapor feedback is complicated by the difficulty in isolating radiative/convective processes from dynamical effects (e.g. ENSO-related changes in subtropical jet structure) and to a lesser degree by uncertainties of cloud contamination in IR retrievals. However, with ever-lengthening time series and sensor improvements we can expect more robust time series measurements and perhaps a more thorough assessment of humidity changes over a greater variety of dynamical flow regimes. Improved cloud penetration via microwave sounding channels (e.g. 183.3 GHz) starting with the Special sensor Microwave Imager-2 (SSM/T-2) and now with the equivalent frequencies on the Advanced Microwave Sounding Unit-B (AMSU-B) sensors will be an important measurement series. Complementary vertical moisture structure from MLS, which will be continued on the Aura spacecraft, will certainly assist in a more robust understanding of UTH and the important intersection of the water cycle and radiative balance of the planet.

What is clearly needed at this point is increased emphasis on assessing the error characteristics of historical satellite retrievals, reprocessing and integrating those retrievals with contemporary and near-term planned improvements in remote sensing, and reconciling these with existing conventional *in situ* data. Our examination here of signals in precipitation, evaporation, and radiative fluxes suggests that at present we can detect regional patterns of interannual variability with considerable skill; we can resolve globally integrated signals with only modest certainty, and for the most part, we have little confidence yet in decadal changes or trends. Nevertheless, the situation is encouraging because in many cases these retrievals have been done without regard to intercalibration of sensor data streams and, in the case of operational retrievals, algorithm changes and improvements that result in spurious changes. A near-term challenge will be to reprocess many of these data streams to enforce more stringent consistency requirements.

We touched only briefly here on assimilation of energy flux quantities into numerical models. Data assimilation strategies are likely the most objective and statistically optimal means of blending diverse measurements, but considerable work is still needed. In the past, data assimilation has been driven by requirements for operational numerical weather prediction with emphasis on use of state-variable information (temperature, wind, and moisture). Blending in water and energy flux data is much more of a challenge because these variables are closely related to model physics parameterizations – traditionally the weakest parts of these tools. There is currently much emphasis on improving the physical basis of model moist processes and radiation so they are more physically consistent and are amenable to accepting constraints by remotely sensed fluxes. The assimilation of TRMM precipitation into the NASA Goddard Earth Observing System (GEOS) model (Hou *et al.*, 2001) is an example of this ongoing work.

A LOOK TO THE FUTURE

One can usefully regard the past 15 years of progress as the first maturation of remote sensing and a period characterized by major advances in retrieval accuracy and breadth of physical processes measured. We are seeing increased integration of measurements from multiple sensors in retrieval algorithms and steady improvement in data assimilation techniques as tools for fitting models with data. Much of the impetus for this has come from the WCRP GEWEX and CLIVAR programs, coordinated national responses to the IPCC process, and other international advocacy efforts that have served as organizing entities for setting scientific and observational remote sensing requirements. These requirements include priorities of quantities to be measured, required new retrieval technologies, analysis strategies, and associated accuracy needs.

What improvements can we expect new remote sensing strategies to contribute? One of the attributes of future missions will be to place more reliance on active remote sensing. In the near-term, the CloudSat mission with its profiling 94 GHz radar to be launched in 2005 will provide unprecedented vertical structure of cloud hydrometeors over the globe. In addition to demonstrating the value of this active remote sensing technology, CloudSat will provide new ways of examining relationships between clouds and other properties of the atmosphere that are important for understanding the earth's hydrological cycle and how cloud feedbacks are established within the climate system (Stephens *et al.*, 2002).

With respect to precipitation and land-surface controls on energy fluxes, several planned efforts are of special note. The Global Precipitation Mission, GPM, is currently envisioned as an expansion of TRMM concepts to a continuous, long-term precipitation monitoring capability. A dual-frequency radar will be at the core of this mission and will include a 35 GHz measurement to improve detection of light rainfall amounts. The concept for GPM involves use of this facility instrument in a high inclination orbit to calibrate a more extensive constellation of passive microwave sensors flying on operational and dedicated research platforms. This strategy allows for ~3 h temporal resolution over much of the globe needed for many hydrometeorological applications. As a true international effort, JAXA and NASA will provide the core platform with other international partners contributing passive instruments, ground validation, and other ancillary processing. The earliest expected launch date for the core platform is currently 2011, although passive components of this system will be in place as extensions of current operational meteorological satellites.

Scheduled for launch in early 2007, ESA's Soil Moisture and Ocean Salinity (SMOS) mission () is to further the development of climatological, meteorological, and hydrological models by observing soil moisture over the Earth's landmasses and sea-surface salinity over the oceans for a period of at least 3 years. SMOS will carry the first ever polar-orbiting satellite-borne 2-D interferometric radiometer MIRAS (Microwave Imaging Radiometer by Aperture Synthesis). From an altitude of 763 km, the novel MIRAS instrument has been designed to capture images of microwave radiation emitted from the surface of the Earth at L-band (1.4 GHz). The NASA Hydrospheric State (HYDROS) mission, projected for launch in 2010 will provide global mapping of soil moisture and freeze/thaw state. HYDROS will combine the attributes of L-band active and passive microwave sensing to meet the resolution (order of tens of kilometers) and accuracy requirements while minimizing undesirable vegetation and atmospheric effects. This mission should help assess how well key hydrologic processes are being represented in models and assimilation systems.

These missions are but a sampling of how continued international efforts to insure remote sensing from space serves the broader earth science community in which global hydrology takes its place. As we consider how far remote sensing of the water cycle has come in recent decades, prospects for the future seem bright. A scientific quest, which was once data limited, is now becoming one of synthesizing consistency from an abundance of detailed, yet admittedly still in many ways indirect, satellite measurements. Consistency of interrelationships between water and energy processes is bound to be a prominent theme as time series of water and energy fluxes are examined. The advances in quantifying hydrologic processes across scales to produce a truly integrated understanding will surely be a continuing challenge, but one which will have considerable scientific and practical yield.

Acknowledgments

The author expresses his appreciation to Dr. William Lapenta for discussions and insight regarding land-surface data assimilation and to Dr. M. Rodell for the GLDAS data presented in Figure 4. This work was supported by the NASA Global Water and Energy Cycle Program, Dr. Jared Entin being the Program Manager.

177: The Role of Large-Scale Field Experiments in Water and Energy Balance Studies

W JAMES SHUTTLEWORTH[1] AND JOHN HC GASH[2]

[1]*Department of Hydrology and Water Resources, University of Arizona, Tucson, AZ, US*
[2]*Centre for Ecology & Hydrology, Wallingford, Oxfordshire, UK*

Over the last two decades, increased awareness of the potential importance of anthropogenic drivers of "global change" and growing interest in predicting climate variability at seasonal to interannual timescales has stimulated the development of new experimental techniques and new modeling methods to upscale conventional observations of land-surface exchanges to area scales consistent with the grid scales used in General Circulation Models, and large-scale experiments in important global biomes that had previously been neglected. The nature, purpose, and scale of such large-scale field experiments, many fostered by international programs such as the World Climate Research Programme (WCRP) and the International Geosphere-Biosphere Programme (IGBP), has evolved with time. Initial studies focused on exploring the value of remotely sensed data when upscaling or provided data at several sites that sampled the most important vegetation covers across large biomes. One important class of experiments, the Mesoscale Field Experiments, laid emphasis on gathering data over an area comparable with that of a Global Circulation Model (GCM) grid square and explored the nature and significance of mesoscale coupling between the land surface and the overlying atmosphere and, in particular, the response of the atmosphere to heterogeneity in vegetation cover. Subsequently, the spatial scale of studies increased in a suite of Continental-Scale Experiments (CSEs) which explored the extent to which the atmospheric component of energy and water budgets can be reconciled with the equivalent surface budgets, fostered improvement in the performance of the regional scale–coupled hydrometeorological models, and investigated "land memory" processes that operate at regional scale and at the seasonal timescales. Recently the emphasis has been on seeking to link several CSEs together in a Coordinated Enhanced Observing Period (CEOP) using satellite systems to provide observations at the global scale. This article describes the evolving purpose and developing nature of large-scale field experiments over the period 1984–2004 and their role in providing improved knowledge and modeling of land-surface energy exchanges.

INTRODUCTION

In the late 1970s and early 1980s there was a rapid increase in awareness of the large-scale changes taking place in the global environment and interest in predicting climate variability. Anthropogenic drivers such as deforestation, desertification, and the buildup of greenhouse gases in the atmosphere became recognized as having the potential to alter the climate of the whole planet and as prospective contributors to what came to be collectively known as "global change". The development of Global Circulation Models (GCMs, *see* **Chapter 178, Modeling of the Global Water Cycle: Numerical Models (General Circulation Models), Volume 5**) and their use for predicting the climatic effects of large-scale land-cover change (e.g. Taylor *et al.*, 2002) and increased radiative forcing by greenhouse gases (e.g. Cox *et al.*, 2000) together with an emerging capability in predicting climate variability at all timescales, including seasonal to interannual, created a need for improved knowledge and modeling of land-surface energy exchange and evaporation at the scale of the grids at which GCMs operate. Typically, the grids used in GCMs have a length scale of hundreds of kilometers and cover an area which in most parts of the world comprises a patchwork of soils and

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

vegetation types. This posed a new challenge to scientists previously used to thinking at the plot or field scale. How can land-surface interactions be adequately represented at the scale of a grid square, biome, or large river basin? To address this question, new experimental techniques had to be created and new modeling methods developed to upscale conventional observations. From the outset, it was recognized that remote sensing would likely play a major role in doing this. At the same time, there was also recognition that field studies of important global biomes had been neglected. Previous observations of energy exchange and evaporation had largely been limited to temperate latitudes. Similar studies were therefore needed in the key biomes important in the context of global change: in the vast, remote, and sparsely populated areas of the tropics and high latitudes; for rainforest, savanna, tundra, and boreal forest biomes. For such biomes, climatic conditions and difficult access combine to make the logistics of experimental field studies challenging and expensive.

To meet the needs of global change science, international programs such as the World Climate Research Programme (WCRP) and the International Geosphere–Biosphere Programme (IGBP) were created and set research agendas to better understand the interactions and controls that define the global environment. A series of large-scale field experiments were initiated in which all the components of the energy, water, and latterly carbon balance were measured simultaneously over large areas.

A CATALOGUE OF EXPERIMENTS AT INCREASING SPATIAL SCALE

Table 1 draws heavily on Dirmeyer and Hoff (2004) and, although not exhaustive, lists most of the major international large-scale field experiments over the period 1984 to 2004. It does not include large-scale field experiments for which the focus was on improving understanding of ocean–atmosphere exchanges or of atmospheric chemistry and aerosols. The most noticeable feature of the experiments included in Table 1 is that they have progressively evolved towards documenting land–surface interactions over increasing spatial scales over this period. Some early experiments, notably those stimulated under the International Satellite Land Surface Climatology Project (ISLSCP), gave emphasis to exploring the use of remotely sensed data to upscale land–surface interactions. In these experiments, data was typically gathered over 100–400 km^2 (e.g. First ISLSCP field experiment (FIFE): Sellers and Hall, 1992; Hall and Sellers, 1995) in some cases simultaneously at more than one location (e.g. Boreal ecosystem-atmosphere study (BOREAS): Sellers *et al.*, 1995; Hall, 1999). Other experiments provided simultaneous data at several sites which sampled the most important vegetation covers at several places across large biomes (e.g. Anglo-Brazilian Climate Observation Study (ABRACOS): Gash and Nobre, 1997).

One important class of experiments, the *Mesoscale Field Experiments* (e.g. HAPEX-MOBILHY: André *et al.*, 1988, 1989. EFEDA: Bolle *et al.*, 1993. HAPEX-Sahel, Goutorbe *et al.*, 1994, 1997), laid emphasis on gathering data over an area comparable with that of a GCM grid square. Subsequently, the spatial scale of studies increased in a suite of Continental-Scale Experiments (CSEs: e.g. GCIP, Coughlan and Avissar, 1996; Lawford, 1999: BALTEX, Raschke *et al.*, 1998: LBA, LBA SCIENCE Planning Group, 1996: GAME, Yasunari, 1993: MAGS: Stewart *et al.*, 1998). Recently the emphasis has been on seeking to link several CSEs together in a Coordinated Enhanced Observing Period (CEOP) using satellite systems to provide observations at the global scale (see Koike, 2002).

MESOSCALE FIELD EXPERIMENTS

The design of Mesoscale Field Experiments owed much to the ocean–atmosphere experiments carried out in the 1960s and 1970s (see Garstang and Fitzjarrald, 1999) which involved intensive measurement campaigns with multiple teams of researchers making coordinated measurements from ships, buoys, balloons, and aircraft. In the equivalent land-atmosphere studies, such as HAPEX-MOBILHY (Hydrological-Atmosphere Pilot Experiment – Modélisation du Bilan Hydrique; André *et al.*, 1988) in France, there was emphasis on simultaneous measurements to sample the surface exchanges of different vegetation covers and soils. Indeed, in the case of HAPEX-MOBILHY, the energy balance, evaporation, and soil moisture for all the major vegetation types in a 10^4 km square were monitored (*see* **Chapter 39, Surface Radiation Balance, Volume 1** and **Chapter 40, Evaporation Measurement, Volume 1** for a description of the techniques). Airborne remote sensing techniques and large-scale flux measurements by aircraft were also added. A critique of how these techniques have developed and how land–surface experiments have contributed to understanding is given by Gash and Kabat (2004) and elsewhere in Kabat *et al.* (2004; Part B). In HAPEX-MOBILHY it was found that, while the mixed agricultural land could be modeled as an aggregated surface, it was necessary to differentiate between agricultural land and forest. The marked difference in surface exchanges between these dissimilar vegetation types was found to result in different rates of convective boundary-layer development and, on occasions, also in different cloud cover (e.g. Shuttleworth, 1988).

HAPEX-Sahel (Goutorbe *et al.*, 1994, 1997) provides a good example of a Mesoscale Field Experiment held as an intensive field campaign. This experiment was designed

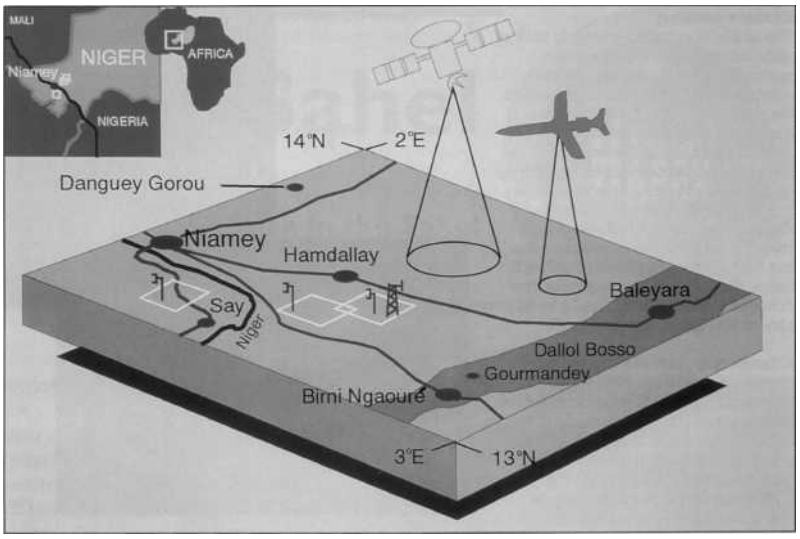

Figure 1 The HAPEX-Sahel experimental square in Niger, West Africa. In August and September 1992, some 180 scientists collected soil moisture and hydrological data, vegetation and flux measurements, and atmospheric boundary-layer and remote sensing data. HAPEX-Sahel is typical of other Mesoscale Field Experiments and was designed to investigate how to represent surface interactions at the GCM grid square scale for a landscape of mixed vegetation

to address the issue of aggregation, that is, how to represent surface interactions at the grid square scale for a landscape of mixed vegetation, but it was also significant in being located in an important area of the world where potential desertification is an issue. Figure 1 shows the experimental layout of the HAPEX-Sahel experiment. Over a period of two months, intensive measurements of energy surface exchange, water, and carbon fluxes, and soil moisture were made at three "super-sites" and, at each of these, for the three main vegetation types present in the landscape. Aircraft were used to make flux remote sensing measurements, tethered balloons, and frequent ascents by free flying radiosondes were used to monitor the atmospheric boundary layer and the atmosphere above, and many plot-scale process studies investigated how the individual water pathways contributed to the overall hydrological functioning of the area. Mesoscale meteorological models were used as the framework for bringing the results together. As was the case for many large-scale field experiments, a special issue of a scientific journal, in this case a 50-paper issue of the Journal of Hydrology (Goutorbe *et al.*, 1997) was used to document many of the results of the study.

One of the key results from HAPEX-Sahel was the discovery that in sparse vegetation, with much bare soil exposed, there is rapid evaporation from the soil in the days after rain. Modeling this flux requires two-source models (*see* **Chapter 45, Actual Evaporation, Volume 1**). Importantly, it also results in instantaneous spatial patterns of evaporation which are controlled by the variability in rainfall rather than vegetation. However, over a season, systematic differences in evaporation otherwise masked by large day-to-day variation emerged for the different vegetation types (Gash *et al.*, 1997). These data, when applied in a GCM modeling experiment (Taylor *et al.*, 2002) in which the improved representation of the land surface was coupled with realistic estimates of demographic and land use change, provided a convincing demonstration of how changes in the land surface may affect climate in the Sahel. Surprising feedbacks between the land surface and the atmosphere were discovered at the meso- (1–10 km) scale. These feedbacks, again resulting from the evaporation from bare soil after rainfall, result in persistent rainfall patterns where rain falls preferentially over areas where it has fallen before (Taylor and Lebel, 1998; Clark *et al.*, 2003).

As previously stated, most of the Mesoscale Field Experiments typically carried out at 10^4 km study sites were primarily focused on investigating how best to represent area-average surface exchanges at grid scales. However, in the case of the ongoing Atmospheric Radiation Measurement Southern Great Plains (ARM-SGP) study (DOE, 1996), although many of the field systems used are similar, the main motivation is to investigate how best to parameterize atmospheric (cloud and radiation) processes in models with grid scales of 100 km or larger. Consequently, substantial additional sensing of the lower atmosphere is included. As part of its purpose, ARM-CART also explores the nature and significance of mesoscale coupling between the land surface and the overlying atmosphere and, in particular, the response of the atmosphere to heterogeneity in vegetation cover.

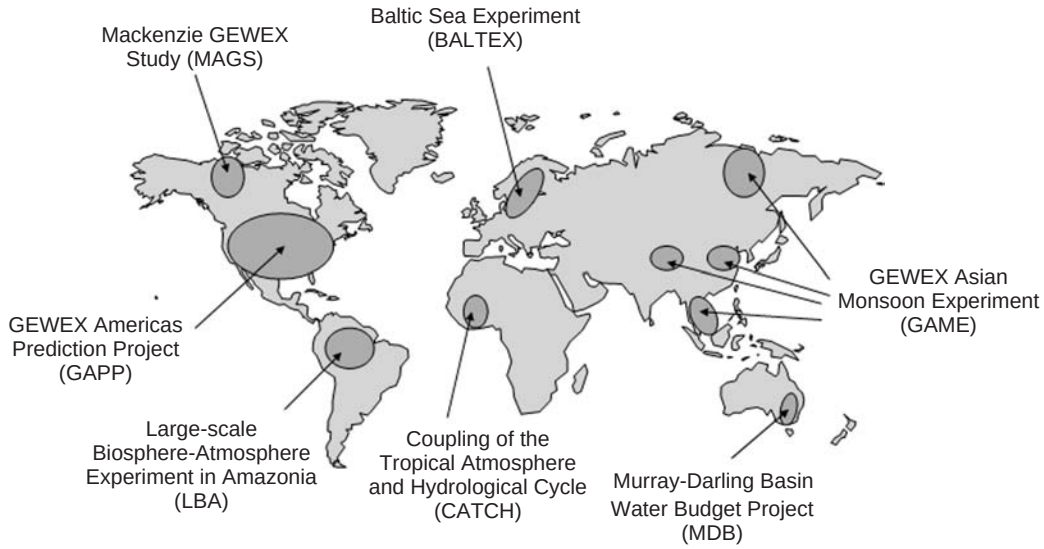

Figure 2 The location of the seven continental-scale experiments CSEs (GAPP, LBA, BALTEX, GAME, MAGS; MDB, and CATCH) coordinated by the GEWEX hydrometeorology panel and selected to sample important hydroclimatic regions across the globe. CATCH is still in development at the time of writing. CSEs operate over study areas substantially greater than Mesoscale Field Experiments, typically with length scales of 1000 km, or greater

CONTINENTAL-SCALE EXPERIMENTS

Over the last decade, WCRP has established several Continental-scale Experiments (CSEs) coordinated by the Global Energy Water-cycle Experiment (GEWEX) Hydrometeorology Panel (**http://ecpc.ucsd.edu/projects/ghp/ghp.html**). CSEs operate over study areas substantially greater than Mesoscale Field Experiments, typically with length scales of 1000 km, or greater. Figure 2 shows the location of seven CSEs (GAPP, LBA, BALTEX, GAME, MAGS; MDB, and CATCH) which were selected to sample important hydroclimatic regions across the globe.

An important motivation for CSEs is to explore the extent to which the atmospheric component of energy and water budgets documented can be reconciled with the equivalent surface budgets at an area scale of 10^6 km^2 or greater, areas this large being necessary for atmospheric estimates to have reasonable accuracy. In practice, however, their most direct and immediate benefit has arguably been to foster a marked improvement in the performance of the regional scale–coupled hydrometeorological models with which each CSE is associated, and in Numerical Prediction Models at several forecast centers around the world. Such improvement was achieved by providing better representation of surface energy and water exchange processes and atmospheric processes through the provision of relevant calibration and validation data. Associated with this improvement in the predictive ability of regional models operating at timescales up to seasonal, there has been a worthwhile improvement in the quality of the model-calculated fields derived by assimilating surface, atmospheric, and remotely sensed data into such models.

The simultaneous availability of improved regional models and continental-scale measurements of geophysical variables in CSEs also allows exploration of the "land memory" processes that operate at regional scale and at the seasonal timescales associated with, for example, soil moisture, snow, and ice cover, and vegetation growth and senescence. In parallel with the improvement in the regional and global models themselves, there has been improvement in the ability to initiate such models, most significantly through the development of Land Data Assimilation Systems (LDAS). A substantial additional benefit from CSEs has been a marked improvement in the interaction between hydrologists and atmospheric scientists, with the result that weather and climate predictions can receive more effective and immediate hydrological application, and the significance of hydrological processes in meteorological forecasting is better understood and represented in models.

COORDINATED ENHANCED OBSERVING PERIOD

It is likely that in the future remote sensing by air- and space-borne platforms of various kinds will be increasingly relied upon as the source of data for documenting energy and water related processes and phenomena. However, many key observational issues currently remain uncertain, such as which types of observations are most useful, what are the preferred horizontal, vertical, and time resolutions of these observations, and how can calibration best

be addressed. Recognizing these issues, the Coordinated Enhanced Observing Period (Koike, 2002) has brought together ongoing simultaneous data gathering by the several CSEs motivated by a desire to stimulate and test the application of a new generation of simultaneously available satellite sensors (TERRA, AQUA, ENVISAT, and ADEOS-II in addition to TRMM, Landsat-7, the NOAA-K series and several other operational satellites).

In practice, the simultaneous gathering of data from several CSEs also provides a new opportunity to test the transferability of understanding and models between CSEs in different climatic regions. The observation and data collection phase of CEOP extends from 1 July 2001 to 30 September 2004 with primary focus on the collection of a 2-year dataset beginning October 2002. Data collection includes not only basic satellite data, but also continuous observations from many CEOP reference sites in each of the CSEs, and data derived by assimilating remotely sensed, atmospheric sounding, and *in situ* climate data into models at many of the worlds leading numerical weather prediction centers. Perhaps CEOP can be viewed as a precursor to a true global scale observational study to document the Earth system as a whole by assimilating data from satellites, aircraft, and balloon systems, ships and bouys, and *in situ* observations over land surfaces into coupled ocean–atmosphere–land models operating at global scale.

178: Modeling of the Global Water Cycle: Numerical Models (General Circulation Models)

RANDAL D KOSTER

NASA/Goddard Space Flight Center, Greenbelt, MD, US

Atmospheric general circulation models (AGCMs) are powerful tools for exploring climate sensitivity and the global water cycle. The wealth of data provided by an AGCM allows a complete statistical characterization of its water cycle, a far more complete picture than would be allowed from real-world observations. AGCM numerical experiments have been used to isolate the mechanisms that control water cycle variability, illustrate the potential for water cycle prediction, and quantify water cycle changes resulting from human activities. The AGCM fields can also be merged with observations (via data assimilation) to provide the best estimates possible of the true water cycle. Unfortunately, biases in simulated fields resulting from coarse resolution and inadequate physical parameterizations continue to plague AGCMs, forcing climate modelers to temper their faith in the models' results.

INTRODUCTION: ATMOSPHERIC GENERAL CIRCULATION MODELS

Atmospheric general circulation models (AGCMs), usually coupled to land-surface models (LSMs) and sometimes to ocean models (OGCMs), are numerical representations of the atmosphere that allow the simulation of global weather patterns. The atmosphere in AGCMs is either explicitly (for grid point models) or effectively (for spectral models) discretized into elements with a length scale of 1–5 degrees in the horizontal and hundreds of meters in the vertical; the discretized time step is typically of the order of minutes. The equations of motion determine transports of mass and energy between the elements during each time step. Meanwhile, various physical parameterizations compute the sources and sinks of energy and water within all elements – they determine how much water vapor is converted to rain, how much radiation is absorbed by the atmosphere, and so on. Simulated weather is averaged over long periods of time to reveal the AGCM's inherent "climate".

AGCMs are used extensively to study and predict variability in climate and the global water cycle. For such applications, these models have some powerful advantages and some severe limitations. One key advantage is the ability of an AGCM to provide complete, global fields of self-consistent data over a wide variety of timescales, ranging from hours to decades or centuries. Parallel ensembles of decadal simulations can provide enough data to characterize completely an AGCM's simulated water cycle, though not at scales below the model's resolution. For some applications, observed data can be combined with model data in an optimal way to produce an enhanced product (see section Data assimilation below). AGCM output includes values for many quantities (e.g. evaporation from land) that simply cannot be measured at the global scale, either now or in the foreseeable future.

Another key advantage of an AGCM is its ability to host sensitivity studies. Modifications of model boundary conditions in the atmosphere (e.g. an increase in CO_2), at the land surface (e.g. projected deforestation), or the ocean surface (e.g. the onset of El Niño conditions) are typically straightforward to implement, and resulting impacts on simulated water cycle components can be quantified and analyzed. Such sensitivity experiments are arguably the best approach we have for predicting the likely impacts of human activities on climate. Sensitivity of modeled climate to changes in model parameterizations can identify the physical mechanisms that control variations in the water cycle in the model and thus, by extension, in the real world.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

The AGCM's main limitation is the inaccuracy of its simulated fields. The aspect of the AGCM that makes it useful for climate studies in the first place, namely, the ability of various model states to feed back on one another, also allows the climate of the model to drift into unrealistic situations – to generate unrealistic annual precipitation totals, for example, or an unrealistic radiation balance. The unwanted drift stems largely from inadequacies in the treatments of the many physical processes at work in the atmosphere, land, and ocean. Because many processes occur at spatial scales well below the resolution of the AGCM, overly simple, inaccurate parameterizations have to be used (section Model parameterizations and limitations), parameterizations that are further hampered by a lack of the global-scale measurements needed to define suitable parameter values. Climate scientists who use AGCMs must constantly qualify their results in light of the AGCM's deficiencies.

MODELED WATER CYCLE COMPONENTS

Together, AGCMs and their coupled LSMs simulate most of the components of the global water cycle. Modeled atmospheric processes include water vapor transport (both vertical and horizontal), cloud formation, and rainfall generation (both convective and nonconvective). Modeled land processes include evapotranspiration, canopy interception, snowpack growth and ablation, runoff generation, and subsurface soil moisture transport. Typically missing from the coupled AGCM-LSM system is a representation of deep groundwater; the modeled soil moisture variables typically represent no more than the top few meters of soil. Glacier and ice sheet dynamics are also typically missing. Oceanic transports of water could be provided through a coupled ocean model.

Our ability to test an AGCM's simulated global water cycle against observations is limited by a paucity of relevant global measurements. Large-scale direct measurements of evaporation, for example, are essentially nonexistent, and direct measurements of soil moisture and atmospheric vapor transport are far from complete. Fortunately, precipitation, a critical component of the water cycle, has been estimated on the global scale by many groups. The Global Precipitation Climatology Project (GPCP), for example, generated a product based on a combination of *in situ* gauge measurements and satellite observations (Huffmann *et al.*, 1997). Figure 1 shows a comparison between observed precipitation, averaged into zonal means, and the corresponding values derived from various AGCMs. The errors for all models are large, particularly in the tropics and midlatitudes.

Even more difficult for AGCMs to capture are the variability characteristics of precipitation. Soden (2000), for example, shows that AGCMs substantially underestimate

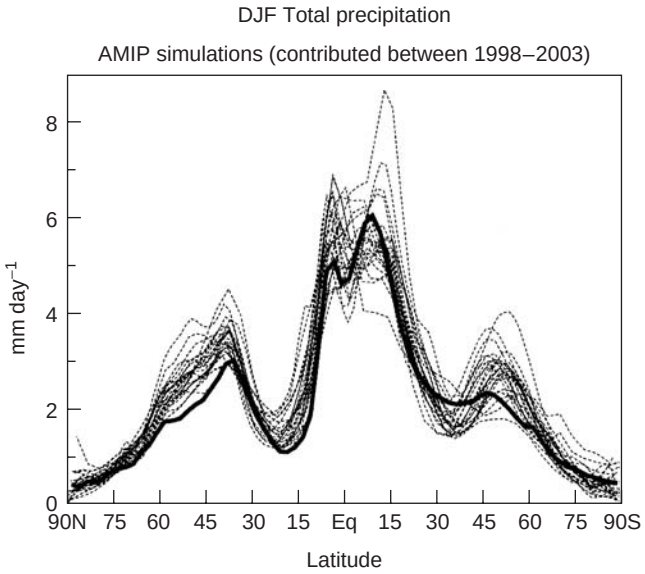

Figure 1 Zonal mean DJF precipitation totals from observations (heavy solid line), as derived from the dataset of Xie and Arkin (1998), and from AGCMs participating in the Atmospheric Model Intercomparison Project (dotted lines). Figure courtesy of Peter Gleckler

the observed interannual variability of precipitation in the tropics. In midlatitudes, on the other hand, an excessive land–atmosphere feedback can lead to overestimates of precipitation variance (Koster *et al.*, 2003). Although observations of year-to-year variability are certainly not perfect, the disagreement is most likely caused by AGCM error. The accurate reproduction of the observed year-to-year variability of the water cycle is typically given less attention in these models than the reproduction of observed means.

Surface and subsurface runoff (streamflow) generated by AGCMs can also be evaluated against observations. One comparison was provided by Russell and Miller (1990), who found, for example, that an early version of the Goddard Institute for Space Studies (GISS) AGCM strongly underestimated Amazon River outflow. Unfortunately, because the realism of simulated runoff depends in large part on the realism of simulated precipitation, and because errors in simulated precipitation abound (Figure 1), an evaluation of AGCM-simulated runoff may say little about the correctness of LSM runoff treatments. For a proper test of an LSM's runoff formulation, the LSM should be driven offline with the most realistic atmospheric forcing possible. Runoffs generated in this way through the Global Soil Wetness Project (GSWP) (Dirmeyer, 1999) tended to be significantly underestimated relative to observations in higher latitudes (Figure 2, from Oki *et al.*, 1999). Work is proceeding to determine if the LSMs are at fault or if strong measurement biases associated with the undercatch of snowfall are responsible.

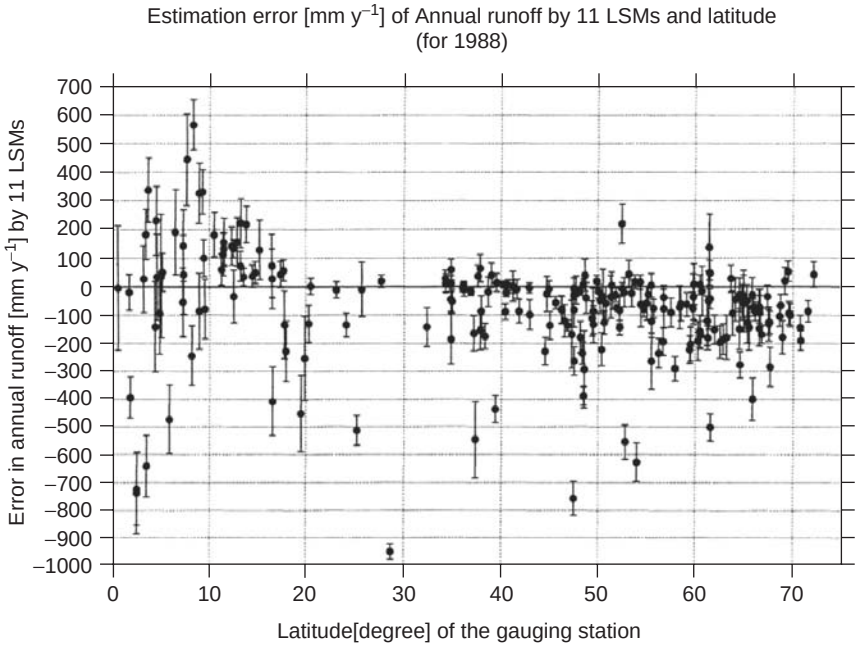

Figure 2 Errors in simulated runoff as a function of latitude, as determined from 11 land-surface models participating in the Global Soil Wetness Project (GSWP) (Reproduced from Oki *et al.*, 1999, by permission of the Meteorological Society of Japan)

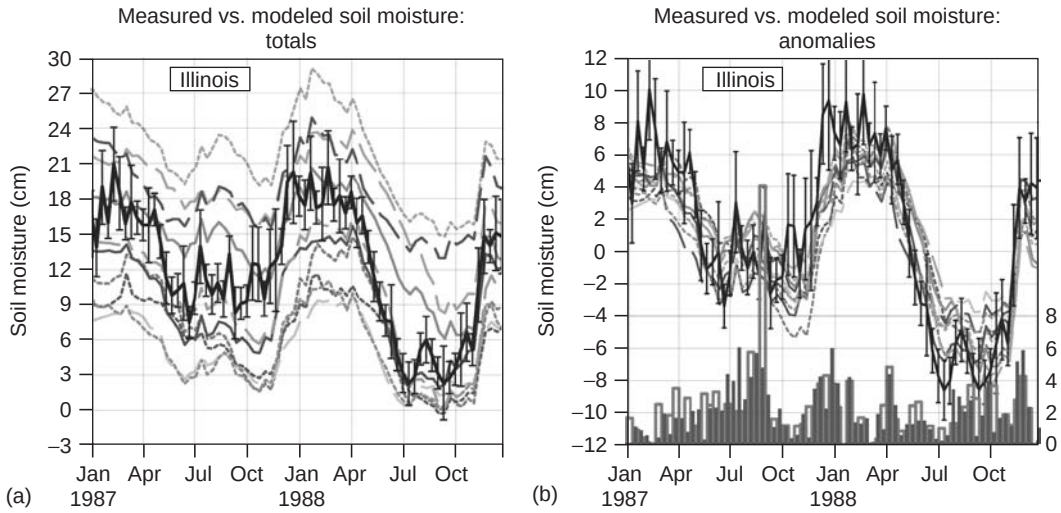

Figure 3 (a) Observed soil in Illinois (black line with error bars) and simulated soil moistures (other lines) in the same region, as determined by several models participating in the Global Soil Wetness Project (GSWP). (b) Same, but for the measured and simulated soil moisture anomalies relative to each dataset's own long-term mean. Histograms for precipitation are provided at the bottom of the graph (Reproduced from Entin *et al.*, 1999, by permission of the Meteorological Society of Japan). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

For similar reasons, while observed soil moisture contents can be compared to AGCM-generated values, a more useful exercise is to compare the observed values with those produced by the LSM running offline with realistic atmospheric forcing. Long-term observations are essentially limited to Asia and small parts of Illinois and Iowa (Robock *et al.*, 2000). These data were used by Entin *et al.* (1999) to examine the soil-moisture contents generated by the LSMs participating in GSWP. Figure 3 shows one of the results. The LSMs successfully capture the amplitude and phase of the seasonal cycle of observed soil moisture but fail to match the observed values' absolute magnitudes. This

is presumably due to the somewhat nebulous meaning of "soil-moisture" in LSMs. (See section Model parameterizations and limitations.)

Atmospheric vapor can be estimated from space. SMMI-derived estimates of total precipitable water (TPW), averaged over the year, are compared in Figure 4 to values simulated by the NASA Seasonal-to-Interannual Prediction Project (NSIPP) AGCM. The overall patterns are well reproduced. Observational estimates of atmospheric vapor transport, however, are more difficult to obtain; satellites cannot as easily sense wind direction or speed, and "*in situ*" radiosonde measurements are low in density in most parts of the world. Vapor transport is usually estimated via data assimilation, which involves the merging of an AGCM with radiosonde and satellite observations (see section Data assimilation below).

The examples above illustrate the sometimes large biases that pervade state-of-the-art AGCMs. Reductions of this bias can occur in two ways. First, the model can be "forced" to have more realistic fields through data assimilation, that is, by using observations to modify its state variables (section Data assimilation). Second, the model's representation of dynamics and physics can be improved through increased resolution and more powerful, realistic

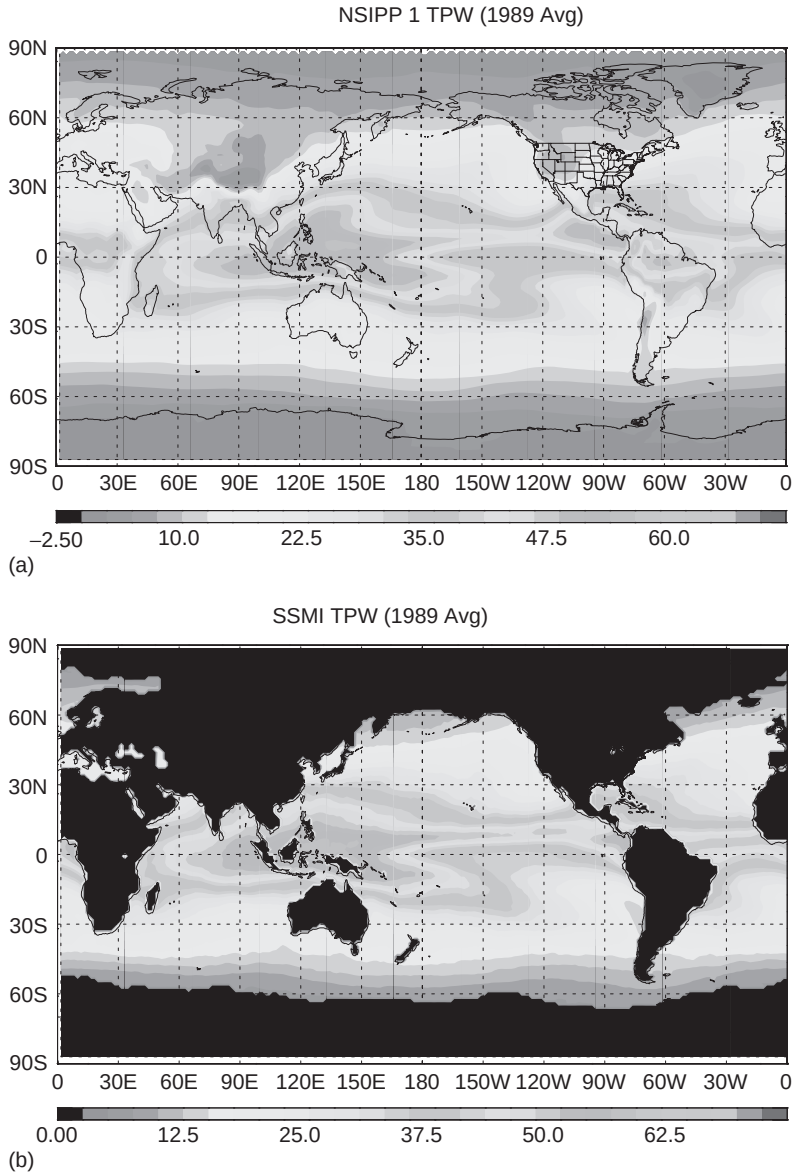

Figure 4 Comparison of total precipitable water (in mm) for 1989 as produced by an AGCM (a) and as measured by satellite (b). The satellite values are undefined over continents. Figure courtesy of Julio Bacmeister, UMBC, Maryland. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

parameterizations. This second approach is critical for climate sensitivity studies (section Variability analyses), which require a maximum number of unconstrained degrees of freedom and thus should not rely on ingested observations. Unfortunately, the pace of such improvements over the last few decades has been plodding at best. The search for reliable parameterizations of nonresolvable subgrid processes (section Model parameterizations and limitations) will continue to challenge modelers in the years to come.

Note that a philosophy adopted by many AGCM modelers is that inaccuracies in an AGCM's climate, if they are small enough, may be quite acceptable for sensitivity studies. The idea is simple – two simulations, one with and one without an imposed modification (e.g. a deforested surface), produce two model climates that can be directly compared. Assuming that the bias of concern appears in both climates, differencing the climates will tend to remove the bias and will thereby highlight climate differences associated with the imposed change. Of course, this approach is predicated on assumed linearities in the modeled system. This assumption is often untenable, particularly when the bias is large.

MODEL PARAMETERIZATIONS AND LIMITATIONS

As noted in section "Modeled water cycle components", an AGCM's simulation of the global water cycle is far from perfect. Much of the error is induced by the necessity of parameterizing physical processes that occur at scales too small to be resolved explicitly by the model. This is not just a temporary problem, one that will soon be eliminated by the advent of faster, more powerful computers. Increasing an AGCM's resolution by two requires about a 10-fold increase in computational power – a factor of two for both horizontal spatial dimensions and a factor of two for the time step. Thus, even if the most powerful computers today became a million times faster, the typical spatial resolution would reduce from about 200 km to about 3 km, still too large to resolve cloud updrafts, individual trees, the hillslope structure that controls runoff production, and other critical components of the Earth's system. Parameterizing the effects of these features with approximate bulk or statistical representations will remain an unavoidable strategy for the foreseeable future.

A cursory description of the evolution of land-surface process models should serve to illustrate some key limitations of parameterizations. The earliest LSMs simply prescribed soil moisture conditions, imposing, for example, dry conditions in deserts and wet conditions in tropical forests. Interactive land surface models were then introduced, the first and simplest being the "bucket" model of Manabe *et al.* (1969), which allows the water level in a soil moisture reservoir and thus the evaporation efficiency to increase during precipitation events and decrease as the water evaporates. In the mid-1980s, Sellers *et al.*, (1986) and Dickinson *et al.* (1986) introduced the "SVAT" (soil-vegetation-atmosphere-transfer) model, which allows vegetation to control the heat and moisture balances of a region. A simplified description of the basic SVAT transpiration calculation is provided in Figure 5.

Recently, various groups have extended the approach to the next level. The physics of photosynthesis is now explicitly included in many models (e.g. Bonan, 1995; Sellers *et al.*, 1996), using parameters that are strongly tied to satellite-based land-surface data. The idea is that because plants and trees open their stomata to maximize carbon uptake while minimizing water loss, an accurate representation of the physics of this uptake is needed to ensure realistic transpiration rates. Such emphasis on the carbon cycle is indeed noted by Sellers *et al.* (1997) as the next logical step (after the SVAT) in the evolution of LSMs. Related to carbon-cycle modeling are many recent efforts to model interactive vegetation phenology and/or species distribution, as noted in section Variability analyses.

While the latter advances are important, they represent an improvement over only one facet of the land surface. Other facets remain relatively simple, and this imbalance

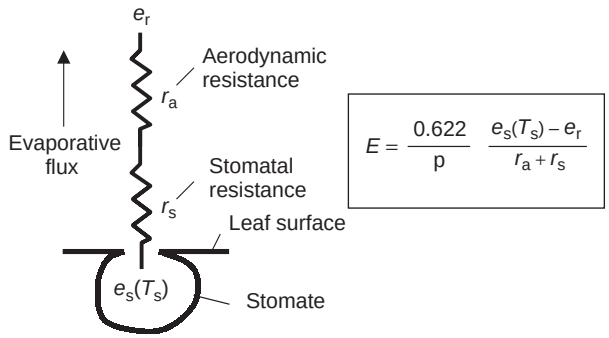

Figure 5 Basis of the "big leaf" transpiration calculation in the standard SVAT model. The vapor pressure within the representative stomate ($e_s(T_s)$, the saturated vapor pressure at the leaf temperature T_s) is separated from the vapor pressure in the air (e_r) by two resistances in series, one associated with the stomatal aperture (r_s) and one associated with transport through the overlying air (r_a, which accounts, for example, for wind speed and turbulent mixing effects). An Ohm's law analogy is applied: evaporation (E) is calculated as the difference between the vapor pressures (analogous to voltages) divided by the sum of the series of resistances. The constants ρ and p in the equation are the air density and air pressure, respectively. A key aspect of the SVAT model is the sensitivity of r_s to the environment – the modeled plants act to shut down transpiration by increasing r_s in times of stress

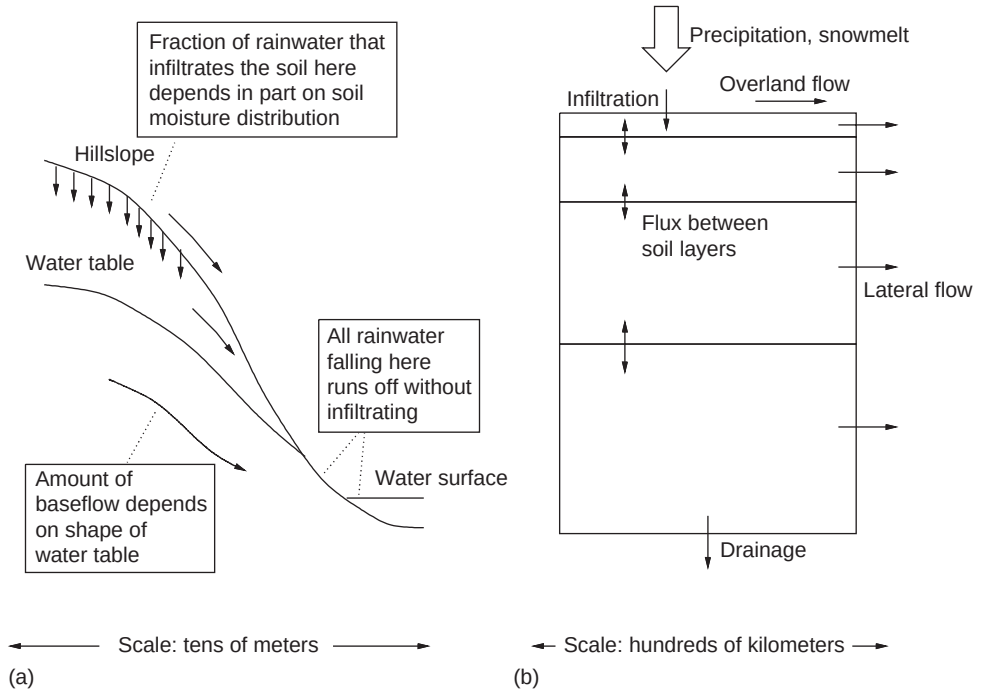

Figure 6 (a) Simple representation of the hillslope processes controlling runoff in nature. (b) Structural framework of a typical LSM. The focus on vertical physics prevents an explicit treatment of the processes highlighted in the left panel

in modeling complexity can lead to severe problems. For example, shown in Figure 6(a) is a representation of hillslope hydrology. The water table intercepts the land surface at the bottom of the hill. Rain falling at the top of the hill may infiltrate the soil, whereas rain hitting the bottom of the hill necessarily runs off. The shape of the water table controls the baseflow rate, an important component of the runoff. Because the soil is drier at the top of the hill, evaporation at the top may be less than that at the bottom.

The point to be made in Figure 6(a) is that subgrid soil moisture heterogeneity, as controlled by topography (among other things), determines in large part the average energy and water budget fluxes produced by a land surface. An explicit representation of soil moisture variability, however, is missing from the great majority of land-surface models – even those with the advanced treatments of photosynthesis and dynamic phenology. In most land-surface models, the soil is treated as shown in Figure 6(b), that is, as a column of vertically stacked soil layers, with soil moisture effectively assumed uniform in the horizontal over distances of hundreds of kilometers. Such a treatment arguably acts as an impassable barrier to a proper treatment of runoff generation. A few LSMs do try to come to grips with the subgrid soil moisture variability problem (e.g. Liang *et al.*, 1994; Famiglietti and Wood, 1994; Stieglitz, 1997; Koster *et al.*, 2000b), tying statistical distributions of soil moisture to observed topography. Such models, however, are arguably still immature.

One may argue that representing a grid cell's hydrology with a stacked layer model (as in Figure 6b), though not optimal for runoff, is acceptable in light of the improvements to evaporation afforded by the more advanced photosynthesis and phenology models. This argument, however, ignores the fact that evaporation and runoff processes are strongly interlinked through their mutual dependence on soil moisture (Koster and Milly, 1997). A poor representation of runoff, which is arguably inescapable with the layer approach, can be a "weak link" that reduces or even eliminates the benefits of an advancement in the treatment of evaporation.

The interaction between the evaporation and runoff schemes also has an impact on the interpretation of modeled soil moisture. The necessity of parameterizing the nonresolvable surface and subsurface physics leads to an LSM "soil moisture" that is arguably more an index of wetness than a physical quantity that can be measured in the field. This explains in large part the apparent poor simulation of soil moisture by various LSMs in Figure 3. The model-dependent nature of the soil moisture variable implies that soil moisture generated in one LSM should not be inserted blindly into another (Koster and Milly, 1997). In time, as representations of LSM physics improve, direct comparisons of simulated soil moisture between models and with observations should become more appropriate.

DATA ASSIMILATION

To quantify the global water cycle, a complete slate of observations, with minimal measurement error, is clearly desirable. A complete set of high-quality, high-resolution observations on the global scale, however, is logistically impossible to collect, both now and for the foreseeable future. For the desired global data, many rely instead on a technique known as data assimilation.

Data assimilation is the optimal marriage between measurements and modeling. In essence, the technique combines measurements and model predictions into a single data set that is superior to either standing alone. The ability of observations to improve on model results should not be surprising, given the model errors outlined in section Modeled water cycle components above. To see how model results could in turn improve on observations, consider the following simple thought experiment. Air temperature is measured in two adjacent regions. The observations in the western region are excellent, with significant spatial coverage and high-quality instruments. In the eastern region, however, observations are spotty, and the instruments used are poor. If we relied on observations alone, we would have only a rough, faulty estimate for the average temperature in the eastern region. If the wind blows from west to east, however, then the temperature in the west (measured extremely well) should have some bearing on the temperature in the east and can be used to improve its estimation. All that is needed for the correction is some representation of how the two regions are physically connected. A model (e.g. an AGCM) that is built upon well-established, fundamental equations of motion and state in the atmosphere can provide the needed representation.

The mathematics underlying data assimilation is complex and is outlined elsewhere in the encyclopedia. Put simply, a given variable (air temperature, humidity, soil moisture, etc.) may have both a measured value and a model-generated value (which reflects, in part, earlier measurements). The "merged" state produced by the assimilation system is a weighted average of these two values, the weights depending on the relative size of their errors. The error analysis – quantifying the measurement error for the observation systems and the evolution of the model errors associated with crude parameterizations, inappropriate parameter values, poorly defined boundary conditions, and so on – is typically key to the system's design.

Various "reanalyses" – data assimilation procedures performed with a single model ingesting decades of data in a consistent way – provide an optimal, though imperfect, view of the global water cycle (e.g. Roads *et al.*, 2002). Figure 7 shows moisture flux fields (July–September) generated with CDAS, the Climate Data Assimilation System of the National Center for Environmental Prediction (NCEP) in the United States. Such a detailed description of moisture transport could not be generated from observations

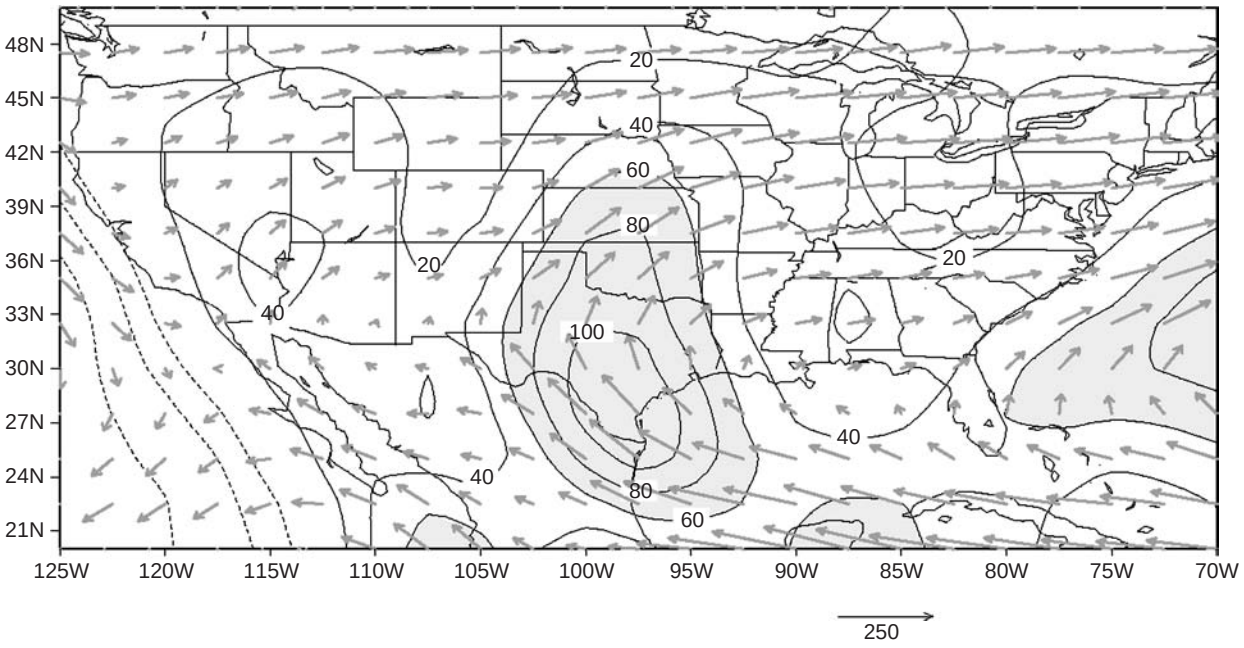

Figure 7 Vertically integrated moisture flux (vector) averaged for the period 1995 to 2000 for July–September from CDAS. The unit vector is 250 kg (ms)$^{-1}$. The meridional flux is shaded and contoured. The contour interval is 20 kg (ms)$^{-1}$. Values greater than 60 kg (ms)$^{-1}$ are shaded. (Figure courtesy of Kingtse Mo, NCEP.) A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

alone. Note, though, that the meridional flux in Figure 7 is not perfect; it should have a maximum in Oklahoma and should be stronger coming out of the Gulf of California (K. Mo, personal communication, 2003).

Assimilating precipitation information into a system is challenging and has been avoided in the first reanalyses. As a result, the precipitation generated by a model in a reanalysis tends to show error relative to the independent observational datasets (Curtis *et al.*, 2001). Note further that fields based on little observational input are not necessarily sound, even if other fields are. Evaporation rates produced by data assimilation systems can be biased (e.g. Betts and Viterbo, 2000); they are arguably less reliable than those generated offline with observed precipitation forcing.

TRACER STUDIES

In addition to providing estimates of quantities that are very difficult to observe, such as evaporation, AGCMs can provide information on quantities that are utterly *impossible* to measure, even though they lie at the heart of the global water cycle. An important example is the distribution of evaporative sources for a given precipitation volume. Any molecule of water that falls as rain or snow in a given region must have had some prior evaporative source – it must have most recently evaporated from some location on the Earth's surface. Establishing the sources of a region's precipitation is important for establishing how that region's climate is "teleconnected" to that of other regions. Unfortunately, definitively determining from observations where water originates is impossible, since all water molecules look alike. Sources can only be inferred indirectly, for example, by examining the rainwater's isotopic content or by making assumptions regarding large-scale mixing of the atmosphere upwind of the precipitation.

AGCMs, however, can "tag" the water that evaporates from a given source region and diagnostically follow it until it precipitates. By dividing the earth's surface into source regions and then tagging the evaporated water from each as an independent tracer, the modeled rainfall at any location can be precisely separated into contributions from the source regions – the relative importance of each source region can be precisely quantified. The procedure can provide, for example, length scales of horizontal vapor transport and water recycling rates (Figure 8).

Tracer studies performed with free-running AGCMs (e.g. Joussaume *et al.*, 1986; Koster *et al.*, 1993) are, of course, subject to the many errors in the AGCM's climate. The results cannot be directly verified and are thus unavoidably questionable. Recently, however, a tracer diagnostic has been incorporated into a full data assimilation system (the NASA Data Assimilation Office system), implying a more reliable representation of tracer transport (Bosilovich *et al.*, 2003). Figure 9 shows an example calculation with this improved system.

VARIABILITY ANALYSES

As mentioned above, the AGCM allows sensitivity experiments that isolate and quantify the physical mechanisms that control the global water cycle. To some extent, any

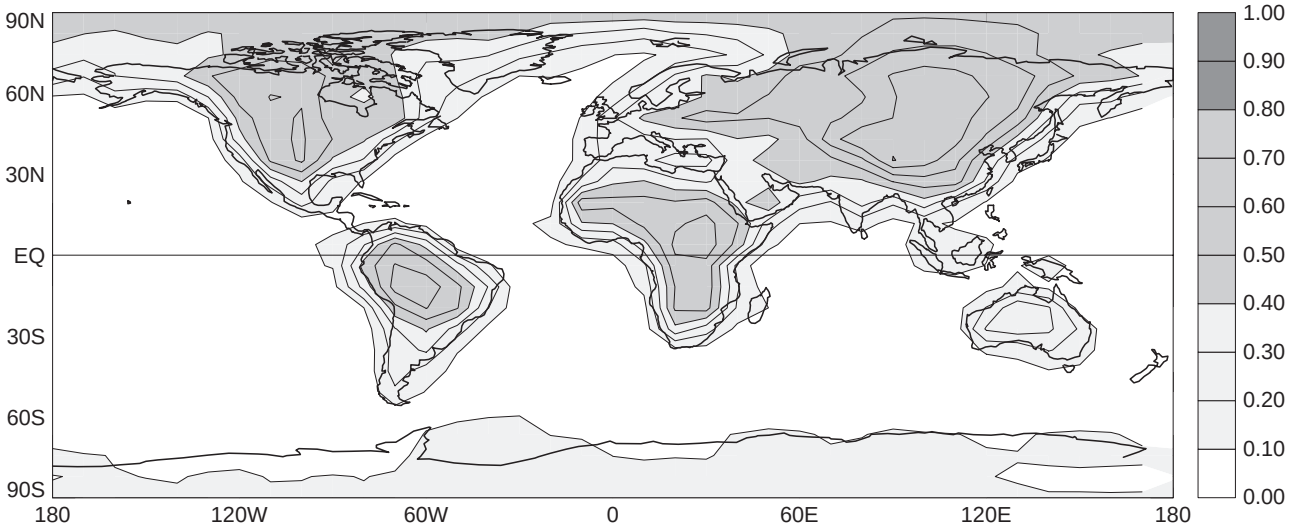

Figure 8 Recycling ratio: fraction of annual precipitation water derived from continental evaporative sources, as determined by a tracer water version of the Goddard Institute for Space Studies AGCM (Reproduced from Koster *et al.*, 1993, by permission of American Geophysical Union)

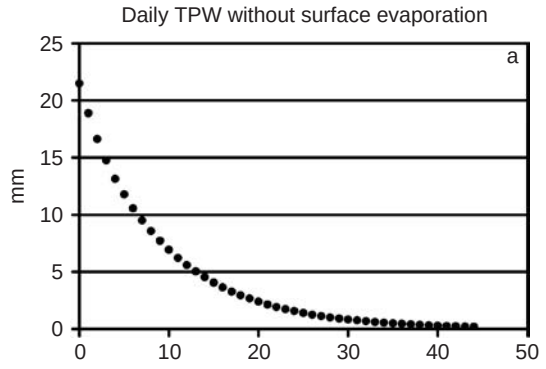

Figure 9 Results of a tracer model simulation in which the initial atmospheric water vapor is tagged as a particular tracer (Bosilovich *et al.*, 2003). The plot shows the reduction (due to rainout) of this tracer with time. The average residence time of water vapor in the atmosphere, as determined by fitting this curve with an exponential, is 9.27 days, which is significantly different from that determined by the more expedient but more approximate method of dividing the total precipitable water by the precipitation flux (7.55 days)

survey of these experiments will be incomplete, given the profusion of existing AGCM climate studies, and it will soon be dated, since new, innovative experiments are constantly being devised and performed. With this caveat in mind, a brief survey is provided here. The intent is to illustrate the type of studies being done without attempting to be comprehensive.

Contributions to Precipitation Variability

Delworth and Manabe (1988, 1989) pioneered the use of AGCMs to evaluate the impact of land variability on climate. Their basic experiment consists of two parallel AGCM simulations – one in which the land-surface soil moisture is free to interact with the atmosphere (e.g. rainfall wets the soil, leading to increased subsequent evaporation) and one in which the land surface is "fixed", meaning that soil moistures are forced to follow a climatological seasonal cycle, so that soil moisture and subsequent evaporation do not respond to anomalies in rainfall. A difference in the character of the atmospheric variability between the two simulations would indicate the existence of land–atmosphere feedback. Land–atmosphere feedback is the process by which rainfall-induced soil-moisture anomalies affect, for example, through modified evaporation, the subsequent evolution of the atmosphere's dynamics. Through land–atmosphere feedback, a period of anomalously heavy rainfall might act to sustain itself.

Delworth and Manabe (1989) found that coupled land processes produced, in their AGCM, a clear impact on near-surface air temperature and humidity. The impact on precipitation, however, was not significant. In a similar study with a different AGCM, Koster *et al.* (2000a) examined the joint impact of land-surface variability and ocean variability on the variability of precipitation. Their results supported a useful interpretation of the following simple tautology:

$$\sigma_{\mathrm{P}}^2 = \sigma_{\text{P-(no land)}}^2 [X_{\mathrm{O}} + (1 - X_{\mathrm{O}})] \frac{\sigma_P^2}{\sigma_{\text{P-(no land)}}^2} \qquad (1)$$

where σ_{P}^2 is the variance of precipitation at a point. According to the equation, this total precipitation variance is the product of the variance that would be obtained in the absence of land–atmosphere interaction ($\sigma_{\text{P-(no land)}}^2$) and an amplification factor ($\sigma_P^2/\sigma_{\text{P-(no land)}}^2$) associated with the interaction. The variance $\sigma_{\text{P-(no land)}}^2$ can in turn be separated into two parts: the fraction explained by ocean variability (X_{O}) and the fraction explained by chaotic atmospheric dynamics ($1 - X_{\mathrm{O}}$). Figure 10, from Koster *et al.* (2000a), shows the global distribution of $\sigma^2{}_{\text{P-(no land)}}$, X_{O}, $1 - X_{\mathrm{O}}$, and $\sigma_{\mathrm{P}}^2/\sigma_{\text{P-(no land)}}^2$, as established in several ensembles of multidecadal simulations using different combinations of enabled or disabled land and ocean variability. In agreement with other AGCM studies (Kumar and Hoerling, 1995; Shukla, 1998; Trenberth *et al.*, 1998), ocean impacts (X_{O}) are limited largely to the tropics; elsewhere, atmospheric chaos ($1 - X_{\mathrm{O}}$) controls precipitation variability. Land–atmosphere feedback amplifies the variability in various parts of the globe. Other studies in this genre include those by Dirmeyer (2001), who examined atmospheric response to prescribed time series of land-surface states, and Douville (2003), who examined the impact of relaxing soil-moisture states to a climatological mean. One study (Koster *et al.*, 2002) suggests a large amount of intermodel variation in the strength of simulated land–atmosphere feedback. Note that observed estimates of feedback strength are not available – our observational networks do not provide the necessary data.

Contributions to Precipitation Predictability

The potential impact of land–atmosphere feedback on precipitation has led to speculation that soil moisture can contribute to precipitation prediction. AGCM studies are uniquely suited to testing this hypothesis. Observed pluvial periods and droughts have been reproduced in AGCMs when soil moistures are maintained at suitably wet or dry levels during the period in question (S. Schubert, as cited in Entekhabi *et al.*, 1999; Hong and Kalnay, 2000). The positive impact of maintaining an observations-based soil-moisture field on precipitation has also been demonstrated in less extreme years (Dirmeyer, 2000). Figure 11, for example, shows where the prescription of land moisture affects precipitation in the Center for Ocean-Land-Atmosphere Studies AGCM. Some studies suggest that the prescription of soil moisture has the largest impact in transition zones between wet and arid regions (Koster *et al.*, 2000a).

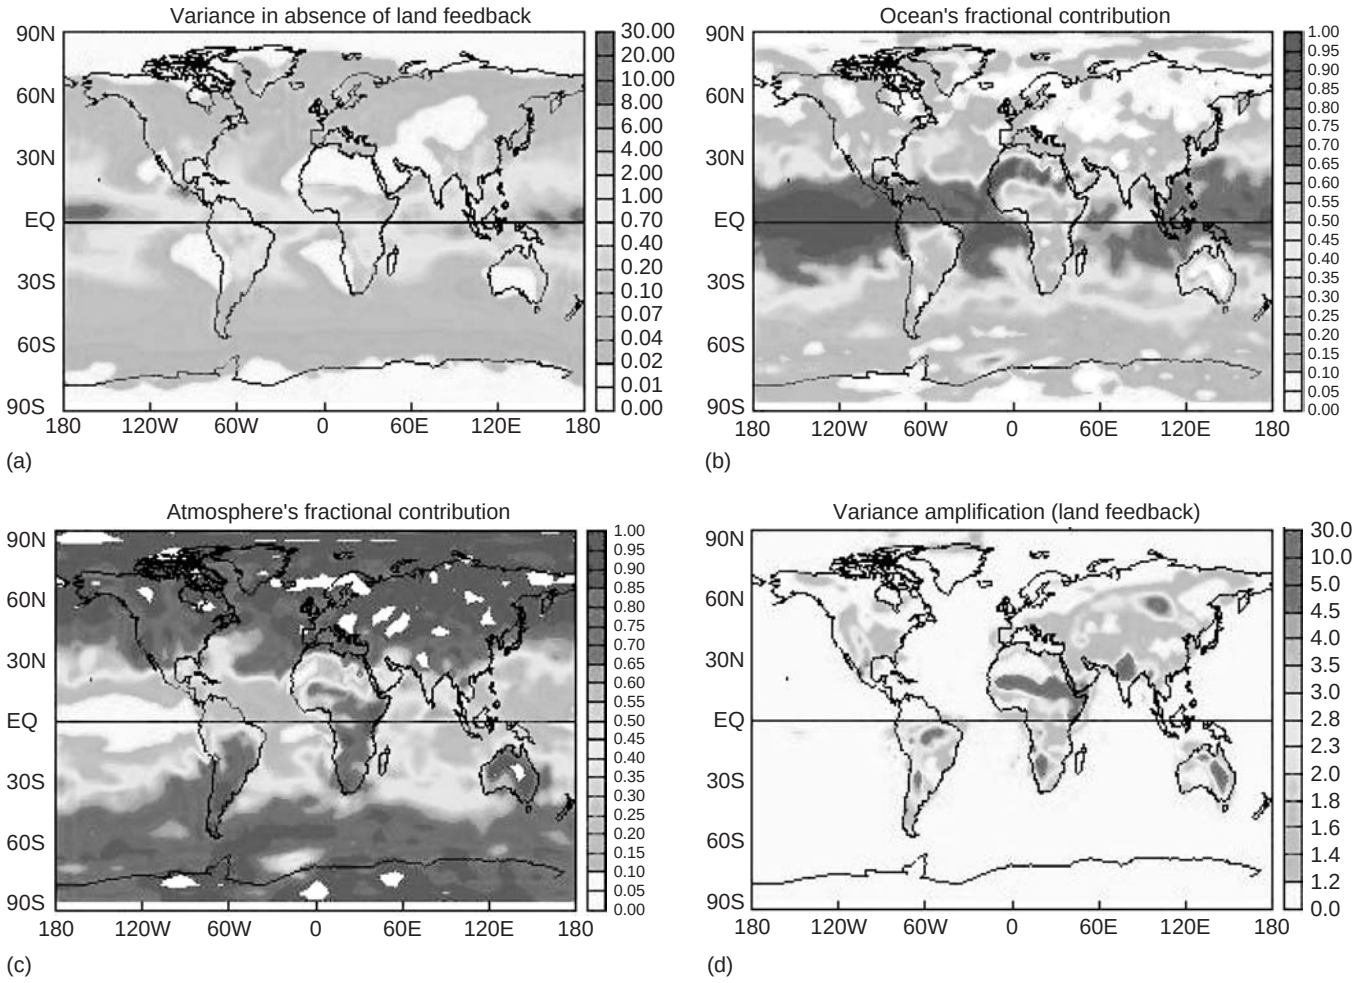

Figure 10 AGCM-generated estimates of contributions to precipitation variance. (a) $\sigma^2_{P\text{-(no land)}}$, the variance that would be achieved in the absence of land–atmosphere feedback. (b) X_O, the contribution of ocean (SST) variability to precipitation variability. (c) $1 - X_O$, the contribution of chaotic atmospheric dynamics to precipitation variability. (d) $\sigma^2_P/\sigma^2_{P\text{-(no land)}}$, the amplification of precipitation variance due to land–atmosphere feedback. (Koster *et al.*, 2000a © 2000 American Meteorological Society). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Of course, for true forecasts, soil moistures may not be prescribed throughout a simulation; they can only be initialized, with hopes that the initial anomaly will last well into the forecast period and that precipitation will continue to respond to the persisting anomaly. Initializing AGCMs with large, idealized soil-moisture anomalies does lead to changes in subsequent AGCM precipitation (Rind, 1982; Oglesby and Erickson, 1989; Beljaars *et al.*, 1996; Schar *et al.*, 1999). Initializing an AGCM with less extreme anomalies can also provide some predictability, though to a lesser level (Wang and Kumar, 1998; Schlosser and Milly, 2002; Oglesby *et al.*, 2002). Comparisons of AGCM-forecasted precipitation against *observed* precipitation allow a quantification of the skill associated with soil-moisture initialization. These studies are still in their infancy and are limited by the short data record. Nevertheless, existing results are suggestive and even encouraging (Fennessy and Shukla, 1999; Viterbo and Betts, 1999; Douville and Chauvin, 2000; Koster and Suarez, 2003; Koster *et al.*, 2004).

Snowpack represents another surface moisture reservoir with a memory long enough to contribute to seasonal prediction. Compared to soil-moisture studies, relatively few AGCM studies have focused on snow-climate feedbacks or on the climatic impacts of snow initialization or specification (e.g. Cohen *et al.*, 1991; Walsh and Ross, 1988; Schlosser and Mocko, 2003). The potential usefulness of the snow reservoir's memory is not yet fully known.

The ocean heat reservoir has a much stronger memory than the land moisture reservoirs. Thus, for long-term prediction, many consider the initialization of the ocean in a coupled atmosphere-ocean modeling system to be

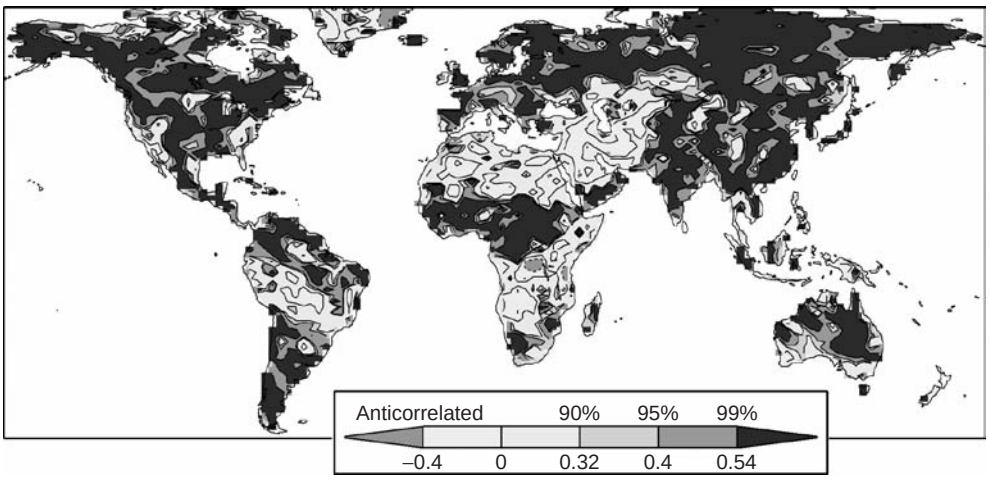

Figure 11 Shaded part indicates regions where a continually prescribed soil wetness has a direct impact, through evaporation, on precipitation simulated during boreal summer in a climate model. Percentages indicate the likelihood that simulated impacts are not the product of chance (Figure courtesy of Paul Dirmeyer, COLA.) A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

most critical. The US National Center for Environmental Prediction (NCEP), the European Center for Medium-Range Weather Forecasts (ECMWF) and other institutions routinely issue seasonal precipitation predictions based largely on predicted sea surface temperatures (SSTs).

Impacts of Anthropogenic Change

Human-induced modification of the land surface – deforestation in the Amazon, for example, or the global-scale conversion of forests to cropland – may already have had a significant impact on the global water cycle. Because the land surface can be modified arbitrarily in AGCMs, these models are effective tools for examining such impacts.

Chase *et al.* (2001) and Pitman and Zhao (2000) incorporated estimates of the natural vegetation distribution (i.e. the vegetation distribution that would exist today if humans were not present) into AGCMs and showed that the climate impacts associated with human modification of land cover are comparable to those predicted under a doubling of CO_2. Amazonian deforestation and its impacts on climate and the water cycle have been the subject of a great many studies (e.g. Henderson-Sellers *et al.*, 1993; Polcher and Laval, 1994; Sud *et al.*, 1996), many of which suggest that deforestation leads to warmer local temperatures and reduced local precipitation (see review by Hahmann and Dickinson, 1997). Some deforestation studies suggest that impacts can also be felt remotely (Gedney and Valdes, 2000; Werth and Avissar, 2002). Other land impact studies have addressed, for example, North American land use change (Bonan, 1997) and desertification in the Sahel (Xue and Shukla, 1993).

The impact of increased greenhouse gases on global temperature has long been a subject of serious study. Their impact on the global water cycle is now being given considerable attention as well (e.g. Roads *et al.*, 1996; Zhang *et al.*, 2001; Costa and Foley, 2000; Pitman and McAvaney, 2002). At issue is whether a warmer atmosphere can induce significant changes in average regional rainfall or, just as important, significant changes in the variability of the hydrological cycle – in particular, an increased likelihood of a devastating drought or flood. AGCMs are the only tool we have for addressing such questions. Their limitations, however, are manifest when comparing the results of AGCMs performing the same climate change experiment (e.g. Gedney *et al.*, 2000). While all of the AGCMs indicate some global warming, they often disagree about the direction of regional hydrological change.

Additional studies

AGCMs are flexible enough for many additional types of water cycle studies. The following is just a sampling.

When evaluating an AGCM climate change experiment (such as one involving a doubling of CO_2), one should remember that parts of the AGCM were calibrated, or "tuned", to produce a reasonable representation of present-day climate. The relevance of such a calibration in a modified climate must clearly be considered. One way to evaluate the multiclimate appropriateness of calibrations is to simulate climates of the past, for which some validation data do exist. The Paleoclimate Modeling Intercomparison Project (PMIP) has organized a number of paleoclimatic simulations and has shown, for example, that the models qualitatively (if not quantitatively) reproduce the monsoon shifts responsible for the relative lushness of northern Africa 6000 years BP (Joussaume *et al.*, 1999).

The monsoon is indeed a unique and critical mechanism for bringing ocean-derived moisture onto continents. AGCM studies of monsoon mechanics have addressed,

for example, the impacts of land evaporation (Lau and Bua, 1998), SST distribution and vegetation representation (Laval *et al.*, 1996), and continental layout (Dirmeyer, 1998) on monsoon strength. Kang *et al.* (2002) describe a multi-AGCM intercomparison of monsoon simulation.

The relative control of energy availability and water availability on the annual water balance of a continental region was examined long ago by Budyko (1974). AGCMs provide a means of addressing such issues with comprehensive data (e.g. Milly and Dunne, 1994; Koster and Suarez, 1999).

Isotopes of water can be followed with the tracer diagnostics described in the section Tracer studies above (Joussaume *et al.*, 1984; Jouzel *et al.*, 1987). These heavy isotopes, which participate in every aspect of the global water cycle, behave just like regular water except for a tendency to fractionate during changes of phase – to favor slightly the condensed phase. The monitoring of isotopic tracers, in conjunction with *in situ* isotope measurements, may reveal important subtleties of the global water cycle (e.g. Hoffmann *et al.*, 2000).

In most AGCM water cycle studies, vegetation characteristics are prescribed a priori. These studies ignore changes in vegetation that occur on the seasonal-to-interannual scale, as manifested by variations in phenology (e.g., the density of leaves, as measured by the leaf area index), and on the decadal to century scale, as manifested by species succession and migration. The tide, however, is turning in this regard. Recent studies have examined the impacts of satellite-derived phenology variations on water cycle variations (e.g. Bounoua *et al.*, 2000; Guillevic *et al.*, 2002). More importantly, some groups have begun modeling phenology and species succession explicitly to allow a full consideration of climate-vegetation feedbacks (e.g., Foley *et al.*, 1998).

The modeling of the carbon cycle in conjunction with the water cycle is a natural step in earth system modeling (Sellers *et al.*, 1997). Variations in the carbon cycle could have a first-order impact on the water cycle – aside from the radiative impacts of increased CO_2, plants exposed to higher CO_2 concentrations tend to transpire less. Dynamic vegetation modules, of the type discussed above, provide a means for modeling the carbon cycle (Cox *et al.*, 2000) and will undoubtedly become more common in AGCMs in the years to come. Nitrogen cycle modeling (Dickinson *et al.*, 2002) is a further logical step in the analysis of the climate system.

SUMMARY

The AGCM and its coupled land and ocean models afford a unique means of quantifying and analyzing the global water cycle. The coupled models can produce a wealth of self-consistent global data across timescales ranging from minutes to centuries. The key benefit of these data, of course, is that they generally have no observational counterparts – much of the data relevant to the global water cycle can only be provided by an AGCM. The AGCM can be run in two modes for water cycle studies. In data assimilation mode, model data is merged optimally with existing observational data to produce a dataset superior to either on its own. In climate simulation mode, AGCMs can host sensitivity experiments that illustrate the mechanisms governing the variability of the water cycle and/or quantify the sensitivity of the cycle to human impacts.

Clearly, the chief limitation to AGCM studies of the global water cycle lies in the errors that continue to persist in the simulated climates. These errors will not simply disappear with the advent of greater computational power. Mitigating the effects of the errors will require the development of improved parameterizations for many nonresolvable physical processes.

The AGCM's limitations naturally temper one's belief in the model's interpretation of the global water cycle and its variability. Nevertheless, given the absence of any superior approach, and given the extensive (though qualified) success already achieved by AGCMs in revealing key mechanisms underlying the Earth's water cycle and climate system, climate scientists will continue to employ AGCMs in a wide variety of variability, predictability, and anthropogenic change studies.

179: Modeling of the Global Water Cycle – Analytical Models

YONGQIANG LIU[1] AND RONI AVISSAR[2]

[1] *Forestry Sciences Laboratory, USDA Forest Service, Athens, GA, US*
[2] *Department of Civil and Environmental Engineering, Duke University, Durham, NC, US*

Both numerical and analytical models of coupled atmosphere and its underlying ground components (land, ocean, ice) are useful tools for modeling the global and regional water cycle. Unlike complex three-dimensional climate models, which need very large computing resources and involve a large number of complicated interactions often difficult to interpret, analytical models are able to provide more direct and intuitive figures of variability and processes in a highly simplified system. They can be a good and efficient alternative modeling tool, especially for studying continental water cycle. This article describes the analytical models developed based on the soil and atmospheric water and energy conservation equations. A fourth-order model is used to illustrate the perturbation equation, solutions, and physical interpretation. Our understanding of some water cycle variability issues, including timescale, persistence, and major physical parameters and processes, obtained from the analytical models is presented.

INTRODUCTION

One of the major improvements in our understanding of the global and regional water cycle during the past three decades was the realization of the importance of soil memory (especially soil moisture) to seasonal and interannual variability of continental water cycle. Atmospheric manifestations of variability in the hydrological cycle occur at multiple timescales, including cloud and precipitation events related to synoptic systems (daily and weekly), floods and droughts (seasonal), the Southern Oscillation (interannual), and climate shifts (decadal). Because an anomaly signal in the atmosphere alone (i.e. isolated from the Earth's surface) can only last for a period of about two weeks, variability of the atmospheric hydrological processes at seasonal or longer scales has to be related in some way to the Earth's surface, which has longer memory.

Soil moisture controls water and energy exchanges by providing available water for evapotranspiration and by determining the partition of radiative energy absorbed on the ground surface into sensible and latent heat fluxes (Avissar, 1995). Therefore, anomalies in soil moisture can result in significant changes in atmospheric hydrological and thermal processes by land–atmospheric interactions (e.g. Mintz, 1984; Avissar and Verstraete, 1990; Betts *et al.*, 1996). Furthermore, with the capacity of retaining anomalous signals over months to seasons (e.g. Delworth and Manabe, 1988; Vinnikov *et al.*, 1996), soil moisture can contribute to long-term atmospheric variability over land by passing its relatively slow anomalous signals to the atmospheric hydrological processes.

The importance of soil moisture in the continental water cycle indicates a fundamental difference with the oceanic water cycle, in which the surface fluxes and long-term anomalies are mostly affected by sea-surface temperature (Cane, 1992). This, of course, is due to the fact that the amount of water available for evaporation is unlimited in the ocean, and its thermal capacity is very large.

Three-dimensional general circulation models (GCMs) and regional climate models (RCMs) have been very useful tools for studying soil-moisture variability and its interactions with atmospheric processes. Coupled with detailed land-surface parameterizations (e.g. Dickinson *et al.*, 1993; Sellers *et al.*, 1986; Xue *et al.*, 1991), these models are able to simulate long-term variations of atmospheric and

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

soil states, hydrological and thermal processes, and water and energy fluxes at the ground surface. The simulation outputs are used to analyze the water cycle variability and its causes (e.g. Delworth and Manabe, 1989; Bonan, 1994; Koster and Suarez, 1995). Experiments of model's response to initial soil-moisture anomalies provide evidence for the possible roles of soil moisture in onset and/or intensification of floods and droughts (e.g. Giorgi *et al.*, 1996) and local water cycle processes (Avissar and Liu, 1996), and improvement of predictability of the water cycle variability (e.g. Schlosser and Milly, 2002; Dirmeyer, 2003).

Considering that three-dimensional climate models need very large computing resources and involve a large number of complicated interactions often difficult to interpret, analytical models can be a good and efficient alternative to study the mechanisms underlying the global water cycle, especially in continental areas. Many analytical models have been developed, based on soil-water balance equation (e.g. Delworth and Manabe, 1988; Rodriguez-Iturbe *et al.*, 1991; Entekhabi *et al.*, 1992; Huang *et al.*, 1996), complete water and energy balance equations of the land-atmosphere system (e.g. Brubaker and Entekhabi, 1996; Liu and Avissar, 1999b), or something in between (e.g. Liu *et al.*, 1992). Analytical models including interactions between soil moisture and the atmospheric planetary boundary layer (PBL) processes also have been developed (e.g. Eltahir, 1998; Findell and Eltahir, 2003).

Analytical models for the land-atmosphere water and energy system have varying levels of complexity. The most basic model is a first-order system composed of a conservation equation for water or heat of the soil or the atmosphere. The most important first-order system is the soil water conservation, which describes the internal variability of soil water and the effects of external processes. The most complete system is the forth-order one, which describes internal variability of each of the four system components and interactions between them. Liu and Avissar (1999b) discussed a forth-order system and compared it with various lower-order systems.

This article describes analytical models of the land-atmosphere energy and water balance and their applications to studying continental water cycle variability. The models are first introduced in the Section "The models", with a focus on the system described in LA99. The solutions and dependence on the water exchange are presented in the Sections "Solutions and Control of seasonal scale by water exchange", respectively. Applications of the models to a number of issues, including water cycle timescales, persistence, and physical mechanisms, are described in the Section "Understanding global water cycle using analytical models". A summary is given in the final section.

THE MODELS

Framework

Figure 1 shows a schematic representation of the continental water and energy cycle system. The atmospheric component is assumed to consist of an air column of height h_a, and the soil component consists of an active layer and a sublayer. Because the soil depths at which thermal and hydrological processes are active are not necessarily identical, they are differentiated between a thermally active layer of depth d_T and a hydrologically active layer of depth d_w. To account for possible diffusion of heat and moisture at the bottom of the active soil layer, soil sublayers of depth d_{To} and d_{wo} are defined for thermal and hydrological processes, respectively.

The atmosphere is characterized by its temperature, T_a, and its specific humidity, q_a. Similarly, the soil is characterized by its temperature, T_g, and its volumetric soil-water content, W_g, for the active layer, and by a constant temperature, T_{go}, and a constant volumetric soil-water content, W_{go}, for the sublayer. The four state variables are determined by the energy and water conservation equations of the soil and atmosphere, and interact with each other through fluxes of radiation, sensible heat flux, latent heat flux (evaporation), and precipitation. Exchanges through diffusion and runoff also affect temperature and moisture of the soil active layer.

Basic Equations

The fourth-order continental water and energy cycle (Liu and Avissar, 1999b, hereafter referred to as LA99) consists of the following set of heat and water conservation equations:

$$C_a \frac{dT_a}{dt} = R_a + H + LP \tag{1}$$

$$M_a \frac{dq_a}{dt} = E - P \tag{2}$$

$$C_g \frac{dT_g}{dt} = R_s - H - LE + K_T(T_{go} - T_g) \tag{3}$$

$$M_g \frac{dW_g}{dt} = P - E - F + K_w(W_{go} - W_g) \tag{4}$$

where $K_T = 2D_T C_g/[d_T(d_T + d_{T0})]$ and $K_w = 2D_w M_g/[d_w(d_w + d_{w0})]$ are forcing factors to restore thermal and hydrologic anomalies to the normal states, respectively; $C_a(= \rho_a c_p h_a)$ and $C_g(= \rho_g c_g d_T)$ are the heat capacity of the atmosphere and the soil, respectively (c_p is specific heat of air at constant pressure, c_g is specific heat of the ground, ρ is density, and subscripts a and g indicate atmosphere and ground); $M_a(= \rho_a h_a)$ and $M_g(= \rho_w d_w)$ are masses of the air column and of a column of water of depth d_w per unit

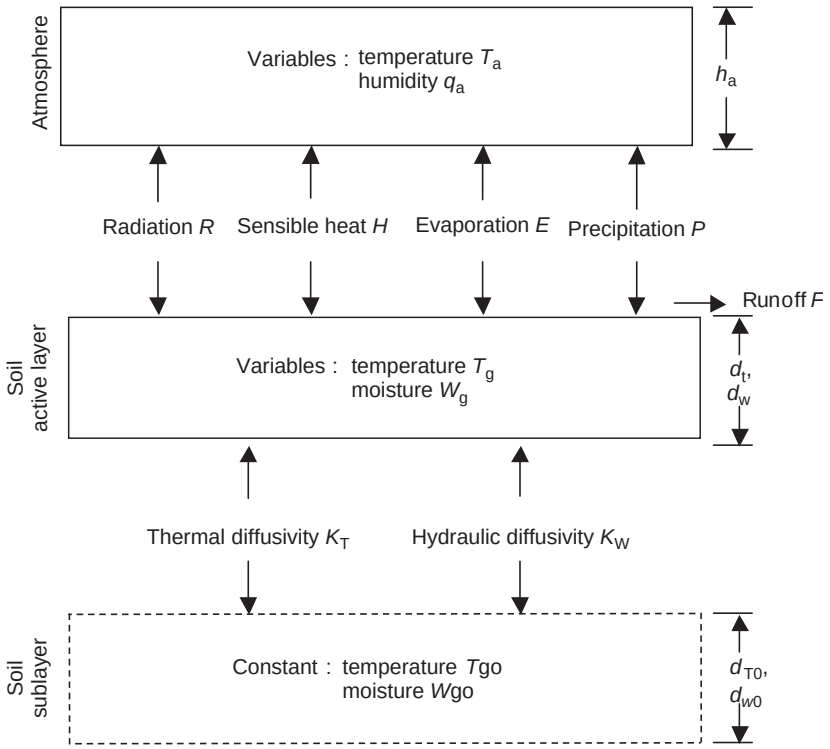

Figure 1 Schematic representation of the continental water and energy cycle system

area; R_a and R_s are the radiation balance of the atmosphere and the land surface; H and E are the sensible heat flux and evaporation on the land surface; P and F are precipitation and runoff; D_T and D_w are the soil thermal and hydraulic diffusivity; and L is the latent heat. It should be mentioned that this is a one-dimensional, vertical representation of land–atmosphere interaction, centered over a land surface, and vegetation and snow are neglected.

Fluxes

The fluxes in equations (1–4) are calculated by the following formulae:

$$R_s = [1 - \alpha_a(1-n) - \alpha_c n - A_a - C_r n]S_0 - \varepsilon\sigma T_g^4 + n\varepsilon\sigma T_a^4 \quad (5)$$

$$R_a = (A_a + C_r n)S_0 + n\varepsilon\sigma T_g^4 - n\varepsilon\sigma T_a^4 - n\varepsilon\sigma T_a^4 - (1-n)G\sigma T_g^4 \quad (6)$$

$$H = H_0(T_g - T_a) \quad (7)$$

$$E = \eta E_p = \eta E_0[q_s(T_g) - q_a] \quad (8)$$

$$P = C_1 W_a \exp(-C_2/R_h)^{C3} \quad (9)$$

$$F = \eta(P - E) \quad (10)$$

The radiative fluxes are calculated following Paltridge (1974). The first term on the right-hand side of equation (5) is the net shortwave radiative flux at the land surface, where S_0 is the incident shortwave radiation at the tropopause, α_a and α_c are the planetary albedo for clear sky and for cloudy atmosphere, A_a is the atmospheric absorption of shortwave radiation, and n is the cloud fraction. The next two terms together represent the net long-wave radiative fluxes. The atmosphere is assumed to be opaque to long-wave radiation at all wavelengths other than in the atmospheric window (7.5–12.5 μm), where absorption is assumed negligible. In this model, long-wave energy transfer occurs only in the atmospheric window and, therefore, it is the only flux that needs to be considered. The constant σ is the Stefan–Boltzmann constant, and ε is the fraction of total blackbody radiation at normal earth temperatures contained within the wavelengths of the atmospheric window. Note that this model represents an averaging condition over time and land area and, therefore, the cloud fraction, n, is never zero.

The first term on the right-hand side of equation (6) is the net shortwave radiative flux of the atmosphere. In this term, the factor C_r accounts explicitly for the extra shortwave absorption in clouds. The second and third terms represent the net long-wave absorption in clouds resulting from exchange of radiant energy with the Earth's surface. In the clear atmosphere, the absorption bands of water vapor become less opaque with increasing height and decreasing water vapor concentration. In effect, the

atmospheric window expands with increasing altitude so that each atmospheric level loses energy directly to space. Since the average temperature lapse to the tropopause is close to adiabatic as a result of mixing, on the average, the temperature at any level bears a fairly constant relation to the surface temperature. Thus, the total long-wave loss from the clear-sky troposphere is likely to be proportional to surface blackbody radiation. This concept is the basis of the last term in equation (6), which contains a simple constant of proportionality G, that was found to be about 0.38 (on average) for a large number of studied typical cases. A detailed discussion of the philosophy behind this scheme, as well as of the values assigned to each of its variables, are given in Paltridge (1974), and are not repeated here for brevity.

In the bulk flux formulae for sensible heat and evaporation (equations 7–8), $H_0 = \rho_a c_p C_{DT} V$ and $E_0 = \rho_a C_{DW} V$; C_{DT} and C_{DW} are the sensible heat and water drag coefficients, respectively, which are strongly dependent upon land surface, and atmospheric dynamic and thermal properties (e.g. vegetation cover and stability); V is the wind speed in the atmospheric surface layer; E_p is the potential evaporation; q_s (T_g) is the saturated air specific humidity at temperature T_g; and $\eta = W_g/W_s$ is the soil wetness, with W_s being the volumetric soil-water content at saturation.

Precipitation is arguably the most important and complex hydrological process in the water cycle and the land–atmosphere interactions system. Both atmospheric dynamics and local water and heat exchanges in the land-atmosphere system can contribute to the essential conditions for the formation of precipitation (i.e. ascending motion of air masses, stratified instability, and water vapor supply). Because the model proposed here does not simulate atmospheric dynamics, precipitation is parameterized with a simple formula, which only accounts for the variances of atmospheric moisture and sensible heat caused by land–atmosphere interactions. The precipitation parameterization (equation 9) is based on the premise that at a given geographic location and a given general circulation pattern, precipitation is mostly related to atmospheric water vapor content, W_a, and the relative humidity, R_h, of the entire air column. This formula is formed by applying dimensional analysis to relations between precipitation and these two factors. C_i ($i = 1, 2, 3$) are empirical constants. In this model, $C_2 = 0.5$ and $C_3 = 4.5$. With its relatively simple form, this parameterization certainly has a very limited capacity in reproducing observed precipitation statistics, which would affect the analysis with the fourth-order model. However, C_1 is derived from the ratio of climatological evaporation to precipitation, namely $r_{EP} = \overline{E}/\overline{P}$, which therefore adds a restraint in estimating average rainfall. Runoff (equation 10) is proportional to the net soil water gain, and to the ratio of soil moisture to its saturation value. The linear relation between runoff and both the net water gain and the ratio is valid mostly for calculation of runoff process at seasonal or longer scales.

Perturbation Equation

The perturbation approach (Holton, 1979) is used to linearize the equations of the model. Accordingly, any variable ϕ is separated into a mean $\bar{\phi}$ and a perturbation ϕ'. Assuming that the perturbations are small as compared to the means, any terms including the product of two or more perturbations are much smaller than a term that includes only one or no perturbation. Thus, for instance, the radiation emitted by a black body at a temperature T is given by $\sigma T^4 = \sigma(\overline{T} + T')^4 \approx \sigma(\overline{T}^4 + 4\overline{T}^3 T')$.

The perturbation equations for the sensible heat and evaporation fluxes are: $H' = H_0(T'_g - T'_a)$ and $E' = \bar{\eta} E_0(\Delta_g T'_g - q'_a)$, where $\Delta_g = \mathrm{d}q_s/\mathrm{d}T|_{T=Tg}$. To develop a perturbation equation for precipitation, the atmospheric water content in equation (9) is first substituted with the product of the specific humidity with the mass of the atmosphere, and the relative humidity by the ratio of the specific humidity to the specific humidity at saturation. Subsequently, we differentiate the expression and assume that the perturbation of a quantity is approximately equal to its differential value, and that the average is expressed by the nondifferential value. As a result, $P'/\overline{P} = P_1 q'_a - P_2 T'_a$, where $P_1 = [1 + C_3(C_2/\overline{R}_h)^{C_3}]/\bar{q}_a$, $P_2 = C_3(C_2/\overline{R}_h)^{C_3}\Delta_a/\bar{q}_{as}$, and $\Delta_a = \mathrm{d}q_s/\mathrm{d}T|_{T=Ta}$. The perturbation of cloud amount is related to the precipitation perturbation as follows: $n'/\bar{n} = P'/\overline{P}$. The perturbation of the radiative fluxes is given by: $Rs' = (\varepsilon\bar{n}\Delta_{La} + R_{s1}P_2\bar{n})T'_a - \varepsilon\Delta_{Lg}T'_g - R_{s1}P_1\bar{n}q'_a$ and $R'_a = -(R_{a1} + R_{a3}P_2\bar{n})T'_a + R_{a2}T'_g + R_{a3}P_1\bar{n}q'_a$, where $R_{s1} = (\alpha_c - \alpha_a - C_r)S_0 - \varepsilon\sigma\overline{T}_a^4$, $R_{a1} = (\varepsilon + \varepsilon')\bar{n}\Delta_{La}$, $R_{a2} = [(\varepsilon + G)\bar{n} - G]\bar{n}\Delta_{Lg}$, $R_{a3} = C_r S_0 - (\varepsilon + \varepsilon')\sigma\overline{T}_a^4 + (\varepsilon + G)\sigma\overline{T}_g^4$, and $\Delta_{Li} = \mathrm{d}(\sigma\overline{T}_i^4)/\mathrm{d}\overline{T}_i$, $(i = a, g)$.

Using these flux perturbations, the heat and water conservation equations (equations 1–4) can be written:

$$\frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{Y} = \boldsymbol{C}\boldsymbol{Y} \tag{11}$$

where $\boldsymbol{Y} = (\boldsymbol{Y}_i) = (T'_a/\overline{T}_a,\ q'_a/\bar{q}_a,\ T'_g/\overline{T}_g,\ W'_g/\overline{W}_g)$ and $\boldsymbol{C} = (c_{ij}) = \boldsymbol{I}_1\boldsymbol{A}\boldsymbol{I}_2$. $\boldsymbol{I}_1$ is a diagonal matrix with elements $[(C_a\overline{T}_a)^{-1}, (M_a\bar{q}_a)^{-1}, (C_g\overline{T}_g)^{-1}, (M_g\overline{W}_g)^{-1}]$, $\boldsymbol{I}_2$ is a diagonal matrix with elements $[\overline{T}_a^{-1},\ \bar{q}_a^{-1},\ \overline{T}_g^{-1},\ \overline{W}_g^{-1}]$, and $A = (a_{ij})$ is a coefficient matrix. This equation represents a set of linear homogeneous differential equations with constant coefficients, whose linearly independent solutions can be written as

$$\boldsymbol{Y}_i(t) = \sum_{j=1}^{4} P_{ij}(t)e^{\lambda_j t} \tag{12}$$

where $\lambda_j = (\lambda_r)_j + i(\lambda_i)_j (j = 1, 4)$ are roots of the characteristic equation of equation (12) given by

$$\sum_{k=0}^{4} d_k \lambda^{4-k} = 0 \tag{13}$$

The parameter λ_r is the perturbation growth rate, and the reciprocal of its absolute value is the e-folding time. If $\lambda_r < 0$, the e-folding time is also called *damping time*. In equation (12), $P_{ij}(t)$ is a polynomial whose order is equivalent to the number of equal roots. In equation (13), d_k are constant coefficients, with $d_0 = 1$ and $d_1 = -\sum_{k=0}^{4} a_{kk}$.

Orders of Models

Equation (11) is a fourth-order analytical model of the continental water and energy cycle system. It contains all interactions (couplings) between the land and the atmosphere, and between hydrological and thermal processes. By assuming no disturbance with soil moisture in the fourth-order model, a third-order model can be obtained. There are no interactions between soil moisture and other model variables. Similarly, three other third-order models can be obtained by assuming no disturbance with soil temperature, air humidity, or air temperature in the fourth-order model. Four second-order models can be obtained by assuming no disturbance with any two of the four system variables. Finally, by assuming no interactions among the four system variables, the fourth-order model becomes four independent first-order models, each of which contains only one of the four variables. In these cases, the variation of the disturbance in the models is caused by self-feedback.

Statistical-Dynamical Models

Delworth and Manabe (1988) described a first-order model of soil water balance equation with a stochastic forcing. Precipitation usually has a much faster pace than soil moisture, suggesting that variation of precipitation could be expressed as "white noise", $z(t)$. Soil moisture can be expressed as "red noise", $y(t)$, which is the output of the following first-order Markov process:

$$\frac{dy(t)}{dt} = -\lambda y(t) + z(t) \tag{14}$$

The stochastic process $z(t)$ can be simulated with observed precipitation series. The solution of this equation indicates the role of the external forcing in variability of soil moisture.

In another first-order model of soil water balance described by Rodriguez-Iturbe *et al.* (1991), precipitation is expressed as

$$P(w) = P_a[1 + f(w, \Omega)] \tag{15}$$

where P_a is the advective precipitation resulting from the atmospheric horizontal transport of water vapor from outside, and Ω is a Gaussian noise of atmospheric processes related to the internal precipitation resulting from the vertical transport of water vapor from the evaporation on the ground. P is related to soil moisture w.

The fourth-order model described by Brubaker and Entekhabi (1996) consists of four stochastic ordinary differential equations in soil moisture, soil temperature, mixed-layer humidity, and mixed-layer potential temperature. The variations of the system are determined by deterministic steady forcing and white-noise perturbation processes. The solution is a physically consistent joint probability distribution.

SOLUTIONS

Table 1 lists the various atmospheric and soil conditions needed to calculate the elements of the matrix C. These values are assumed to be representative of annual conditions under current climate over land. The values for the radiative flux are adopted from Paltridge (1974). A few values of parameters related to other processes are taken from the Biosphere-Atmosphere Transfer Scheme (BATS, Dickinson *et al.*, 1993) and from the results of the simulation with the Community Climate Model (CCM2) (`http://www.cgd.ucar.edu/cms/ccm.html`) coupled with BATS (`http://www.atmo.arizona.edu/faculty/research/bats/batsmain.html`) performed by Bonan (1994). For instance, in BATS, the active soil layer is 1 m deep for 11 of the 16 land-cover types, and 1.5–2 m deep for the other types. The soil sublayer is 9 m deep for all land-cover types. Here these two layers are assumed to be 1 m and 10 m deep, respectively. The ratio of evaporation to precipitation (r_{EP}) in the CCM2-BATS simulation is 0.60 (Both evaporation and precipitation are spatially and temporally averaged before taking the ratio). The corresponding land surface sensible and latent heat fluxes in the CCM2-BATS simulation are about 33 and 61 W m^{-2}, respectively. On the basis of these values of the fluxes, as well as climatological values of T_a, T_g, q_a, and η provided in Table 1, one can obtain H_0 and E_0 from equations (7–8), respectively.

Equation (13) has four solutions. The number of solutions is reduced to three and two for the third- and second-order models, respectively. The solutions, given in Table 2, measure damping times or scales. Note that each solution (scale) represents a perturbation mode of the system, rather than a timescale of a variable. The damping times with the fourth-order model are of the orders of one day, one week, two months, and eight months. Thus, hereafter, they will be referred to as daily, weekly, monthly, and seasonal-scale processes, respectively. The monthly and seasonal scales, which represent long-term variations, will be referred to as long-term scales. The damping time points out how fast

Table 1 Parameters used in the continental water and energy cycle system

Parameter	Meaning	Unit	Mean	Range in FAST[a]
T_a	Air temperature	K	255.0	250.0–260.0
q_a	Air specific humidity	g/kg	5.0	3.0–7.0
T_g	Soil temperature	K	285.0	280.0–290.0
W_g	Soil volumetric water content	%	250.0	10.0–40.0
S_0	Solar radiation at tropopause	$W\,m^{-2}$	330.0	–
r_{EP}	Ratio of evaporation to precipitation	%	60.0	45.0–75.0
n	Cloud fraction	%	50.0	35.0–65.0
d_T	Depth of thermally active soil layer	m	10.0	7.5–12.5
d_{T0}	Depth of thermal soil sublayer	m	10.0	–
d_w	Depth of hydrologically active soil layer	m	1.0	0.75–1.25
d_{w0}	Depth of hydrological sublayer	m	10.0	–
h_a	Height of air column	km	10.0	9.0–11.0
D_T	Soil thermal diffusivity	$10^{-7}\,m^2\,s^{-1}$	5.0	2.5–7.5
D_w	Soil hydraulic diffusivity	$10^{-8}\,m^2\,s^{-1}$	5.0	2.5–7.5
C_g	Soil heat capacity	$JK^{-1}\,m^{-3}$	1.0	0.75–1.25
W_s	Saturated soil volumetric water content	%	40.0	30.0–50.0
H_0	Turbulent sensible heat exchange index	$W\,m^{-2}\,K^{-1}$	1.0	0.5–1.5
E_0	Turbulent water vapor exchange index	$10^{-3}\,kg\,m^{-2}\,s^{-1}$	4.5	3.5–5.5
ρ_a	Air density	$kg\,m^{-3}$	0.75	–

disturbances decay with time. Consequently, it provides essential information for understanding at which climatic scale a particular perturbation in the water cycle persists. A damping time of a few days implies that the considered perturbation is relevant to short-term, synoptic-scale processes, but is unlikely to have a significant impact on longer timescales. On the other hand, a damping time of several months suggests a potential impact on seasonal climatic processes.

CONTROL OF SEASONAL SCALE BY WATER EXCHANGE

1. Relative Importance of Model Parameters: The Fourier Amplitude Sensitivity Test (FAST) was used to identify which parameters mostly affect the damping times obtained from this fourth-order continental water and energy cycle model. A complete description of the theory and implementation of FAST and approximations used in computer implementation, mainly following Cukier *et al.* (1973), was given in Collins and Avissar (1994).

The number of parameters in the FAST computer program used in this analysis is limited to 15. The chosen parameters from the fourth-order model are listed in Table 1. Among the parameters which are included in the FAST analysis, the role of solar radiation in the damping times cannot be directly examined by the sensitivity analysis because the latent and sensible heat fluxes have been prescribed separately, without any constraint on the balance between the surface net radiation and the two fluxes (the role of solar radiation will be discussed below using a regular sensitivity analysis technique); d_{T0} and d_{w0} have similar roles to d_T and d_w; and ρ_a has a similar role to h_a. Normal distributions of the 15 input parameters were considered, and their ranges are also given in that table. Figure 2 depicts the partial variance of the damping times, which shows the sensitivity of model output parameters to the variation of individual input parameters in terms of a percentage of the variance. It appears that the longest damping timescale, which is about 9.5 months, is very sensitive to soil moisture, ratio of evaporation to precipitation, soil temperature, and soil moisture at saturation. Each of these parameters contributes more than 10% to the total variance. In addition, drag coefficient of water vapor flux, depth of hydrologically active soil layer, air humidity, and soil hydraulic diffusivity have some impact on the variance. It is interesting to note that all these parameters are related

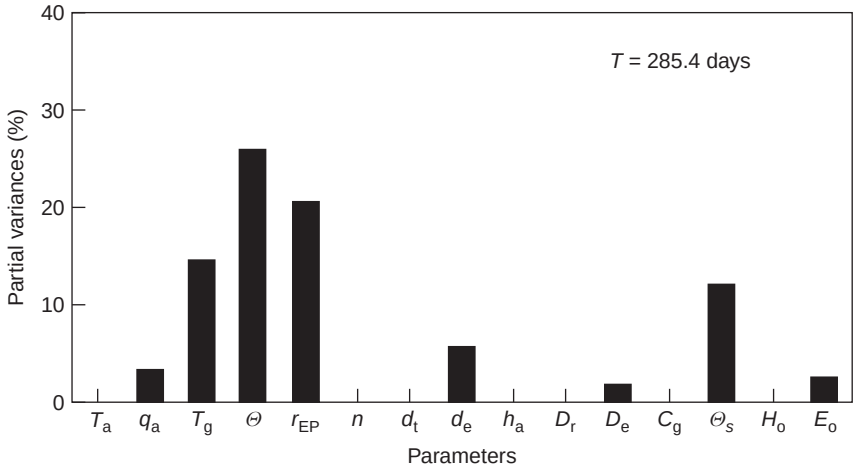

Figure 2 FAST analysis of the fourth-order model outputs for the seasonal scale indicated by the average damping time T obtained from all model runs. Partial variances reflect sensitivity of the damping times to the model inputs (Liu and Avissar, 1999b © 1999 American Meteorological Society)

to soil hydrological processes. Indeed, the ratio of W_g to W_s affects the actual evaporation, E_0, T_g, and q_a affect the potential evaporation, r_{EP} is related to evaporation and precipitation, and D_w and d_w affect the transfer of water between the active soil layer and the soil sublayer. Thus, clearly, the parameters associated with soil hydrology determine the length of the longest process in the water cycle.

2. Sensitivity to Model Parameters: On the basis of the FAST analysis, the effects of a number of the most important parameters on the seasonal damping timescale are examined using a regular sensitivity technique, that is, analyzing a perturbation in the timescale due to a change in a parameter. These parameters can significantly modify the magnitude of the damping timescale. For instance, an increase of E_0 (which is proportional to the turbulence activity in the atmospheric surface layer) from 3.5 to $5.5 \times 10^{-3}\,\mathrm{kg\,m^{-2}\,s^{-1}}$, results in a reduction of the damping time from 283 to 196 days. When r_{EP} and W_s increase, they result in a very significant increase of the damping time. A dry soil ($W_g = 0.1$) has a damping time of 485 days, but a wet soil ($W_g = 0.4$) has a damping time of only 153 days, emphasizing that a moist soil damps a perturbation much faster than a dry soil does.

The evaporation equation (equation 8) consists of two variables, namely, potential evaporation, E_p, and a fraction factor, η. E_p increases with T_g and E_o, and decreases with increasing q_a. Therefore, it can be derived from the relations between these three parameters and the damping time that the damping timescale decreases with increase in potential evaporation. The relations between the damping time and W_g and W_s indicate that the damping time decreases with increasing η. The combined effects of E_p and η result in decrease of the damping time with increase in actual evaporation.

The runoff parameterization (equation 10) consists of two variables as well, that is, η, and the difference between precipitation and actual evaporation $(P - E)$. The latter term is inversely proportional to r_{EP}. Figure 3 shows that the damping time increases from 138 to 393 days with variation of r_{EP} from 0.45 to 0.75 or, equivalently, decreases with $(P - E)$. Therefore, together with the variation of η, the damping time decreases with increase in runoff.

The last term in the right-hand side of equation (4) is the exchange of soil moisture between the active layer and the sublayer, which acts as a force-restore term for soil moisture disturbances. Its intensity is proportional to D_w, and inversely proportional to d_w. The damping time decreases with increasing D_w, and increases with d_w (not shown). Therefore, it decreases with a faster exchange between the two soil layers. d_w is also a measure of the total available water in the active layer. For a given forcing, as expressed by the right-hand side terms in equation (3), the larger d_w, the slower the variation rate of soil moisture, and the longer the damping time. This effect is somewhat similar to that of soil heat capacity in damping the variation of soil temperature. However, evaporation and runoff affect the damping time much more significantly than the exchange between the two soil layers does.

The above results indicate that the smaller the fluxes of water in the continental water and energy cycle system (i.e. evaporation, runoff, and underground diffusion), the longer the damping time is, and, therefore, the more significant persistence is.

By using the Bowen ratio to relate sensible to latent heat flux, the role of solar radiation in the seasonal scale can be examined. From such an analysis, it appears that the damping time decreases from 295 to 206 days as solar radiation increases from 300 to $380\,\mathrm{W\,m^{-2}}$.

UNDERSTANDING GLOBAL WATER CYCLE USING ANALYTICAL MODELS

Timescales of Water Cycle

The timescale relevant to this analysis is the period spanned by an anomalous hydrological process. For nonoscillation variability, it is the time period during which anomalies maintain the same sign, and for oscillation variability, it is the half-time period of the oscillations. This analysis aims to identify the major scales at which land-surface processes can contribute to water cycle variability.

1. Interpretation of solutions in terms of timescales: The solutions of the analytical models measure timescales of variability in the water and energy cycle system. This can be illustrated by the first-order model of soil water balance equation (Delworth and Manabe, 1988):

$$\frac{\mathrm{d}w(t)}{\mathrm{d}t} = P - E - F \tag{16}$$

where $w = M_g W_g$. P is an external forcing and F is related to P. E can be calculated by

$$E = \lambda w(t) \tag{17}$$

where $\lambda = E_p / W_s$. Considering the perturbation form of equation (16) and assuming no perturbations in precipitation and runoff, the solution is

$$w(t) = w(t=0)\mathrm{e}^{-\lambda t} \tag{18}$$

indicating that initial soil-moisture perturbation damps exponentially with a rate of λ. The reciprocal of the rate is the e-folding time $= 1/\lambda = W_s/E_p$. This time is used to measure timescale of soil-moisture variability.

2. Scale: Delworth and Manabe (1988) obtained a globally averaged scale of soil-moisture variability of about one to two months based on the simulations with the Geophysical Fluid Dynamics Laboratory (GFDL) GCM. A value of three months was obtained based on the soil-moisture measurements in Russia (Vinnikov *et al.*, 1996) and about two and half months based on the soil-moisture measurements in North China (Entin *et al.*, 2000).

Perturbation strength, defined as the time period over which a perturbation maintains the same sign as an initial anomaly, is presented in Figure 3. It is calculated using a 10-year CCM2-BATS simulation conducted by Bonan

(1994) and it ranges between about two to eight months (Liu and Avissar,1999a).

These studies suggest that the major scales at which land-surface processes could affect the long-term atmospheric water cycle variability are the monthly and seasonal scales. Global climate models have provided some numerical evidence for these analytical results (e.g. Yeh *et al.*, 1984; Liu and Avissar, 1999a). Yeh *et al.* (1984) conducted a numerical experiment of initial soil moisture forcing with a simplified version of the GFDL GCM, and showed that the induced anomalies in evaporation, precipitation, and soil moisture last for three to five months.

3. Timescales in different-order models: Interactions between soil moisture and other variables included in some higher-order models could significantly increase the length of a scale, as indicated by the timescales obtained from the four solutions of equation (17). A seasonal scale as long as eight months is obtained (Table 2).

The damping times in the four third-order systems (Table 2) indicate that the seasonal damping timescale appears only in the third-order systems with disturbance of soil moisture. The longest damping time in the first three systems varies between 196 and 236 days. This emphasizes that the soil moisture feedback, and its interactions with the other variables, are the primary cause for the damping timescale. In the third-order system without physical processes related to soil-moisture disturbances, the maximum damping timescale is only of the order of two months. In addition, among the various interactions, the one between soil moisture and air humidity is the predominant: Excluding this, interaction results in a reduction of the damping time from 232 to 196 days. On the other hand, the exclusion of the interactions involving air and soil temperature has little impact on the damping timescales.

Four second-order systems are considered in Table 2. With System (i), which does not account for soil-variable perturbations, the disturbances sustain for a period of about one month. However, a damping time of about six months is obtained with System (ii), which does not account for air-variable perturbations. Considering these results and those obtained with the third-order systems, it seems that atmospheric disturbances can persist on the seasonal scale only if there are interactions between atmospheric variables and soil moisture. The other two second-order systems further illustrate the importance of the moisture processes. Clearly, thermal disturbances have a short-time impact on the water cycle, while moisture disturbances persist for as long as eight months.

Each of the four first-order models contains only one of the four perturbation variables. Obviously, in these cases, the variation of the disturbances in the systems is caused by self-feedback. The results show that the damping time is about three and a half months for the first-order system that accounts for soil moisture perturbations, and several days to three weeks for the other systems.

It is concluded from the above results that self-feedbacks are the primary factors affecting the timescale of perturbation. Specifically, soil-moisture feedback causes the seasonal-scale perturbation. The interactions between soil moisture and the other variables of the water and energy cycle system (mainly air humidity), cause a significant increase of the seasonal timescale. For atmospheric disturbances to persist at the seasonal scale, interactions between the atmosphere and soil moisture must be considered.

Persistence of Water Cycle

It has long been recognized that precipitation can persist over relatively long time periods (i.e. months to seasons), a feature known as *persistence of atmospheric disturbances*. This property indicates that if an anomaly occurs in a month or season, then there is a good chance for this anomaly to occur in the following month or season as well. Therefore, this property is quite useful for the predictability of the system. Using autocorrelations between adjacent monthly or seasonal rainfall and other atmospheric variables, many studies (e.g. Namias, 1952) demonstrated the existence of such persistence.

Land can contribute to precipitation persistence through its long memory and interaction with the atmosphere. For example, following a dry spring, soil would likely be desiccated during the summer. This would result in a relatively large sensible heat flux injected in the atmosphere from the ground surface, which could perhaps maintain anticyclonic circulations. Under such circumstances, one could expect reduced summer rainfall. A theoretical framework of the role of soil-moisture memory in precipitation statistics was presented by Koster *et al.* (2000), which indicates that a larger soil-moisture memory would lead to a larger correlation between initial precipitation and its subsequent variability.

1. Interpretation of model solutions in terms of persistence: The solutions of the analytical models also measure persistence of anomalies in the water and energy cycle system. Persistence can be estimated using autocorrelation of a variable. For soil moisture, persistence can be related to its timescale by (Delworth and Manabe, 1988)

$$r(\tau) = \mathrm{e}^{-\lambda\tau} \tag{19}$$

where r and τ are autocorrelation and time lag, respectively. This relation indicates that the larger the timescale is, the more significant the persistence of soil-moisture anomalies is.

2. Persistence signals: Persistence of the land-atmosphere system has been investigated with simulated data series.

Using multiyear simulations produced with the GFDL GCM, Delworth and Manabe (1988) analyzed the variability in soil moisture and found statistically significant persistence of soil moisture. Liu and Avissar (1999a) obtained similar results from an analysis based on a simulation with the CCM2-BATS, as shown in Figure 3. The one-month lag autocorrelation coefficients of soil moisture vary between about 30% and 90%, with a global average of 61%. Correlations are statistically significant at a 99.9% confidence level (critical value of 29.6%) almost everywhere. This emphasizes a strong persistence of the simulated soil moisture.

3. Control of persistence by water exchange: The solution of the first-order model (equation 16), λ, is determined by potential evaporation, with a fixed water field capacity. A larger potential evaporation leads to a faster decay rate and thus a less significant persistence of soil-moisture disturbances. Because potential evaporation is larger at low latitudes and in warm seasons, persistence of soil moisture is more significant at high latitudes and in winter (Delworth and Manabe, 1988). In Figure 4, autocorrelation coefficients tend to increase from about 30% in the equatorial regions to 80–90% at high latitudes.

Persistence also depends on climate regime; it is stronger in drier geographic regions (Liu and Avissar, 1999a). For soil moisture, the coefficients are less than 55% in the moist Southeast China, and over 80% in the dry Northwest China. Persistence of the other three variables (soil temperature, air humidity, and temperature) has the same dependence on climate regime as soil moisture. In addition, a global analysis (Liu and Avissar, 1999a) depicts relatively large autocorrelation coefficients in dry northern Africa and a strong contrast between this region and the moist tropics, where autocorrelation coefficients are relatively low.

Physical Mechanisms

1. Feedbacks: The evolution of the disturbances in the fourth-order continental water and energy cycle system is controlled by two mechanisms: self-feedbacks, which are measured by the four diagonal elements in the matrix **C** (equation 11, Table 3), and interactions, which are measured by the 12 other elements of this matrix. All the four diagonal elements are negative. Thus, the average of the roots, which is equal to the average of the four diagonal elements of the matrix **C**, is also negative. A negative value indicates a negative self-feedback, which results in disturbance decay.

Table 3 Values of matrix $\mathbf{C} = (c_{ij})(\times 10^{-6})$

	$j = 1$	$j = 2$	$j = 3$	$j = 4$
$i = 1$	−0.641	0.007	0.1171	0.0
$i = 2$	4.494	−1.708	19.79	0.6672
$i = 3$	1.673	0.0456	−9.178	−0.2195
$i = 4$	−0.264	0.9961	−1.113	−0.0883

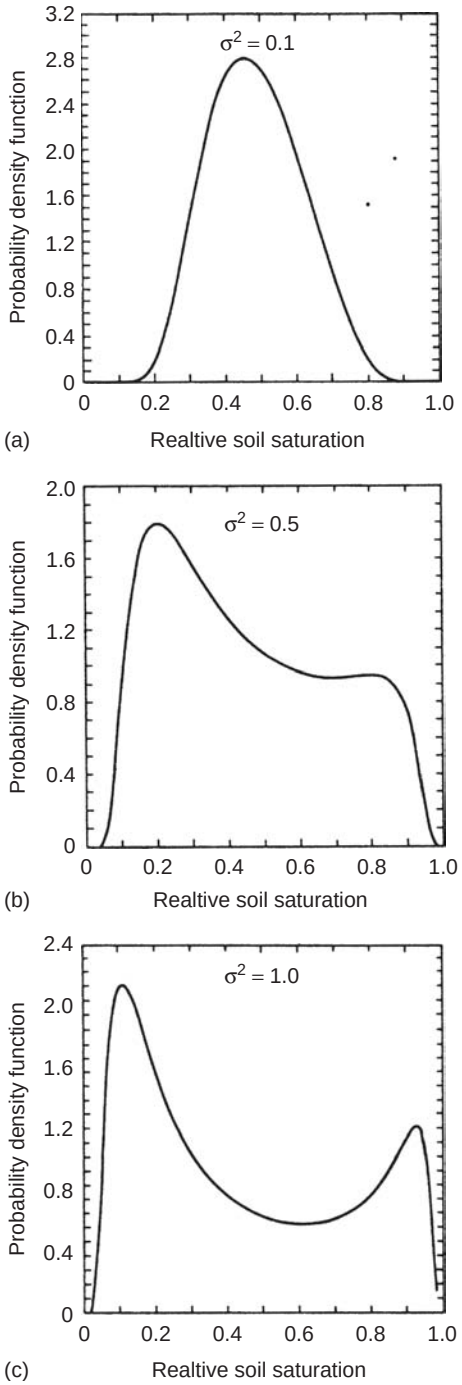

Figure 4 Steady state probability density functions of soil moisture under different atmospheric forcing (Reproduced from Rodriguez-Iturbe, ID *et al.* (1991) by permission of American Geophysical Union)

A physical explanation to the roles of these self-feedbacks can be given by using the perturbation equation (equation 11). For instance, a positive perturbation of air-temperature results in a decrease of the sensible heat released in the atmospheric surface layer from the land surface, and in an increase of the heat lost by long-wave radiation. In addition, one can expect a decrease in precipitation, which results in a reduced release of condensation latent heat, due to the corresponding lower relative humidity. These effects induce a negative air-temperature tendency. Similarly, a positive perturbation of soil temperature results in an increase in heat loss to the atmosphere by sensible heat flux, latent heat flux, and long-wave radiation, and into the soil sublayer by conduction, which leads to a decrease in soil temperature. A positive perturbation of air moisture results in a decrease of the amount of water evaporated from the land surface and, possibly, in an increase in condensation, which removes vapor from the atmosphere. Finally, a positive perturbation of soil moisture results in an increase in evaporation to the atmosphere, in runoff, and in the amount of water lost by percolation to the soil sublayer.

2. Interactions: There are also positive interactions in the system, as indicated by the positive elements of the matrix **C**, which can promote the growth of disturbances. For example, a positive perturbation of soil moisture results in a more humid atmosphere due to a stronger evaporation at the land surface, and a moister atmosphere is likely to produce more precipitation, which in turn increases soil moisture.

The overall evolution of the disturbances (i.e. amplification or decay with time) depends on the relative importance of the feedbacks and the interactions. Because all the roots of the water and energy cycle system (and their mean) are negative (Table 3), disturbances decay with time. Thus, one can expect that self-feedbacks have a predominant impact on this system.

In the fourth-order model developed by Brubaker and Entekhabi (1996), self-feedbacks of soil moisture (through control of infiltration and evaporation) and temperature (through dependence of surface specific humidity) serve to restore each state individually, and interactions between soil moisture and temperature (through soil moisture control of evaporation and the temperature dependence on surface specific humidity) act to reinforce anomaly of the other state.

3. External forcing: The soil water balance equation with the precipitation expressed by equation (15) (Rodriguez-Iturbe *et al.*, 1991) allows us to study variation in soil moisture in response to atmospheric forcing and feedback. The forcing was found to lead to transitions from one stable mode of soil moisture to another. Figure 4 shows soil moisture under different intensities of atmospheric forcing indicated by σ^2. For weak forcing (a), there is a steady state with soil moisture most probably occurring at 0.5. This is the value of an equilibrium solution of the water balance equation without atmospheric forcing (that is, $\sigma^2 = 0$). For moderate forcing (b) and strong forcing (c), the system has a quite different property. Two states of soil moisture are obtained with the most probable values of 0.2 and 0.8. The soil frequently experiences persistent dry and wet anomalies. Atmospheric forcing may lead to transitions from one to another state.

SUMMARY AND DISCUSSION

Analytical models for examining continental water cycle have been described and applied to studies of timescale, persistence, and physical mechanism of the water cycle variability. A fourth-order model of land-atmosphere energy and water balance was used as an example to show the procedure for obtaining the perturbation equation, its solutions, the impacts of the system properties, and the physical interpretation.

The analytical results indicated that the fourth-order model has seasonal, monthly, weekly, and daily damping timescales. The seasonal scale appears only in those third- or second-order models that include disturbance of soil moisture. This emphasizes that the soil moisture feedback, and its interactions with the other variables, are the primary cause for the scale. In the model without soil moisture disturbance, the maximum timescale is only about two months. In addition, among the various interactions, the one between soil moisture and air humidity is the predominant; excluding this interaction results in a reduction in the length of the seasonal scale by more than one month.

Perturbations in the land-atmosphere system could persist for seasons. Thus, persistence is an inherent property of the continental water and energy cycle. This result provides theoretical support to the studies of Namias (1952) and others, who indicated that atmospheric anomalies possess monthly-to-seasonal persistence. The timescale and persistence features were also obtained in a number of numerical simulation and observation studies (e.g. Walker and Rowntree, 1977; Rind, 1982; Rowntree and Bolton, 1983; Yeh *et al.*, 1984; Walsh *et al.*, 1985; Liu *et al.*, 1993; Gao *et al.*, 1996; Vinnikov *et al.*, 1996). In a study using the National Center for Atmospheric Research (NCAR) Community Climate Model(CCM2) coupled with the Biosphere-Atmosphere Transfer Schemes (BATS) and observations of soil and atmospheric variables in China, Liu and Avissar (1999a) showed that soil moisture variability has significant persistence, with timescales on the order of months to seasons.

The seasonal damping timescale is mostly affected by the physical factors related to soil moisture (i.e. evaporation, runoff, and soil-moisture diffusion), and the monthly damping timescale is mainly affected by the thermal characteristics of the system. The soil-moisture self-feedback is a primary cause for the seasonal damping timescale, and

interactions between soil moisture and the other variables of the system greatly increase length of the damping timescale. These results clearly emphasize the importance of soil moisture in the variability and the causes of water cycle at seasonal timescale and support findings from other investigations with more complex tools. For instance, Castelli and Rodriguez-Iturbe (1995) found that land–atmosphere interactions can influence local atmospheric processes through the modification of the vertical lapse rate, and large-scale processes through the global dynamics of baroclinic waves. The advection rates of mass and energy, and the strength of the ageostrophic frontal circulations are particularly important in that case. Betts *et al.* (1996) showed that the monthly precipitation pattern is quite sensitive to initial soil moisture in the FIFE and BOREAS experiments. They suggested that, due to the memory of the soil-moisture reservoir, some predictability exists at monthly and seasonal scales. Avissar (1995) emphasized the importance of an appropriate representation of soil moisture's role to global climate model. While the analytical models described in this article are able to provide significant insights on the continental water cycle, it is important to keep in mind that only small-amplitude disturbances in a linear system were considered here. One obvious limitation with such models is that they neglect scale interactions in the climate system. In the real world, short-time forcings can generate long-time fluctuations. The relations between the tropical convection activities, the 30–60 day low-frequency fluctuation, and the El Nino/Southern Oscillation are examples of such interactions.

The timescale of the land-atmosphere system obtained by the linear forth-order model is independent on the sign of the initial perturbation in soil moisture. Actual processes in the land-atmosphere system are nonlinear. For example, evapotranspiration, which is a major parameter for the seasonal timescale, is specified to be linearly proportional to soil moisture in the forth-order model. In other words, the increasing rate of evapotranspiration with soil moisture is constant. But evapotranspiration actually increases nonlinearly with soil moisture (Lowry, 1959); the increasing rate is smaller when the soil is dry and larger when the soil is wet for the bare soil. This suggests that the seasonal timescale or persistence time period of the land-atmosphere system should be different when the soil is abnormally dry and wet.

The fourth-order analytical model described here does not have positive growth modes. Two factors contribute to this. First, the model does not have external forcing related to, for example, atmospheric dynamics, which causes disturbances in the water cycle. Second, the nature of development of the system (i.e. growth or decay) depends very much on model parameters. In this study, climatological values have been given to these parameters. Thus, results presented here reflect the climatological behavior of the water cycle. However, the model could give solutions that indicate growing disturbances by selecting specific sets of parameters reflecting local, short-term conditions.

Another limitation with the analytical models is that it is unable to examine the interaction between the seasonal cycle and the processes involved in the models. For example, many parameters used in the fourth-order model of LA99 have significant seasonal cycle. Among those, which are important to the seasonal timescale and persistence, soil moisture, soil temperature (therefore, potential evaporation), and solar radiation are much smaller in winter than in summer. This suggests that the damping time of the seasonal scale should be longer in winter. In other words, perturbation in the land-atmosphere system described by the fourth-order system should last longer in winter. This feature was found in the analysis of a 3D climate modeling study (Delworth and Manabe, 1988) but cannot be showed with this analytical model in which the model parameters are annual averages.

Snowpack and vegetation are two other primary processes involved in the water cycle. Snow can significantly affect soil moisture and, therefore, affect persistence of the water cycle. Vegetation can influence long-term water cycle variability by modifying surface albedo, intercepting precipitation, extracting soil water from deep layers through transpiration, and resisting runoff. Vegetation dynamics have a significant influence on the seasonal and interannual water cycle (e.g. Dickinson *et al.*, 1998; Lu *et al.*, 2001). Thus, snow and vegetation processes, in addition to soil moisture, need to be included in analytical models to better understand seasonal and interannual variability of the water cycle.

180: Short-Term Predictions (Weather Forecasting Purposes)

GEORGE KALLOS AND IOANNIS PYTHAROULIS

Atmospheric Modeling and Weather Forecasting Group, School of Physics, University of Athens, Athens, Greece

In recent years there is a growing need in hydrology for high-resolution precipitation predictions. Accurate quantitative precipitation forecasts at various spatiotemporal scales can be made by the atmospheric numerical models that utilize sophisticated parameterization schemes to represent the various physical processes. Two soil parameterization schemes are presented here: a) the bucket model which is a simple single-layer scheme and was the first one to be used in numerical models, and b) the multilayer Oregon State University scheme which is currently utilized in operational and research mode. A number of successful short-term predictions of severe precipitation events are also presented. These predictions were produced by various full-physics numerical models, such as the SKIRON/Eta modeling system, RAMS and the UKMO Unified model, under different forcing mechanisms. The performance of the models in representing the spatiotemporal variability of precipitation is mainly discussed. In general, the atmospheric numerical models exhibited a skill in providing accurate short-term predictions of the spatiotemporal variability and severity of precipitation.

INTRODUCTION

In recent years, there is a growing appreciation of the importance of the surface conditions in controlling weather and climate on different temporal and spatial scales (Garratt, 1993). Several studies have shown the significance of the sea surface temperatures in forcing the atmosphere. Over land, the variability of soil properties affects the partition of the surface energy fluxes and it ultimately controls the near-surface atmospheric variables (Avissar and Pielke, 1989; Li and Avissar, 1994; Betts *et al.*, 1996). The evolution of the atmospheric boundary layer and the development of synoptic and mesoscale circulations, such as surface fronts, depend on soil hydrology (e.g. Segal *et al.*, 1989b; Chang and Wetzel, 1991; Fast and McCorcle, 1991).

The land surface and the atmosphere have been shown to interact through feedback mechanisms that range from diurnal to seasonal scales (Dooge, 1992; Betts *et al.*, 1996). In his pioneer work, Horton (1931) represented the hydrological cycle as a balanced closed cycle. Following Dooge (1992), Figure 1 presents a conceptual diagram of the interactions between the land surface and the atmosphere that control the soil water content. It describes the behavior of the soil and the fluxes of moisture during wet periods and dry periods. The circular diagram starts with the end of a long period of rain (point A). The upper soil layer is considered to be saturated and the evolution of the soil water is determined by evaporation. The rate of evaporation is at the potential rate (Shuttleworth, 1993) and the flux is controlled by the atmosphere. The combined effects of evaporation and subsurface outflow will limit the supply of water from the root soil layer into the atmosphere (point B), and evaporation will drop below its potential rate. In this case, the flux is controlled by the soil. In the beginning of the wet period (point C), precipitation starts falling on a dry enough soil. In the absence of heavy precipitation, the rate of infiltration into the surface of the dry soil will be almost equal to the rate of precipitation, and the evolution of soil water will be atmospheric-controlled through the precipitation rate. If the soil becomes moist enough that not all precipitation can percolate through the surface (point D), some of it goes into runoff. In this case, the regime is again controlled by the soil, and the rate of infiltration is dictated by the soil conditions.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

The above discussion indicates the need of hydrology for accurate precipitation forecasts. This quantity is a sink of atmospheric moisture while at the same time it moistens the surface of the earth and the soil. The natural environment is divided in catchments that range from a few square meters to millions of square kilometers. Therefore, the spatial and temporal scales of rainfall forecasts that are appropriate for water resource applications vary significantly. For example, flash floods are floods that occur suddenly, within 6 h of the event, on small streams and fast-moving rivers, while river floods occur on rivers and major streams because of prolonged heavy rain events and usually last over a relatively long period up to several days (LaPenta *et al.*, 1995). Nowadays, there is a large demand for quantitative precipitation forecasts with high spatial and temporal resolution by various sources, such as flood control agencies, water and emergency management agencies, and hydrologic forecasters. Opitz *et al.* (1995) argued that quantitative precipitation forecasts allow for longer lead times for river flood and crest stage forecasts, providing users additional time for preparedness.

Quantitative predictions of precipitation and soil conditions can only be made with numerical models that take into account the relevant laws of dynamics and thermodynamics and use realistic initial conditions. The state-of-the-art atmospheric models include detailed information about the characteristics and the state of the earth's surface, and sophisticated parameterization schemes for precipitation, cloud, radiation, boundary layer, surface, and soil processes. Thus, they are expected to exhibit a skill in predicting the spatiotemporal variability of intense precipitation events and their consequences.

The numerical models generally exhibit a high skill in predicting the state of the atmosphere in short ranges. However, the accuracy of the predictions falls rapidly in longer ranges, that is, in timescales longer than about 2–3 days, especially under certain weather conditions. The model resolution and the level of complexity of the various parameterization schemes are important issues for the forecast skill, especially in operational forecasting in which model run-time is a key parameter.

The model resolution also plays a critical role on whether explicit predictions can be made on the catchment size. Nowadays, most of the operational global modeling systems use a resolution of 25–50 km, while the operational regional models use meshes with a grid size down to about 10 km. In special cases, mesoscale numerical models used for nowcasting purposes employ a very high horizontal resolution of 1–2 km. This means that in operational weather forecasts, even at short ranges, the hydrology can only be represented in regional to large-scale catchments.

This article mainly deals with short-range weather forecasts produced by a number of state-of-the-art numerical models using various horizontal resolutions. Section "Parameterization of land-surface processes" describes two schemes widely used to represent the land-surface processes in operational atmospheric models. A number of case studies of severe precipitation events are discussed in the Section "Case studies of severe precipitation events". Finally, some concluding remarks are presented in the final section.

PARAMETERIZATION OF LAND-SURFACE PROCESSES

The land-surface parameterization schemes are an important constituent of the atmospheric models (Viterbo, 2002) because they define the lowest boundary conditions. Thus, they exert an important influence on both global climate and weather prediction models. Beljaars *et al.* (1993) demonstrated considerable sensitivity of the ECMWF forecast model to the complexity of the land-surface parameterization scheme. Sensitivity studies with numerical weather prediction models indicate that anomalously wet land surfaces tend to overestimate the precipitation amounts locally. On the other hand, unrealistic drying of the soil may lead to overestimation of the skin temperature. Henderson-Sellers *et al.* (1995) argued that soil moisture anomalies persist in weather forecast models because they prompt fairly substantial differences in the predicted rainfall during the first few days of simulation.

During the 1990s, a large number of land-surface schemes were evaluated and intercompared in the framework of the World Climate Research Programme Project for Inter-Comparison of Land Surface Parameterization Schemes (PILPS; see Table 1). PILPS was a project designed to improve the parameterization of the continental surface, especially the hydrological, energy, momentum, and carbon exchanges with the atmosphere (Henderson-Sellers *et al.*, 1993). The findings of this major project have been documented extensively in the literature (e.g.

Henderson-Sellers *et al.*, 1993, 1995, 2003; Henderson-Sellers, 1996 and references therein) and they are of potential use to research that deals with both climate and numerical weather prediction models.

In the following sections, the hydrological considerations of two land-surface parameterization schemes will be described. The bucket model was chosen because of its simplicity and for historical purposes since it was the first attempt to parameterize land-surface processes in atmospheric numerical models. On the other hand, the Oregon State University (OSU) model is a multilayer scheme that represents a large number of hydrological processes and is widely used for research and operational purposes.

The Bucket Model

This scheme was introduced by Manabe (1969) and it was a first attempt to incorporate the effects of the earth's surface hydrology into a general circulation model. A number of numerical models have employed the scheme of Manabe or variations (e.g. Arakawa, 1972; Delworth and Manabe, 1988; Robock *et al.*, 1995; Pitman *et al.*, 2003).

The bucket model is a simple scheme that does not take into account the role of vegetation and soil type variability, and it does not include a canopy parameterization. The soil hydrology is represented in one layer that extends from the surface to 1 m depth. The choice of the soil layer of 1 m depth was due to the work of Romanova (1954) in the steppes and forest zones, and to the fact that most of the root system of a plant is concentrated in the top 1 m depth.

The amount of evaporation and the soil moisture content (SMC) are calculated following the concepts of Budyko (1956) that make use of a soil moisture availability parameter. The surface evaporation depends mainly on meteorological factors, and it is assumed to be equal to the "potential evaporation" when the soil moisture exceeds a certain critical amount. Otherwise, the evaporation is equal to a fraction of the "potential evaporation" that depends on the available soil moisture. In summary:

$$E = E_{\mathrm{o}}, \qquad \text{if } W \geq W_{\mathrm{K}} \tag{1}$$

$$E = E_{\mathrm{o}}\frac{W}{W_{\mathrm{K}}}, \quad \text{if } W < W_{\mathrm{K}} \tag{2}$$

where E_{o} is the "potential evaporation", W is the soil moisture contained in the soil layer from the surface to 1m depth, and W_{K} is a critical soil moisture value. According to Alpatev (1954), when soil moisture is not lower than 70–80% of its field capacity, evaporation from crop field is close to the value of "potential evaporation", that is, $W_K = 0.75 \cdot W_{\mathrm{FC}}$, where W_{FC} is the field capacity of moisture. For W_{FC}, a single value of 0.15 m was used.

In Manabe (1969), the evaporation (E_{o}) from a sufficiently wet land surface or ocean is calculated by:

$$E_{\mathrm{o}} = \rho(h) \cdot C_{\mathrm{D}}(h) \cdot |V(h)| \cdot (r_{\mathrm{ws}} - r(h)) \tag{3}$$

where ρ is the air density, h is the height of the lowest model level, C_{D} is the drag coefficient, V is the wind velocity, r is the mixing ratio, and r_{ws} is the saturation mixing ratio of water vapor.

In the absence of snow cover, the rate of change of soil moisture and surface runoff follow Budyko (1956) and they are expressed as:

$$\frac{\partial W}{\partial t} = R_{\mathrm{A}} - E, \qquad \text{if } W < W_{\mathrm{FC}} \tag{4}$$

$$\frac{\partial W}{\partial t} = 0 \;\&\; r_{\mathrm{f}} = R_{\mathrm{A}} - E_{\mathrm{o}}, \quad \text{if } W = W_{\mathrm{FC}} \text{ and } R_{\mathrm{A}} > E_{\mathrm{o}} \tag{5}$$

where R_{A} is the rainfall rate and r_{f} is the surface runoff, that is, runoff occurs when the soil exceeds its maximum moisture capacity. In the presence of snow, the above rates are modified taking into account the soil moisture source through snow melting and omitting the sink of soil moisture through evaporation.

The above assumptions lead to a simplified representation of the soil hydrological cycle since a large number of processes such as the interception of rainfall by the canopy, the plant evapotranspiration, the subsurface runoff, the variability in field capacity of moisture due to the soil type, the storage of infiltrated water, and so on are not considered. The bucket method has been shown to overestimate the latent heat fluxes. Pan (1990) argues that even when the soil is wet, there still exists some stomatal resistance in the plants that will reduce the evaporation from the potential value. On the other hand, in dry soils, the use of the surface temperature to infer the saturation-mixing ratio can lead to overestimation of evaporation.

In the previous decades, when the computer power was not sufficient to use advanced schemes, the bucket model was still in use and a number of authors presented various improvements to the original bucket model (e.g. Pan, 1990; Milly, 1992). Nowadays, complex multilayer schemes, which utilize all the available information about the canopy and soil characteristics, are employed in order to represent the surface and soil hydrology.

OSU Scheme

The OSU land-surface model is an advanced parameterization scheme that was originally developed by Mahrt and Pan (1984) and Pan and Mahrt (1987). A detailed description of the scheme is provided by Ek and Mahrt (1991). Modified versions of the scheme have been implemented in various widely used atmospheric numerical models including the operational NCEP-Eta model (Chen *et al.*, 1997), the SKIRON/Eta modeling system (Kallos, 1997), the weather forecasting system POSEIDON (Papadopoulos

et al., 2002), and the Penn State-NCAR MM5 model (Chen and Dudhia, 2001).

In this section, the methodology used for the hydrological processes in the SKIRON/Eta modeling system will be discussed. The SKIRON/Eta system is based on the NCEP-Eta model. A detailed description of its characteristics and configurations is to be found in Kallos (1997), Nickovic *et al.* (1998), Papadopoulos *et al.* (2002), and others. This model runs in operational and research mode in a large number of meteorological centers and institutes such as the University of Athens, the Hellenic Centre for Marine Research, the Hellenic National Meteorological Service, the Atmospheric Sciences Research Centre of the University of Albany, and others.

The land-surface scheme that represents the ground processes and calculates the energy exchanges in the soil is based on an active multilayer soil model (Mahrt and Pan, 1984) coupled to a plant canopy model (Pan and Mahrt, 1987). According to the original formulation of the scheme, the calculations for the soil temperature and moisture proceed at two layers, from the surface to 0.1 m and from 0.1 to 2 m. Storage of water is allowed in the underlying deeper layer. Papadopoulos (2001) showed that the behavior of the scheme improves significantly with the use of at least six vertical layers. This is because of the better representation of the second order differences in the soil moisture tendency equation. A schematic representation of the six-layer soil scheme currently used by the SKIRON/Eta modeling system and the corresponding depth of each layer are presented in Figure 2. It illustrates the main processes that determine the amount of soil moisture in each layer and the interactions between the atmosphere and the top layer, such as the evaporation (E), the interception and infiltration of precipitation, the vertical flux of moisture (F), and the runoff (R).

Evaporation

An important parameter for the calculation of the soil moisture and for the atmospheric forecasts in general is the evaporation from the surface of the land. The total evaporation (ET_a) from the soil and the canopy surface is obtained by adding the direct evaporation (E_d) from the top soil layer, the transpiration (E_t) via canopy, and

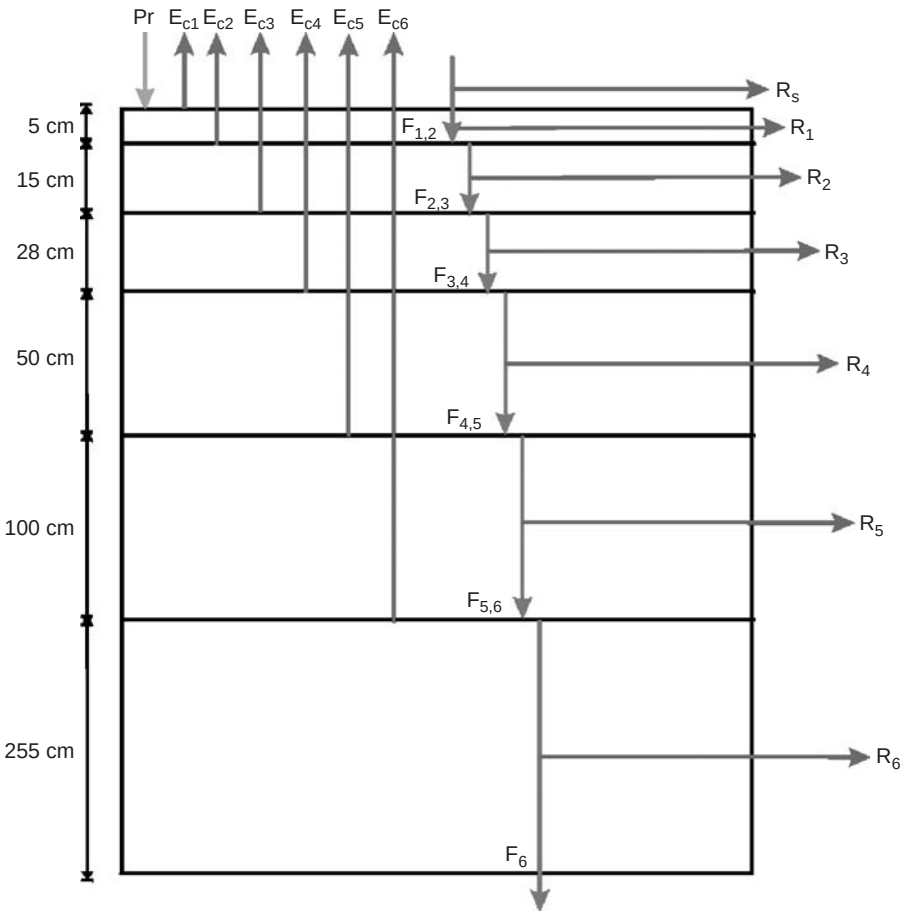

Figure 2 Schematic representation of the multilayer soil hydrology scheme used by the SKIRON/Eta modelling system (Papadopoulos, 2001). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

the evaporation of the precipitation (E_c) intercepted by the canopy:

$$ET_a = E_d + E_t + E_c \tag{6}$$

The total evaporation cannot exceed the potential evaporation (ET_p).

1. *Potential evaporation*

The potential evaporation is used to compute the actual evaporation in the model. Each component of the right-hand side of the above equation can be also bounded by the potential evaporation ET_p. The usual Penman relationship has been modified (Mahrt and Ek, 1984), since the surface temperature is needed to compute the net radiation. The expression for the potential evaporation used in the model is:

$$ET_p = \left(\frac{A \cdot RR + RAD \cdot DELTA}{DELTA + RR}\right) \cdot \frac{\rho \cdot c_p \cdot c_h}{L_v} \tag{7}$$

where,

$$\begin{aligned} A &= (q_{0s} - q_0) \cdot \frac{L_v}{c_p} \\ RR &= 1 + \frac{4 \cdot \sigma \cdot T_{air}^4 \cdot R_d}{p_{sfc} \cdot c_p \cdot c_h} \\ RAD &= \frac{F_{net}}{\rho \cdot c_p \cdot c_h} + (\vartheta_{air} - T_{air}) \\ DELTA &= \frac{dq_s}{dT} \cdot \frac{L_v}{c_p} \\ F_{net} &= RSW_{in} - RSW_{out} \\ &\quad + RLW_{in} - \sigma \cdot T_{air}^4 - S \end{aligned}$$

where q_{0s} and q_0 are the saturation and the actual specific humidity at the first model level, respectively, L_v is the latent heat of evaporation ($2.5 \times 10^6\,J\,Kg^{-1}$), c_p is the specific heat of dry air ($1004.6\,J\,Kg^{-1}\,K^{-1}$), θ_{air} and T_{air} are the potential and actual air temperature at the first model level, respectively, R_d is the gas constant for dry air ($287.04\,J\,Kg^{-1}\,K^{-1}$), p_{sfc} is the surface pressure (Pa), c_h is the surface exchange coefficient for heat and moisture ($m\,s^{-1}$).

2. *Direct evaporation*

The direct evaporation from the top soil layer is calculated when the potential evaporation is greater than zero. At the air–soil interface, the direct evaporation is:

$$E_{dir} = \left(-D_{SMC} \cdot \left(\frac{\partial SMC}{\partial z}\right)_0 - K_{SMC_0}\right)(1 - \sigma_f) \tag{8}$$

where SMC is the soil moisture content, D_{SMC} is the soil water diffusivity ($m^2\ s^{-1}$), and K_{SMCo} is referred to as the hydraulic conductivity at surface ($m\,s^{-1}$), which are functions of the volumetric water content (Mahrt and Pan, 1984). The dimensionless parameter σ_f (ranges between 0 and 1) is the plant shading factor.

Chen *et al.* (1996) suggested an alternative way to calculate the direct evaporation using the equation:

$$E_{dir} = g(SMC) \cdot (1 - \sigma_f) \cdot ET_p \tag{9}$$

where the function *g (SMC)* is defined as

$$g(SMC) = \frac{SMC - SMC_{wilt}}{SMC_{ref} - SMC_{wilt}} \tag{10}$$

The soil moisture content limit SMC_{ref} refers to an upper reference value, which is the SMC value when gravity drainage of moisture in the viscous soil is allowed at a rate of $5.79 \times \times 10^{-9}\ m\,s^{-1}$ (equal to $0.5\,mm\,day^{-1}$). The SMC_{wilt} is the value of soil moisture content below which permanent wilting of the plant occurs and it corresponds to maximum potential energy needed to extract water from inside the soil. In the latter way of calculating the direct evaporation, the heterogeneity in the surface cover and the soil texture and composition are considered.

The direct evaporation (E_{dir}) can proceed at a potential rate (ET_p) when the apparent soil moisture at the surface (SMC_1) is greater than the air-dry value (SMC_d), that is, when the soil is sufficiently wet (demand control stage). When the soil dries out, the evaporation can only proceed at the rate by which the soil can diffuse water upward from below (flux control stage), in which case $SMC_1 = SMC_d$ and $E < ET_p$.

3. *Canopy evaporation*

The evaporation of the precipitation intercepted by the canopy (E_c) is calculated by:

$$E_c = ET_p \cdot \sigma_f \cdot \left(\frac{CMC}{CMC_{max}}\right)^{C_{factr}} \tag{11}$$

where CMC is the canopy water content (in m), CMC_{max} (in units of m) is the maximum (saturated) water capacity for a canopy surface (chosen equal to 0.005 m), and C_{factr} is a dimensionless constant that according to Pan and Mahrt (1987) is considered to be 0.5. The rate of change of the canopy water content is

$$\frac{dCMC}{dt} = \sigma_f \cdot PRCP - E_c \tag{12}$$

where $PRCP$ is the total precipitation intercepted by the canopy in the physics timestep. If the canopy moisture content (CMC) exceeds the CMC_{max}, the excess precipitation is considered to fall to the ground.

4. *Transpiration*

The soil water is transferred to the leaves of the plants through their roots and then to the atmosphere through plant transpiration. The model also incorporates plant transpiration (E_t) through the equation

$$E_t = \sum_{i=1}^{N} \left[ET_P \cdot \sigma_f \cdot PC \cdot \left[1 - \left(\frac{CMC}{CMC_{max}}\right)^{C_{factr}}\right] \cdot g(SMC_i) \cdot \frac{\Delta z_i}{z_N} \right] \tag{13}$$

where N is the number of soil layers, ET_p the potential evaporation, σ_f (ranges between 0 and 1) is the plant shading factor, plant coefficient (PC) is a dimensionless plant coefficient (ranging between 0 and 1), CMC and CMC_{max} are the actual and the saturated water capacity for a canopy surface, C_{factr} is equal to 0.5, and z_i is the depth of each soil layer.

The soil model uses the PC for the reduction in transpiration due to internal plant physiology. The PC is calculated using the formula

$$PC = \frac{RR + DELTA}{RR \cdot (1 + RC \cdot c_h) + DELTA} \tag{14}$$

where,
$$RR = 1 + \frac{4 \cdot \sigma \cdot T_{air}^4 \cdot R_d}{p_{sfc} \cdot c_p \cdot c_h}$$
$$DELTA = \frac{dq_s}{dT} \cdot \frac{L_v}{c_p}$$

RC is the canopy resistance that depends on the incoming solar radiation, air temperature, atmospheric water vapor pressure deficit at the lowest model level, and soil moisture availability and is calculated as (Noilhan and Planton, 1989; Jacquemin and Noilhan, 1990):

$$RC = \frac{RC_{min}}{RCS \cdot RCT \cdot RCQ \cdot RCSOIL} \tag{15}$$

where,
$$RCS = \frac{\frac{RC_{min}}{RC_{max}} + ff}{1 + ff}, \text{ with}$$
$$ff = 0.55 \cdot 2 \cdot \frac{RSW_{in}}{R_{gl}}$$
$$RCT = 1 - 0.0016 \cdot (T_{ref} - T_{sfc})^2$$
$$RCQ = \frac{1}{1 + HS \cdot (q_{0s} - q_0)}$$
$$RCSOIL = \sum_{i=1}^{N} \left(\frac{\Delta z_i}{z_N} \cdot g(SMC_i) \right)$$

where RC_{min} is the minimum stomatal resistance (depending on the vegetation type), RC_{max} is the maximum stomatal resistance and is set equal to $5000\,s\,m^{-1}$, RSW_{in} the incoming solar radiation, R_{gl} and HS are functions of vegetation type, T_{ref} is a reference temperature equal to 298 K, T_{sfc} is the skin surface temperature, q_{0s} and q_0 are the saturation and the actual specific humidity at the first model level, respectively, Δz_i is the thickness of the I soil layer, and z_N is the depth of the deepest sublayer.

Soil Hydrology

After obtaining the total evaporation, it is checked whether the CMC exceeds the maximum capacity. The canopy moisture excess is assumed to fall on the ground. The next step is the determination of the rainfall infiltration rate. The precipitation amount that cannot infiltrate or reevaporate (e.g. in the case of heavy precipitation) is specified to be surface runoff. The rest of the surface water is assumed to move in the soil. To calculate the vertical soil moisture gradient among the soil layers, the soil moisture tendency equation is solved using the integrated form of:

$$\frac{\partial SMC}{\partial t} = \frac{\partial}{\partial z} \left(D_{SMC} \cdot \frac{\partial SMC}{\partial z} \right) + \frac{\partial K_{SMC}}{\partial z} \tag{16}$$

where the soil water diffusivity, D_{SMC}, and the hydraulic conductivity, K_{SMC}, are functions of SMC (Clapp and Hornberger, 1978).

Runoff within layers is allowed if the SMC exceeds the maximum capacity of the specified soil type. The minimum allowable value of SMC is 0.02. The moisture loss due to gravitational percolation (i.e. drainage) occurs through the bottom of the lowest soil layer.

Snow Pack

The OSU scheme takes into account the effects of snow on the land surface and soil hydrology. In the presence of snowfall, the snow depth is calculated and is converted to a liquid equivalent snow depth. If the equivalent snow depth is greater than 10^{-6} m. (in a timestep), the actual evapotranspiration, the soil moisture, and the heat flux are calculated using the snow pack considerations.

If the snow layer is thick, it will evaporate/sublimate for the entire timestep at the potential evaporation rate. On the contrary, when the snow depth is thin, the evaporation cannot be maintained at the potential rate, and it is assumed that the snow will be evaporated completely over the timestep.

In the presence of snow, the snow melt is calculated and it is added to the effective precipitation that falls on the top soil layer. The soil hydrology operates as in soil without snow coverage, with the difference that the soil moisture is updated setting the effective evapotranspiration equal to zero.

CASE STUDIES OF SEVERE PRECIPITATION EVENTS

Extreme rainfall resulting from rapidly developing systems in the Mediterranean often lead to devastating floods causing significant loss of life and property damage. This kind of extreme weather phenomena is considered as the second most important natural disaster after the earthquakes in several Mediterranean countries. Since it is impossible to avoid them, a correct understanding of their principal cause can help in the early and accurate prediction and, therefore, trigger the necessary operations for the rescue of human lives and reduction of material damage.

A number of short-range predictions of severe precipitation events in the Mediterranean region will be illustrated in this section. These case studies correspond to real events,

well-documented in the literature, that were triggered by different forcing mechanisms and were predicted successfully by the utilized numerical models. The severity of these storms, their societal impacts, and the challenge they provide in order to examine the forecasting capabilities of the numerical models are the most important reasons for their choice.

The Storm of October 1994 over Greece

During October 21 1994, Greece was affected by a frontal depression that caused catastrophic floods and many casualties in urban areas as well as in the countryside (Lagouvardos *et al.*, 1996). The cold front passage was associated with heavy precipitation amounts that exhibited significant spatial variability. Eleven deaths were reported during this event, nine of them inside the Greater Athens area. The transportation, telecommunication, and energy supply networks were significantly damaged, especially in the eastern part of the country.

The observed total accumulated precipitation during a 24-h period (from 0600 UTC on 21 October to 0600 UTC on 22 October 1994) is presented in Figure 3. A band of heavy precipitation extended northward through Peloponnisos into the area of Athens. The maximum precipitation (96 mm) in Athens was reported near the city center, in the station of Nea Philadelfia, where most of the damages occurred. In central Greece, where important flooding was reported, the maximum precipitation amount was 149 mm. In northern Greece, heavy precipitation was observed in Trikala (east of the Pindos mountains) and in Katerini (east of mount Olympos) with maxima of 113 and 84 mm, respectively. These two regions of heavy precipitation were separated by a dry band. The precipitation pattern exhibited a substantial spatial variability that was investigated by model simulations.

Lagouvardos *et al.* (1996) simulated this event using two different numerical models. Their main aim was to

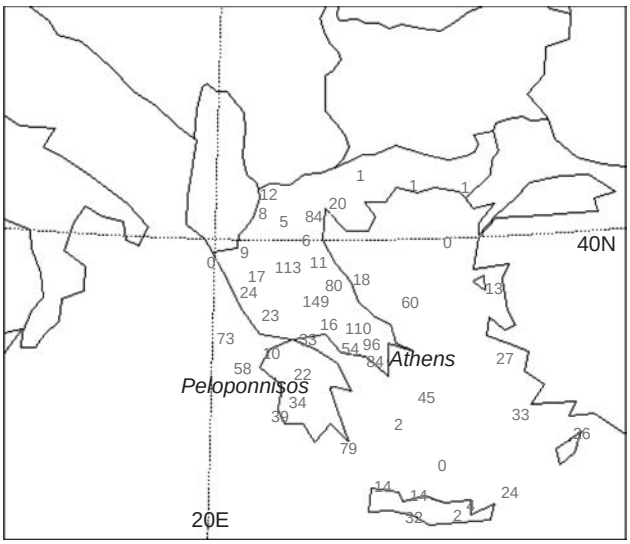

Figure 3 Total accumulated precipitation in mm from 0600 UTC 21 October to 0600 UTC 22 October 1994, reported by the surface stations (Reproduced from Lagouvardos *et al.,* 1996 by permission of American Geophysical Union (AGU)). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

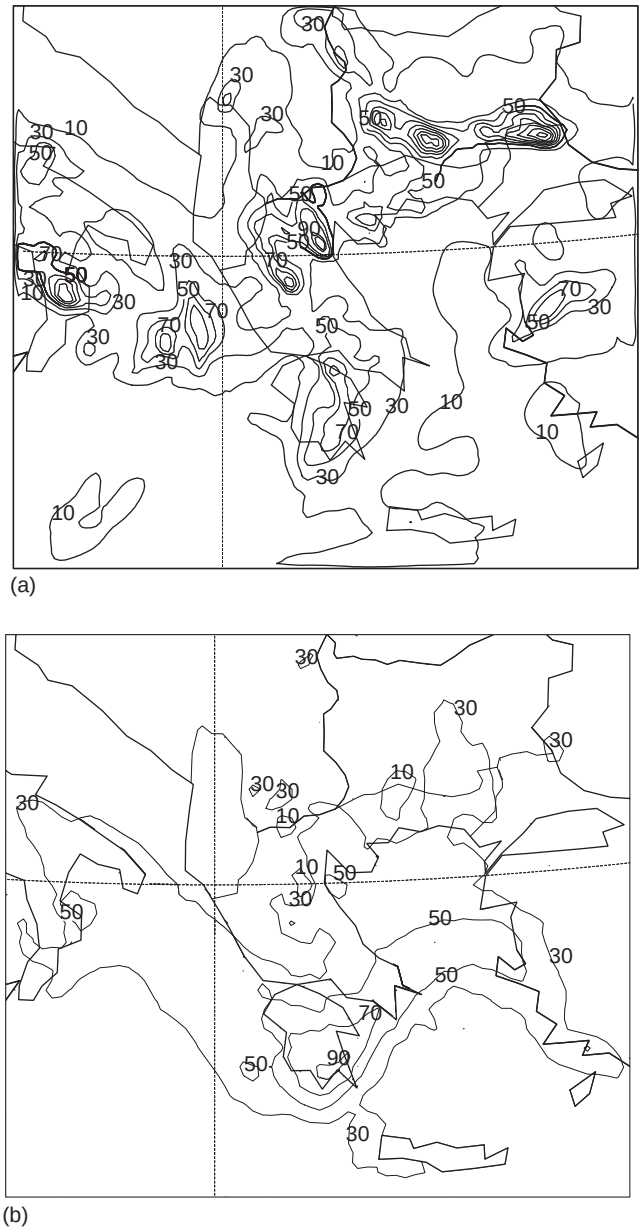

Figure 4 Total predicted accumulated precipitation from 0600 UTC 21 October to 0600 UTC 22 October 1994 (contour interval of 20 mm) from (a) RAMS inner grid and (b) SKIRON/Eta model (Reproduced from Lagouvardos *et al.,* 1996 by permission of American Geophysical Union (AGU))

investigate the capability of the numerical models to reproduce the spatial variability of precipitation at mesoscale. The two models were the Regional Atmospheric Modelling System (RAMS) and the SKIRON/Eta modeling system. RAMS used two nested grids: the outer encompassed eastern Mediterranean with a grid spacing of 40 km, and the inner covered Greece with a grid spacing of 10 km. SKIRON/Eta employed one nest that covered the central and eastern Mediterranean with a grid spacing of 25 km.

Both models were initialized at 0000 UTC, 21 October 1994, and they represented the mesoscale flow associated with the frontal depression in good agreement with the available analyses and observations. The 24-h total accumulated precipitation fields predicted from 0600 UTC on 21 October to 0600 UTC on 22 October, from the inner nest of RAMS and SKIRON/Eta models, are presented in Figure 4. The RAMS model simulations were considered as successful in describing the main mesoscale features of the precipitation pattern. The model predicted well the heavy precipitation observed over southern Greece as well as the two regions of heavy precipitation separated by a dry region over northern Greece. Also, the predicted precipitation amounts compared quite well with the observations. However, the spatial variability of precipitation within the Athens region was not represented adequately because of the model resolution. On the other hand, the SKIRON/Eta model succeeded in reproducing the main mesoscale features of the precipitation field, but its major shortcoming was the underestimation of the precipitation amounts especially in northern Greece. Finally, Lagouvardos *et al.* (1996) investigated the main sources and paths of air masses that affected Greece during this flood. Figure 5 depicts the air masses to originate in a number of areas around Greece (northern Africa, Sahara, Black Sea), to be enriched in moisture over eastern Mediterranean, and finally to move over Greece provoking catastrophic floods.

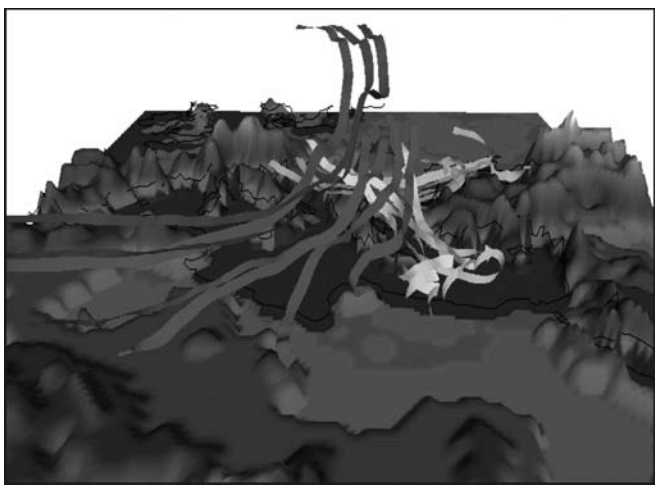

Figure 5 SKIRON/Eta trajectories showing the origin and the paths of the air masses that affected Greece during the storm of 20–21 October 1994. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

In summary, both numerical models exhibited a skill in reproducing the observed mesoscale pattern of the extreme precipitation event of 21 October 1994. The model resolution was a limiting factor in representing the details of the observed precipitation pattern and amounts in local scale. It is noted that it is very difficult to analyze the spatiotemporal variability of precipitation, especially in convective events, given the low-density of the rain gauge network.

Thunderstorm Activity Associated with Convergence Zones

A typical summer storm activity occurring over Greece was investigated by Kotroni *et al.* (1997). On 10 July 1994, a thermal low prevailed over the Anatolian plateau while central Europe and the Balkans were under the influence of a high-pressure system associated with a very weak pressure gradient over the Greek peninsula. A weak northeasterly flow resulted from this synoptic configuration. These conditions are favorable for the development of local thermal circulations and for the triggering of convergence. At the 500 hPa level, there was a trough oriented from north to south with its axis extending from the eastern part of central Europe to western Greece and the Ionian Sea. Thus, cold air advection was evident over the Balkans and Greece in the layer 850–500 hPa. The combination of the cold air advection with the low-level convergence resulted in convective activity over the Greek peninsula. Moreover, the radiosonde observations from Athens (Greece) and Sofia (Bulgaria) revealed the existence of potential instability in the middle and lower troposphere of both areas. At 1200 UTC, the CAPE reached a value of 2083 J kg^{-1} over Athens, showing that the air was potentially unstable to a high degree.

Thunderstorms developed over northern Greece in the morning of 10 July, and by 1200 UTC, the activity affected the whole peninsula (Figure 6a, b). Maximum convective activity was observed over central Greece at 1300 UTC. During the afternoon, the storms affected mainly the eastern part of the peninsula (Figure 6c, d), while after 1800 UTC, the activity gradually decayed.

The detailed structure of the atmosphere during this event, the characteristics and origin of the air masses which fed the storm activity, and the potential of predicting such events were examined through modeling. RAMS and HYPACT models were utilized in this study. Kotroni *et al.* (1997) initialized RAMS at 0000 UTC 10 July 1994 and the duration of the simulation was 24 h. Two nested grids were employed: (i) the outer, that covered the Balkans with a grid spacing of 20 km and (ii) the inner that covered the Greek peninsula with a 5-km horizontal grid spacing.

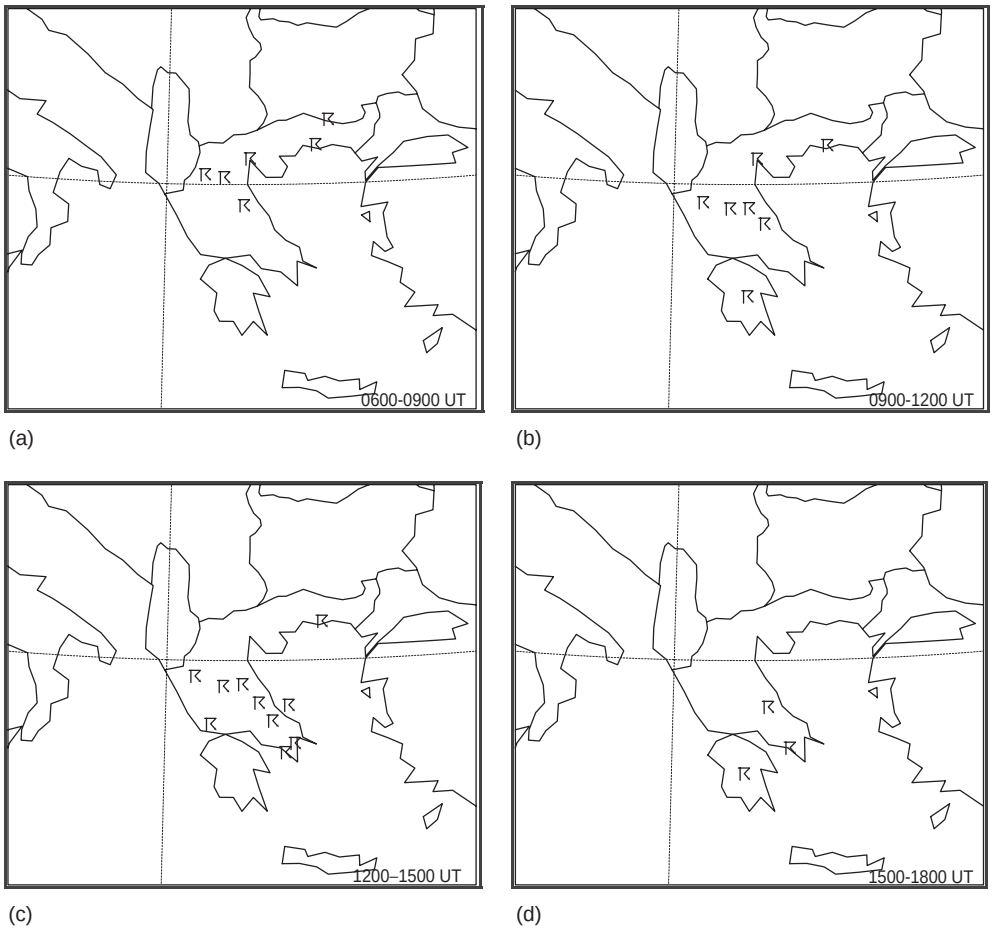

Figure 6 Reported thunderstorm activity during three hours intervals (a) from 0600 to 0900 UTC, (b) from 0900 to 1200 UTC, (c) from 1200 to 1500 UTC and (d) from 1500 to 1800 UTC, 10 July 1994 (Reproduced from Kotroni *et al.*, 1997 by permission of Royal Meteorological Society)

RAMS model predicted the synoptic conditions in good agreement with the surface synoptic network observations. Over the Greek peninsula, organized convergence was evident on an axis oriented NW to SE through central Greece, following the main axis of the topography, and over the southern part of the peninsula. The organized convergence along the main axis of the peninsula gave rise to a mechanical lifting of the air masses that met a colder air aloft.

Quite strong vertical motions were predicted over the Greek peninsula due to the differential heating and complex topography. Figure 7 presents a horizontal section of the vertical velocity field, inside the inner grid of RAMS at a height of 1500 m above ground at 1300 UTC. A band of significant upward vertical motion is associated with the convergence zone. At low levels, the strongest updrafts, exceeding $3.5\,\mathrm{m\,s^{-1}}$, were predicted over central Greece and Albania.

Regarding the time evolution of the preferred location for convective activity at the time of the initiation of thunderstorm activity at 1000 UTC, updrafts with a maximum of $2\,\mathrm{m\,s^{-1}}$ (confined to the first 4 km) are predicted in the western part of the peninsula. Later on, at the time of maximum activity (1300 UTC), the updrafts extend up to 10 km with a maximum of $5\,\mathrm{m\,s^{-1}}$ at about 6 km. The model has now shifted the convective shells by about 100 km towards the east, in agreement with the observed thunderstorm activity (Figure 6c).

Vertical sections of mixing ratio revealed the inflow of moist air masses from the maritime regions on both sides of the peninsula, which feed the convective activity and are injected aloft in the region of the strongest convection. The origin of the air masses feeding the convective activity with moisture was investigated using the HYPACT dispersion model. Particle releases parallel to the west and east coasts of the Greek peninsula were used as tracers of air masses originating from the marine boundary layer (Figure 8). The position of the sources and the distance from the coast were defined on the basis of inspection of the wind flow simulated by RAMS. Southward advection of the air

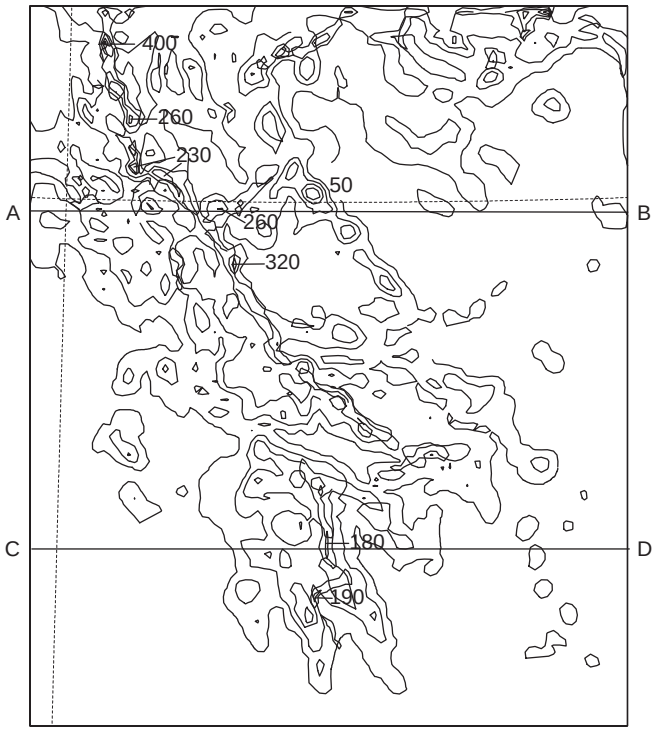

Figure 7 Horizontal section of RAMS inner grid at $z = 1500$ m AGL at 1300 UTC, 10 July 1994. Bold lines denote vertical velocity with 100 cm s^{-1} interval. Only values exceeding 50 cm s^{-1} are shown, while maximum values at each location are denoted with bold numbers (in cm s^{-1}). masses, away from the peninsula, was predicted during the morning hours of 10 July 1994. Later on, the development of thermal circulations begins to advect the air masses towards the coasts of Greece. These air masses enter

within the mainland and they converge towards the main mountain axis.

A similar case of summer thunderstorm activity over Greece was studied by Papadopoulos (2001) with the use of SKIRON/Eta modeling system at a horizontal resolution of 0.125°. The accumulated precipitation predicted between 0600 and 1800 UTC on 21 June 1999 appears in Figure 9. Two areas with maximum precipitation amounts were predicted in northern Greece, in agreement with the maximum reflectivity image of the local radar (Figure 10). Moreover, Papadopoulos (2001) showed that the precipitation amounts predicted by the numerical model were in good quantitative agreement with the local rain gauge measurements.

In summary, the model simulations represented successfully the spatial and temporal evolution of the convection associated with typical summer storms occurring over Greece. Kotroni *et al.* (1997) concluded that the thunderstorm activity showed a selective spatial distribution because of the locality of thermal circulations. This could be correlated with the more vegetated and irrigated areas that supply the convective cells with moisture. The impact of vegetation and soil wetness on the moisture content of the boundary layer and the potential for development of convective clouds has been pointed out by Segal *et al.* (1989a,b). Moreover, Chen *et al.* (2001) showed that the landscape variability at small and large scales significantly affects the location and intensity of

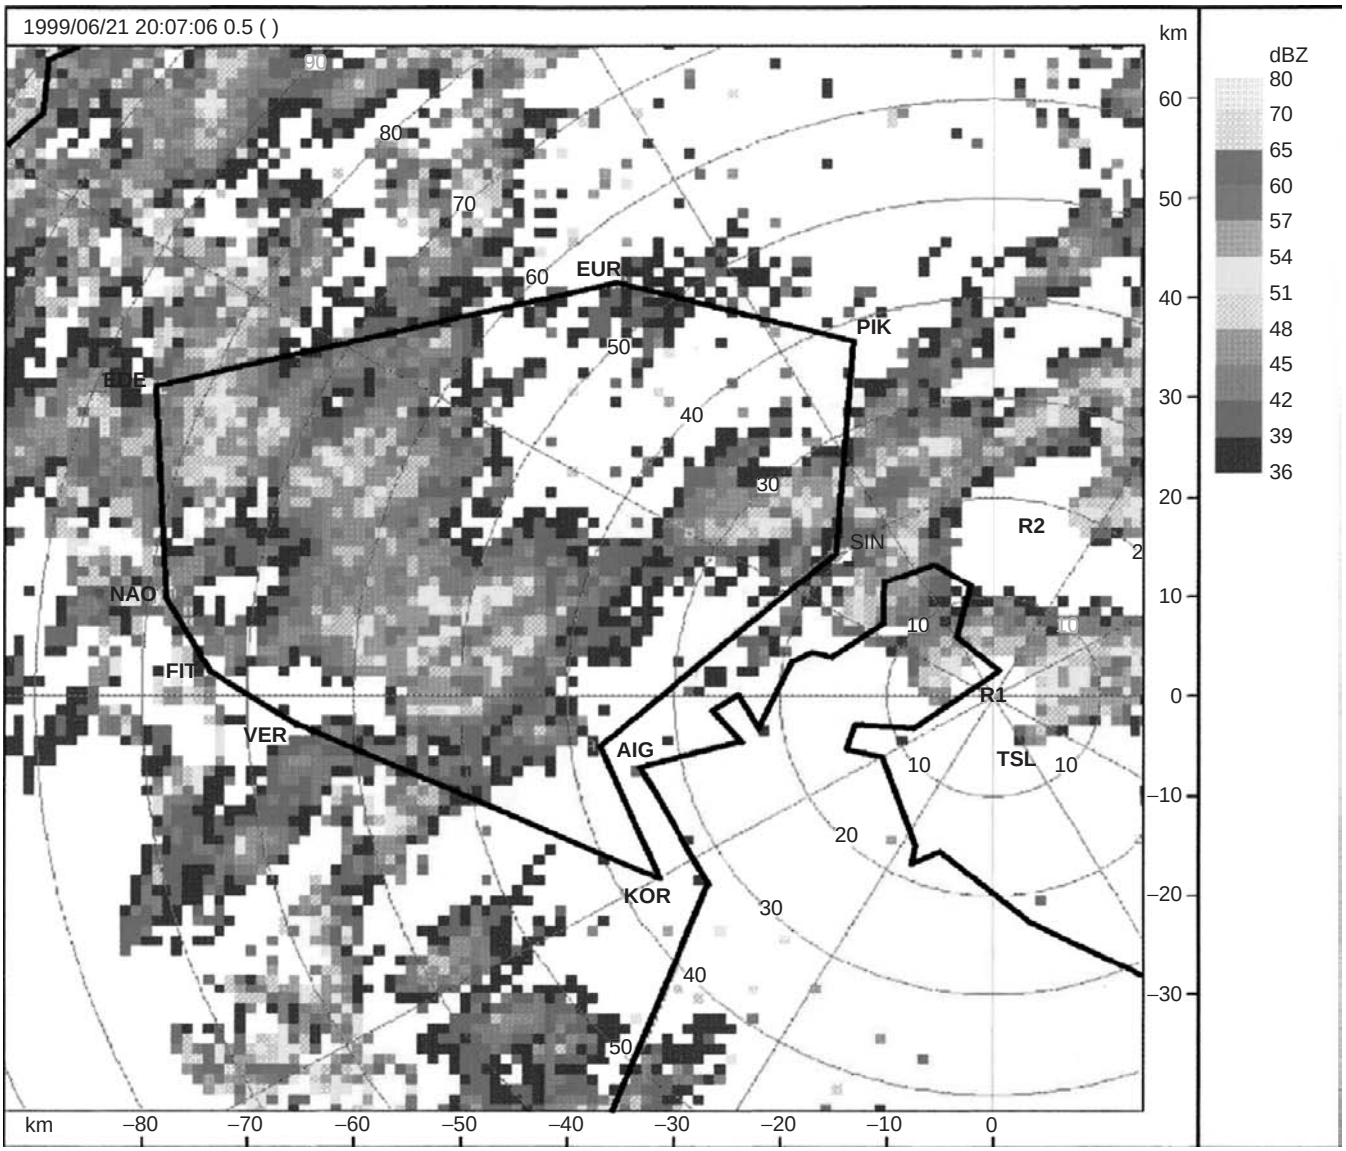

Figure 10 Maximum reflectivity image from the radar of the airport of Thessaloniki, Greece, on 21 June 1999. (Papadopoulos, 2001). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

moist convection, while Grasso (2000) suggested that the movement of a dryline and the magnitude of the low-level water vapor gradient are sensitive to changes in soil moisture.

The ''Hurricane-like'' Mediterranean Cyclone of January 1995

In mid January 1995, a small hurricane-like cyclone was detected by the Meteosat and the polar-orbiting NOAA satellites over the central Mediterranean Sea. Hereafter, it will be called *the Mediterranean cyclone*. Generally, most of the cyclogenesis occurring in the Mediterranean is caused by the lee effect of the surrounding mountains. Sometimes, small cyclones with intense convection and looking remarkably like tropical cyclones develop over the Mediterranean Sea. At least 10 times in the past 40 years, similar cyclones have been documented (e.g. Rasmussen and Zick, 1987; Reale and Atlas, 1998; Lagouvardos *et al.*, 1999; Pytharoulis *et al.*, 2000).

The Mediterranean cyclone formed at about 0330 UTC on 15 January 1995 over the sea between Greece and Sicily, close to western Greece. Before its formation, a synoptic scale low was present and strong convection was observed. Afterwards, the larger-scale parent low continued to move eastwards and decayed, while the Mediterranean cyclone remained in a wider low-pressure area. The latter system evolved for about three days, moving southwards, and finally it made landfall in northern Libya at about 1800 UTC on 17 January.

Deep convection was associated with the Mediterranean cyclone during almost all of its lifetime. The satellite images revealed a well-organized vortex with a clear "eye" (Figure 11) and several cumulonimbi. At 0600 UTC on 16 January, four ships provided reports from the vicinity of the disturbance. The ship nearest to the vortex center reported a 23 m s^{-1} (45 knots) surface wind. Lagouvardos *et al.* (1999), using data from the Special Sensor Microwave/Imager (SSM/I), concluded that surface winds of 28 m s^{-1} (54 knots) were associated with the vortex on 16 January. The threshold value of the maximum sustained surface winds for a tropical depression to be upgraded to a named tropical storm is 34 knots (Foley, 1995).

A number of modeling studies have been conducted on the Mediterranean cyclone (Blier and Ma, 1997; Lagouvardos *et al.*, 1999; Pytharoulis *et al.*, 2000), examining the predictability of its genesis and track, as well as the characteristics of its structure. The United Kingdom Meteorological Office (UKMO) Unified Model used by Pytharoulis *et al.* (2000) predicted successfully the formation of the Mediterranean cyclone and its track for the first 24–30 h. Figure 12 illustrates the predicted surface pressure and the instantaneous rate of total precipitation as well as the actual location of the system. The comparison of the location of the simulated vortex with the location of the actual system reveals that the model performed very well for the first 24–30 h. Afterwards, the model moved the cyclone in the correct path but faster than in reality, and important differences (6–8 hPa) appeared in the minimum surface pressure.

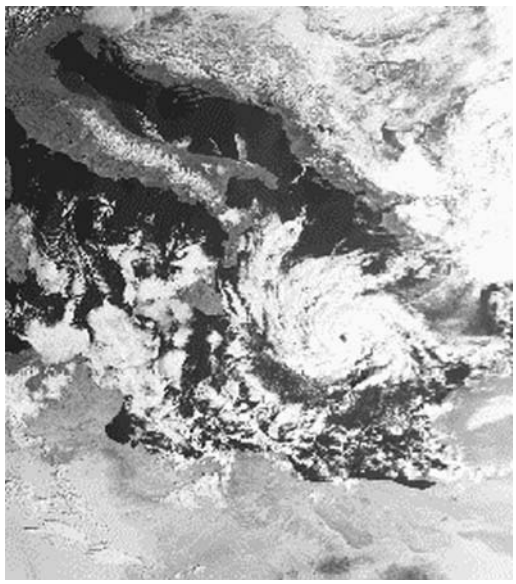

Figure 11 Visible MeteoSat satellite image showing the location and the structure of the Mediterranean cyclone at 0900 UTC on 16 January 1995

The numerical model almost always predicted a precipitation-free area at the center of the cyclone while the heaviest precipitation was predicted to fall in the area of the cyclone corresponding to the eyewall. In the area close to the cyclone, the largest part of the precipitation was produced by the convection scheme. Heavy precipitation rates were sometimes due to the large-scale precipitation scheme, indicating that there is grid-scale saturation and/or that resolved scale motions are dominating the production of precipitation in those areas. Unfortunately, there was no measurement of precipitation amount in the region of the vortex since it evolved over the sea. However, the simulated precipitation pattern, as illustrated in Figure 12, seems to be very reasonable. With one exception, precipitation was always reported from ships in the vicinity of the cyclone. No rainfall was reported at 1200 UTC on 15 January by a ship located south of the vortex. Figure 12 shows that the model predicted no precipitation south of the cyclone at that time, in agreement with this observation. Similar simulations produced with the SKIRON/Eta modeling system (using a horizontal resolution of 0.25 degrees) resulted in the development of a hurricane-like vortex with a cloud-free "eye" at the center (Figures 13, 14).

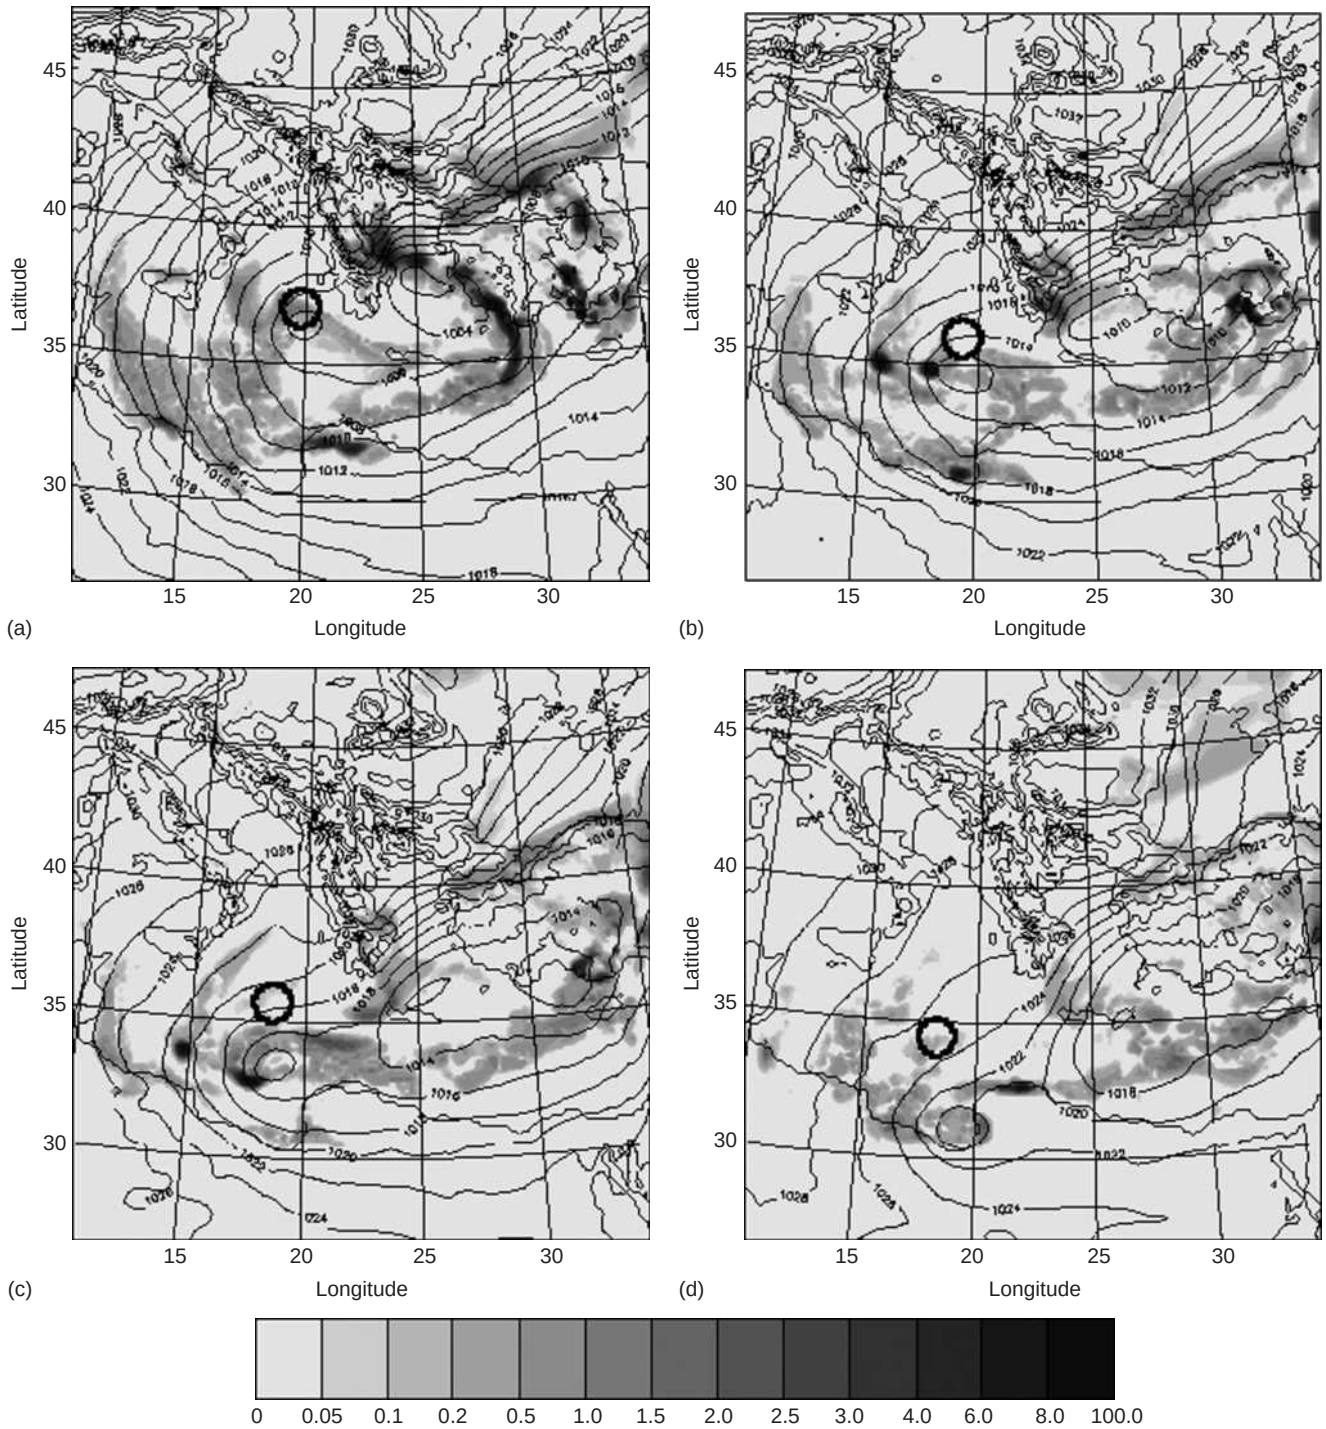

Figure 12 The mean sea-level pressure forecast and the instantaneous rate of total precipitation expressed in mm h^{-1}, at (a) T + 12, (b) T + 24, (c) T + 30 and (d) T + 42 (from 0000 UTC on 15 January 1995). The isobars are drawn every 2 hPa. The scale below the panels corresponds to the rate of precipitation and is expressed in mm h^{-1} (Unified Model). The actual location of the Mediterranean cyclone is indicated by the small cycle (Reproduced from Pytharoulis *et al.*, 2000 by permission of Royal Meteorological Society)

A similar hurricane-like cyclone appeared in the western Mediterranean basin on 6–7 October 1996 (Figure 15). Papadopoulos (2001) studied the system using the SKIRON/Eta modeling system with a horizontal resolution of 0.125°. The model successfully reproduced the track and the characteristics of the actual system, including a cloud-free "eye" surrounded by spiral cloud bands (Figure 16). Moreover, the model predicted the most intense convective activity to occur near the center of the storm in the region that corresponds to the eyewall (Figure 17).

In summary, the numerical models successfully predicted the formation and the track of these Mediterranean cyclones and the associated precipitation pattern. The strong winds, heavy precipitation, low visibility, and generally the severe weather associated with this kind of cyclones make them a great danger for the coastal areas. Many damages and casualties associated with actual tropical cyclones are not only due to their ferocity but also to the floods they cause at landfall (e.g. Hurricane Mitch in Central America in 1998). Certainly the "hurricane-like" cyclones

Numbers indicate the accumulated precipitation at Korinthos and Desfina stations (305 and 198 mm respectively) (Reproduced from Kotroni *et al.,* 1999 by permission of Royal Meteorological Society)

that form in the Mediterranean cannot attain the strength of the Atlantic hurricanes because of a smaller reservoir of available energy from the sea and to the smaller size of the Mediterranean basin. Finally, the successful application of the numerical models for such events is very promising since they provide important guidance to the local forecasters.

The Floods over Central and Southern Greece in January 1997

On 11 and 12 January 1997, a major precipitation event occurred over the eastern Mediterranean and especially over central and southern Greece (Kotroni *et al.*, 1999) in association with the passage of a cold front. Heavy precipitation caused severe damages over southern Greece in Peloponnisos, where several cities experienced severe flooding. More than 300 mm of accumulated precipitation were measured at the station of Korinthos (Figure 18) within 24 h, ending at 1800 UTC, 12 January 1997. Flooding was not only restricted over Peloponnisos. Heavy precipitation (200 mm within 24 h) caused severe problems in the road network and some bridges collapsed in central Greece, while in Athens, flooding was reported in some suburban areas (more than 70 mm of rain within a few hours).

Kotroni *et al.* (1999) suggested that a significant factor that provoked the floods was not only the amount of the precipitation but also the fact that almost 50% was produced before the arrival of the cold front over Greece. It is speculated that the high precipitation amounts that fell before the passage of the cold front brought the soil conditions closer to saturation, reducing its infiltration capacity. In such cases, most of any additional rainfall becomes surface runoff contributing to floods, especially in heavy precipitation events such as the cold front passage that is discussed here.

This severe storm was studied by Kotroni *et al.* (1999) with the aid of the RAMS modeling system. The model was initialized at 1200 UTC on 11 January 1997 and the duration of the simulation was 36 h. Two nested grids were employed: (i) the outer, that covered southern Europe with a grid spacing of 40 km and (ii) the inner that covered the Greek peninsula with a 10-km horizontal grid spacing.

It is interesting to compare the 24-h accumulated precipitation pattern ending at 1800 UTC, 12 January 1997 (Figure 19), as it was predicted within the inner grid of RAMS, with the observed precipitation pattern (Figure 18). Figure 19 shows that most of the precipitation was accumulated along the eastern coasts of Greece. The orographic enhancement and lee side minima associated with the topography of the Greek peninsula appear to be simulated quite realistically. The model represented the amounts and the locations of the maximum precipitation amounts in good agreement with observations. The precipitation amount predicted by RAMS exceeded 350 mm within 24 h over northern Peloponnisos and central Greece, where severe

Figure 19 24-h accumulated precipitation ending at 1800 UTC 12 January 1997 (at 50 mm intervals), predicted inside the inner grid of RAMS. The 100 and 200 mm contour lines are in bold (Reproduced from Kotroni *et al.*, 1999 by permission of Royal Meteorological Society)

floodings occurred. Moreover, the spatial extent of the precipitation was predicted adequately by the numerical model.

Finally, the storm characteristics were used by Kotroni *et al.* (1998) in order to estimate the Probable Maximum Precipitation (PMP) value for the Sperhios river catchment in central Greece. Some bridges collapsed over Sperhios river catchment and the road network was damaged because of the heavy precipitation. The methodology of Collier and Hardaker (1996) was followed in this task. The PMP over a particular catchment is defined by the World Meteorological Organization as "the greatest depth of precipitation for a given duration meteorologically possible for a given size of storm area at a particular location at a particular time of year, with no allowances made for climatic trends".

In order to produce a fine resolution 3-D wind field to be assimilated into the storm model, a third inner grid was configured over Sperhios river catchment (with a horizontal resolution of 2 km). The 36-h PMP over Sperhios river for a storm with the characteristics of the one that affected Greece on 11–12 January 1997 appears in Figure 20. The storm model used to estimate PMP produced the maximum values over the Sperhios river, in agreement with the floods and the damages that occurred in the area. These results suggest that the combination of the numerical models with a number of tools, such as the above-mentioned storm model, can provide to the hydrologists very valuable information about the spatiotemporal variability of precipitation.

A Severe Frontal Cyclone over Greece in March 1998

On 25 and 26 March 1998, central and southern Greece were affected by a deep frontal cyclone associated with intense thunderstorm activity and heavy snowfall (Papadopoulos, 2001). The bad weather caused serious problems in the Greater Athens area, while the transportation was disrupted in many regions of central Greece. The observed rainfall amounts that appear in Figure 21 indicate that the strongest rainfall was due to mesoscale phenomena.

An analysis of this storm was provided by Papadopoulos (2001) who utilized the SKIRON/Eta modeling system at a horizontal resolution of 0.125°. On 25 March 1998, the cyclone was located over the sea south of Italy and it was developing in association with strong latent heat fluxes (not shown). At 0600 UTC on 26 March, the depression was located south of Greece. The southeasterly flow that was established in southern Greece transported moist air

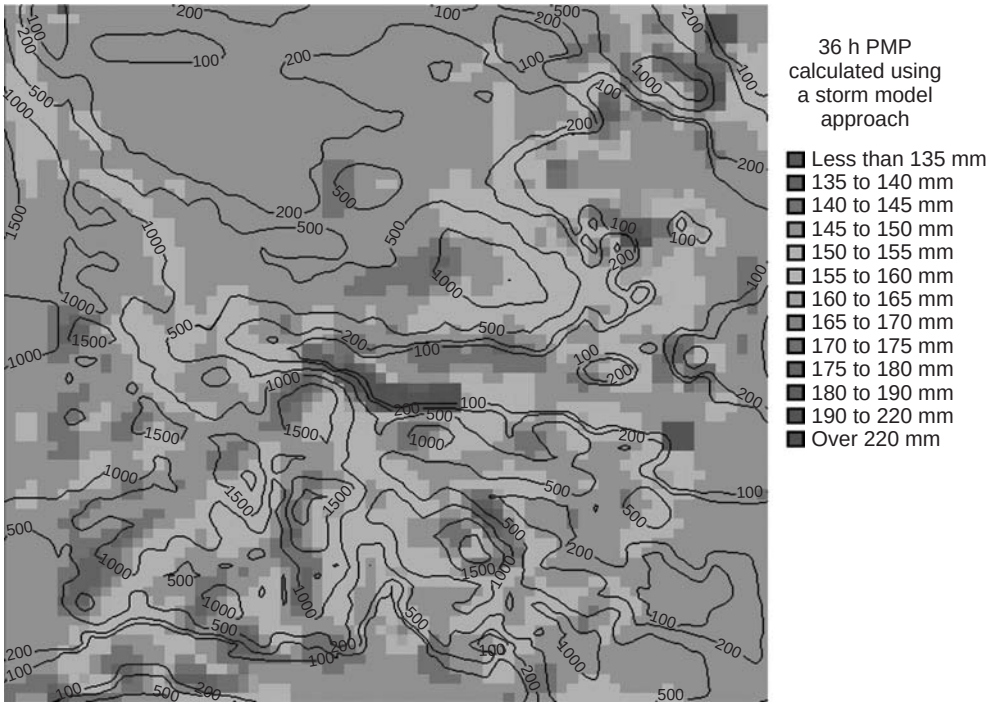

Figure 20 Contour plot of topography shaded by the 36-h Probable Maximum Precipitation for the storm of 11–12 January 1997 in the Sperhios river catchment. (Kotroni *et al.*, 1998). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

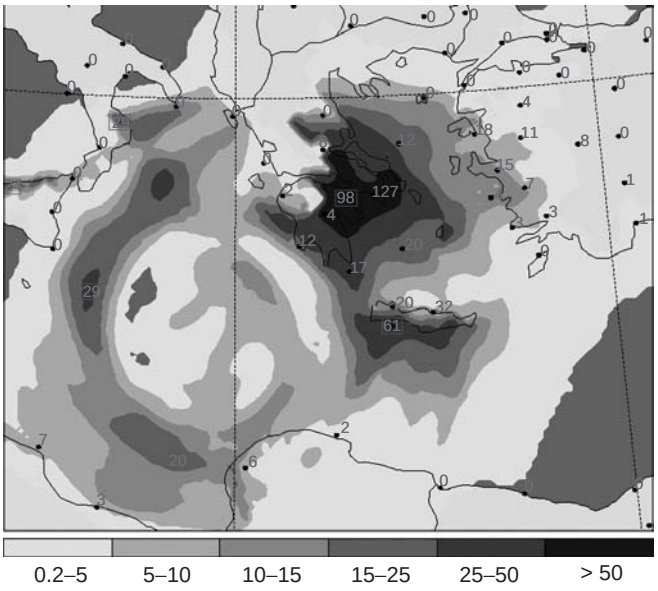

Figure 21 The accumulated rainfall (mm) predicted by SKIRON/Eta between 1800 UTC, 25 March 1998 and 0600 UTC, 26 March 1998. The framed numbers show the maximum predicted rainfall amount, while the numbers next to the black dots show the observed precipitation amount at each station. (Papadopoulos, 2001). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

masses from the Aegean Sea to continental Greece at low levels. Cold air masses were advected at higher levels by the prevailing northeasterly flow. The convergence of the warm and moist air masses at low levels (Figure 22) in combination with the presence of cold air aloft provoked intense thunderstorm activity in the Greater Athens area (Figure 21) and heavy snowfalls in central Greece (not shown). The continuous inflow of moist air at low levels contributed to the long duration of the system.

The comparison between the observed and predicted rainfall amounts (Figure 21) shows that the numerical model represented adequately the spatial distribution of rainfall. A finer horizontal resolution would be required in order to predict the magnitude of the maximum rainfall amounts in better agreement with observations and to analyze the structure of the phenomenon at the catchment scale.

CONCLUDING REMARKS

The case studies presented in this chapter revealed that the atmospheric numerical models exhibit a skill in providing accurate short-term weather forecasts. The predictions of the spatiotemporal variability and the amount of precipitation, especially in extreme weather events, are vital information for the hydrologists. However, nowadays the hydrology can be represented more accurately in regional to large-scale catchments, especially in an operational mode.

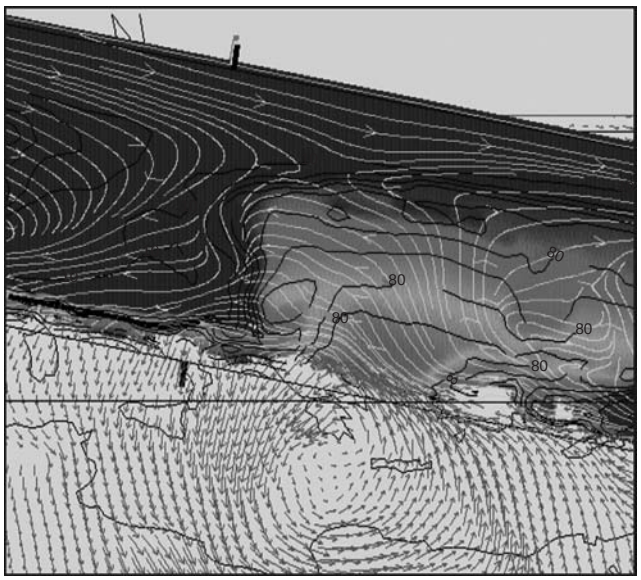

Figure 22 The SKIRON/Eta predicted flow at 400 m above sea level (arrows), streamlines and the relative humidity (contours) on a vertical section at 0600 UTC, 26 March 1998. (Papadopoulos, 2001). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

The explanation of this behavior is twofold. Firstly, the numerical models generally lack the necessary resolution in order to make explicit predictions for small-scale catchments. Even for short-term nowcasting purposes, the model resolution is not finer than about 1–2 km. Secondly, the routinely available meteorological observations, even in dense networks such as central Europe, resolve the atmospheric conditions in meso-α and meso-β scales. The meso-γ scale circulations are very rarely analyzed by the observational network. Therefore, the initial conditions utilized by the numerical models generally lack the necessary spatial resolution. This means that the use of very high resolution of less than 1–2 km may not always provide better forecasts. Mass *et al.* (2002) showed that the transition from 36 to 12 km grid spacing produced a beneficial effect on the weather forecasts, while only small improvements appeared in the verification statistics as grid spacing decreased from 12 to 4 km. They concluded that the value of high resolution might be more obvious near substantial mesoscale terrain or in areas with a dense observation network.

On the other hand, the meteorological radars have the ability to scan weak precipitation and thunderstorms over large areas very quickly and make quantitative estimates of precipitation at very high resolution. However, even the most advanced advection methods that utilize the radar products cannot provide accurate forecasts for a period longer than one hour.

Finally, the analysis of the flood of January 1997 (Section "The floods over central and southern Greece in January 1997") showed that the hydrologists need information not only about the precipitation rates during an extreme event but also about the preexisting conditions of the soil. If the soil is already saturated, the falling precipitation will not be infiltrated but it will become runoff. This situation is likely to lead to flooding depending on the precipitation amounts and the topographic features. Thus, the operational short and medium range weather forecasting systems are invaluable tools for the hydrologists and the local authorities since they exhibit the necessary forecast skill and also they allow the issuance of warnings for the public and the farmers in a reasonable time frame.

181: Long-Term Predictions (Climate Simulation and Analysis)

RICHARD A BETTS

Hadley Centre for Climate Prediction and Research, Exeter, UK

The global hydrological cycle is expected to change over the next century as a consequence of human perturbations to the Earth System. Human activities are modifying the composition of the atmosphere, in particular the concentrations of greenhouse gases such as CO_2 and the concentrations of aerosols. This exerts a radiative forcing of the climate system, which already appears to be warming the global climate. These changes are predicted to increase in the future, and are expected to modify precipitation and evaporation regimes, and hence impact on hydrology, with streamflow increasing in some regions and decreasing in others. Furthermore, changes in atmospheric composition may also affect ecosystems directly, with plant physiological responses to CO_2 increasing carbon storage, modifying biogeography, and decreasing evapotranspiration. This may have further effects on hydrology in addition to climate change. Human-induced changes in land cover, such as deforestation and afforestation, may also directly modify hydrology and climate by perturbing the surface water and energy budgets as well as by contributing to radiatively-forced climate change through changes in atmospheric composition. This article compares and contrasts the climatic, ecological, and hydrological changes predicted as a result of these three human perturbations to the Earth System, and discusses the key interactions between them.

INTRODUCTION

Human Perturbations to the Earth System

Human activities are perturbing the Earth System in multiple ways (*see* **Chapter 33, Human Impacts on Weather and Climate, Volume 1** and **Chapter 34, Climate Change – Past, Present and Future, Volume 1**). Concentrations of carbon dioxide, methane, and other key gases are increasing, causing an enhancement of the "greenhouse effect" in which heat radiation emitted by the Earth's surface is absorbed and reemitted by the atmosphere. This is the most likely cause of the rising temperatures observed worldwide over the last century (IPCC, 2001; *see* **Chapter 34, Climate Change – Past, Present and Future, Volume 1**). Continued increase of the greenhouse effect in this way is expected to cause significant changes in climate and weather patterns (IPCC, 2001), with major consequences for other components of the climate system such as the hydrological cycle and ecosystems (*see* **Chapter 200, Changes in Regional Hydroclimatology and Water Resources on Seasonal to Interannual and Decade-to-Century Timescales, Volume 5**).

As well as exerting a radiative forcing on the climate system, increasing concentration of atmospheric CO_2 may also exert a forcing through direct effects on plant physiology. Photosynthesis generally increases with CO_2 concentration, a mechanism often termed "CO_2 fertilization". Furthermore, a number of studies have shown that plant stomata open less under higher CO_2 concentrations (Field *et al.*, 1995), which directly reduces the flux of moisture from the surface to the atmosphere (Sellers *et al.*, 1996). If this were to occur on a large scale, this could have a significant impact on the surface water balance of the landscape, affecting runoff and the supply of moisture to the atmosphere. In regions where much of the moisture for precipitation is supplied by evaporation from the land surface, reduced stomatal opening may also contribute to decreased precipitation. Furthermore, a decrease in moisture flux modifies the surface energy balance, increasing the ratio of sensible heat flux to latent heat flux and therefore warming the

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

air near the surface. A decrease in stomatal opening may therefore cause an increase in near-surface air temperature through this physiological forcing alone, independent of any radiative forcing.

Although this may be partly offset by increases in leaf area (Betts *et al.*, 1997), this offset may not be total. While it is yet to be established whether such responses are universal, it is therefore possible that rising CO_2 concentrations could exert two forcings on the climate system; (i) radiative forcing of global climate modifying atmospheric circulation patterns, and (ii) physiological forcing modifying near-surface temperature and also reducing the supply of moisture for precipitation.

Although the forcing by increasing greenhouse-gas emissions includes a contribution from deforestation, this is only one means by which land-cover change can influence climate. Vegetation influences the surface fluxes of radiation, heat, moisture, and momentum, so if the character of the vegetation cover is modified, changes to the climate can result. Conversion of forest to cropland or pasture can reduce the aerodynamic roughness of the landscape and decrease both the capture of precipitation on the canopy and the root extraction of soil moisture; these changes tend to decrease evaporation and hence the fluxes of moisture and latent heat from the surface to the atmosphere, which acts to increase the temperature near the surface. Also, a forested landscape generally has a lower surface albedo than open land, particularly in conditions of lying snow when shortwave radiation is trapped by multiple reflections within the forest canopy. Deforestation can therefore lead to increased shortwave reflection, which provides a cooling influence. The relative importance of these processes depends on local conditions and can vary with season and location.

Changes in global ecosystems under climate change may themselves exert further effects on climate. These feedback could be both global and local in nature. Changes in total carbon storage of an ecosystem will modify the concentration of CO_2 in the local atmosphere, and since CO_2 has a long residence time and is well mixed, this change will be spread throughout the global atmosphere. Changes in vegetation structure may also modify regional climates through the surface energy and water budgets. In many cases such feedback will be predominantly local, mainly affecting the environment of the ecosystem providing the feedback. In other cases, biotic feedback can exert significant remote effects through teleconnections, sometimes extending across the globe.

The various human perturbations to the climate system have the potential to produce major impacts either individually or in combination. The combined effect of these perturbations acting together may be very different to the linear sum of the individual perturbations acting in isolation. This article reviews the current state of the art in the use of numerical models for projections of anthropogenic changes to the climate system, and discusses potential interactions between the different perturbations.

Using Models for Long-term Projections

Guidance on the nature of future environmental changes can in principle be gained through several methods. One method is to refer directly to a past event or state similar to that expected for the future, that is, an analogue. For example, in order to assess the climatic effect of a doubling of the atmospheric CO_2 concentration, one could in principle refer to a period in the Earth's history when the CO_2 concentration was at this level and examine the differences in climate relative to the present day. In general, analysis of paleoclimate and paleoecological data can provide many useful insights into the operation of the Earth system and potentially provide opportunities for validation of climate models. However, the use of the past as a guide to specific states in the future relies on such an analog state having existed and having left useful evidence, and this is often not the case in practice. To continue the above example, atmospheric CO_2 seems not to have been at double the present-day level for more than twenty million years (IPCC, 2001), outside the period of extensive, reliable paleoreconstruction for many aspects of the climate system. Therefore our ability to assess the implications of doubling CO_2 through the analogue method is limited.

Another technique might be to examine current trends and make some assumptions regarding the continuation of these into the future, that is, an extrapolation. For example, one could correlate the observed changes in atmospheric CO_2 and climate and extrapolate these to infer the climatic effects of doubling CO_2. However, the changes observed to date are relatively small compared to the natural internal variability of the climate system, so many apparent climate changes cannot be reliably correlated with CO_2 rise.

A further problem with both the analogue and extrapolation techniques is the difficulty in accounting for multiple sources of perturbations acting together. Since the different human influences on the climate system may interact in complex, nonlinear fashions, past changes associated with any individual perturbation may not be a useful guide to their contributions to combined perturbations.

The most promising technique for assessing future changes is to use observations and experiments to gain understanding of the system and its components, and synthesize this in a model (*see* **Chapter 201, Land-Atmosphere Models for Water and Energy Cycle Studies, Volume 5**). This allows the modeler to potentially explore the properties of the system beyond those that have been directly observed. If the model validates well against reality in those aspects that can be directly observed, the model can then be used as a controllable "virtual reality" to provide information on the aspects of the system that cannot be directly observed. This can provide improved

understanding of the behaviour of the system, and allow projections of future behavior to be made.

While a perfect "virtual reality" would include every detail of the entire system, the level of detail is in practice limited by the knowledge of the modeler and the capacity of the computers on which the model simulations are performed. An appropriate level of detail is therefore chosen within pragmatic boundaries on the basis of the particular application of the model. For example, a model of interactions between particular species of plant will require treatment of detailed physiological processes at a level at which interspecies differences are significant. In contrast, a model of the interactions between large-scale vegetation patterns and atmospheric processes may assume interspecies differences to be negligible in comparison with the differences between functional types such as trees and grasses.

In modeling studies of climate change, the climate system is typically represented as a number of subsystems such as the atmosphere, the biosphere, and the land surface. The interactions between these subsystems can be treated with two different methods. The traditional, disciplinary method is to assume a linear cause-effect chain in which one subsystem is simulated first, and the resulting state is then applied as input to a second subsystem model, and so on. For example, projections of radiatively forced climate change and its impacts on ecosystems and hydrology generally consist of such a linear sequence of simulations with models of different components of the climate system. Scenarios of greenhouse-gas and aerosol emissions are derived with models that follow scenarios of future changes in population, technology, and economic state. These emissions scenarios are then translated into scenarios of greenhouse-gas concentrations in the atmosphere, using models that consider the processes acting to reduce concentrations either by chemical processes in the atmosphere or uptake at the land and ocean surfaces. These scenarios of greenhouse-gas rise are then applied as inputs to climate models such as General Circulation Models (GCMs), which compute the radiative forcing due to the greenhouse-gas rise and the consequent changes in climate. The resulting climate scenarios are then applied to further models that simulate the response of ecosystems, hydrology, and other aspects of the Earth system including human societies.

One advantage of using a chain of loosely coupled models is that is allows each subsystem model to be developed to best represent the particular subsystem, such as with appropriate spatial resolutions and time steps, without any constraint imposed by a need for compatibility with the other models. For example, coarse-resolution output from a global-scale climate model can be used in combination with statistics of fine-scale climatic features in order to provide input to a higher resolution hydrology model capturing catchment-scale topographic detail. A second advantage is that any biases in the output of one model can potentially be accounted for by adjustment of data prior to input to the next model. For example, such adjustment is frequently used when applying climate model output to climate impacts models, in order to remove systematic errors from the climate simulations. A third advantage is that analysis of causes and effects is relatively straightforward, as processes can be broken down into components.

However, the use of a linear cause-effect chain of subsystem models neglects the possibility of feedback between the subsystems. For example, if an ecosystem model simulates major changes in terrestrial carbon storage in response to a simulated climate change, this might imply a potential feedback to atmospheric CO_2 and hence climate, which was not accounted for in the original climate simulation. Furthermore, some subsystem models represent the same processes at the interface between the subsystems, but with inconsistent methods. Atmospheric models, for instance, include models of surface evaporation in order to simulate a conservative water cycle. Hydrological models also simulate surface evaporation, but often at a higher spatial resolution and with different treatments of aspects such as surface saturation. If the evaporation simulated by a hydrological model is different to that simulated by the atmospheric model from which its input data is derived, the input data is inconsistent with the simulation.

In the light of these drawbacks, an alternative modeling approach has come into use in the last decade, involving the coupling of models of the climate subsystems to allow two-way interactions. While this means that model features such as resolution may be an additional constraint on some of the subsystem models, and makes adjustment of biases and understanding of model behavior more difficult, it does ensure consistency between the models and allows the simulations to include feedback within the climate system.

This article describes a range of models used to assess potential future changes in the climate system. Both linear sequences of models and tightly coupled model systems are described, as both approaches provide insight into mechanisms of change in the Earth system.

Model assessments of future changes in the climate system typically fall into one of two categories. One category is sensitivity studies, in which the response of the system to some illustrative perturbation is examined. Examples of this are simulations of the climate sensitivity to doubled CO_2 or to a complete deforestation of a particular region. Such studies are used to assess and understand in principle the potential effects of perturbations, in a simple and clear manner. The other category is scenario studies, where the perturbation is intended to represent a particular expected change more closely. Scenario studies are typically more complex than sensitivity studies, so may be less easy to interpret although the final outcome may be more representative of an actual future change.

The following discussion will include both scenario and sensitivity studies.

MODELS OF THE CLIMATE SYSTEM AND ITS COMPONENTS

Atmosphere and Ocean General Circulation Models

Models of the atmosphere and oceans are fundamental tools in projecting climate changes. One widely used form of atmospheric model is the General Circulation Model (GCM), which simulates the global circulation of the atmosphere based on equations of fluid motion and thermodynamics along with other meteorological processes such as cloud formation, precipitation, and absorption and emission of solar and terrestrial radiation. Similarly, oceanic GCMs simulate the circulation of the oceans. Ocean and atmospheric GCMs are routinely used together as a coupled model, to allow for key interactions through evaporation, precipitation, fluxes of heat and transfers of momentum. Atmospheric GCMs also represent similar interactions with the land surface, and it is often the output of the GCM land surface schemes that are of greatest interest in projections of climate change from a human perspective. GCM and surface schemes take account of the characteristics of the land surface in terms of the topography and nature of the land cover. GCMs used for global simulations currently use spatial resolutions of approximately $1^\circ - 3^\circ$ in the horizontal and 15–40 levels in the vertical.

Regional Climate Models (RCMs) are essentially GCMs applied over a portion of the Earth's surface rather than the entire globe. The smaller area of coverage means that spatial resolution can be higher, typically 20 km–50 km in current RCMs, providing more precise regional detail and better representation of smaller-scale atmospheric phenomena such as storms or orographic rainfall. RCMs are typically nested within GCMs that provide the atmospheric conditions at the boundary of the RCM area, such as temperature, humidity, wind velocity, and pressure.

Similarly, mesoscale models operate on similar principles to GCMs but at a resolution higher still than RCMs (approximately 1 km–10 km). Mesoscale models can capture fine-scale details of the atmosphere and underlying surface, such as detailed orography or patterns of land cover. Again, mesoscale models are nested within a larger, more coarse-resolution model such as RCM or GCM in order to obtain boundary conditions.

Ecosystem Models

Biogeography models represent ecosystems at large scales. Instead of modeling individuals, biogeography models consider ecosystems as entities in themselves. Environmental factors such as climate and soil type are used to determine the character of an ecosystem through either (or both) mechanistic modeling of physiological processes or/and empirical relationships derived from observations. These models therefore simulate the potential natural vegetation that would exist under the applied conditions if given sufficient time for successional processes to complete. Input data typically consists of mean climate variables for each calendar month of the year, so the modeled ecosystems are effectively simulated under a single year of mean climate. Output data represent that mean ecosystem state for each grid cell, either in terms of structural or physiological characteristics such as leaf area index (LAI) or net primary productivity (NPP), or in terms of an ecosystem classification such as "evergreen needleleaf forest" or "savanna".

Biogeography models may be used in conjunction with GCMs, RCMs, or mesoscale models to directly investigate ecosystem responses to the simulated climate changes and for studies of feedback between ecosystems and climate. They do not include time-dependent responses of ecosystems to environmental changes, and assume ecosystems to be at equilibrium with the climate, so are best applied to sensitivity studies and simulations of slow, long-term changes, rather than scenarios of rapid change in which time-dependency is important. In the context of anthropogenic climate change over decadal or century timescale, biogeography models cannot make specific predictions but can be used as a guide to the potential sensitivity of ecosystems to projected changes.

Dynamic global vegetation models (DGVMs) combine the large-scale applicability of biogeography models with time-dependent vegetation dynamics. Terrestrial vegetation is modeled at the global scale including the dynamics of competition and succession. Plant physiological processes such as photosynthesis, respiration, and transpiration are modeled mechanistically, but the calculations are applied to large-scale ecosystems (e.g. GCM resolutions of approximately 3°) rather than specific individuals. DGVMs take time-dependent input data such as monthly climatic variables for many years or decades, and output large-scale ecosystem structure, which again varies in time. The inclusion of rates of growth and spreading therefore makes DGVMs suitable for time-dependent modeling of vegetation responses to transient climate change.

Different DGVM modeling groups employ a range of different approaches to representing vegetation dynamics at large scales. Since individual species would be too numerous to model explicitly, all DGVMs represent vegetation in terms of plant functional types (PFTs), which effectively group together species of plants according to functional similarities. The number of PFTs identified can vary between models. For instance, the VECODE model (Brovkin *et al.*, 1997) identifies only evergreen and deciduous trees and grass, whereas other models (LPJ, Sitch *et al.*, 2003) and (IBIS, Foley *et al.*, 1996) distinguish dry and

cold deciduousness, tropical, temperate, and boreal trees, and C3 and C4 grasses. Competition between PFTs is either represented in terms of individuals over several patches and scaled up to the grid cell (HYBRID; Friend *et al.*, 1997) or in terms of competition between populations (TRIFFID; Cox, 2001).

DGVMs are concerned with the general functional character of vegetation rather than the behavior and distribution of particular species, so cannot directly model biodiversity. However, DGVMs can be used to investigate a number of processes of relevance to climate change and biodiversity. Changes in the general viability of a PFT under a climate change will imply potential impacts on species within that PFT. Furthermore, changes in the abundance of species making up a particular PFT can impinge on the resources available to the species of another PFT, so changing competitive balances between PFTs suggests changes in ecosystem structure that have implications for biodiversity. If a PFT is simulated to disappear in a particular location, this may be taken to imply a threat of local extinction of all species within that PFT. However, it should be noted that the PFT by definition do not represent the diversity within a group of similar species, some of which may be more resilient than others.

Synergies between the direct effects of climate change and the indirect effects acting via competing PFTs can therefore be investigated with DGVMs. The extra effects of CO_2 fertilization, again acting both directly on a given PFT and indirectly through competition, can also be investigated.

Hydrological Models

Hydrological models simulate the land surface components of the water cycle, namely, evaporation and runoff, in response to meteorological inputs. The boundary conditions of hydrological models typically include landscape topography, soil characteristics (such as grain size and infiltration properties) and vegetation characteristics (such as rooting depth and aerodynamic roughness). The domains of hydrological models range from individual catchments to the globe, with horizontal resolutions typically decreasing with domain size.

The more sophisticated and/or higher resolution hydrological models are typically used "offline" in studies of the impacts of climate change on surface hydrology (e.g. Arnell *et al.*, 2001). However, climate models and ecosystem models generally include their own surface hydrology submodels as a necessary component of the climate or ecological system (e.g. Cox *et al.*, 1999). Such models are typically simpler than the "offline" hydrological models in terms of their representation of landscape- and soil-related processes such as horizontal transport and water table depth. Nevertheless, hydrological submodels within climate and ecosystem models allow for interactions and feedback between hydrology and climate or ecosystem processes.

Coupled Ecosystem-climate Models

Given the potential for major feedback from ecosystems, it is clear that predictions of future climate change should consider ecosystem responses and their effect on climate. This has led to the development of "Earth-system Models", which couple models of the physical climate system (the atmosphere and oceans) to models of the terrestrial and marine biosphere (Foley *et al.*, 1998; Cox *et al.*, 2000; Ganapolski *et al.*, 2001). The physical and biological models interact via biogeochemical cycles and through the impact of life on the physical properties of the Earth's surface. Some current models feature a DGVM and/or an interactive carbon cycle included within an existing GCM to provide detailed simulations with as much mechanistic process representation as possible. Other models use approximations in the more complex parts of the Earth System (e.g. atmospheric dynamics) in order to increase computational efficiency and facilitate a greater number of simulations – such models are termed *Earth-system Models of Intermediate Complexity* (EMICs).

The inclusion of DGVMs in GCMs allows climate prediction simulations to include feedback from ecosystems responding to climatic changes at global and regional scales (Cox *et al.*, 2000). Coupled GCM-DGVMs are therefore potentially valuable for understanding and predicting synergistic responses of ecosystems to climate change over timescales of centuries and spatial scales of hundred of kilometers. Betts *et al.* (2004) discuss the global vegetation dynamics simulated by the Hadley Centre coupled climate-vegetation model for a greenhouse-gas emissions scenario over the next century.

Earth-system Models of Intermediate Complexity (EMICs, e.g. Ganapolski *et al.*, 2001) use simpler representations of the atmosphere and biosphere to allow simulations over longer periods than those possible with GCMs. They can therefore be used to explore long-timescale global synergies over millennia. Their high computational efficiency allows multiple simulations exploring many combinations of drivers and internal feedback processes.

Ecosystem processes are therefore now beginning to be included in climate models. This new generation of climate system models provides great opportunities to investigate how ecosystems affect their own environmental conditions, and also how ecosystems interact with each other through the shared mediums of the atmosphere, oceans, and continental water flows.

RADIATIVE FORCING BY CHANGES IN ATMOSPHERIC COMPOSITION

Radiatively-forced Climate Change

Most recent work on climate projections has been centered around scenarios of greenhouse emissions and concentrations published by the Intergovernmental Panel on Climate

Change (IPCC) in the Special Report on Emissions Scenarios (SRES). These scenarios are based on a number of narratives characterizing global demographic, economic, and technological changes over the twenty-first Century, and provide a range of potential future trajectories for greenhouse-gas emissions. For example, the scenarios of CO_2 changes range from small decreases by 2100 to increases of around 400%. When these are translated into atmospheric concentrations, with feedback effects of climate change not considered, CO_2 concentrations (currently at approximately 370ppmv) are projected to rise to between 500 and 950 ppmv by 2100.

A large number of GCMs have been used to simulate climate change under scenarios of anthropogenic greenhouse-gas changes. GCMs vary in their sensitivity to a given radiative forcing, and in conjunction with the large number of scenarios this results in a wide range of results from the climate change simulations (Figure 1). While all models simulate a rise in global mean temperatures due to increasing greenhouse-gas concentrations, the extent of this rise ranges from 0.9 to 5.8 Ks relative to the preindustrial climate. However, despite the differences, the results of these simulations still have a number of key features in common. For example, the models show more rapid warming over the land surface than over the oceans, owing to the large heat capacity of water (Figure 2). The models also project more rapid warming at high latitudes than at low latitudes, owing to positive feedback on the warming arising from the melting of snow and ice. While snow and ice reflect a large proportion of solar radiation back to space, the underlying ground and ocean surface is generally darker and absorbs a greater fraction of the radiation. Melting of snow and ice therefore exposes the darker underlying surface, increasing the fraction of solar radiation absorbed and causing a further warming of these regions.

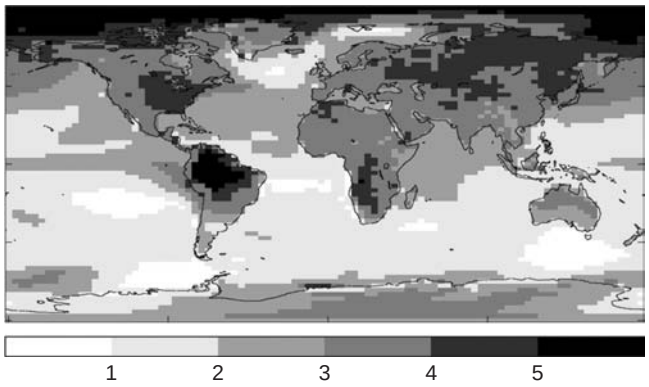

Figure 2 Changes in temperature (K) relative to 2000 simulated by the HadCM3LC GCM. 30-year mean centered around 2080. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

The different models show much less agreement on changes in precipitation with rising GHG concentrations, although there is still some general agreement at large scales. Global mean precipitation is generally simulated to increase, as a result of an increased supply of moisture to the atmosphere by evaporation from the oceans and continents in a warmer world (Figure 3). Regional-scale differences, however, differ greatly from model to model, with the differences often being in sign as well as magnitude

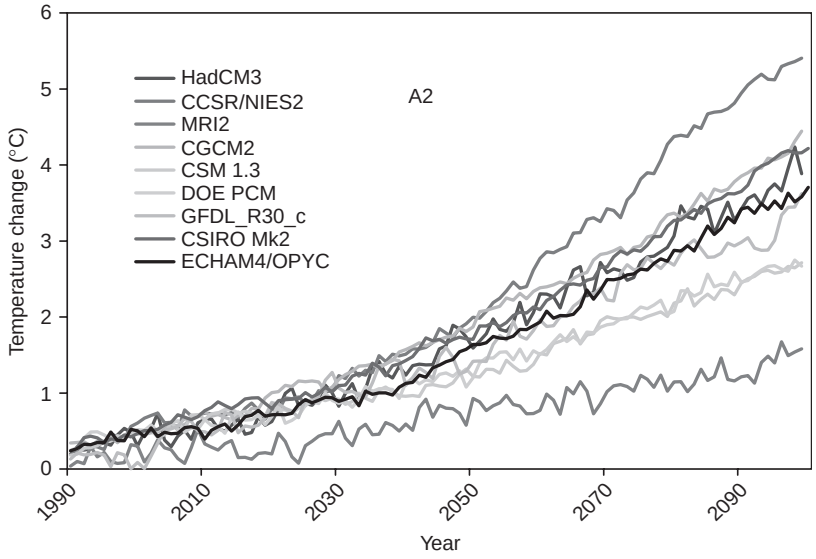

Figure 1 Projections of global mean near-surface air temperature rise by 9 different General Circulation Models (GCMs) under the same scenario of greenhouse-gas concentration changes. The scenario is SRES A2 (IPCC, 2001) (Reproduced by permission of Intergovernmental Panel on Climate Change (IPCC)). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

(Figure 4). These variations between models are often due to differences in the simulated changes in atmospheric circulation. Demonstration of predictive skill in local precipitation remains one of the greatest challenges for GCMs.

One notable result in some models, but not all, is a reduction in precipitation over Amazonia (Figure 3), associated with more rapid warming of the ocean surface in the equatorial east pacific. This pattern of warming in the Pacific ocean is reminiscent of an El Nino event (Cai and Whetton, 2001), during which precipitation is also reduced over Amazonia. This increased warming is in a region of the ocean that is beneath a descending portion of the Hadley-Walker large-scale atmospheric circulation cell, and the warming ocean surface tends to oppose descending motion, which suppresses the overall circulation leading to less ascent of the atmosphere over Amazonia. Reduced ascent implies reduced convection and hence reduced precipitation, with crucial implications for this region, which is dependent on its currently high rainfall rate.

Effects of Radiatively forced Climate Change on Global Ecosystems

Most studies of the impacts of radiatively forced climate change on global ecosystems also consider the effects of CO_2 fertilization. To gain insight into the roles of the two forcings, many such studies also consider the impacts of each forcing separately. This is useful as it allows the implications of climate change alone to be assessed, irrespective of any other properties of the gases responsible for the change. The results therefore apply to a given climate state whether it is caused by changes in CO_2 or any other greenhouse gas. This is important because other greenhouse gases are also increasing in concentration, and not all of these will also exert a fertilization effect.

Haxeltine (1996) and Betts *et al.* (2000) performed sensitivity studies with biogeography models under climate

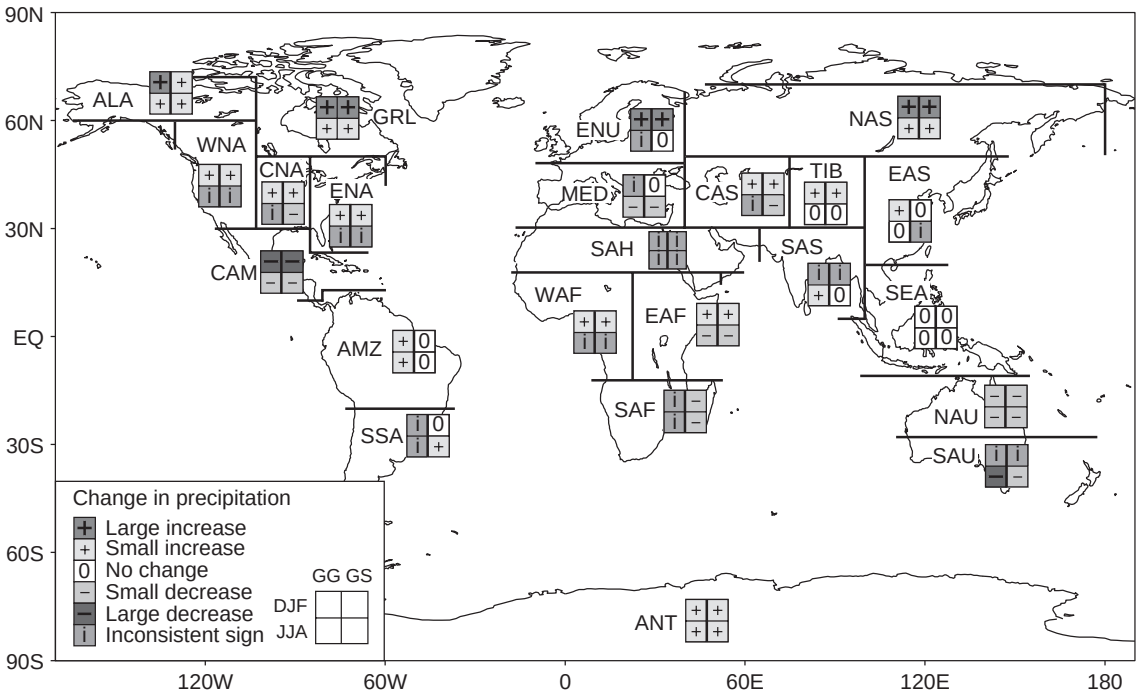

Figure 4 Illustration of differences in precipitation changes over the twenty-first Century simulated by different GCMs (Reproduced by permission of Intergovernmental Panel on Climate Change (IPCC)). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

changes simulated by GCMs with greenhouse-gas radiative forcing doubled relative to the present-day. In both cases simulations both with and without CO_2 fertilization were performed. In a simulation without CO_2 fertilization, the BIOME3 model simulated and expansion of the boreal forests northwards into areas currently occupied by tundra (Haxeltine, 1996). A similar simulation with the DOLY model produced an increase in leaf area index, and further simulation showed that this was due mainly to the warmer temperatures (Betts *et al.*, 2000). As well as a general increase in high-latitude tree cover, BIOME3 simulated an increase in the ratio of evergreen needleleaf to deciduous needleleaf trees, and an increase in the ratio of broadleaf to needleleaf trees. This again reflects a warming climate.

BIOME3 simulated a decrease in forest cover in parts of the tropics, for example, central Africa, attributed to increased temperature and water stress favoring C4 grasses over C3 woody plants. DOLY simulated increases in LAI with temperature in moister regions, and decreases with temperature in drier regions. LAI was simulated to decrease in areas where precipitation decreased.

The global mean net primary productivity simulated by BIOME3 increased by 6% relative to the present-day as a result of climate change. It was found that the climatically induced redistribution of vegetation was necessary to realize this increase in NPP increase; when global vegetation patterns were fixed at the present-day state, global mean NPP increased by only 1%.

Cramer *et al.* (2001) used 6 DGVMs to make projections of global vegetation responses to transient climate change simulated with the HadCM2 GCM under the IS92a greenhouse-gas and sulphate aerosol concentration scenario. Vegetation simulations were performed with and without CO_2 fertilization. The DGVMs showed global vegetation responses to climate change alone, which were similar to those simulated by the biogeography models described above, with increasing forest cover in temperate and boreal regions but less in the tropics (Figure 5). A particular feature of this study was a major reduction in forest cover in the eastern half of Amazonia, as a consequence of a significant reduction in precipitation and increase in temperature.

The DGVMS simulated a range of changes in global mean NPP under climate change, some increasing and some decreasing. A key influence on decreasing NPP was the drying climate simulated in Amazonia. The DGVMs also simulated increases in soil respiration under the warming climate, which generally offset any increases in NPP. The simulated net atmosphere-land carbon flux was therefore negative in most regions in most models throughout the twenty-first Century, suggesting an almost universal release of carbon from terrestrial ecosystems as a consequence of climate change alone.

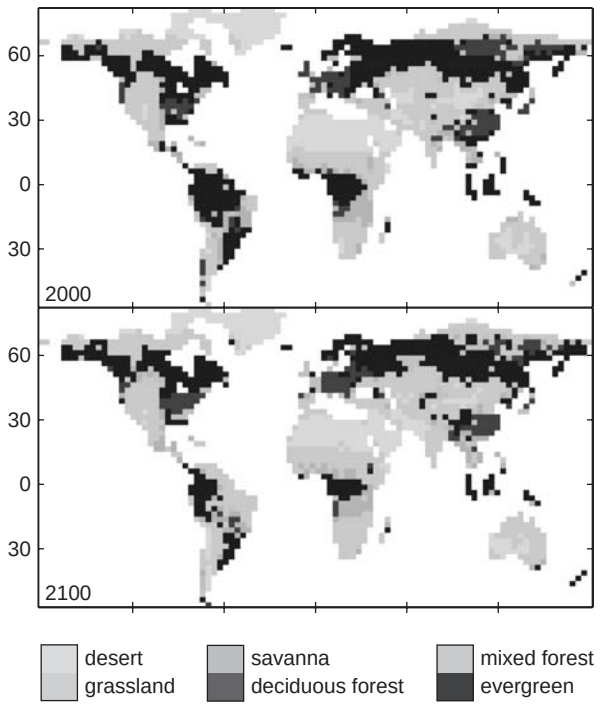

Figure 5 Dominant vegetation types simulated for 2000 and 2100, considering only changes in climate and neglecting CO_2 fertilization effects. Each data point shows the mode result of 6 Dynamic Global Vegetation Models (DGVMs). (Reproduced from Cramer *et al.*, 2001, with permission of Blackwell Science Ltd). Effects of Radiatively Forced Climate Change on Global Hydrology

Many studies of the impacts of climate change on surface hydrology use catchment-scale models driven by GCM or RCM output, processed to correct biases and improve regional detail. When such models are applied to catchments in which a significant fraction of the precipitation currently falls as snow, winter runoff is generally simulated to increase under climate change while spring runoff decreases. This is due to the warmer climate causing more winter precipitation to fall as rain rather than snow. Rainwater contributes to runoff very rapidly, whereas snow is effectively stored until the spring thaw and only then does the water contribute to runoff. The exception to this is very cold regions where the warming is not sufficient to cause a significant shift from snow to rain.

In other regions, changes in runoff generally reflect changes in precipitation, with areas receiving more precipitation producing greater quantities of runoff. However, increases in temperature also exert an important influence in some regions, leading to increases in evaporation that are significant enough to offset the increases in precipitation

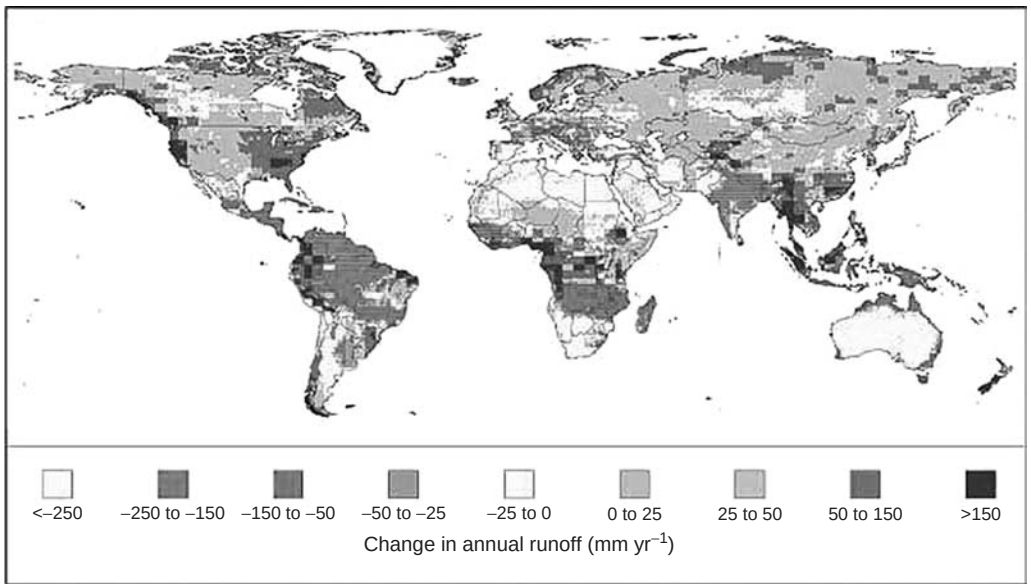

Figure 6 Changes in annual mean runoff by relative to the present day, simulated by a macroscale hydrology model under climate changes simulated by the HadCM2 GCM. Arnell, 1999. (Reproduced by permission of Intergovernmental Panel on Climate Change (IPCC)). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

and hence cause a decrease in runoff. However, the local characteristics of catchments can also exert an important influence. For example, if groundwater forms a significant component of the catchment water budget, runoff in summer may be affected predominantly by precipitation the previous winter.

Arnell (1999) used a global-scale hydrological model with climate model projections from the HadCM2 GCM (Figure 6). Under the simulated 2050s climate, annual mean runoff was simulated to increase in most of the high and midlatitudes as a result of increases in precipitation, except in Europe and central Siberia where the warming caused sufficient increases in evaporation to offset precipitation increases. Increased runoff was also simulated in China and central Africa, again as a result of increased precipitation, but in large parts of the subtropics runoff was simulated to decrease. In some of these areas this is again a result of the warming increasing evaporation by more than the increase in precipitation, but in northeastern Amazonia and Southwest Africa the decreased runoff results from reductions in precipitation. Global mean runoff was simulated to increase by 6.5%.

The DGVMs used by Cramer *et al.* (2001) included hydrological submodels as part of the ecosystem models. When driven by output of the HadCM2 under the IS92a concentration scenario, without any direct effect of CO_2 on transpiration but with transpiration being modified by ecosystem responses to climate change, these models simulated global mean runoff changes from -1 to $+9\%$ by 2100 relative to the present.

PHYSIOLOGICAL FORCING OF THE CLIMATE SYSTEM BY CARBON DIOXIDE

Effects of Physiological Forcing on Ecosystems

Projections of the direct effects of rising CO_2 on vegetation are generally made using models incorporating mechanistic descriptions of plant physiological processes, based on individual-level observational and experimental studies. In particular, photosynthesis is generally observed to increase with rising CO_2, but the rate of this increase reduces with rising CO_2, implying a saturation of photosynthesis at high CO_2. Pot and plot-scale studies also indicate an increased efficiency of water use due to the reduced opening of stomata under higher CO_2. Biogeography models and DGVMs generally adopt some methodology for scaling up of these processes to generate projections at large scales.

Model simulations of global vegetation responses to increasing CO_2 (neglecting any associated climate change) show an increase in net primary productivity (NPP) and carbon storage. Cramer *et al.* (2001) simulated global mean NPP and carbon stocks to nearly double by 2100 when CO_2 effects were included without climate change. These simulations also featured some changes in global vegetation distribution, mainly due to increased water-use efficiency allowing more growth in semiarid regions. The African and South American equatorial forests expanded into savanna regions, and the relative viability of woody vegetation also increased in India. Australia became more grass-covered, and the boundary between the Sahara desert and the Sahel moved northwards.

Enhancement of photosynthesis by increased CO_2 plays an important part in the response of the climate system to anthropogenic carbon emissions. Along with increased uptake in the oceans, this increased uptake of CO_2 by enhanced photosynthesis provides a partial buffer against the anthropogenic emissions, such that the atmospheric CO_2 concentration currently rises at approximately only 50% of the rate of emissions (IPCC, 2001). This "airborne fraction" of emissions is a crucial component of projections of future CO_2 rises, and any changes in this fraction could significantly influence the rate of CO_2 rise. A saturation of photosynthesis at high CO_2 would contribute to an increase in the airborne fraction. This has major implications for climate change, as the current 50% airborne fraction may be providing only a temporary buffering of the full effect of anthropogenic CO_2 emissions.

Effects of Physiological Forcing on Hydrology

Reduced transpiration also implies an increase in the proportion of water remaining at the land surface. This implies an increase in runoff as a consequence of the physiological impact of rising CO_2 on vegetation (Wigley and Jones, 1985).

In simulations with vegetation-hydrology models under the IS92a scenario of CO_2 increase, ignoring any associated radiatively forced climate change, Cramer *et al.* (2001) found all but one of their models to simulate an increase in global runoff owing to the physiological effects of CO_2 rise. The simulated changes in runoff ranged from -3 to $+47\%$. It should be noted that the simulations included dynamic vegetation, so the physiological forcing could also exert an impact through changes in leaf area and vegetation distribution. This is important, because such changes in vegetation structure may affect climate through changes in land surface properties as well as through stomatal closure. The changes in runoff therefore arose from physiological impacts on plant stomata, leaf area, and vegetation distribution.

The Section "Effects of radiatively forced climate change on global hydrology" noted that Cramer *et al.* (2001) simulated a change in runoff of -1 to $+9\%$ with the DGVMs driven by climate change without CO_2 physiological forcing. When both climate change and physiological forcing were included, the changes in runoff were $+1$ to $+45\%$. This suggests that rising CO_2 could increase global mean runoff more through physiological forcing of transpiration than radiatively forced climate change. In regions where radiatively forced climate change does not significantly increase local precipitation, increased runoff may still occur as a result of physiological forcing.

Effects of Physiological Forcing on Climate

Effects of Physiological Forcing on Surface Temperature

The rate of transpiration influences the partitioning of energy fluxes between latent heat and sensible heat, and reduced transpiration implies a smaller latent heat flux and larger sensible heat flux, which will warm the air near the surface. If stomata open less wide under higher CO_2 concentrations, this would be expected to exert a further warming influence on climate in addition to that associated with radiative forcing. In a doubled-CO_2 sensitivity study with the SiB ecosystem model coupled to a GCM, Sellers *et al.* (1996) found the simulated surface air temperature in the tropics to increase by $0.4-0.7$K as a result of physiological forcing alone. By comparison, the warming was 1.7 K as a result of radiative forcing alone. So while physiological forcing exerted a smaller influence than the radiative forcing, the relative effect was not insignificant.

In a similar experiment with the HadAM3 GCM incorporating the MOSES ecosystem model, Cox *et al.* (1999) found global land temperatures to rise by 3.1 K owing to radiative forcing alone, and additional 0.4 K when physiological forcing was included. The land climate sensitivity to doubling CO_2 was therefore increased by 12% by the inclusion of physiological forcing.

Effects of Physiological Forcing on Precipitation

A decrease in transpiration also implies a decreased return of moisture to the atmosphere. In regions such as Amazonia where a large proportion of water for precipitation is supplied by evaporation from the land surface rather than advection from over the oceans (Salati and Vose, 1984), reduced transpiration by stomatal closure could lead to reduced precipitation. Betts *et al.* (2004) examined the possible effect of this in Amazonia, using a coupled climate-biosphere model. Two simulations were performed, both with increasing radiative forcing from CO_2 rise according to the IS92a scenario, but with only one simulation including CO_2-induced stomatal closure.

The two simulations showed marked differences in precipitation in many regions across the globe by the end of the twenty-first Century (Figure 7). Over Amazonia, for example, the simulation with stomatal closure featured a more drastic decrease in precipitation. In western Amazonia, this was due to a reduced evaporative return of water to the atmosphere through reduced canopy conductance (Cox *et al.*, 1999).

However, there were also large-scale patterns of precipitation increase and decrease across the globe, indicative of differences in the global atmospheric circulation. These are attributable to different rates of land surface warming in the two simulations as described above. In the simulation including CO_2-induced stomatal closure, the generally lower rate of transpiration leads to greater warming over

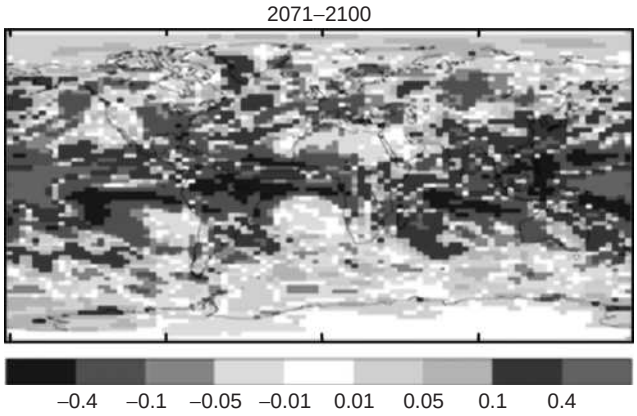

Figure 7 Effect of physiological forcing (reduced stomatal opening under higher CO_2) on global precipitation patterns. Difference in precipitation (mm day^{-1}) between simulations with and without physiological forcing. 30-year mean centered around 2080. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

land (Sellers *et al.*, 1996; Betts *et al.*, 1997; Cox *et al.*, 1999). Since the northern hemisphere includes more land than the southern hemisphere, a greater rate of warming over land leads to an interhemispheric difference in warming that would be expected to modify global atmospheric circulation. In particular, the Inter-Tropical Convergence Zone (ITCZ), an area of ascending air motion and hence precipitation, is drawn northwards by a warmer northern hemisphere. This changed the patterns of precipitation around the equator, bringing more rainfall to some regions but less to others.

LAND USE FORCING OF THE CLIMATE SYSTEM

The nature of vegetation cover is a major influence on the physical properties of the land surface. In general, a forested landscape exhibits a lower surface albedo, a larger aerodynamic roughness and a greater availability of moisture for evaporation than a nonforested landscape. Trees significantly increase evaporation by drawing-up soil moisture and transpiring it through their leaves, and also by enhancing turbulent transport by increasing the aerodynamic roughness of the landscape. Removal of forest cover would therefore be expected to lead to decreased evaporation and a reduction in the absorption of solar radiation. When resulting from a large-scale change, these changes in land surface properties can significantly influence regional climates and wider-scale atmospheric circulations. Since the extent of forest cover is changing rapidly around the world, especially in the tropics, which are now generally being deforested, this is another area in which long-term projections of climatic, ecological, and hydrological states are required.

A large number of modeling studies have examined the climate sensitivity to total deforestation in tropical regions such Amazonia. There is general agreement among these studies that complete deforestation would cause a warming of surface temperature and reduction in precipitation, owing to a reduced level of transpiration from the deforested landscape (*see*, for example, Lean and Rowntree, 1997 for summary). The smaller flux of moisture due to reduced transpiration causes a reduction in the ratio of latent to sensible heat fluxes, so the air near the surface is warmed. Since much of the rainfall in the Amazon basin relies on water transported from over the oceans through the repeated cycling of water through rainfall and evaporation (Salati and Vose, 1984), the reduced transfer of moisture to the atmosphere also decreases the recycling of moisture across the continent. Less moisture is therefore available for precipitation in the center and west of the Amazon basin. In addition, an increase in surface albedo results in a smaller heating of the surface by the net radiation balance, suppressing ascent and hence causing less moisture to be drawn into the region (Charney, 1975). A reduced frictional drag exerted by the deforested landscape will also act to reduce this moisture convergence. All these mechanisms will tend to reduce precipitation (Figure 8).

Large-scale deforestation in the tropics may also exert more far-reaching effects, with changes in the near-surface

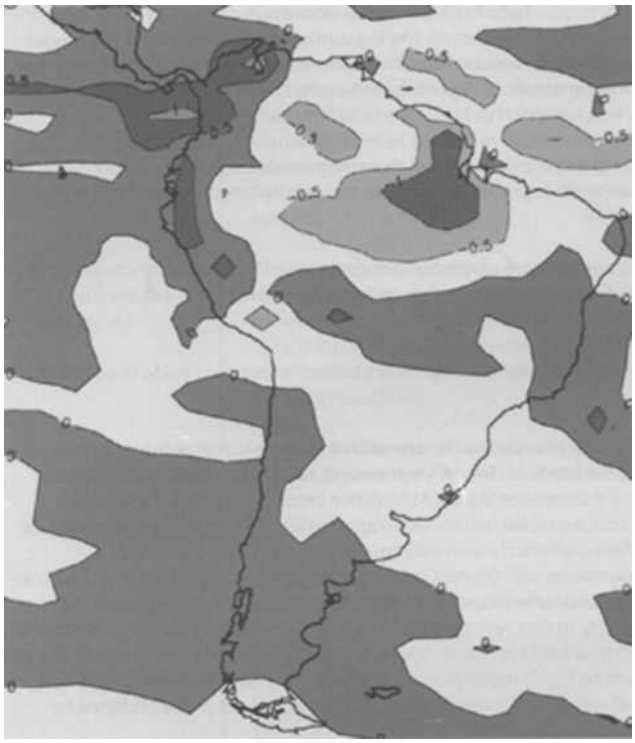

Figure 8 Simulated changes in annual mean precipitation as a result of complete deforestation of Amazonia (Lean and Rowntree, 1993). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

energy balance modifying the large cells of ascending and descending motion near the equator. Changes to these may cause shifts in the atmospheric circulation that propagate across the globe. Gedney and Valdes (2000) found that complete deforestation of Amazonia could lead to increased precipitation in Europe through this mechanism.

Feedback from the oceans may enhance the effects of land-cover change on climate. For example, Delire *et al.* (2001) found that in the Indonesian Archipelago, the impacts of deforestation on wind speeds may be sufficient to modify ocean up-welling and cause warming over the surrounding ocean surfaces, in addition to the warming caused over land by reduced evaporation. This amplified warming may impact global-scale atmospheric circulations.

Since changes in land cover such as deforestation have been shown to potentially impact evaporation and precipitation, it follows that such activities would also impact runoff. Lean and Rowntree (1993) found an 8% reduction in simulated runoff from Amazonia following complete deforestation, as a result of decreased precipitation outweighing the decrease in evaporation. However, surface runoff was simulated to increase by 27% at the expense of subsurface runoff, because infiltration rates were assumed to decrease after deforestation. Infiltration rates in forest soils were assumed to be high owing to the presence of litter and tree root systems, while infiltration in land deforested for pasture was assumed to be low owing to soil compaction during the deforestation process and by the presence of livestock.

The issue of partial deforestation may, however, be more complex. High-resolution mesoscale models that resolve the patterns of partial deforestation suggest that the fragmentation of the forest cover may induce small-scale atmospheric circulations that can increase atmospheric ascent and therefore enhance convection (Roy and Avissar, 2002). Therefore, partial deforestation may actually increase precipitation if the supply of moisture from advection remains unchanged. With current computing limitations, atmospheric models with resolution high enough to capture the effects of fine-scale forest fragmentation can only be applied over relatively small regions. Since actual patterns of deforestation often consist of fine-scale partial clearance over large areas, there is a need to investigate the interactions between mesoscale circulations and large-scale advection and evaporative recycling. There is therefore a requirement for large-domain modeling studies with either higher resolutions or adequate parameterizations of fine-scale circulations.

While tropical forests exert a cooling effect on their regional climates, forests in cold regions exert a warming influence through their large impact on surface albedo, which outweighs the influence of transpiration. Forests are generally darker than open land, particularly when snow is lying because trees generally remain exposed while cultivated land can become entirely snow-covered (Harding and Pomeroy, 1996). Snow-free foliage is considerably darker than snow, but even if large quantities of snow are held on the canopy, multiple reflections within the canopy scatter rather than reflect shortwave radiation, which also reduces the landscape albedo (Harding and Pomeroy, 1996). Models suggest that the resulting low surface albedo causes boreal and cool-temperate forests to exert a warming influence on climate relative to non-forested land (Bonan *et al.*, 1992; Thomas and Rowntree, 1992).

Deforestation of the boreal and temperate forests would therefore exert a cooling influence on climate (Douville and Royer, 1997), and indeed from the global perspective, most deforestation until the mid twentieth century had occurred in the temperate regions exerting an overall local cooling effect (Brovkin *et al.*, 1999; Betts, 2001; Govindasamy *et al.*, 2001). However, in more recent decades, land abandonment in western Europe and North America is leading to reforestation, which would cause a warming influence. This point is particularly important in the context of the potential use of afforestation and reforestation to slow radiatively forced climate change (UNFCCC, 1997). Since forest growth sequesters carbon dioxide from the atmosphere, this is one means by which the rise in atmospheric CO_2 could potentially be slowed providing a possible means of mitigating radiatively forced climate change. However, in the case of afforestation in cooler regions, the cooling influence of carbon sequestration could be partly or wholly offset by the warming influence of decreased surface albedo (Betts, 2000). Temperate and boreal afforestation and reforestation could therefore provide a less effective means of climate change mitigation, or even an unintentional means of exacerbating climate warming.

INTERACTIONS BETWEEN FORCINGS

The above discussion has considered three anthropogenic forcings of the climate system, and reviewed studies of them acting in isolation. However, in reality these would be expected to act together, so it is their combined effects that are of greatest interest when making projections of future changes in the climate system. While in some cases the combined effects may be similar to a simple sum of the individual effects, in other cases the forcings may interact nonlinearly causing more unexpected results.

The radiative and physiological forcings exerted by CO_2 rise may exert nonadditive impacts on local surface temperatures and precipitation through modifications of the atmospheric circulation. For example, Sellers *et al.* (1996) found the radiatively forced warming in high northern latitudes to be locally reduced when physiological forcing was included, as a consequence of circulation changes.

A major issue is the relative impact of radiatively forced climate change and CO_2 fertilization on terrestrial ecosystem, and in particular their total carbon storage. Section "Effects of radiatively forced climate change on global ecosystems" discussed the potential redistribution of ecosystem types and a projected release of carbon from global ecosystems as a result of a warmer climate, while Section "Effects of physiological forcing on ecosystems" discussed the projected increase in carbon storage due to physiological responses to increased CO_2 concentrations. A key question is therefore whether terrestrial carbon stocks will increase or decrease under scenarios of rising CO_2 and the associated climate change.

Haxeltine (1996) found that climate warming alone increased NPP by 6%, largely as a result of a net expansion of woody vegetation under climate change. The effect of CO_2 fertilization was to increase NPP by 30% in the absence of any forest expansion, but when climatically induced forest expansion was considered the overall increase in NPP was 43%. This suggests that the effects of climate change of biogeography may be a key factor in limiting NPP responses to increased CO_2 concentrations.

Considering the overall net exchange of carbon between the atmosphere and terrestrial biosphere, including soil respiration in addition to NPP, it would be expected conceptually that CO_2 fertilization would dominate initially and then be overtaken by the effects of warming, as CO_2 fertilization saturates at higher CO_2 concentrations while respiration is generally observed to increase with temperature. A number of model projections of ecosystem responses to scenarios of CO_2 rise and radiatively forced climate change are consistent with this expectation (e.g. Cao and Woodward, 1998; Cramer *et al.*, 2001), with the terrestrial biosphere simulated to be a sink of carbon initially but then becoming a weaker sink or even a carbon source by the end of the twenty-first century.

Cramer *et al.* (2001) found CO_2 fertilization and climate change to interact nonlinearly. By 2100, climate change alone generally led to a negative net atmosphere-land carbon flux or net ecosystem productivity (NEP), which is the difference between NPP and soil respiration. However, CO_2 increase alone led to positive NEP. The linear sum of these effects was a general increase in NEP, but in simulations driven by both CO_2 and climate change together, negative NEP was simulated in many parts of the tropics.

Betts *et al.* (2004) found the dieback of Amazonian forest under a drying climate to be reduced but not eliminated by CO_2 fertilization. This was despite the further reduction in local precipitation induced by stomatal closure. Physiological forcing therefore enhanced the drying of the climate but slowed the forest dieback due to the increased water-use efficiency.

ECOSYSTEM FEEDBACK ON CLIMATE CHANGE

Sections "Effects of radiatively forced climate change on global ecosystems" and "Effects of physiological forcing on ecosystems" showed that CO_2 rise and radiatively forced climate change may alter the character of global ecosystems. Conversely, Section "Land use forcing of the climate system" illustrated the influence of changes of the physical characteristics of ecosystems on the climate. Widespread increases or decreases in forest cover projected in response to CO_2 rise and climate change may therefore make further additional contributions to the regional and global climate changes through alterations to the land surface properties. Furthermore, the net changes in global carbon stocks discussed in Section "Interactions between forcings" may influence the rise in CO_2 itself. Ecosystems may therefore exert a number of feedback on climate change, both at the regional and global scale.

Feedback via the carbon cycle have been investigated by Cox *et al.* (2000), Friedlingstein *et al.* (2001) and more recently by other groups (e.g. Thompson *et al.*, 2004). Since these studies were similar in methodology and produced broadly similar results, at least in terms of the feedback on atmospheric CO_2 rise, only the study by Cox *et al.* (2000) will be discussed here in detail.

Cox *et al.* (2000) used the HadCM3LC coupled climate-carbon cycle model, which includes the TRIFFID DGVM (Cox, 2001) and HadOCC ocean carbon cycle model (Palmer and Totterdell, 2001) in a version of the HadCM3 GCM (Gordon *et al.*, 2000). Atmospheric CO_2 concentrations were calculated interactively within then model as opposed to being prescribed from an externally derived scenario.

A simulation of climate and ecosystem change from 1860 to 2100 was performed, with the input perturbation being the CO_2 emissions from the IS92a scenario. This contrasted with the usual approach to GCM climate simulations, which use CO_2 concentrations rather than emissions as the input driving data. Terrestrial ecosystems and the ocean carbon cycle to respond to the CO_2 rise and climate change and feed back on the CO_2, so the model simulated the changes in both climate and CO_2 simultaneously and consistently.

A second simulation was performed with the interactive carbon cycle but with the radiative effect of CO_2 excluded from the calculations. This therefore allowed the model to simulate the changes in CO_2 due to the anthropogenic emissions and the responses of the oceans and terrestrial biosphere to the CO_2 rise, but without any climatic effect inducing a feedback. Comparison between this simulation and the first simulation quantified the effect of climate change on the atmospheric CO_2 rise.

A third simulation was driven by prescribed CO_2 concentrations rather than emissions, with the CO_2 concentrations calculated without the effect of climate change as in

simulation 2. Comparison between this and the first simulation therefore showed the importance of the climate-carbon cycle feedback on the climate change itself.

In the second simulation, neglecting the effects of climate change on the carbon cycle, the terrestrial biosphere was projected to take up 620 Gigatonnes of carbon (GtC) by 2100, two-thirds of this in the soil. In contrast, the first simulation (including the effects of climate change) projected an overall loss of 90 GtC, owing to large losses from the soil and smaller uptake in vegetation (Figure 9a) Climate change therefore induced a deficit of 710 GtC in the terrestrial biosphere in comparison with the changes projected without the effects of climate change. With CO_2 uptake by the oceans also considered, this feedback resulted in CO_2 concentrations rising to 1000 ppmv by 2100 rather than 700 ppmv as projected without the feedback (Figure 9b).

This feedback was found to significantly increase the rate of global warming. In the third simulation, with a CO_2 rise of only 700ppmv, the global mean temperature rise over land was 5 K, whereas in the first simulation with all feedback included the warming over land was 8 K (Figure 9c) The inclusion of climate-carbon cycle feedback was therefore to enhance the rate of global land warming by 50%. This magnified the patterns of precipitation change across the world, with regions of drying generally become even drier while regions of wetting became wetter still (Figure 10).

Friedlingstein *et al.* (2001) and Thompson *et al.* (2004) also found the atmospheric CO_2 rise and global warming to be accelerated by positive feedback between climate change and the terrestrial biosphere. However, in contrast to Cox *et al.* (2000), the models used in these two studies simulated the terrestrial biosphere to merely weaken as a sink of carbon rather than actually becoming a source of carbon. The positive feedback were therefore weaker than that found by Cox *et al.* (2000).

As well as changes in carbon stocks, the simulations also featured changes in the character and distribution of global ecosystems (Figure 11) As the climate warming accelerated in the cold regions, shrub cover continues to expand in the arctic tundra and on the Tibetan plateau. The boreal forests continue to become more dense, and also spread towards the pole. In gridboxes on northern edge of boreal forest, tree cover becomes more dense, implying a northward movement of the treeline. A number

of dry regions such as central Asia showed a greening trend, consistent with increased water-use efficiency but also partly a result of increased rainfall. Other dry regions such as Southwest Africa continue to lose tree and shrub cover – a decrease in rainfall is simulated in SW Africa. The forests of Southeast Asia and central Africa increased in density in the absence of future deforestation. However, the forests of Amazonia showed a very large reduction in tree cover as a result of decreased rainfall. Some signs of the beginning of this process were already simulated by 2000, with broadleaf tree cover reducing in the northeast of Amazonia in response to a drier climate than that simulated for 1860. The reduction in rainfall spreads towards the southwest through the twenty-first century, and the tree cover reduced until it is less than 1% in the northeast quarter of Amazonia by 2100. Almost all of the Amazon basin loses at least 50% of its tree cover by the end of the simulation, to be replaced mainly by C4 grass but also with large areas of bare soil. The general character of the region is therefore fundamentally changes from dense evergreen broadleaf forest to savanna, grassland, or even semidesert.

These changes in terrestrial ecosystems in these simulations exerted some significant feedback on regional climates through changes in the physical properties of the land surface. To examine the extent of these feedback, Betts *et al.* (2004) performed a fourth simulation with vegetation fixed at the preindustrial state, driven by the same CO_2 concentration scenario as the third simulation above. Comparison between the third and fourth simulations therefore reveals the extent of biogeophysical feedback on climate change.

The general global patterns of climate change were similar in the two simulations, with almost all changes in temperature and precipitation being of the same sign irrespective of the inclusion of vegetation feedback. This implies that vegetation feedback are not a significant influence on atmospheric circulation in comparison with the greenhouse-gas forcing. However, some of the regional climate changes were significantly affected by vegetation feedback (Figure 12) In particular, the precipitation reduction over Amazonia was found to be enhanced by 25% by feedback from the loss of forest cover. In the western part of the basin, the feedback was greater still, magnifying the precipitation reduction by over 30%. The larger precipitation decrease in western Amazonia was attributed to drought-induced dieback of the eastern forests contributing to further rainfall reductions in the west. The forest loss also increased surface albedo, which reduced convection and moisture convergence, providing a further positive feedback on rainfall reduction (Charney, 1975).

The expansion of the boreal forests and tundra shrub cover exerted a further feedback on climate warming. The more extensive vegetation cover resulted in a lower surface albedo, which increased the absorption of solar radiation. This provided a further 1 K of warming in addition to the 6 K simulated with fixed vegetation cover, a feedback of approximately 15%.

Friedlingstein *et al.* (2001) also found a reduction in precipitation to be simulated in Amazonia in their model, but the model did not include dynamic vegetation so there was no feedback on climate through biogeophysical effects. The model used by Thompson *et al.* (2004) included the IBIS2 dynamic vegetation model (Foley *et al.*, 1996; Kucharik *et al.*, 2000), but this model did not produce a drying in Amazonia. The carbon cycle and biogeophysical feedback simulated by HadCM3LC (Cox *et al.*, 2000; Betts *et al.*, 2004) are therefore more extreme than those simulated by other modeling groups. However, HadCM3LC has been shown to successfully reproduce the historical CO_2 rise and the observed interannual relationship between Pacific sea surface temperatures, variability in the CO_2

rise and precipitation in Amazonia (Jones *et al.*, 2001; Cox *et al.*, 2004).

UNCERTAINTIES IN PROJECTIONS: THE IMPLICATIONS OF SYNERGISMS AND FEEDBACK

Many of the projected changes discussed here have major implications for both human and ecological communities. It is therefore vital to consider the reliability of these model projections as indicators of actual future change. Such a consideration requires an understanding and of the processes involved in the changes in the climate system, so that the implications of uncertainties in the different components of the system can be recognized.

Uncertainties in all components of the climate change process are recognized. Uncertainties exist in the scenarios of socioeconomic change, the translation of these into GHG emissions scenarios, the subsequent responses of GHG concentrations, the implications of these for global and regional climates and the impacts on ecological and hydrological systems. A typical approach to quantifying uncertainty is to make projections with a large number of models, which are assumed to sample the range of plausible representations of processes. The IPCC (2001) illustrated this with a number of GCMs simulating climate changes under a given scenario of GHG concentrations. Global mean temperature was simulated to increase by between 1.3 and 4.5 K by 2100 under this scenario. When this was extended to more scenarios, with both GCMs and simple models approximating the GCM responses, the projections of global warming ranged from 0.9 to 5.8 K by 2100.

Uncertainty is typically viewed as increasing along the chain from socioeconomic scenarios to climate impacts, as each component in the process is subject to its own uncertainties and also those in the processes to which it responds. For example, while uncertainties in regional climate change provide a major source of uncertainty in projections of hydrological change (Arnell *et al.*, 2001), incomplete understanding of large-scale responses of transpiration to CO_2 introduces further significant uncertainties in potential changes in the surface water budget.

However, the potential existence of significant feedback within this chain may mean that the large uncertainties at the end of the chain propagate back towards the beginning. For example, it has been illustrated here that the regional climate changes simulated in some regions exert feedback on global climate change through the effects of forest dieback on atmospheric CO_2 rise. Since regional climate change predictions are subject to considerable uncertainty, the importance of the feedback to global climate implies that the uncertainties in global climate are also subject to uncertainties that depend on the regional-scale uncertainties. Betts *et al.* (2004), for example, showed that the uncertainties over possible Amazonian rainfall reductions lead to uncertainties in carbon cycle feedback, which imply a 10% uncertainty in global mean temperature rise.

Moreover, uncertainties in ecosystem responses to climate change may significantly contribute to uncertainties in the climate change itself. In particular, uncertainties in the response of soil respiration to warming (Jones and Cox, 2001) also lead to uncertainties in the rise of atmospheric CO_2 concentrations and hence global warming. The potential positive feedback found by Cox *et al.* (2000) suggest that uncertainties surrounding the temperature response of soil respiration imply a 50% uncertainty in the rate of global warming simulated by one climate model under a given emissions scenario. This is comparable with the uncertainties associated with the range of responses of different climate models to a given concentration scenario as described above, implying that the true uncertainty may be much greater owing to incomplete understanding of critical processes.

While this does not imply that the uncertainties in global climate change are greater than those in regional climate change or ecosystem response, it does imply that the uncertainties in the different components of climate change may be more similar than previously assumed. The "cascade of uncertainty" from higher confidence in emissions to lower confidence in impacts may not be as steep as formerly assumed.

SUMMARY AND CONCLUSIONS

Human-induced changes in atmospheric chemistry and land cover are projected to cause significant changes in climate, ecology, and hydrology around the globe. An enhancement of the greenhouse effect by increased concentrations of CO_2 and certain other gases is projected to increase global average temperatures by between 0.9 and 5.8 K by 2100. Warming in some regions may well be greater. Precipitation patterns are also projected to change, causing some regions to be drier and others wetter.

Direct physiological responses of vegetation to increased CO_2 may constitute an additional, secondary, forcing of the climate system, especially from hydrological and ecological perspectives. This forcing acts directly on ecosystems, enhancing photosynthesis and therefore modifying growth and development. Plants are also observed to reduce the opening of their stomatal apertures under increased CO_2, which reduces the loss of water by transpiration. Changes in transpiration at large scales would influence runoff, precipitation, and surface temperature.

Increased concentrations of CO_2 may therefore exert two forcings on the climate system, both resulting in impacts on ecosystems and hydrology. Radiative forcing affects ecosystems indirectly via climate change, while

physiological forcing may also affect plant functioning and the surface water budget directly through increased water-use efficiency and fertilization of photosynthesis.

Changes in land cover, such as the extent of forest cover, are projected to exert further impacts on climate through modifications to the surface energy and moisture budgets and the atmospheric circulation. Major changes in land cover are expected to occur as a direct result of human activities such as forest clearance. In addition, climate change may itself lead to shifts in the global patterns of ecosystems. As well as being critical to biodiversity and human well-being, such changes could exert significant feedback on climate change and potentially increase its magnitude.

Changes in climate, ecosystems, and hydrometeorology depend on complex interactions between the atmosphere, biosphere, and hydrological cycle. While numerical models remain the best tools for examining these interactions and assessing the implications of anthropogenic perturbations to the climate system, projections made with these models are nevertheless, subject to significant uncertainties. However, all models agree that significant changes, particularly a warming of climate and redistribution of rainfall and water resources, can be expected. This information in itself can provide a basis for preparing for the future.

182: The Hydrological Cycle in Atmospheric Reanalysis

ANTON BELJAARS, ULF ANDRAE, PER KALLBERG, ADRIAN SIMMONS, SAKARI UPPALA AND PEDRO VITERBO

Research Department, European Centre for Medium-Range Weather Forecasts, Reading, UK

Atmospheric (re-)analysis is a powerful tool to create data sets that provide a good description of the atmosphere including the hydrological cycle. Atmospheric analysis systems use a numerical weather prediction model to propagate the state of the atmosphere in time. Observations, which are irregular in space and time, are inserted into the system in such a way that an optimal blend is obtained between the background fields (forecast from e.g. 6 hours before) and the observations. Observations range from traditional surface observations and radiosondes, to commercial aircraft observations, cloud track winds from satellites and profiling measurements from infrared and microwave instruments in space. Re-analyses are performed to benefit from the most recent model improvements, data assimilation improvements and increased computer power and to obtain a time series that does not suffer from system changes as in operational numerical weather prediction. Current re-analyses have a spatial resolution of the order of 1 degree with a temporal sampling interval of 3 to 6 hours. Re-analysis products have the advantage of being projected on a global numerical grid and have no gaps.

The ECMWF 40-year Re-Analysis is described as an example. Its realism is discussed by comparing with observations of precipitation, vertically integrated water vapor, moisture convergence and surface fluxes over land and ocean. It is concluded that re-analysis products are very useful to study the hydrological cycle in the atmosphere. The synoptic variability is particularly good although biases may exist in some of the parameters.

INTRODUCTION

Data assimilation is a powerful tool to integrate observations of different types which are irregularly distributed in space and time, into a single analysis of the atmosphere. A forecast model is an integral part of data assimilation systems and is used to provide consistency between variables and to propagate the atmospheric state in time. Analyzed model variables in current numerical weather prediction (NWP) systems are surface pressure, the two horizontal wind components, temperature, and specific humidity. It also provides a series of derived parameters like cloud cover, precipitation, and turbulent and radiative fluxes. The ECMWF 40-year ReAnalysis (ERA-40) includes the analysis of ocean waves and atmospheric ozone (the actual length of ERA-40 is 44 years, from 1958 to 2001). Because surface-boundary conditions are needed, an externally provided sea surface-temperature analysis is used and land root zone soil moisture and soil temperatures are also analyzed with an indirect method. Future systems will include analysis of cloud variables and precipitation.

An important feature of data assimilation in NWP is that consistency of the fields in time and space is achieved by using a forecast model and a constraint (e.g. geostrophy) on corrections due to observations (analysis increments). A clear example is moisture. Moisture is correlated with temperature because it is constrained by its saturation value and carries the history of vertical motion, with subsidence leading to dry air and ascending motion leading to saturation. Therefore, even without moisture observations, the moisture fields look very realistic because they are controlled by horizontal and vertical advection and model physics.

A major benefit of data assimilation is that an uninterrupted time series (e.g. with time intervals of 3 or 6 h) of

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

global fields is obtained. The quality of these fields depends of course on the amount and quality of the data and on the quality of the assimilation model, but even in the case of missing data in a particular area, an analysis will be produced by the forecast model that is based on earlier data.

NWP centers produce analyses on a daily basis, because they need them as an initial state for weather forecasting (*see* **Chapter 180, Short-Term Predictions (Weather Forecasting Purposes), Volume 5**). These analyses are very useful and form the basis for many diagnostic studies. However, analysis and forecasting systems evolve continuously and are typically changed once or twice per year. It is well known that particularly the analysis of vertical motion and the hydrological cycle are to some extent system dependent. So these system changes lead to changes in the characteristics of the fields, clearly undesirable for applications where long time series of data are required. From the application point of view, it is desirable to have the best possible quality of analysis, which means that there is a preference for a recent system. Over the years, computer capacity has increased and data assimilation systems have improved. The consequence is that with current systems higher resolution analyses of better quality can be produced than the operational ones of say 10 years ago. On the other hand, reanalyses have less computer time available per analyzed day than operational systems because, to be practical, production rates have to be of the order of one month per day.

To get the best possible analyses without system changes, reanalysis projects have been launched. The principal global analyses that have been completed are the NCEP/NCAR 40 and 50-year reanalyses (Kalnay *et al.*, 1996; Kistler *et al.*, 2001), the NASA reanalysis (Schubert *et al.*, 1993), the ECMWF 15-year reanalysis ERA-15 (Gibson *et al.*, 1997) and the ECMWF 40-year reanalysis ERA-40 (Uppala *et al.*, 2003). All this work would not have been possible without a massive data gathering and archiving exercise (Kalnay and Jenne, 1991). For the earlier years, the meteorological data was not available in electronic form and had to be quality controlled and coded in a standard format for modern data assimilation systems. Much of this work was done by NCAR/NCEP and several conventional data sources were made available to the different reanalysis centers. The different sources were merged at ECMWF and satellite radiance data sets (VTPR, TOVS, SSM/I) were processed from their raw form.

Reanalyses have two basic products: (i) The analysis and short-range forecast fields on a standard grid and (ii) information on acceptance or rejection of observations and on the fit of the observations to the analysis and the first guess (analysis statistics). Both products are important for validation and verification studies which provide feedback for model and analysis system development. Also, the importance of analysis statistics on the quality of the observations should not be underestimated (Andersson and Järvinen, 1999). It can be used to improve the observations through bias adjustments, correction of coding mistakes and through flagging of unreliable data. The whole sequence of activities gives reanalysis a cyclic nature: The output of the project and the subsequent studies provide feedback for system development and improvement to the observation databases (Figure 1). These observation databases are shared among the different centers.

In this article, a short description of the ERA-40 system will be given as an example of a state-of-the-art reanalysis system. The accuracy of analysis products is still difficult to quantify. Kalnay *et al.* (1996) distinguish three levels of products. The A-level fields, that are most reliable because data are used directly for these fields. Examples are temperature, pressure, and the rotational part of the flow. B-level fields are indirectly analyzed with the divergent flow as an example. Finally, C-level fields are even more indirect as they are the result of a model simulation. Precipitation and turbulent fluxes are examples of level C data. It is therefore important to compare products from different analyses and to compare with independent observations. In this article, a few comparisons will be shown with *observations that have not been used by the system*. Emphasis will be on hydrology related parameters and hydrological applications. More information on ERA-40 can be found in Uppala *et al.* (2005) and at URL **`http://www.ecmwf.int/research/era/`**

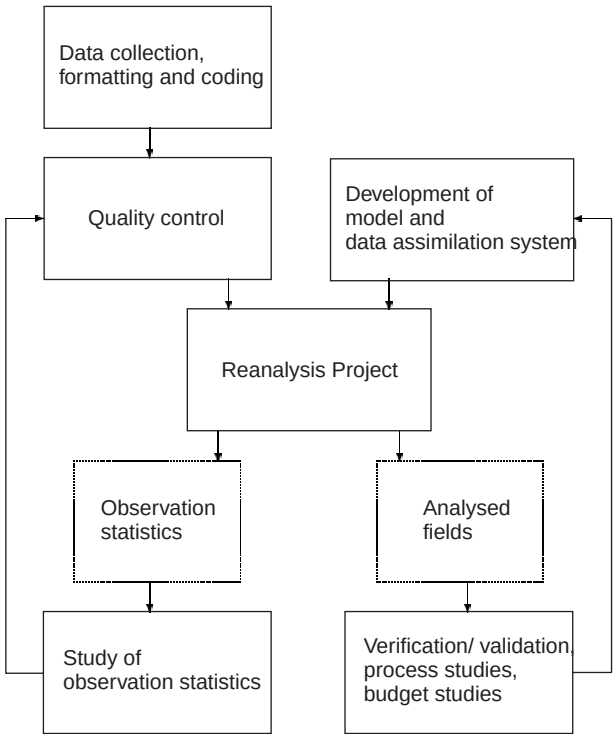

Figure 1 Flow diagram of reanalysis projects

DESCRIPTION OF THE ERA-40 SYSTEM

The ERA-40 system uses the ECMWF Integrated Forecasting System (IFS) developed in collaboration with Meteo France. The model applies a spectral representation with triangular truncation at wave number 159 (T159). The grid point spacing in physical space is about 125 km all over the globe due to a gradual decrease of grid points along a latitude circle towards the poles (a reduced Gaussian grid). The model has 60 "hybrid" levels in the vertical which are terrain following near the surface and pressure coordinates at the top of the model. The lowest model level is at about 10 m above the model surface; the top of the model is at 0.1 hPa. The model has prognostic variables for the two horizontal wind components, temperature, specific humidity, cloud cover, cloud water/ice, and ozone. From these variables, only the wind components, temperature, specific humidity, and ozone are constrained by observations. The model has a comprehensive physics package to describe radiative transfer, turbulence, subgrid orographic drag, moist convection, cloud processes including precipitation, land-surface processes, and simple ozone chemistry.

An analysis is generated every 6 h by adding increments to the background field (a short-range forecast, often called *the first guess*) to obtain a better fit to the available observations. The three-dimensional variational method (3DVAR, Courtier *et al.*, 1998; Rabier *et al.*, 1998; Andersson *et al.*, 1998) is used. It computes the equivalent of the observations, for example, through interpolation to radiosonde locations or through a radiative transfer model to find the radiance in a particular satellite channel. Then an adjoint model is used to find the sensitivity of these simulated observations with respect to the model fields. Finally, a minimization algorithm is applied to minimize the distance between the simulated and real observations and the analysis distance to the background by adjusting the model fields. Estimates of error variances and covariances of the background fields together with observation errors are used to achieve an optimal blend of first guess and observations and to obtain a proper spreading of observation information in the horizontal and vertical. Furthermore, a constraint is applied to obtain balance between mass and wind fields (Derber and Bouttier, 1999).

The ERA-40 intermittent analysis with a 6-hourly interval is consistent with the observation times of the main conventional observations (e.g. radiosondes and SYNOP's). However, many observations do not coincide with the main synoptic hours and, therefore, the observations are grouped in 6-hourly intervals from 3 h before to 3 h after analysis time. To account for the time evolution, the background field is compared to the observation at the appropriate time and for this purpose the first guess forecast runs up to 9 h. The departures of the observations from the background are, however, interpreted as if they apply to the synoptic time (see Figure 2 for a schematic representation of the analysis cycling).

Sea-surface temperature and sea ice cover are obtained from NCEP and specified as a daily updated fixed surface-boundary condition (Rayner, 2002). The surface-boundary condition over land is much more complicated. To provide a boundary condition for moisture and heat fluxes, the land-surface module has four soil layers to describe the evolution of soil moisture and soil temperature. The scheme relies on near-surface meteorology, radiative fluxes, and precipitation from the atmospheric model for its forcing and it returns sensible and latent heat flux. To represent surface heterogeneity, the model uses a tile approach in which six different subareas with different fractions have their own surface-energy balance (Van Den Hurk *et al.*, 2000). To prevent soil moisture and soil temperature from drifting, a soil analysis scheme is applied. It is based on the idea that temperature and moisture in the boundary layer will drift if soil moisture and/or soil temperature are biased, because the surface will provide biased fluxes to the boundary layer. The screen level temperature and specific humidity observations are used to quantify such drift and used to make corrections to soil moisture and/or soil temperature. The Optimum Interpolation (OI) method is used, as described by Douville *et al.* (2001). This method assumes a perfect model representation of the land surface which can be questioned because land-surface processes are complex and the model's representation of for example, soil type, and vegetation characteristics has limited accuracy. In spite of these shortcomings, the method will adjust the surface-soil moisture in such a way that the surface fluxes of sensible and latent heat are realistic.

DATA SOURCES

Conventional data from radiosondes and surface observations from land, ships, and buoys (so-called SYNOP reports) have traditionally been the backbone for

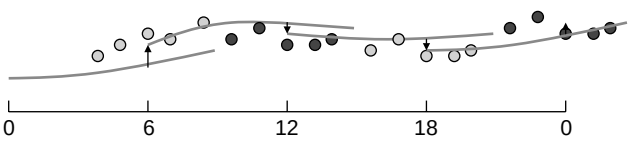

Figure 2 3DVAR cycling in ERA-40. The lines indicate the 9-h first-guess forecasts which are compared at the correct time with the observations (dots). The differences between observation and first guess are used at the synoptic times of 0, 6, 12, and 18 UTC to compute corrections to the first guess as indicated by the vertical arrows. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

atmospheric analysis. The radiosondes are obviously very important for the upper air and provide temperature, moisture, and wind information. SYNOP observations from land provide surface pressure and humidity information for the atmospheric analysis. SYNOP observations over the ocean are used for wind and surface pressure. Screen-level observations over land are also used to make a separate analysis of 2 m temperature and humidity, which is needed as input for the soil analysis scheme.

With the increase in commercial aviation, aircraft reports have become an important source of information, providing wind and temperature data for the upper air analysis.

A relatively new source of data are the meteorological satellites with good global coverage but limited vertical resolution. For most satellites, radiance observations are used directly in conjunction with a forward observation operator that simulates the measurement of the satellite channels using model fields as input. The cloud motion winds from geostationary satellites are an exception to this. For ERA-40, cloud imagery has been reprocessed by EUMETSAT (European Meteorological Satellite Agency) to obtain wind vectors, which are offered to the analysis system as wind observations.

Satellite coverage changes enormously over the ERA-40 period. During the early years from 1958 to 1972, no satellite radiance data was available and the upper air analysis relies predominantly on radiosonde data. From 1973 to 1978, there are infrared observations from the Vertical Temperature Profiler Radiometer (VTPR), which are for the first time used in ERA-40 as raw radiances. From 1979 onwards, infrared and microwave sounders are available from the Television and Infrared Observational Satellite Operational Vertical Sounder (TOVS) suite of instruments (High Resolution Infrared Sounder HIRS, Microwave Sounder Unit MSU, Stratospheric Sounder Unit SSU, Total Ozone Mapping Spectrometer TOMS). Introduction of the TOVS data had a big positive impact on the quality of the Southern Hemisphere analysis. The Special Sensor Microwave Imager (SSM/I) started in 1987 and is particularly important for atmospheric water vapor and surface-wind assimilation over the ocean (*see* **Chapter 65, Estimation of Water Vapor and Clouds Using Microwave Sensors, Volume 2**). Another instrument that is important for the ocean-surface wind is the scatterometer in operation from different platforms since 1991. The scatterometer is an active instruments that takes information from backscattered radar signals from the ocean surface.

Although the analysis system may be the same for the entire analysis period, the results are still affected by changes in the observing system. Figure 3 shows the number of reports from radiosondes, satellites, and surface observations over the years. It was a design choice of ERA-40 to make maximum use of all available observations. The biggest change over the ERA-40 period is in the satellite data, which is particularly relevant for the Southern Hemisphere where the number of conventional observations is limited.

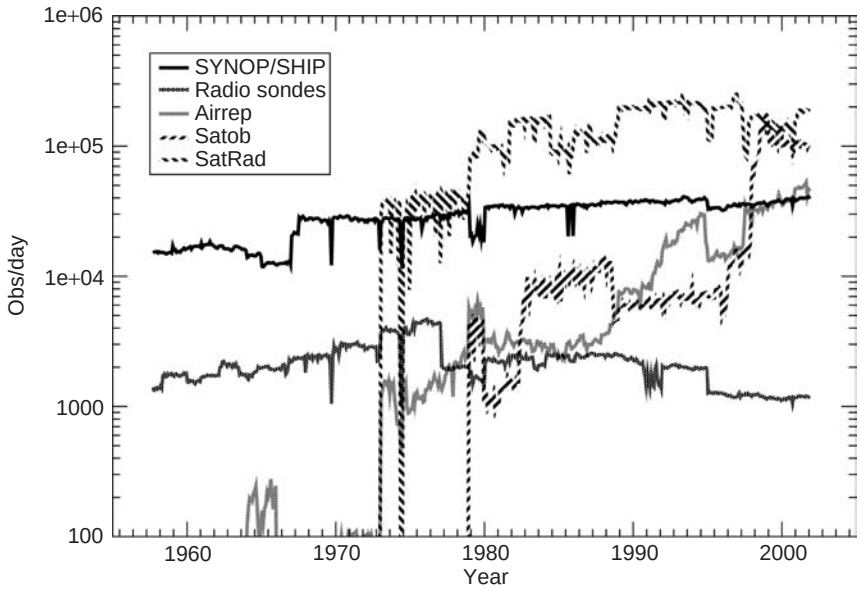

Figure 3 Number of observations of different type during the ERA-40 period in number of reports per day. SYNOP/SHIP's are the conventional surface observations over land and ocean, Radiosondes are conventional upper air observations, AIREP's are the aircraft reports, SATOB's are the geostationary satellite cloud track winds, and SATRAD are the satellite radiance observations. THE ATMOSPHERIC BRANCH OF THE HYDROLOGICAL CYCLE

Atmospheric moisture is obviously a key component of the hydrological cycle (*see* **Chapter 25, Global Energy and Water Balances, Volume 1**). It is a greenhouse gas, a major carrier of energy and highly relevant for precipitation. However, it is fair to say that the analysis of moisture in the atmosphere is still in its infancy as most of the development in data assimilation has been on temperature and wind. Routine moisture observations are difficult, often biased and one may wonder how accurate an atmospheric analysis of moisture is. Moisture is constrained by other variables and influenced by horizontal and vertical advection. Over the ocean, SSM/I radiances are used to control vertically integrated moisture. An example of vertically integrated water vapor is given in Figure 4. The model first guess is compared with an independent retrieval from SSM/I with an empirical algorithm (*see* **Chapter 65, Estimation of Water Vapor and Clouds Using Microwave Sensors, Volume 2**). The patterns of the vertically integrated moisture are remarkably similar, which suggests that the moisture variability is well captured by the analysis system. This is also clear from a 17-month-long time series of moisture difference between the sea surface and the 3.2 m level (model interpolated to the buoy observation level) compared to observations from the PACS buoy (not assimilated) in the Eastern Pacific (Figure 5). This difference is controlled by exchange with the surface, by advection, by evaporation of

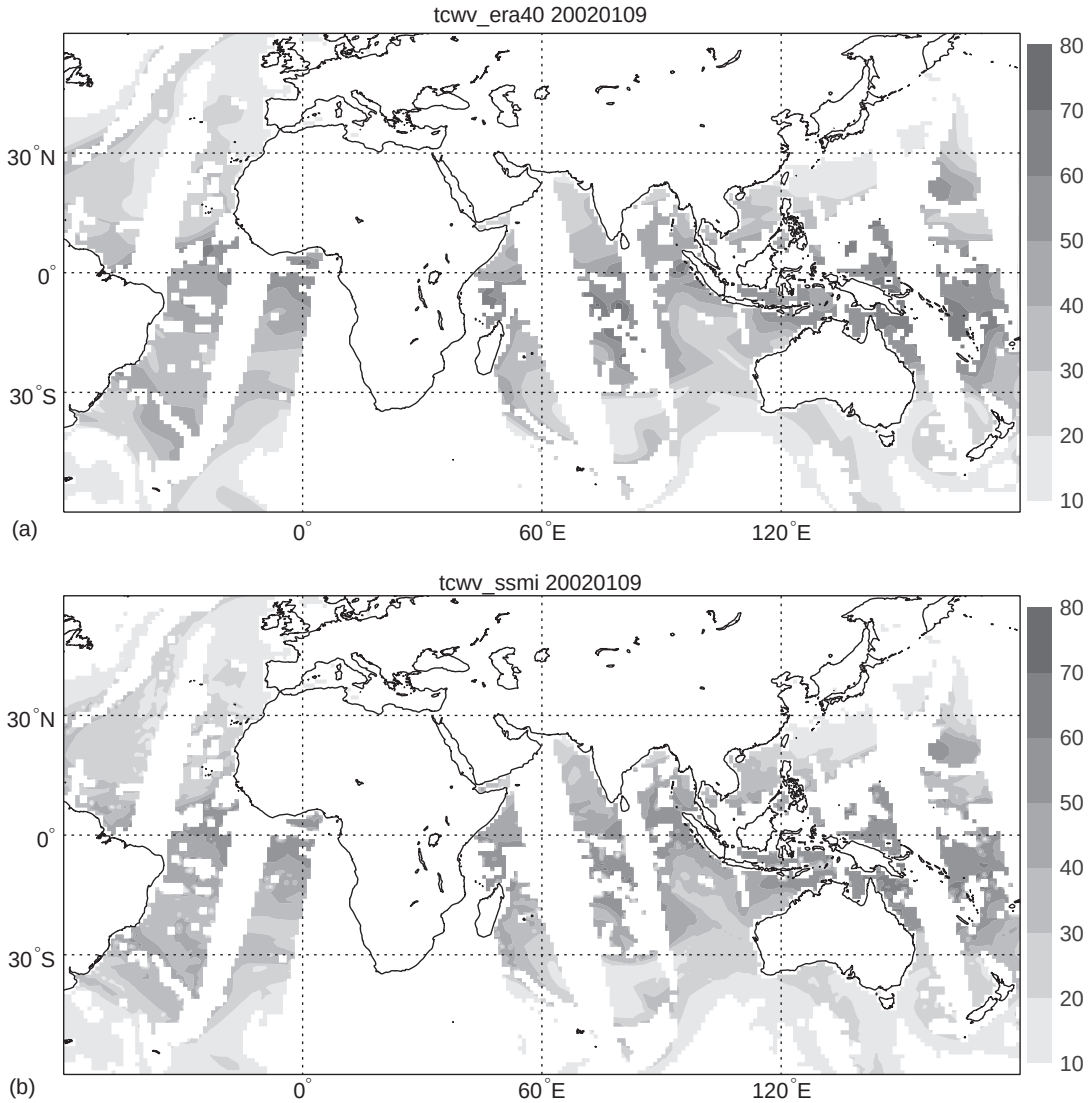

Figure 4 Total column water vapor in kg/m^2 from ERA-40 (a) and from an empirical algorithm using SSMI (b). For both plots, a mask has been applied that excludes missing SSMI data and areas where SSMI is contaminated by rain. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

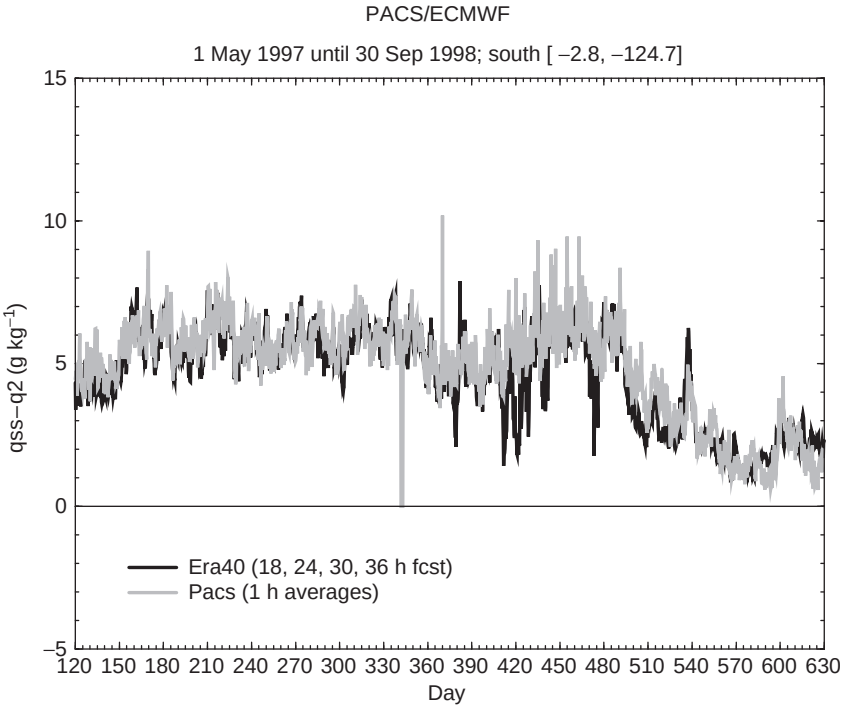

Figure 5 Time series of moisture difference between the sea surface and the observation level of 3.2 m in the Western Pacific (3 °S, 125 °W). ERA-40 data are black and PACS buoy observations are in grey (data are provided by the Woods Hole Institute of Oceanography; Weller and Anderson, 1996). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

precipitation, and mixing processes in the boundary layer that transport moisture away from the surface. A considerable amount of the variability as seen in the observations is captured by the short-range forecasts (18-, 24-, 30-, and 36-h forecasts). The last months of this period are particularly interesting because a cold SST anomaly develops, resulting in advection of warm moist air over a relatively cold surface which reduces the ocean/air moisture difference. This example clearly illustrates that particularly in data-sparse areas, the dynamical information is important for the moisture analysis.

Precipitation is a parameter that is not analyzed directly but it is simulated by the model physics during short-range forecasts. Two types of precipitation are distinguished: (i) convective precipitation due to condensation in convective updraught in moist unstable areas, and (ii) large-scale precipitation due to microphysical processes in clouds for example, in frontal areas with large-scale ascent, and also in convective areas where the convection scheme detrains ice to the cloud variables. Figure 6 shows a 3-h average of total precipitation from ERA-40, compared to retrievals of rainfall over the oceans from the TRMM Micro wave Instrument (TMI), which was not used in ERA-40. The main precipitation areas are well captured, although there are big differences in the details. This is partially because the ERA-40 precipitation chart represents the average over 3 h, whereas the TMI product is a snap shot. Furthermore, TMI is not capable of detecting the low precipitation rates. However, this Figure indicates that the synoptic variability is captured and that the ERA-40 system tends to smear out the precipitation fields due to its spatial and temporal averaging.

Figure 7 shows monthly averages of 12- to 24-h forecasts from ERA-40 as a scatter plot against Global Precipitation Climatology Project (GPCP) data (over land mainly based on gauge data (*see* **Chapter 35, Rainfall Measurement: Gauges, Volume 1**)). The correlation is rather good in all climatological regimes but systematic biases do exist and depend on the area. In a comparison with independent data over the Mackenzie catchment area, Betts *et al.* (2003) found a good correspondence for monthly averaged precipitation with errors of the order of 10% dependent on the period (i.e. dependent on the data that went into the system) and dependent on forecast range.

The largest bias is seen over the tropical oceans and is related to the so-called spinup problem. A time series of monthly tropical mean precipitation is shown in Figure 8 (c). The level of precipitation is substantially higher than for example, the GPCP estimate which is a little over 3 mm day^{-1}. In the ERA-40 system, some of the difference is related to an imbalance between model and satellite observations. The satellite observations add moisture to the

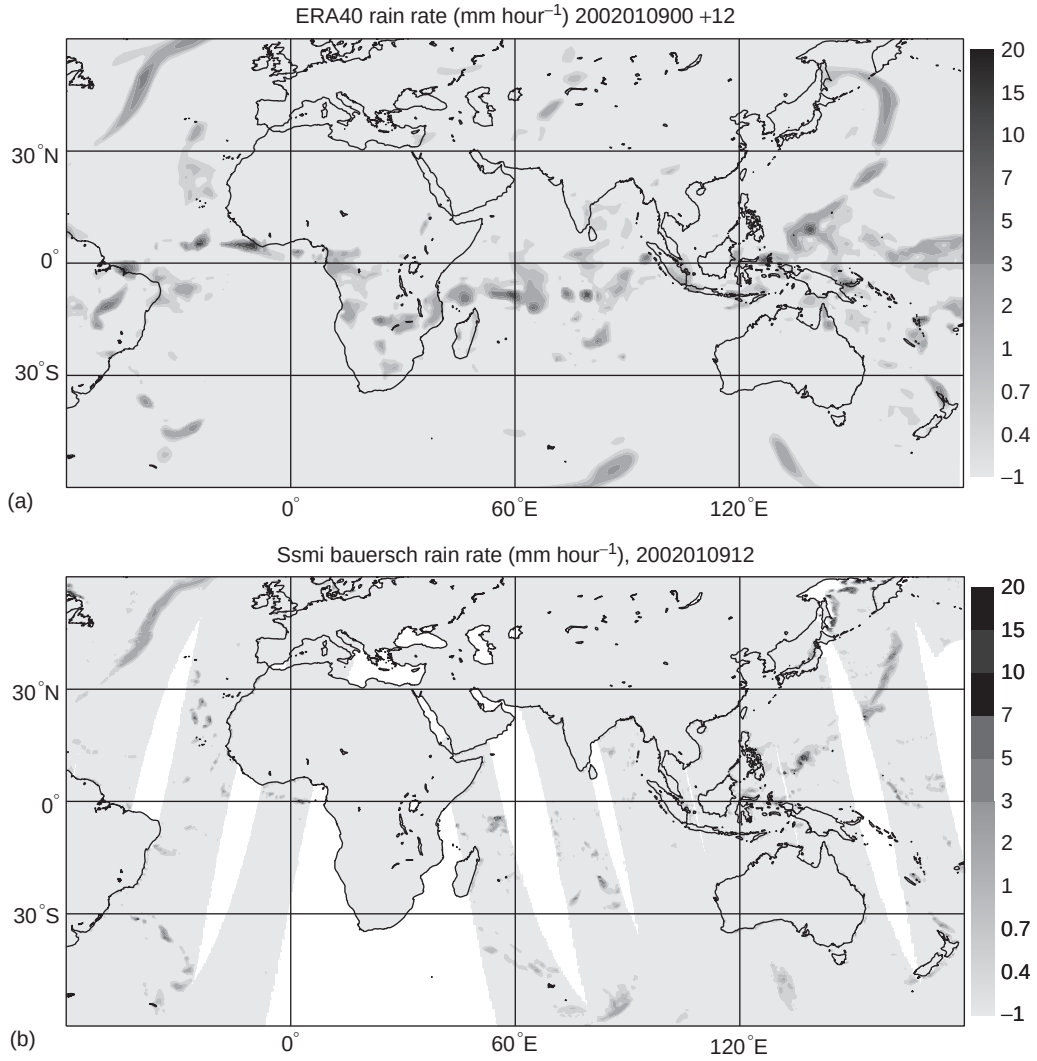

Figure 6 Example of a 3-hourly averaged precipitation field from ERA-40 (a) and a retrieval of instantaneous precipitation over the ocean from TMI with the Bauer and Schlüssel (1993) algorithm. (b) The 3-hourly period is from 9 to 12 UTC 20020109. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

system in a systematic way and this moisture rains out in the beginning of the forecast. This is illustrated in the part (b) and (c) of Figure 8. The amount of atmospheric moisture increases in the analysis with the introduction of satellite observations. Also, the increments (i.e. the amount of moisture that is added by the analysis to the first guess using observations) increase in time. Before the satellite era, there are virtually no increments. The introduction of VTPR in 1973 is clearly visible and later the increments increase with the growing number of satellite observations. The increased increments of total column water vapor applied 4 times per day, actually match the increased precipitation rather closely, suggesting that the added water vapor leads to additional but spurious rain during the early hours of the forecasts. The grey curve (from daily 12- to 36-h precipitation) and the black curve (from 0 to 6 h precipitation 4 times per day) in the part (c) of Figure 8, show a slight increase of precipitation with forecast range in the presatellite era and a systematic decrease later. The spin-down of moisture is only 2 to 5% and is within calibration accuracy of most instruments. However, in terms of precipitation, the additional amount of moisture put into the system every 6 h is very large and leads to substantial biases. The character of the precipitation spin-down is further illustrated in Figure 9, showing that it takes about three to four days for the model to reach its own equilibrium. The reason is that the excessive latent heat release during the 6-h data assimilation cycling maintains a Hadley circulation that is about 20% stronger than in the model climate (not shown). It is difficult to verify the strength of the Hadley circulation, but the spin-down over a period of a few days is obviously an artifact of the data assimilation system.

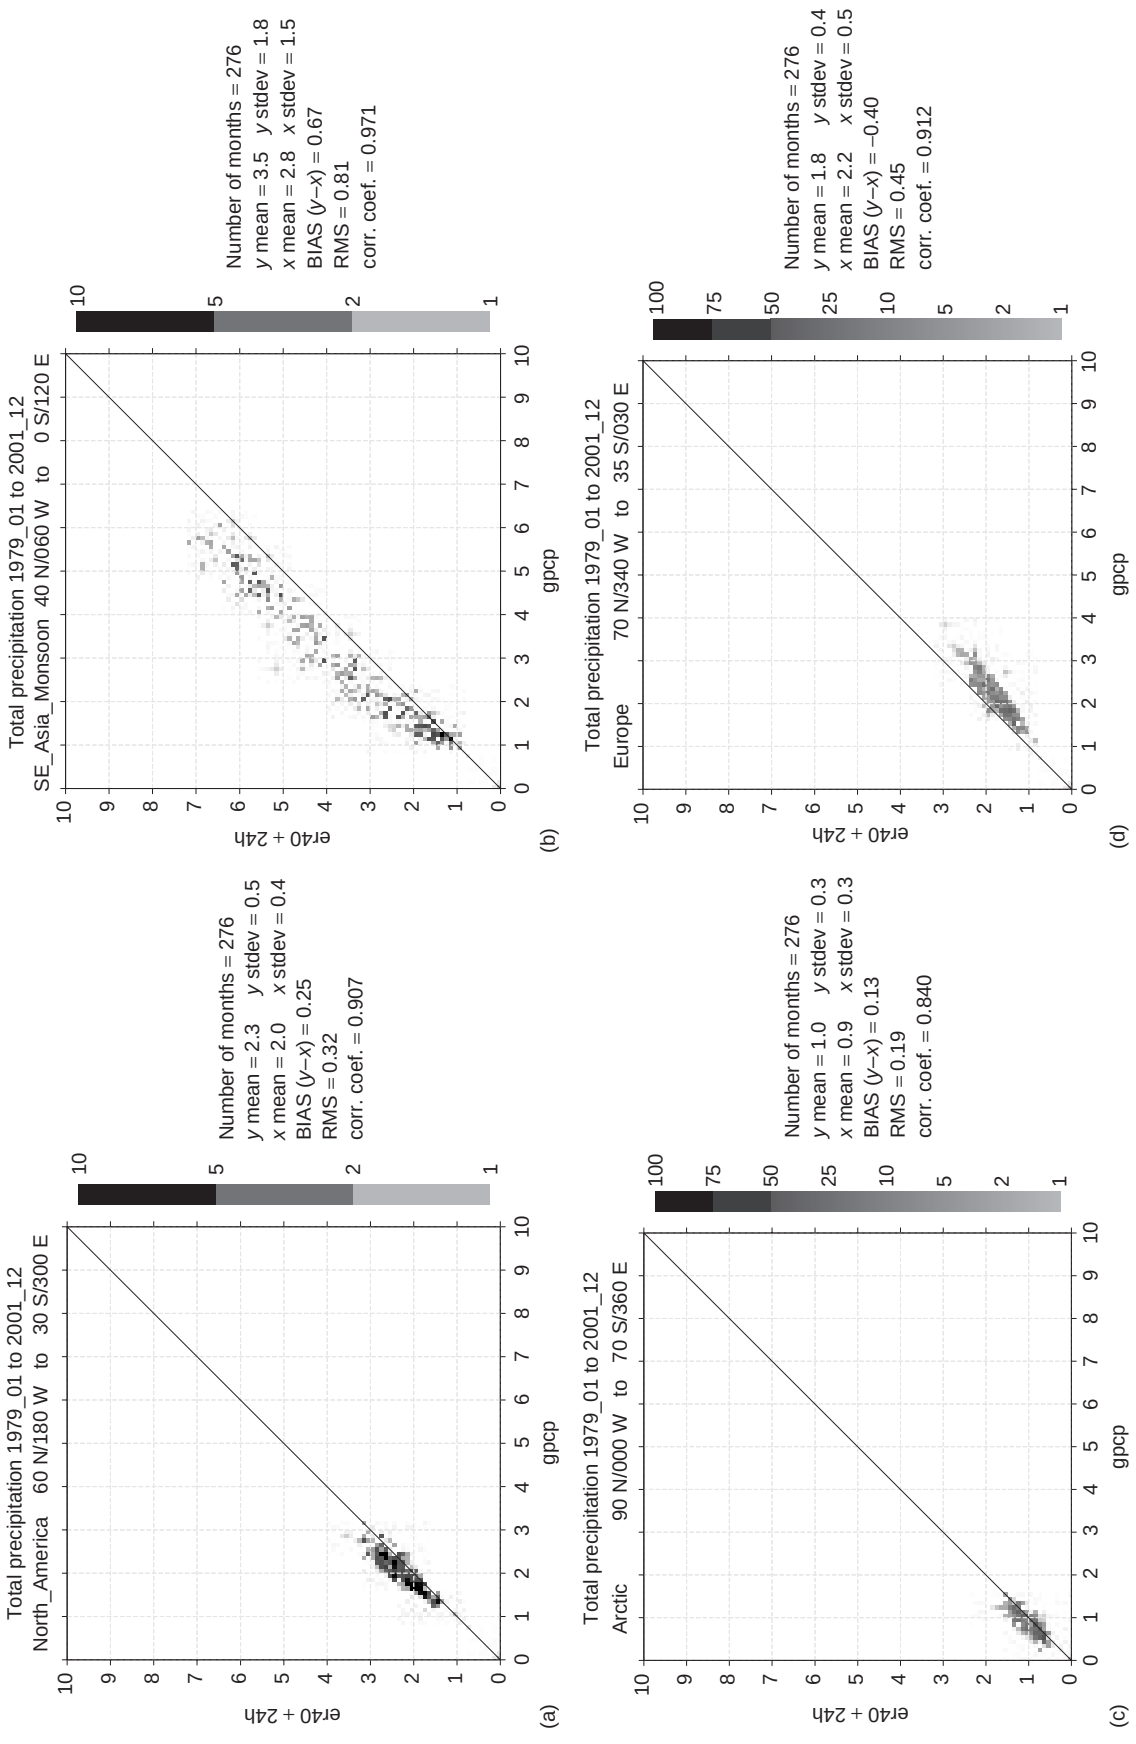

Figure 7 Monthly total precipitation over four different areas from ERA-40 1979–2001 compared to GPCP data. The units are mm day^{-1}; the number of points are color coded. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

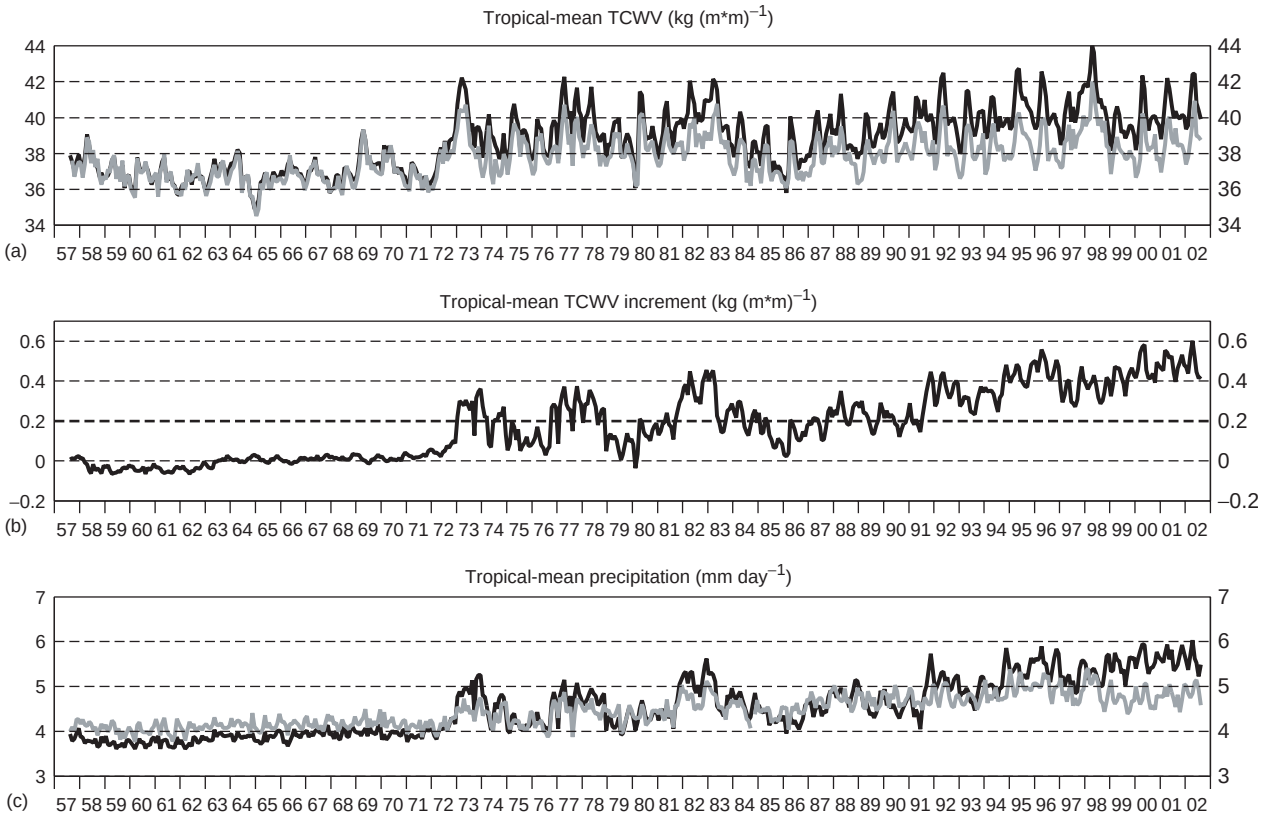

Figure 8 Time series of monthly tropical mean total column water vapor (TCWV, a), TCWV increment every 6-hourly analysis cycle (b), and precipitation (c). In part (a), the black curve is the analysis and the grey curve the 24-h forecast. In part (c), the black curve is from 0- to 6-h forecasts 4 times per day and the grey curve is from the 12 to 36-h daily forecasts. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

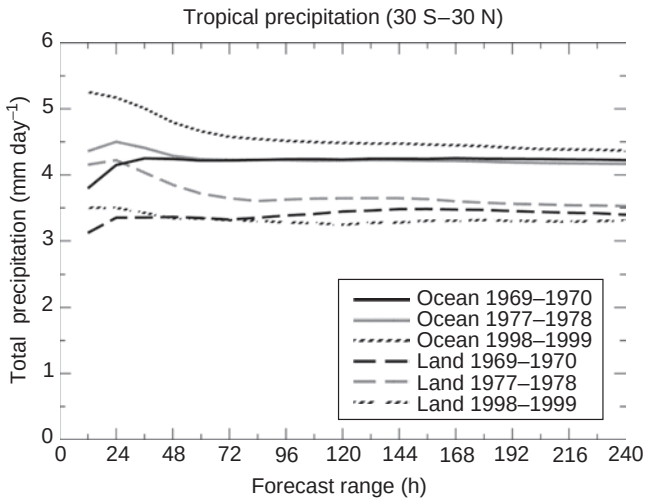

Figure 9 Evolution tropical precipitation averaged over the ocean (solid), land (dashed) during the 10-day forecast for 2-year periods with different observing systems. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

To summarize, ERA-40 was designed to use as much available data as possible, resulting in a good representation of synoptic variability. The side effect is that a too active hydrological cycle is maintained in the tropics due to a slight imbalance in moisture between observations and model. It is difficult to say whether the bias is due to model errors, due to observation biases or due to the way the observations are used. Precipitation over tropical oceans is highly biased compared to GPCP and drifts to higher values with the increasing number of satellite observations.

TURBULENT FLUXES OVER THE OCEAN

Ocean fluxes are important for a variety of applications for example, budget studies, ocean modeling, ocean wave simulations. Several climatologies of ocean fluxes exist, based on ship observations and/or satellite observations and NWP analysis products. A good review of these products and a comprehensive intercomparison study is given by Taylor (2000). In their basic form, most products do not satisfy the global energy and water-budget constraints, and therefore adaptations are often made. The resulting products that focus on say monthly climatology tend to have closed energy and water budgets by construction, but they do not have the day-to-day variability. NWP products are at the other extreme; they have the short timescale variability (diurnal, synoptic), but they do not (yet) satisfy large-scale budget constraints.

An example of a 10-year average of surface-latent heat flux of ERA-40 is shown in Figure 10. Such a field looks very similar to other climatologies (e.g. the da Silva *et al.*, 1994 climatology as shown in Figure 10), but it is very difficult to give estimates of uncertainty. Therefore, a

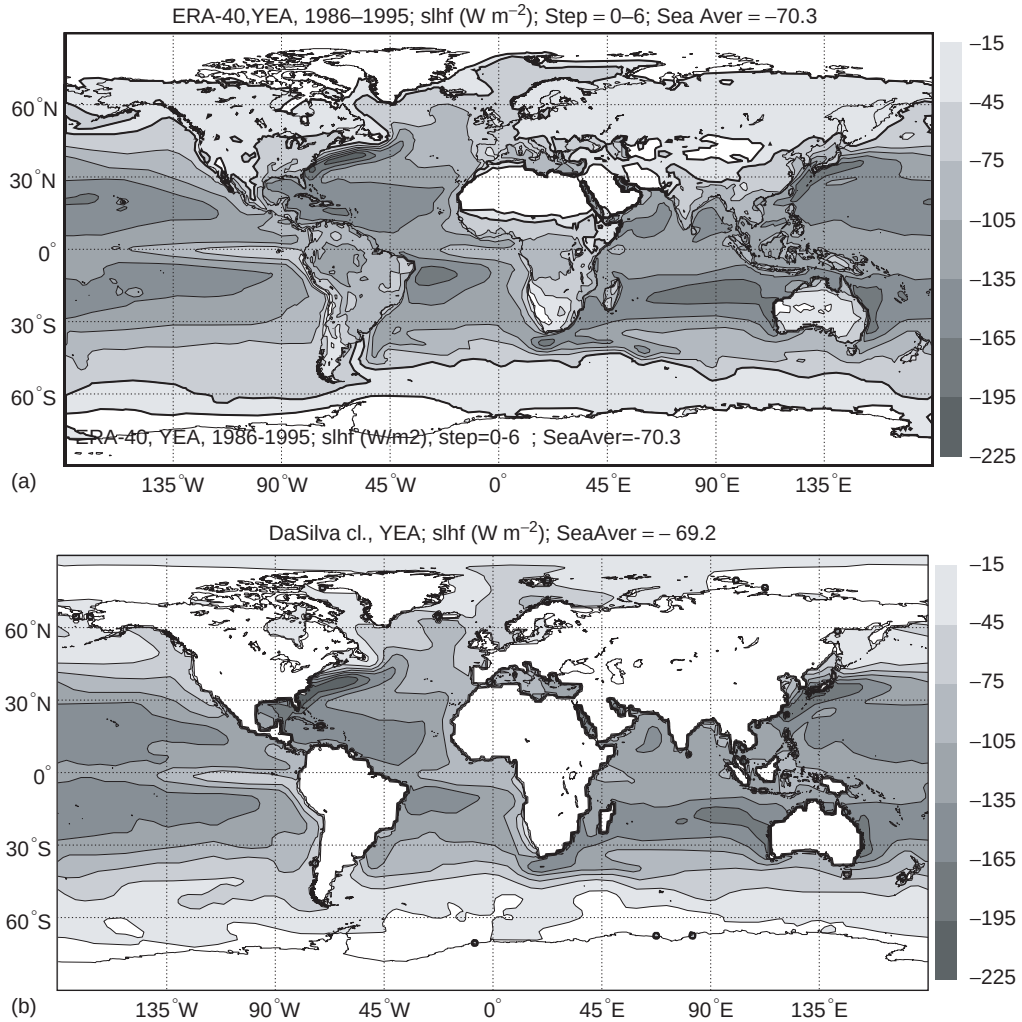

Figure 10 Surface-latent heat flux from ERA-40 averaged from 1986 to 1995 (a) and the climatology over the ocean by da Silva *et al.* 1994, (b). Negative fluxes are upward. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

comparison is made with research-quality buoy data that are not used in the ERA-40 assimilation. Point observations over the open ocean are representative for a large area because of the homogeneity of the ocean surface. Time series of 6-hourly fluxes of latent heat and net solar fluxes for the Atlantic IMET buoy (Weller and Anderson, 1996) are shown in Figure 11 in comparison with the ERA-40 fluxes. The reanalysis fluxes follow the observations very well, although small systematic biases exist. This Figure again illustrates that the analysis products do have a very realistic level of variability even in data-sparse areas over the ocean.

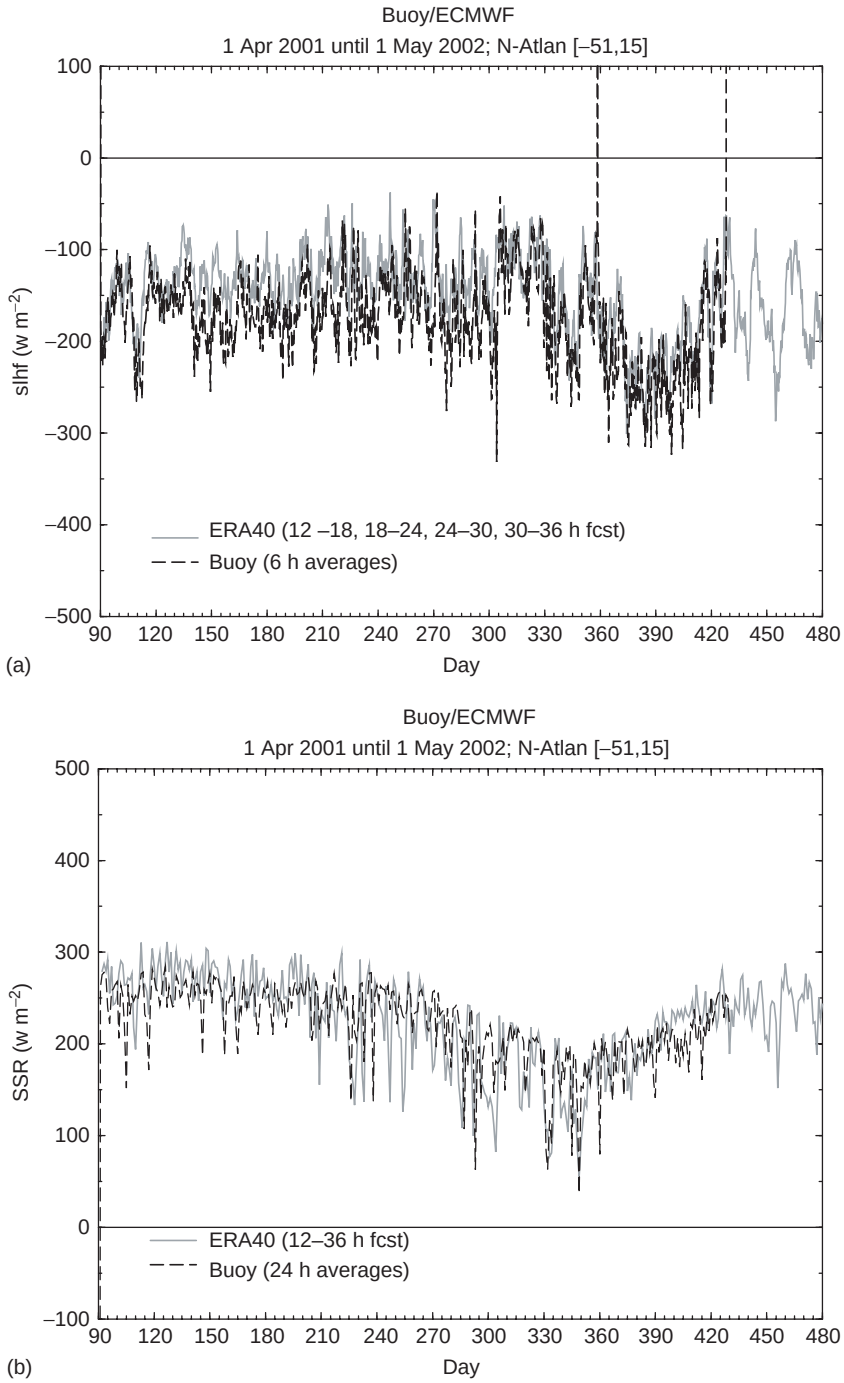

Figure 11 Time series of 6-hourly latent flux (a) and net solar radiation (b) from the Atlantic IMET buoy (51 °W/15 °N) and ERA-40. The time period is from 1 April 2001 to 1 May 2002 (data provided by the Woods Hole Institute of Oceanography; Weller and Anderson, 1996). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

TURBULENT FLUXES OVER LAND

Fluxes over land from reanalyses are more uncertain than fluxes over the ocean. Over the ocean, there is a fairly well-observed boundary condition, namely, the sea-surface temperature, which makes the turbulent fluxes only dependent on atmospheric variables (wind, temperature, and specific humidity) and on the air-sea transfer coefficients which are reasonably well known (Zeng *et al.*, 1998). Over land, the situation is much more complicated. There is a close balance between available energy at the surface (net radiation) and the sensible and latent heat fluxes, with the ground heat flux as a small residual (at least during day time). The partitioning between sensible and latent heat flux is controlled by soil moisture availability with near-surface soil moisture affecting bare soil evaporation and the root zone soil moisture controlling the plant transpiration (*see* **Chapter 70, Transpiration and Root Water Uptake, Volume 2**). The land-surface system is very complex and only represented in models in a very simplified way, so there is a real question about the accuracy of reanalysis fluxes over land.

On the other hand, climatology of turbulent surface fluxes over land is virtually nonexistent, because simple and robust observational methods are not available. So, reanalysis products and other model-derived products are well worth exploring. Verification is possible with new technology that allows for flux observations with reasonable accuracy at research sites (e.g. with eddy correlation equipment (*see* **Chapter 40, Evaporation Measurement, Volume 1**)). Many "flux towers" exist with most of them providing data during campaigns. This material is ideal for verification over land, because it is completely independent of the reanalysis. An example of a 5-year time series of 7-day averages of fluxes is presented in Figure 12 for the Cabauw location in the Netherlands. The part (a) of the Figure 12 shows that the downward short-wave radiation in the model has a good annual cycle, but also a very reasonable variability on the weekly timescale. The latter means that clouds are sufficiently well represented to modulate the solar radiation in a realistic way. The net radiation shows the same variability but has a positive bias, which is probably related to a difference in surface albedo between the observational site (0.23) and the model value for this area (0.18). The ratio of sensible and latent heat fluxes (Bowen ratio) is fairly small, because evaporation is seldom restricted by soil moisture. The consequence is that latent heat flux dominates and follows the net radiation and shows relatively small errors. The biggest errors are seen in the sensible heat flux with generally an overestimation of the upward flux (negative) in summer and also an overestimation of the downward heat flux (positive) in winter.

Comparisons as shown in this section are not without problems. Point observations may not be representative for a large area, and observations often have problems with closure of the surface-energy balance. However, with more observations becoming available and also observations over typical subareas of a grid box (e.g. over forest as well as low vegetation), it will be possible to reduce the uncertainty.

In spite of the uncertainties, reanalysis products are relevant for the energy and moisture budgets over land, because very little other information exists. Existing climatologies are based on long-term averages of observed radiation, precipitation and runoff, but are obviously limited to large areas and exclude the short timescales (Brutsaert, 1982). Reanalysis in conjunction with many *in situ* observations and budget constraints will hopefully lead to good documentation of biases and deficiencies. It may even be possible to improve the reanalysis products by applying corrections.

OPTIONS FOR RESEARCH

Reanalyses generate a wealth of information covering timescales from a few hours to the full length of a reanalysis with a spatial resolution of typically 100 km. This data is very useful in the study of atmospheric processes, and in the study of large-scale budgets. Parameters that are not analyzed directly are only indirectly constrained by observations and may be model dependent. It is therefore important to intercompare products and do validation studies using independent data. The Coordinated Enhanced Observing Period (CEOP) by the GEWEX Hydrometeorology Panel is such an initiative. CEOP gathers analysis products and research-quality observations at different locations to allow for validation and large-scale budget studies. Such studies will give important information on the quality of analysis products and will also suggest correction procedures for systematic errors.

An example of a large-scale budget study is given by Seneviratne *et al.* (2004). They use the vertically integrated atmospheric moisture field and its convergence from ERA-40 to determine the net moisture flux at the surface (precipitation minus evaporation) and compare it with the observed soil moisture budgets (soil moisture change minus runoff). Figure 13 shows a good correspondence between the atmospheric and soil budgets. It means that the analysis of moisture in this area is sufficiently accurate to give information about the soil water budget. It should be remembered that this is an area with a rather good radiosonde network to constrain the moisture field. The traditional way of doing moisture budgets is to use the radiosonde data only (Peixoto and Oort, 1992). Data assimilation has a clear advantage here, because: (i) the system provides consistency with other observations like temperature and wind, (ii) the system also uses other observations for example, surface observations, aircraft reports, and satellite data,

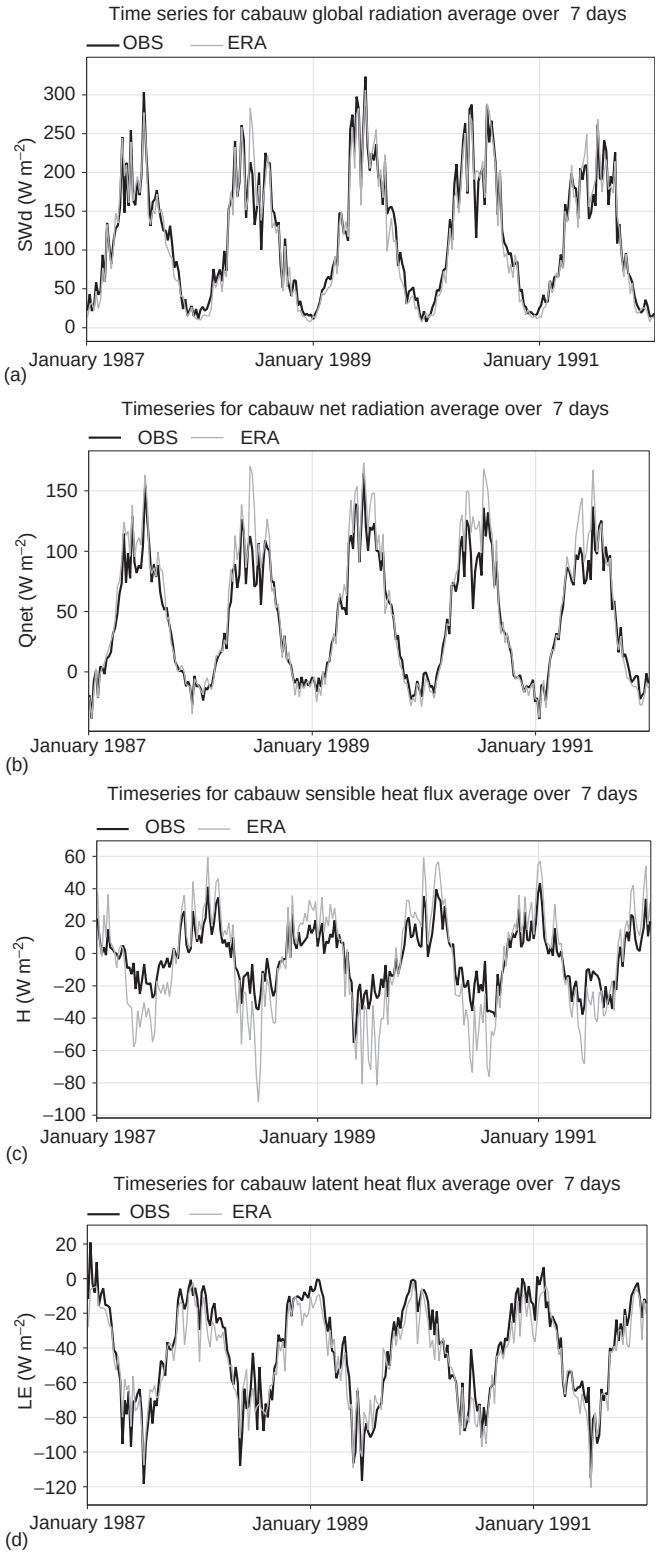

Figure 12 Time series of weekly averages of downward solar radiation (a), net radiation (b), sensible heat flux (c) and latent heat flux (d) from ERA-40 compared to observations at the Cabauw tower in the Netherlands (Beljaars and Bosveld, 1997). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

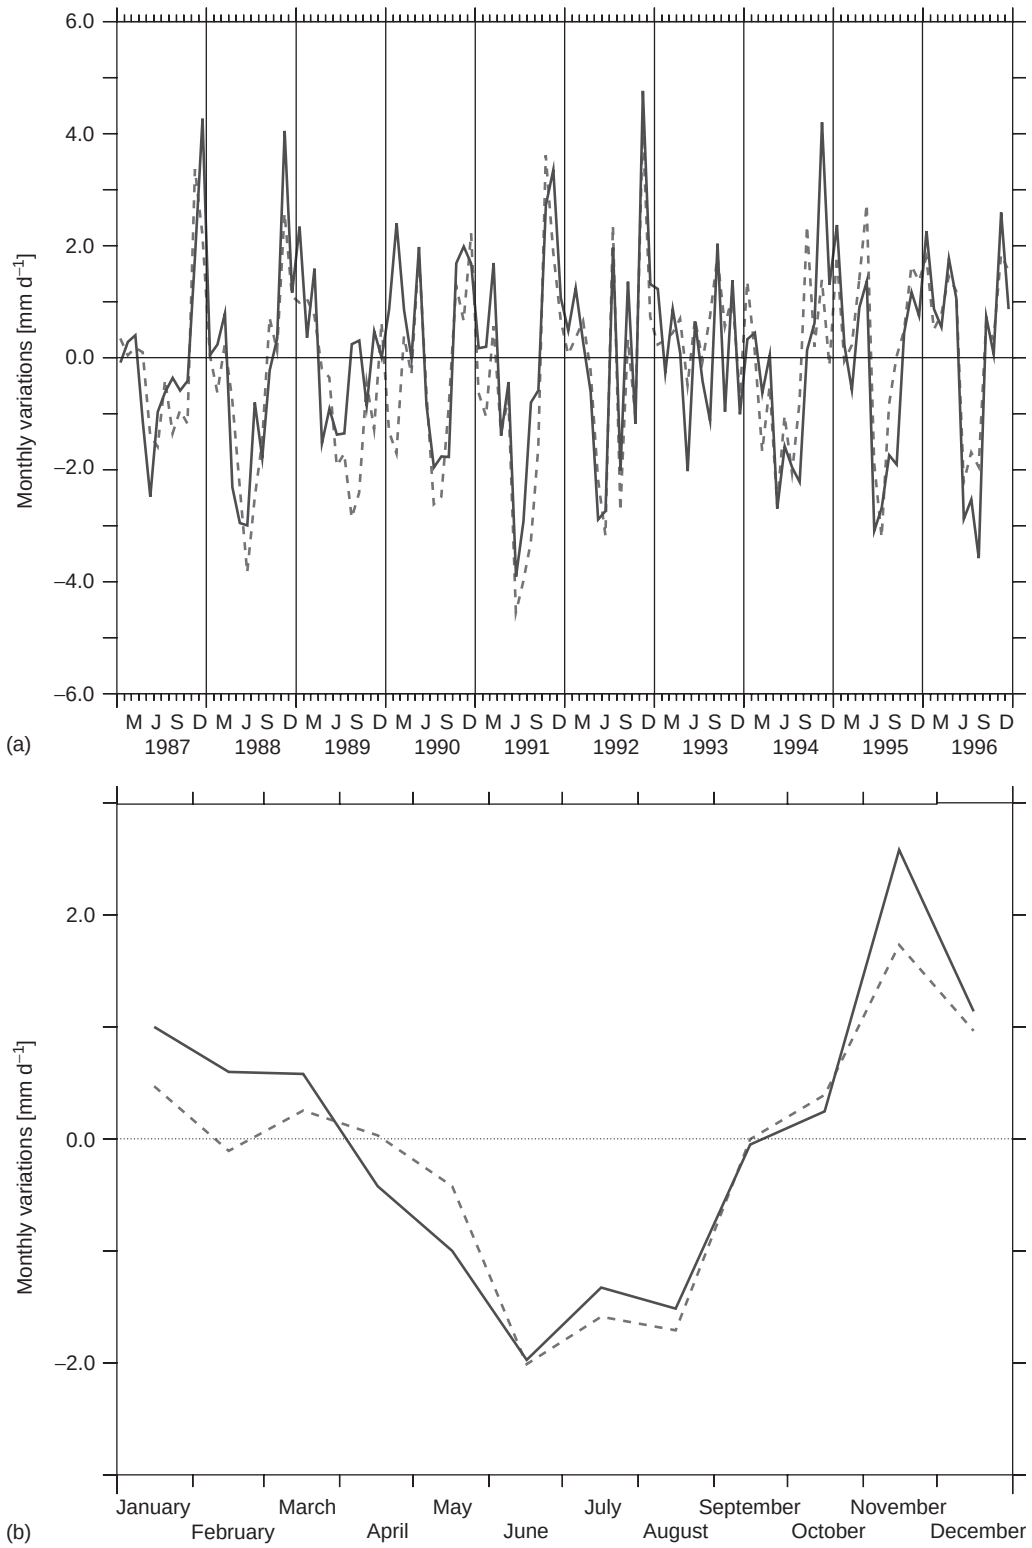

Figure 13 Atmospheric moisture convergence minus runoff minus the change of atmospheric moisture content (dashed) compared to the observed change of soil moisture content (solid) for a river catchment area in Illinois. The atmospheric moisture convergence and the atmospheric moisture content are from ERA-40. The figure (a) shows a 10-year time series of monthly averages. The figure (b) represents the mean annual cycle. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

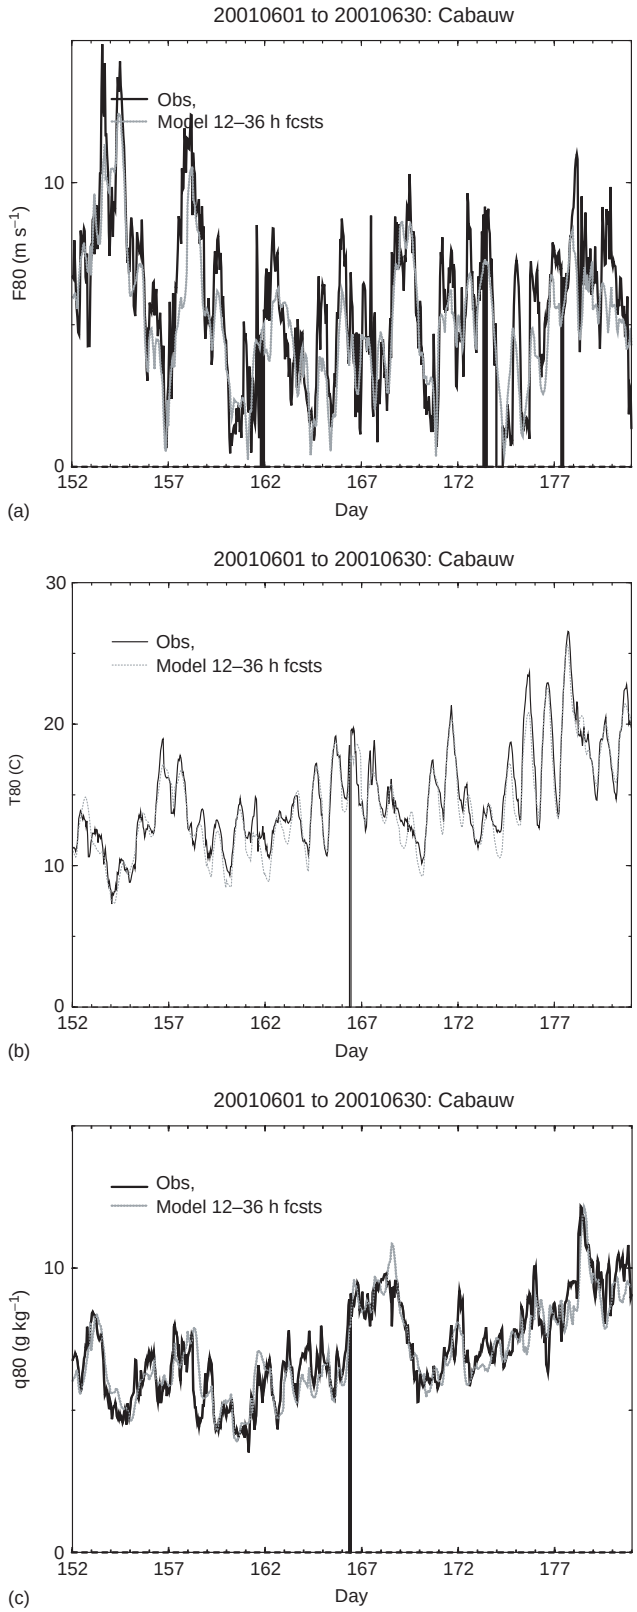

Figure 14 Time series for June 2001 of hourly observations of wind speed (a), temperature (b) and specific humidity (c) from the Cabauw tower in the Netherlands at a height of 80 m, together with hourly ERA-40 data at 100 m from the nearest grid point (the observations have been provided by Fred Bosveld from KNMI)

(iii) it is trivial to compute moisture convergence from the gridded results, and (iv) data assimilation has high time resolution.

Another example of an application is the analysis of soil moisture on a continental scale. Soil moisture observations are difficult and not available on a global scale. Therefore, land-surface models are used to simulate soil moisture using observed atmospheric forcing, that is, downward radiation, precipitation, wind, temperature, and moisture at some height above the surface. The resulting soil moisture products are model dependent and comparison of different models is used to gauge the uncertainty (Dirmeyer *et al.*, 1999). Of course, soil moisture from reanalysis can be used directly, but in this case precipitation and radiation are also simulated by a model rather than observed. To drive land-surface models with an atmospheric boundary condition, gridded fields of temperature, moisture, and wind are needed with sufficient time resolution to resolve the diurnal cycle. Reanalysis fields are highly suitable for such an application, and therefore ERA-40 data is one of the data sets to be used in the ISLSCP-II project (International Satellite Land Surface Climatology Project), which is a follow-up of the ISLSCP-I project to collect land-surface data (see Sellers *et al.*, 1995), but now over a 10-year period. The choice of the height above the surface for atmospheric forcing is not obvious, therefore, two options are provided: the lowest model level at a height of about 10 m and the 4^{th} level from the surface which is at a height of about 100 m. The latter is believed to be the most suitable, because it is still fairly close to the surface, but is less influenced by the surface-boundary condition as used in ERA-40 (e.g. roughness lengths). A one-month time series of wind, temperature, and moisture is shown in Figure 14 compared to observations from the Cabauw mast in The Netherlands (not used by ERA-40). The time series shows the high level of realism of the basic atmospheric parameters even in the boundary layer, where boundary layer and land-surface parameterization aspects may play an important role. The high level of realism makes them very suitable for applications as forcing in land-surface models.

CONCLUDING REMARKS

Reanalysis is a powerful way of integrating a large volume and a wide range of atmospheric observations into a synthesis of the atmosphere and land surface, using the same state-of-the-art method over the entire period of interest. Reanalyses provide a wealth of atmospheric fields in a gridded format at high time resolution for a long period of time, and therefore open many options for research. Some reanalysis fields are more directly constrained by observations than others. For instance, the large-scale atmospheric flow and temperature are well represented, but model-derived fields or less well-observed fields (e.g. precipitation, moisture, turbulent, and radiative fluxes) are less accurate. We focused here on the hydrological cycle and concluded that many derived fields show realistic synoptic variability. Clear statements about the accuracy of the different elements of the hydrological cycle are difficult to make mainly because the accuracy of the verification material is not known. The moisture fields in ERA-40 might well be within calibration accuracy of most routine observations. However, there is a systematic mismatch of a few percent between moisture observations and the model equilibrium, leading to moisture increments in the tropics. This results in excessive oceanic precipitation in the tropics during the first days of the forecast and to a too active hydrological cycle. On the other hand, the ocean evaporation might be as accurate as existing monthly climatologies with the advantage of high time resolution. More research is needed to establish the accuracy.

Preliminary studies have shown that over well-observed land areas (e.g. North America and Europe) moisture convergence from reanalyses is a valuable product in the context of budget studies. Accuracy of precipitation depends on the area and is often between 10 and 20% for monthly averages. The largest uncertainty is in evaporation because of the lack of ground truth. Verification for a single station shows that the latent heat flux follows the net available energy rather closely, because it is a location with virtually no water stress. Many more stations and more research is needed to establish how accurate these surface fluxes are. Such research is timely because observation technology has evolved and many flux towers exist.

This article illustrates the large-scale connectivity of the atmosphere–ocean coupled system and generalizes the concept to regional scales and to other components of the earth system. Connections at a distance, or teleconnections, can occur by the direct transfer of mass by changes in regular circulations or by propagating waves initiated by a variety of mechanisms. Questions as to what extent recognized teleconnection patterns can be associated with identifiable forcing mechanisms, to what extent these patterns are interrelated and how they might cause, react to, or interact with changing forcing such as changes in atmospheric composition, land cover, or the distribution of sea ice to produce climate changes are examined.

INTRODUCTION

The term teleconnection is usually defined as a coherent atmospheric response to remote forcing such as particular sea surface temperature or atmospheric pressure patterns. The term is generally applied to a disturbance in the atmospheric circulation that is persistent and of large spatial scale (continental and above). However, a more complete definition should refer to a teleconnection as any transmission of a coherent effect beyond the location at which a forcing occurred. Seasonal weather forecasters noticed certain persistent atmospheric circulation features and were using these patterns for seasonal weather forecasts by the 1950s based on theoretical development by Bjerknes and Rossby in the previous decades (Namias, 1953, 1959).

Circulating fluids, such as the atmosphere and oceans, communicate information over large parts their volume and these teleconnections can be defined to occur in two ways. First, the atmosphere and oceans organize themselves into coherent circulations on a variety of time and spatial scales. These include the Hadley cell, subtropical jet streams, monsoons, sea and mountain breezes, and the oceanic thermohaline circulation. A change to the overall strength or position of the circulation will generally be noticeable over a wide area. Secondly, disturbances associated with these coherent circulations generate waves of several kinds that propagate in fluids in different ways and can be quite persistent. These waves do not necessarily follow the path of the coherent circulations mentioned above and can generate regional climate anomalies far from the source of the original disturbance.

The atmosphere–ocean system appears to oscillate in certain quasi-periodic teleconnection patterns that typically move between different states on a variety of timescales (Barnston and Livzey, 1987). These transitions between states can be quite abrupt or rather gradual, both indicative of the nonlinear character of the climate system (Rial *et al.* 2004). Recognizable climate anomalies associated with each phase of a particular oscillation are then transmitted over wide areas of the globe through the mechanisms mentioned above.

The simplest way to identify such patterns in observational data is to choose points on the globe and correlate that point with every other point. In this way, coherent regions of correlation and anticorrelation may become apparent. More sophisticated statistical methods, such as empirical orthogonal function (EOF) analysis or rotated principal component analysis (RPCA), seek to isolate independent patterns and to maximize the variability associated with the major patterns. Recognized teleconnection patterns seem to result from the internal dynamics of the atmosphere and/or ocean rather than from forcing from outside the

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

earth system and for this reason they are often referred to as natural modes of variability. Teleconnections offer potential long-term weather predictability based on their persistence and oscillatory behavior and potentially hold the key to understanding the relation between natural and anthropogenic climate change.

Several critical questions as to the nature and mechanics of teleconnections, however, remain. These questions reflect uncertainty as to how to define more-or-less independent patterns and how individual patterns are related to each other, to what extent teleconnection patterns can be associated with a response to an identifiable forcing mechanism, what physical mechanisms are involved in a propagating pattern, and finally, how might teleconnection patterns react to, or interact with, changing forcing such as a atmospheric composition changes, land-cover changes, or changes in the distribution of sea ice? The United States Climate Prediction Center actively monitors 13 separate teleconnection patterns in the Northern Hemisphere for weather and climate forecasting purposes. We will not discuss each pattern extensively, but instead use several of the major teleconnection patterns as illustrations of the remaining uncertainties.

We begin with the apparently more complicated teleconnections, those involving both the atmosphere and the oceans including El Niño/Southern Oscillation and the Madden–Julian Oscillation (MJO).

TYPES OF TELECONNECTIONS

Ocean to Atmosphere/Atmosphere to Ocean

El Niño/Southern Oscillation

El Niño/Southern Oscillation (ENSO) teleconnection patterns can be thought of as resulting from the interannual warming and cooling of equatorial Pacific sea surface temperatures (SSTs) and associated atmospheric circulation changes. This is an arbitrary starting point in the cycle as the changes in SST are likely themselves the result of distant atmospheric and oceanic forcing. ENSO appears to be the result of a series of internal interactions and feedbacks between ocean and atmosphere. The opposing phases of ENSO, the warm El Niño and the cold La Niña, though occurring quasi-periodically with roughly a 3–7 year cycle, have not proved to be highly predictable (Landsea and Knaff, 2000) despite considerable effort.

The ENSO cycle has weather and climate implications in the tropics and across the extra-tropics of both hemispheres. Climatologically, the warmest water in the equatorial Pacific occurs in the western Pacific warm pool (Figure 1a). The tropical signature of El Niño include large, persistent, warm SST anomalies in the eastern and central equatorial Pacific (Figure 1b), a relaxation of the easterly, near-surface winds; an anomalous tilting of the thermocline along the equator towards the east and an associated reduction in cold, nutrient-rich upwelling waters in the eastern equatorial Pacific which in turn affects fisheries production. Warm SST anomalies in the central and eastern Pacific are thought to be caused by an eastward traveling oceanic Kelvin wave following the relaxation of surface easterlies. This shift allows the main Pacific convective storm center from the western Pacific warm pool to shift to the east following the warm SST anomalies. The reduction in cold, upwelling waters in the eastern Pacific further enhances the warm SST anomaly. The La Niña pattern can be thought of as an amplification of the climatological SST patterns with unusually cold SSTs in the central and eastern Pacific and warm SSTs in the west (Figure 1c).

Rising motion due to convective storms in regions of high SST form the starting point for the entire large-scale, tropical circulation, including the north–south Hadley cell and the east–west Walker cells. Changes in the magnitude and spatial pattern of tropical convection therefore alter the magnitude and pattern of the Walker cells and affect the upper-level tropical outflow in the Hadley cell which feeds the higher latitude zonal jet (e.g. Bjerknes, 1969; Krishnamurti, 1961; Chen *et al.*, 1988; Oort and Yienger, 1996). The altered position of the Pacific Walker cell is such that large shifts in atmospheric mass occur with pressure drops in the eastern Pacific and increases to the west. This east-west change in pressure is the basis for the Southern Oscillation index (SOI), a measure of ENSO phase and strength.

Climatologically, rising air and therefore heavy precipitation occur in the western Pacific while the eastern Pacific is under the subsiding branch of the Walker circulation and so is relatively dry. El Niño causes shifts in tropical circulation, which generally create drier than average conditions in the western Pacific including Indonesia, Australia, and India and above average precipitation over parts of South America. El Niños also tend to cause warmer than average conditions over parts of the tropics and into the extra-tropics (Halpert and Ropelewski, 1992). El Niño patterns are so powerful that these events can generally be seen in a general warming of the area-averaged tropics. This warming can also be detected in the globally averaged temperature. For instance, 1998, a year of a very large El Niño event, is the warmest year of the satellite record in the global average. La Niña, on the other hand, is associated with enhanced rainfall in western Pacific regions and decreased rainfall in the central and east Pacific. La Niña is generally associated with cold regional anomalies that are less easily seen in the globally averaged temperature.

Individual El Niño events vary considerably from the average in terms of duration, time of onset and magnitude and appear to have certain longer-term fluctuations that hamper prediction. For instance, a strong and persistent correlation between reduced Indian monsoon rainfall

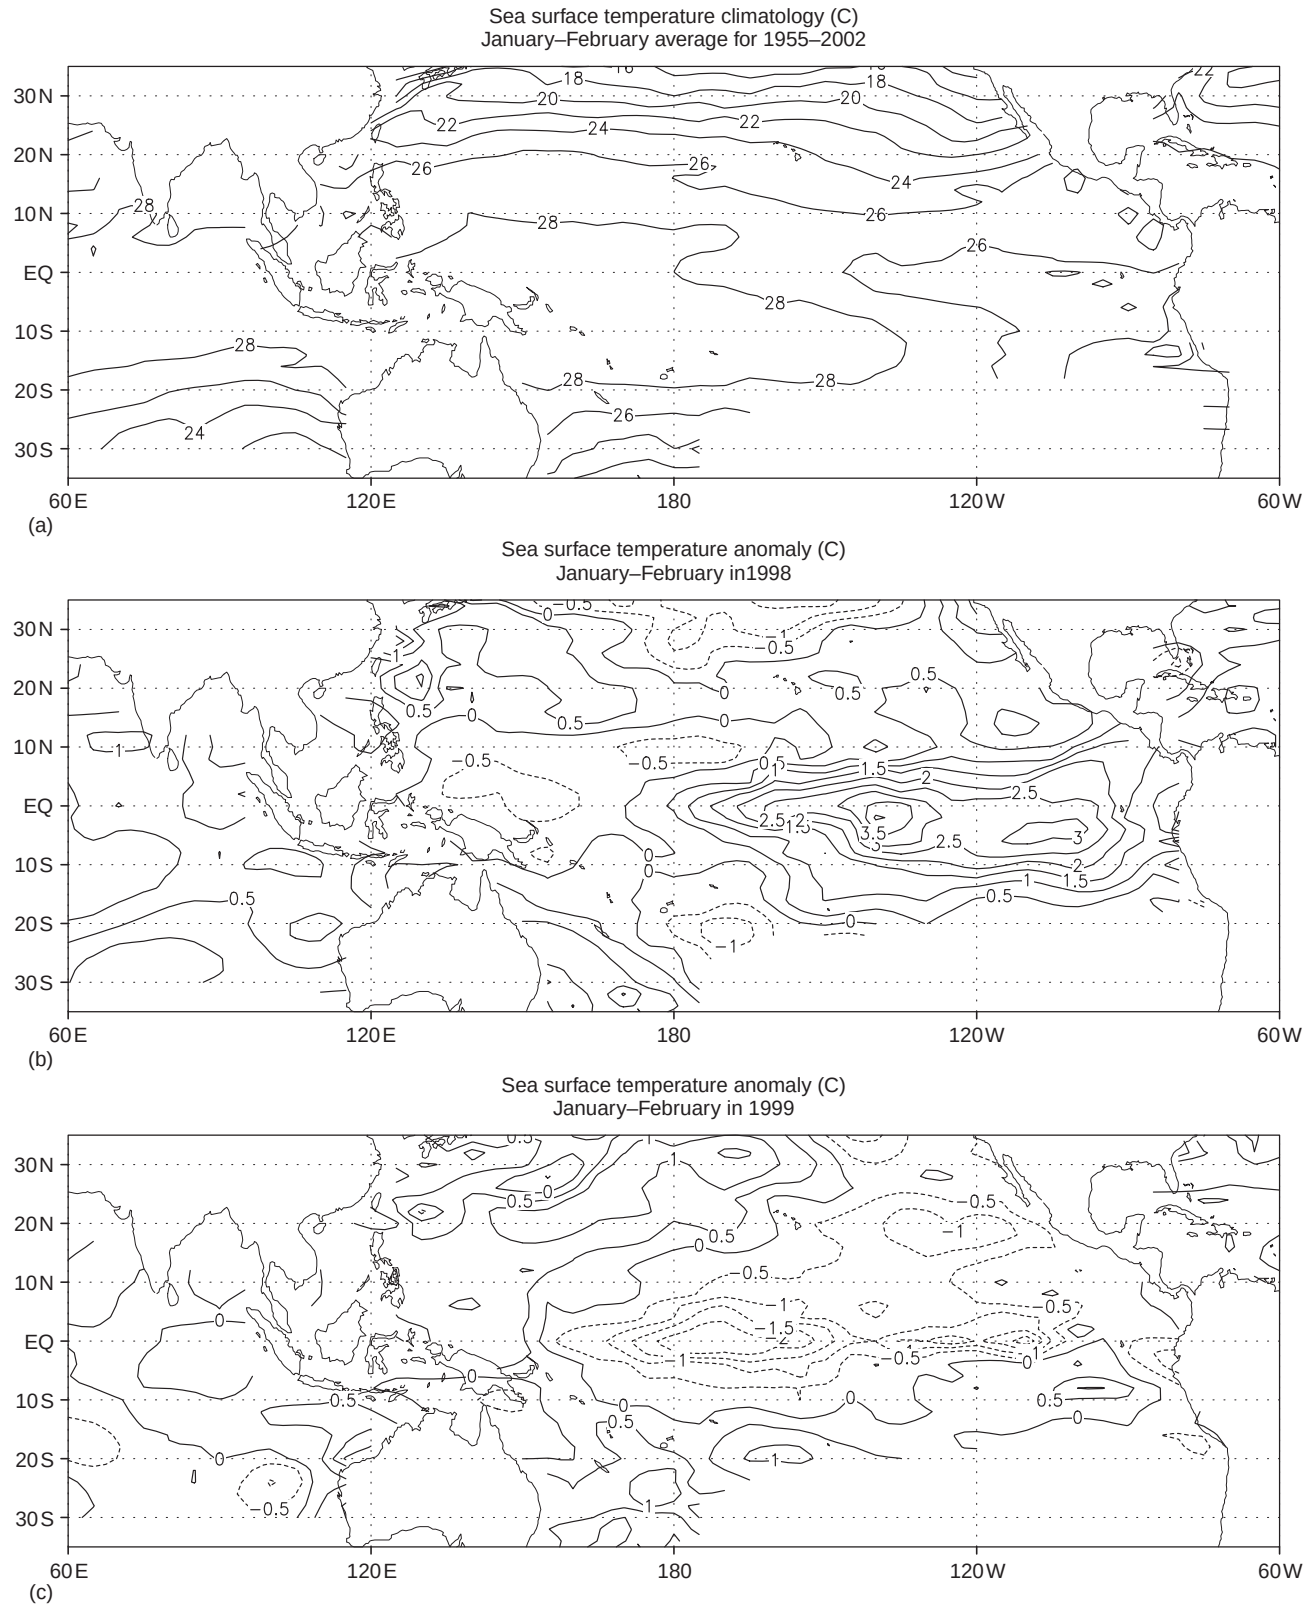

Figure 1 January and February tropical Pacific sea surface temperatures. (a) Climatology with the warmest temperatures in the western Pacific, (b) anomalies for 1998, a strong El Niño year with warmer than usual temperatures in the eastern Pacific, and (c) anomalies for 1999, a La Niña year with cool anomalies in the central and eastern Pacific

and El Niño has diminished in recent years for unknown reasons. Suggested mechanisms further illustrate the interconnectivity of the atmosphere–ocean system and include a higher latitude warming strong enough to enhance the monsoon and overcome the rain suppressing effects of El Niño or a small shift in El Niño convective anomalies, which in turn, shifts the downward branch of the Walker circulation away from India. (Kumar *et al.*, 1999).

Apart from affecting the mean zonal and meridional flow in the tropics, changes in upper-level outflow from tropical convection may also force anomalous atmospheric Rossby waves which can propagate to higher latitudes in a westerly background flow (e.g. Wallace and Gutzler, 1981; Tiedtke, 1984; James, 1994; Tribbia, 1991; Berbery and Nogues-Paegle, 1993). Such wave propagation out of the tropics into high latitudes in great arching patterns is a readily identifiable teleconnection pattern called the *Pacific North American Pattern* (PNA) which arches in a great circle northward from the tropical Pacific and eastward across North America and then southward towards the tropics. Discussion as to whether El Niño distinctly forces the PNA or simply modifies the statistics of an already existing mode of variability is ongoing (Straus and Shukla, 2002). Interestingly, details of each individual ENSO event may be very different in terms of season of onset, duration, strength, and exact location of convective anomalies. The extratropical patterns generated by Rossby waves tend to be roughly similar from event to event though the details of the pattern from event to event can be different (Hoerling and Kumar, 1997). This gave rise to the quite successful westerly duct hypothesis that Rossby waves can only escape the tropics at certain times of year and in certain locations because they cannot propagate in regions of ambient easterly winds. Winter season winds near Southeast Asia turn from easterly to westerly so waves generated within the tropics by shifts in convective activity can escape to higher latitudes from generally the same region (Webster, 1981; Hoskins and Karoly, 1981). It also appears that the extratropical waves may be more a function of the position and strength of the Southeast Asian jet on which the waves are excited, making the response less sensitive to the details of the tropical convective anomalies (Sardeshmukh and Hoskins, 1998).

Regionally, ENSO teleconnections can also be quite important.

In Northern Hemisphere winter, more intense storms occur farther north during El Niño years. Warmer than average conditions occur in the northern United States, eastern Canada, and near Japan. Extratropical effects for La Niña are, in some sense, the opposite of those caused by El Niño with warm conditions in the southern United States and cold, wet conditions in the northwest United States, Japan and southern Africa in northern winter. Correlations with ENSO in many climate variables have been reported across the globe though these correlations tend to be relatively weak and not highly statistically significant and therefore do not offer strong predictability in any single event. Strongly significant and repeatable teleconnections cover only a small portion of the area of the globe but are still highly important climatologically. In other regions, ENSO can offer probabilistic forecasting information.

While the chain of events constituting an El Niño or La Niña is well recognized and provides some statistical predictability in regions around the globe once the phase of ENSO is established (discussed in the Section "Predictability: numerical forecasts using teleconnection patterns"), actual understanding of the mechanisms which start the chain of events or stop it once started have been elusive, and the prediction of the onset of El Niños by both dynamical and physical models have yet to display skill relative to a simple climatology and persistence model of ENSO onset (Landsea and Knaff, 2000). One theory for ENSO is the delayed-oscillator theory (Suarez and Schopf, 1988; Battisti and Hirst, 1989) which posits an unstable atmosphere–ocean system where oceanic Rossby waves generated from previous El Niños or La Niñas act as the excitation for the next ENSO event. Other mechanisms such as monsoonal activity (Webster and Yang, 1992) and the MJO (discussed in the Section "Madden–Julian oscillation") have also been proposed as modulators of ENSO though such theories only lengthen the chain of causality as these phenomena are themselves even less understood than ENSO. Finally, Penland and Sardeshmukh (1995) have hypothesized that the tropical Pacific atmosphere/ocean system is not an unstable system waiting for triggering mechanisms but that the ENSO variability is best thought of as a response of the tropical Pacific system to stochastic climate noise.

Recent trends in ENSO and other teleconnection patterns will be discussed in the climate change section below.

Madden–Julian Oscillation

An example of the difficulties in associating an observed teleconnection pattern with physical mechanisms is the Madden–Julian Oscillation. First identified in the 1970s, the MJO is characterized by an observed, eastward moving atmospheric circulation anomaly and associated convection anomalies that can be identified in the wind, cloud, and outgoing long-wave radiation (OLR) fields along the equator with an approximate 40–50 day time period. The convective anomalies are strongest over the Indian Ocean and eastward over the west Pacific warm pool to the date line. Little sign of convective anomalies appear from the central through eastern Pacific. The MJO differs from the relatively spatially fixed teleconnection patterns such as the Arctic Oscillation (discussed below) in that it travels across the Pacific with a speed of approximately $5–10\,\mathrm{m\,s^{-1}}$.

The exact nature of the forcing of the MJO and its method of eastward propagation have eluded adequate theoretical

explanation as yet (Waliser *et al.*, 1999) and the oscillation is not well represented in model simulations (Slingo *et al.*, 1996). This is a problem in that the MJO dominates tropical climate variability at intra-annual timescales (while ENSO dominates interannual variability). Theories for the initiation and propagation of the MJO have centered on the wave convective instability of the second kind (CISK) mechanism (Lau and Peng, 1987) and the wind evaporation feedback (Emmanuel, 1987; Neelin *et al.*, 1987). However, both have failed to produce adequate representations of the MJO. Wave CISK theory typically produces oscillations with phase speeds of $15\,\mathrm{m\,s^{-1}}$ or greater, which is significantly faster than observed phase speeds. Wind-evaporative feedback mechanisms require easterly winds at the surface. While surface winds are easterly in much of the tropics, regions where the oscillation is most noticeable have climatological westerly winds at the surface.

The idea that the MJO is part of a coupled atmosphere–ocean oscillation, similar to ENSO, is the subject of active research (e.g. Waliser *et al.*, 1999; Woolnough *et al.*, 2000). Recent research (Seo and Kim, 2003) conclude that the MJO is a coupled oscillation of the ocean–atmosphere system and represents an interaction between two classes of waves, Rossby and Kelvin waves, leading to a self-generating and self-propagating disturbance.

The MJO is associated with the timing of the active and break period of both the Indian and Australian monsoons (Madden and Julian, 1994) and may have some role in triggering ENSO events (Kessler *et al.*, 1996; Zhang and Gottschalk, 2002) further complicating ENSO prediction. There does not appear to be a strong signal of the MJO in the extra-tropics (Madden and Julian, 1994).

Teleconnections in the Atmosphere

North Atlantic Oscillation-NAO/Arctic Oscillation-AO

Whether the major mode of mid and high Northern Hemisphere variability is better characterized as a regional oscillation known as the *North Atlantic Oscillation* (NAO) or a circumpolar mode referred to as the Arctic Oscillation (AO, Deser, Clara, 2000; Wallace and Thompson, 2002; Ambaum *et al.*, 2001) remains an open question illustrating the sometimes ambiguous way the atmospheric circulation organizes itself.

The NAO is a north–south oscillation of mass between the subtropical North Atlantic and Arctic. A measure of the NAO is an index generally defined as a pressure difference between a high-latitude station representative of the Icelandic low (Reykjavik or Stykkisholmur, Iceland) and a subtropical station (Lisbon or Gibraltar) representative of the other center of action in the Azores surface high-pressure system. A positive NAO index is an indication of more meridional flow across the Atlantic, which allows for warmer and more moist conditions in northwestern Europe while the negative phase is an indication of zonal flow and colder temperatures in western Europe and more moisture in southwestern Europe. The phase of the NAO also modulates climate in eastern North America (Wettstein and Mearns, 2002) and North Atlantic, particularly in winter months. The NAO, like ENSO, is an interannual oscillation with an irregular pattern of several years.

A related pattern, the AO, has been recently thought to be a more general mode of variability that actually includes the oscillation in the North Atlantic but expands it to a more symmetric annular mode, meaning that mass oscillates between the Arctic and lower latitudes in a giant ring around the circumference of the globe (Figure 2). The Arctic oscillation is seen in the first EOF in sea level pressure as three main centers of action, one in the Arctic, and two in the lower latitude centers in the North Atlantic and the North Pacific (the oscillation is not perfectly annular). The North Pacific center is substantially weaker than the North Atlantic center, giving rise to controversy as to which pattern, the AO or NAO, is actually climatologically more significant, and whether the AO is simply an artifact of statistical analysis (Deser, Clara, 2000; Ambaum *et al.*,

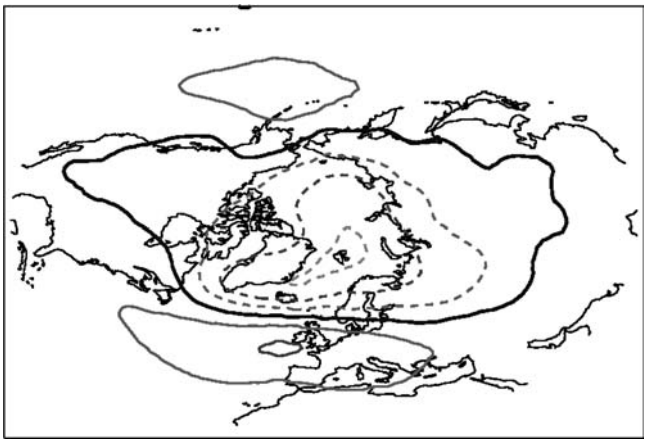

Figure 2 First EOF of sea level pressure from NCAR/NCEP Reanalysis showing the major mode of variability in the Northern hemisphere circulation including both the NAO and the AO. EOF analysis shows the preferred spatial organization of variability over time. In this case, three nodes are visible, one centered in the Arctic Ocean and two others at low latitudes in the Pacific and Atlantic oceans of opposite sign (thick dark contour is zero). The interpretation of this figure is that atmospheric mass oscillates back and forth between the high-latitude node and the two low latitude nodes. If one only looks at the Arctic-North Atlantic nodes this is the NAO. All three nodes comprise the AO and suggest a more annular character as the zero line extends around the globe. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

2001). Pressure in the two lower latitude centers of action is observed to be anticorrelated with pressure in the Arctic as would be expected in a coherent, annular movement of mass from high latitudes to lower latitudes. However, the two lower latitude centers of action are only very weakly correlated with each other suggesting that the AO is not really a globally coherent pattern. Wallace and Thompson (2002) suggest that other modes of variability are masking the coherence of the lower latitude pattern but it is still unclear which pattern will become favored.

In an effort to produce an idealized annular mode in a general circulation model, Cash *et al.* (2002) applied zonally symmetric surface boundary conditions and examined individual annular mode events (as opposed to a long-term average) and conclude that, even with no zonal changes in surface conditions, the primary mode is best conceived of as a series of regionally localized, north-south shifts in mass more in line with the NAO conception of Northern Hemisphere variability.

Monahan *et al.* (2001) suggest that the two patterns are not independent and the question may come down to the subjective judgment as to which paradigm organizes thinking most productively as suggested by Wallace (2000).

Teleconnection patterns are of interest because of the potential for long-term predictions if the source of the teleconnection can be understood. This is still not the case with the NAO/AO. Many studies have examined the factors involved in forcing variability in the AO/NAO and have found a variety of potential mechanisms within the earth system: SST (Rodwell *et al.*, 1999; Schneider *et al.*, 2003; Mehta *et al.*, 2000), snow cover (Gong *et al.*, 2002), volcanism (Stenchikov *et al.*, 2002), random stochastic variability (Schneider *et al.*, 2003; Tanaka, 2003; Wunsch, 1999), and stratospheric dynamics (Zhou *et al.*, 2001; Baldwin and Dunkerton, 1999; Black, 2002). Robertson (2001) concludes that the Arctic Oscillation is an inherent mode of atmospheric variability alone and that coupling a model to an interactive ocean does not change the simulated AO relative to a simulation with fixed SSTs suggesting limited predictability even with a knowledge of SST distribution.

Pacific Decadal Oscillation-PDO

The Pacific Decadal Oscillation (PDO) is a longer-term oscillation than those discussed previously. The average PDO phase persists for several decades though the period for an individual event is also quite a bit more variable than previously discussed patterns. PDO oscillations have energy peaks at both 15–25 year and 50–70 year timescales (Minobe, 1997) and is an example of interdecadal atmospheric variability. Such long-term patterns are of great interest because of the possibility of long-term predictive skill. However, as with other teleconnection patterns, the source of the PDO is not currently known and the predictability has not proved highly successful. It also remains unclear whether the PDO has been a consistently dominant mode of variability over long time periods. For instance, Gedalof and Mantua (2002) conclude that the PDO was less of a climatic factor in the nineteenth century than at present based on long-term proxy records.

While the PDO teleconnection pattern looks somewhat similar to El Niño, the strongest anomalies are in the extratropics with secondary signatures in the tropics, the opposite as observed with El Niño. The similarity in patterns may be explained by the observation that the PDO may actually be forced by ENSO anomalies, which are subsequently projected onto lower frequency variations by stochastic climate variability (Newman *et al.*, 2003). Such a forcing mechanism, if it proves robust, would make the PDO another coupled atmosphere–ocean mode of variability but we categorize it as atmospheric only until further evidence is accumulated. The PDO seems also to have utility in long-range forecasting. For example, Castro *et al.* (2001) have used a combination of ENSO and the PDO to diagnose summer precipitation patterns and temporal evolution in the western United States.

Teleconnections From Land to Atmosphere

The high interconnectivity of the atmosphere–ocean system suggests that other perturbations to the earth system might be reflected far from the original disturbance and may have some influence on previously discussed teleconnection patterns. Here, we examine the example of land-cover changes in detail but a variety of processes, such as perturbations due to atmospheric pollution including aerosol clouds, may be operating in very complicated ways which are only beginning to be appreciated or investigated.

Large-scale land-cover changes, particularly in the tropics appear to generate remote climatic effects and may interact with better-known teleconnection patterns. The three major tropical convective heating centers are associated with the land surfaces of Africa, Amazonia, and the maritime continent of Indonesia, Malaysia, New Guinea, and surrounding regions (e.g. Kreuger and Winston, 1973). Changes in this vegetation structure has major impacts on the momentum and radiant energy absorbed at the surface and its partitioning into latent and sensible forms which affect surface temperatures and the structure and strength of convective storms (e.g. Dickinson and Kennedy, 1992; Nobre *et al.*, 1991; Eltahir, 1996; Polcher and Laval, 1994; Baidya Roy and Avissar, 2002).

Teleconnections resulting from land-cover changes in climate models have been discussed by Franchito and Rao (1992), McGuffie *et al.* (1995), Chase *et al.* (1996) and Zhang *et al.* (1996). Others have also noted isolated extratropical effects due to simulated tropical vegetation changes (Sud *et al.*, 1996; Sellers *et al.*, 1996). Chase *et al.* (2000) examined general circulation model (GCM) model simulations of the effect of observed levels of land-cover change globally and found strong evidence of

changes in global scale circulations and for the propagation of Rossby waves into the mid latitudes. Pitman and Zhao (2000), Zhao *et al.* (2001), Bounoua *et al.* (2002) again demonstrated that the remote effects of observed levels of land-cover change were prevalent in a variety of models under a range of configurations and model assumptions and that remote temperature anomalies resulting from land-cover change could be similar in magnitude as effects of the historical increase of the radiative effect of increased CO_2 (Chase *et al.*, 2002). Gedney and Valdes (2000), also using a GCM, specifically examined the effects of a wholesale removal on the Amazonian rainforest on remote climates and found significant evidence for a reduction in large-scale circulations generated by tropical convection and for propagating Rossby waves which affected rainfall in Northern Hemisphere winter. Werth and Avissar (2002) and Avissar and Werth (2004) find statistically significant teleconnection patterns due to deforestation in Amazonia, Central Africa, and Southeast Asia (Figure 3). Defries *et al.* (2002) examined potential impacts of future land-use changes and found regional temperature anomalies of up to 1.5 °C in regions not directly affected by land-cover changes. Such teleconnection patterns due to human activity might be expected to interact with natural modes of variability and this is an ongoing area of research.

Teleconnection patterns also strongly affect the biosphere, which implies high levels of interaction and mutual self-adjustment between these components of the earth system. For instance, Asner *et al.* (2000) attribute changes in net primary production in Amazonian forests of up to 18% due to ENSO oscillations and found that El Niño years were responsible for large fluxes of CO_2 into the atmosphere in the tropics. Kitzberger *et al.* (2001) found that forest fires in the Southwest United States and in Patagonia, Argentina were related to phases of ENSO. El Niño years are wet in these regions allowing plant growth and accumulation of fuel. La Niña years are dry in these regions and so the high fuel loads become desiccated leading to high rates of burning. Additionally, the effects of teleconnection patterns are not limited to the primary producers. Nott *et al.* (2002) found that seasonal ENSO and NAO weather

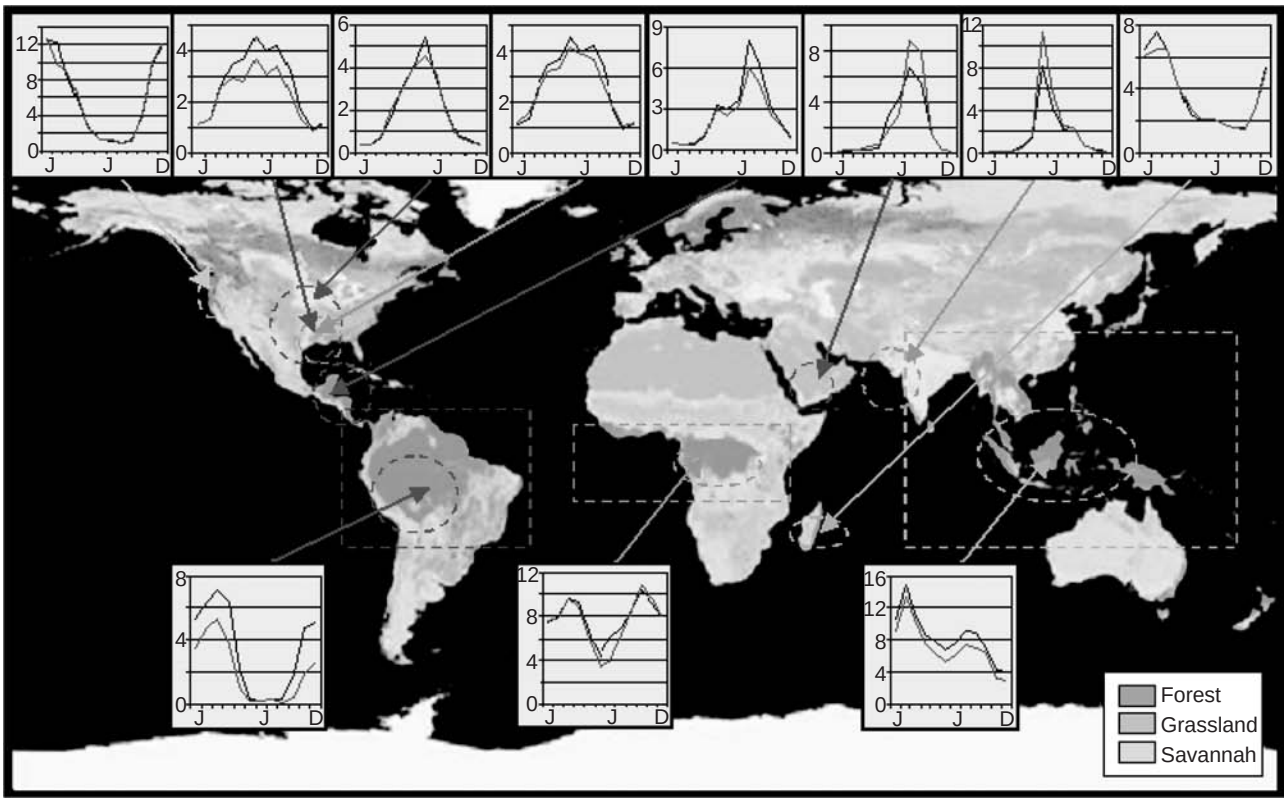

Figure 3 Annual cycle of precipitation (mm day^{-1}) in continental regions particularly affected by large-scale deforestation of Amazonia (dark grey), Central Africa (grey), and South-East Asia (light grey). The dark-grey curves show simulated mean monthly precipitation before massive tropical deforestation (i.e. the ''control'' case). whereas the grey curves show precipitation after deforestation. The size and location of the color-coded areas corresponding to the deforested regions are at scale. Ellipses indicate regions where tropical forest (dark grey on the 1-km resolution land-cover map used for the background) was replaced with a mixture of shrubs and grassland (derived from Avissar and Werth, 2004). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

changes resulted in strong effects on the productivity of a variety of bird populations.

Regional Teleconnections

While the term teleconnection is usually applied to patterns with continental-scale variations that are long lasting, the term can also be generalized to distant influences resulting from changes in smaller scale circulations, or from changes in ecosystem function. For example, Chase *et al.* (1999) found weather influences in the high Rocky Mountains due to the presence of irrigated farmland in the plains below. Irrigated regions affected the daily summer mountain-plains breeze by altering temperature patterns thereby allowing communication between the two regions. Such changes in local circulation regime would be expected to alter the transport of pollutants or atmospherically transported micronutrients and so may be of importance in many locales. Along similar lines, Eastman *et al.* (2001) described a "biological teleconnection" where changed ecosystem characteristics affected local weather such that effects were communicated to regions to regions distant from actual changes in surface characteristics.

A final example of the complex regional nature of some teleconnections and how human effects on climate might be difficult to pinpoint is an observational study of the effect of irrigation on downwind rainfall patterns. Moore and Rojstaczer (2002) found a maximum increase in summer precipitation some 90 km away from the irrigated region.

PREDICTABILITY: NUMERICAL FORECASTS USING TELECONNECTION PATTERNS

The atmosphere-ocean system is nonlinear making long-term prediction of individual weather events impossible. Even assuming a perfect climate model, small errors in the observed initial conditions invariably grow exponentially in magnitude and spatial scale. Therefore, long-term weather and climate forecasts use expected probabilities of certain types of weather based on statistical relationships from past observations. These relationships often take the form of teleconnection patterns.

One major advance in long-range forecasts is the realization that ENSO has documented effects in many parts of the globe. Many regions show a statistical tendency towards more or less precipitation or higher/lower temperatures depending on the phase of ENSO. ENSO has a fairly regular periodicity allowing for some skill in predicting changes in phase just from climatology or persistence. Several dynamical models also try to predict the future phase and resulting teleconnections of ENSO though these have not been dramatically more successful than knowledge of the climatology and persistence (Landsea and Knaff, 2000). The phase of ENSO is the single most important factor going into long-range forecasts today.

A statistical technique called a *canonical correlation analysis*, used in long-range climate forecasts, combines a series of indicators, including teleconnection indices, to infer possible preferred future patterns. This technique uses model-simulated weather patterns, global SST patterns, surface temperature, and precipitation for the past year to infer information about persistence and trends over the year. ENSO is emphasized in this analysis but other natural modes of variability such as the NAO are also accounted for. This analysis makes use of the forecast for La Niña, El Niño, or neutral conditions in the equatorial Pacific and then takes into account the confidence that this one phase of ENSO will exist.

Such information is used in a series of forecast simulations that differ slightly in order to estimate the envelope of possible atmospheric responses under such conditions. The relative occurrence of a particular climate pattern in these ensemble forecasts determines the probability of an individual event being forecast.

CLIMATE CHANGE

"Greenhouse Gas Warming" and Projection on Natural Modes

The major teleconnection patterns such as ENSO, NAO/AO, and the PDO occur in an irregularly periodic manner. Longer-term structure characterizes each of these patterns with periods of stronger or weaker intensity, altering periodicity and shifts favoring one phase of the oscillation over the other. The variability of climate due to these teleconnection patterns is therefore variable over longer timescales. Such longer-term variability has yet to be explained and appears to be particularly important in assessing present-day and future human impacts on climate.

For example, recent shifts favoring the warmer phase of two natural teleconnection patterns, ENSO and NAO/AO have been directly linked to a large portion of the observed Northern Hemisphere winter warming signal (Palecki and Leathers, 1993; Hurrell, 1996; Corti *et al.*, 1999). A trend in the NAO index toward more positive values since the early 1960s has been documented (Hurrell, 1996). Similarly, the observed SO index has shown a tendency towards more negative (El Niño-like) values since the middle of the century with a steep change to more negative values in the mid 1970s. Hurrell (1996) demonstrates that when these two natural circulation influences are removed from the time series, no discernible upward surface temperature trend remains (See Figure 4 in Hurrell, 1996). While such observations might be taken as an indication that recently observed warming is natural rather than a result of rising greenhouse gases, Corti *et al.* (1999) argue that greenhouse warming might be expressed in terms of changes in natural modes of variability. Stone *et al.* (2001) do find a general

projection of climate change on the most dominant modes of variability suggesting that these need to be actively monitored for future change.

Therefore, the question remains whether recent shifts towards more and larger El Niños is a reflection of natural variability or is forced by human activity. Cobb *et al.* (2003), examining isotope signatures in fossil corrals, conclude that past variability of ENSO cycles is unrelated to the mean temperature and that eras in the past 1100 years have seen ENSO cycles that rival present-day fluctuations. This observational study supports the statistical analyses of Rajagopalan *et al.* (1997) and Wunsch (1999) who both found the present trend toward more and larger El Niño events to be within the bounds of natural variability. Trenberth and Hoar (1996), however, in a differing statistical analysis, found recent trends to be statistically unusual and concluded that this was evidence for human influence on climate.

Reports from model simulations as to circulation changes due to increasing greenhouse gases are, at present, contradictory. There have been reports of changes, which favor a positive shift in the Southern Oscillation (more La Niña-like) (e.g. Timmerman *et al.*, 1999; Hu *et al.*, 2001) while others find a tendency for increasing negative phase (e.g. Meehl *et al.*, 2000; Collins, 2000). Still others find no change (e.g. Tett, 1995) or an increase in amplitude in both phases of the SO but no clear favoring of one phase over the other. Additionally, reported changes in the SO typically occur at CO_2 levels far above present levels of forcing and are therefore not entirely applicable to present-day conditions.

Simulated changes in the NAO/AO under increased greenhouse gases and/or aerosols also have a quite complicated response between simulations. Paeth *et al.* (1999) show a steadily increasing NAO index in climate change simulations starting at about the correct time but find no statistical significance. Shindell *et al.* (1999) show a positive trend in model-simulated NAO with present-day levels of CO_2 forcing, however, the trend between 1959 and 2000, the period of observed increase in the NAO index, is static (see Shindell *et al.*, 1999: Figure 2b). Fyfe *et al.* (1999), also show an increase in the NAO but only at much higher levels of CO_2 forcing than presently observed.

Further complicating the picture, Osborn *et al.* (1999) find the opposite effect with a decreasing NAO index in climate change simulations starting at present-day and continuing through the century. Zorita and Gonzalez-Rouco (2000), in a head-to-head comparison of two climate models, found highly variable results between the models. In the first model examined, they found positive AO trends in the first realization and negative AO trends in the second realization using different initial conditions. The second model had a clear positive trend in two realizations though at differing times in the simulation (i.e. under different greenhouse forcing) so that present observations are still not well explained.

Finally, it is unclear how robust the results from any single model are. For example, Collins (2000) found a shift towards a more El Niño-like state at four times natural CO_2 (approximately 12 times present levels) though when small details of the model formulation were changed the simulation produced the opposite change in circulation.

Other Human Influences on Teleconnection Patterns

There exists some evidence for a highly complicated human effect on natural climate variability. Chase *et al.* (1996) found that climate model-simulated tropical circulation shifts due to historical changes in vegetation were consistent with conditions favorable for inducing El Niño events at the expense of La Niña while Chung and Ramanathan (2003) found in model simulations that atmospheric haze originating in southern Asia and due mostly to human activity (such as clearing of agricultural land) also led toward conditions which favored El Niño at the expense of La Niña.

Human effects on teleconnection patterns may also be quite indirect.

For example, Alexander *et al.* (2004) find a NAO-like pattern in response to model-simulated changes in Arctic sea ice extent suggesting that should a warming climate cause large changes in sea ice, a large part of the effect would be seen in changes in circulation patterns. Similarly, changes in snow cover in a warming world would be expected to affect other large-scale circulations, such as the Indian monsoon system (Blanford, 1884; Fasullo, 2004a), which also interacts with ENSO. While such interactions require further confirmation, the potential effect of human activity on climate and circulation variability is apparently multifaceted and complex.

ISOLATED OR INTERCONNECTED?

A fundamental question concerning the major patterns of teleconnections is how independent they are. Because a definitive "cause" of any teleconnection pattern is elusive, it is possible that subsets of the patterns are in reality interrelated and part of a larger oscillatory phenomenon. Signs of interrelatedness are appearing more frequently in studies of teleconnection patterns.

For instance, there are indications that tropical Pacific SST patterns and hence ENSO may have some impact on the evolution of the NAO/AO pattern (Hoerling *et al.*, 2001; Schneider *et al.*, 2003). Further, it appears that South Pacific SST patterns may influence the development of tropical SSTs on decadal timescales (Bratcher and Giese, 2002). Hakkinen and Mo (2002) find that tropical

Atlantic Ocean temperature anomalies in boreal winter are related to forcings in the North Atlantic due to NAO fluctuations that generate equatorward propagating Kelvin waves, and are also influenced by teleconnections from the tropical Pacific, which can either work in conjunction or in opposition to each other. Gong and Ho (2003), find a significant relationship between the AO and East Asian summer monsoon rainfall due to a northward shift of the East Asian jet stream. As discussed previously, the Asian summer monsoon is known to interact with ENSO and the MJO. Further, Yang *et al.* (2002) find a teleconnection between the strength of the East Asian jet stream and weather downstream in East Asia, the Pacific, and North America, which appear distinct from ENSO patterns. Branstator (2002) further highlights the importance of remote effects due to the East Asian jet by showing that perturbations to the jet can be circumglobal in nature (an indication that the regional analysis of teleconnection patterns may be fundamentally misleading) and may, in part, be responsible for the patterns associated with the NAO. Kiladis and Weickman (1992) find forcing of El Niño variability by high-latitude storms. Xie and Tanimoto (1998) find a decadal teleconnection pattern spanning both hemispheres from the southern subtropics to the high northern latitudes apparently unrelated to the other patterns mentioned here but suggesting that the major teleconnection patterns may be linked by a variety of mechanisms. Miller *et al.* (2003) find a statistical association between the phases of the AO and the MJO further suggesting regular tropical/extratropical interactions between modes of atmospheric variability.

Therefore, it appears that evidence is emerging that the climate system is coupled in a variety of complicated ways and that conceiving of variability in terms of a series of isolated teleconnection patterns may give way to a view that each of the patterns is interrelated in some way, each forcing and being forced by the others. Long chains of causality linking some or all modes of variability might improve predictability if the chains of events are regular, though past experience indicates that relationships between the modes vary with time.

SUMMARY

This discussion illustrates the large-scale connectivity of the atmosphere–ocean coupled system and generalizes the concept to regional scales and to other components of the earth system. These connections at a distance, referred to as teleconnections, can occur by the direct transfer of mass by changes in regular circulations or by propagating waves initiated by a variety of mechanisms.

We have not discussed in detail several processes, which could rightfully be included in this section such as the regional monsoon systems, local winds, or the oceanic thermohaline circulation that, if changed, could have large climate repercussions all around the globe. We have, however, addressed the basic remaining uncertainties as to the nature of teleconnection patterns with prominent examples. Questions remain as to what extent recognized teleconnection patterns can be associated with an identifiable forcing mechanism, to what extent these patterns are interrelated and how they might cause, react to, or interact with changing forcing such as changes in atmospheric composition, land cover, or the distribution of sea ice to produce climate changes?

184: Global River Carbon Biogeochemistry

JEFFREY E RICHEY

School of Oceanography, University of Washington, Seattle, WA, US

The fluxes of dissolved and particulate carbon from land through fluvial systems to the oceans and to the atmosphere represent important pathways in the global carbon cycle. The processes controlling the distributions of solute species in river waters are established initially by weathering within the watershed, and physical transport via runoff. Superimposed on the underlying geochemical and physical processes is production and mineralization by terrestrial and aquatic biota. These factors play out differentially across the world's river basins, producing chemical signatures that vary from river to river. As a global aggregate, there would appear to be a net sink (between continental sedimentation and marine sedimentation and dissolution) of ~1 to 1.5 Pg year^{-1}. These sinks are partially compensated for by the outgassing. These processes are geographically very dispersed, with the continental sedimentation occurring in northern temperate regions, and much of the marine sedimentation and outgassing occurring in more tropical regions.

BIOGEOCHEMICAL DYNAMICS IN RIVER BASINS

A significant challenge for global biogeochemistry is to determine how the interaction of hydrological and biogeochemical cycles functions at the land surface, on regional to continental scales, producing the river flow and chemical load delivered to the oceans. Riverine transport represents a major link in the global cycles of bioactive elements, which modulates the biosphere over geological time (Meybeck, 1982). Dissolved and particulate organic matter (DOM and POM) in river systems serve as important heterotrophic substrates (Vannote *et al.*, 1980), provide an integrated continuous record of processes within drainage basins (Meybeck, 1982; Degens *et al.*, 1991), and constitute a major source of reduced carbon to the world ocean (Olson *et al.*, 1985; Schlesinger and Melack, 1981). The transfer of organic matter (OM) from the land to the oceans is the main pathway for the ultimate preservation of terrigenous production in modern environments, a key link in the global carbon cycle (Ittekkot and Haake, 1990; Hedges *et al.*, 1992). Terrestrial OM losses support significant heterotrophic activity within rivers, estuaries, and marine systems alike (Kaplan and Newbold, 1993; Mayer *et al.*, 1998), while natural and especially anthropogenic nutrient loading promote primary production. Where and when this river-borne OM is finally respired is of consequence to global carbon models (Stallard, 1998). Thus, understanding the processes that control the pathways from initial source to final mineralization of riverine organic matter is important on both regional and global scales.

At regional scales, river basins are natural integrators of surficial processes (Figure 1). Large rivers owe their flow and chemical loads to a much denser network of small rivers and streams bordered by areas of periodically inundated land, so that upland areas are dissected by corridors of wet soils and flowing water. Hence, understanding the hydrological and chemical patterns observed at the mouths of major rivers requires delineating the sequences of biogeochemical processes operating across multiple time and space scales. As embodied originally by the River Continuum Model, river properties should vary systematically downstream as processes affecting primarily the interactions of flowing water with the landscape give way to within river transport and processing (Vannote *et al.*, 1980; Minshall *et al.*, 1985). They should respond with differing magnitudes and lags to natural or man-made perturbations depending on the processes involved and the downstream transfer rates of their characteristic products. The central premise of a river basin model is that the constituents of river water provide a continuous, integrated record of upstream processes whose balances vary systematically

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

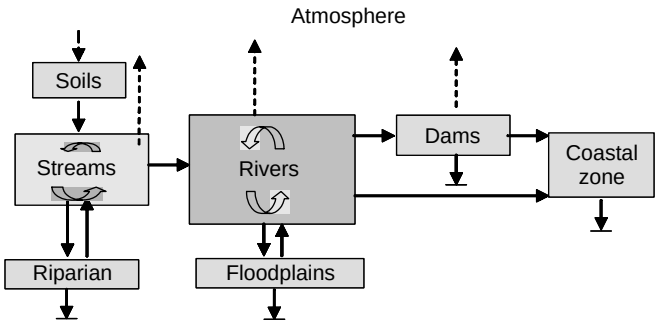

Figure 1 Schematic figure of the major reservoirs and pathways in fluvial systems. Inputs from land occur directly or pass through the riparian zone. Streams coalesce to form larger rivers that exchange with their floodplain. Rivers can pass directly to the coastal zone, or be retained behind dams. Dotted lines indicate exchange with the atmosphere, grounded areas indicate sinks, arrows within boxes indicate internal transformations (adapted from Richey, 2004)

depending upon changing interactions of flowing water with the landscape and the interplay of biological and physical processes (Karlsson *et al.*, 1988; Billen *et al.*, 1991). Hence, the chemical signatures of riverine materials can be used to identify different drainage basin source regions, reaches or stages and can be tied to landscape-related processes such as chemical weathering and nutrient retention by local vegetation (Meyer *et al.*, 1988). Because of the dynamic nature and abrupt moisture gradients of river corridors, the cumulative signal from a series of low-order streams may be manifest by higher-order rivers in a nonadditive manner.

The intent of this article is to develop a quantitative understanding through a heuristic and mass balance model of the sequence of processes from uplands to floodplains that produce the integrated hydrological, chemical, and biological signals at the mouths of the major tributary basins of large-scale river systems. The guiding questions to be addressed in this article include,

- *How does a large river system obtain and subsequently modify its biogeochemical composition?* This question can be separated into several parts.
- *How is the biogeochemical signature which persists through the river system imparted by the (aggregated) land surfaces?* That is, where do particular materials enter the river system, under the control of what process(es)? Observations of minimal changes in bioactive element forms and compositions within a study reach suggest that the mainstem of a major river is effectively transporting a complex compositional fingerprint that is imprinted somewhere upstream.
- *How is the land-derived signature modified through transit within the river system?* While the compositional fingerprint may be imprinted upstream, how do internal dynamics, such as production/respiration and sediment deposition/mobilization cycles modify that fingerprint, and in turn influence downstream export?
- *What are the time sequences of the sources, quantities, and chemical attributes of the river-borne fluxes of C, N, and P to the ocean? What are the physical and chemical controls operating on those fluxes at continental scales?* These questions in turn address a central problem in riverine ecology, which is to determine how the dynamics of flowing waters change as they increase in size from first-order springs and seeps to the world's great rivers.

RIVER BIOGEOCHEMISTRY: THE BASIC PARAMETERS AND PROCESSES ACROSS SCALES

A watershed, as the landscape through which all waters flow from their highest source before draining naturally to the sea, can be considered to be a fundamental organizing unit of the land surface. Rain or snow falls to the land surface, some of which is returned to the atmosphere (via evapotranspiration), some is stored in the soil (as soil moisture), and the balance drains into stream networks, mobilizing with it dissolved solutes and particulate materials from the landscape (Figure 2). As streams descend, tributaries and groundwater add to their volume, creating ever-larger rivers. Biological and chemical processes affect the materials in transport. As rivers leave the highlands, they slow down and start to meander and braid, and move between the river's main stream and its floodplain, modifying the flow regime and creating critical ecological (and biogeochemical) niches. The diversity of a river lies not only in the various types of land surfaces (or land uses) it flows through but also in the changing seasons and the differences between wet and dry years. Disruption of the linkages between the landscape and rivers and between rivers and

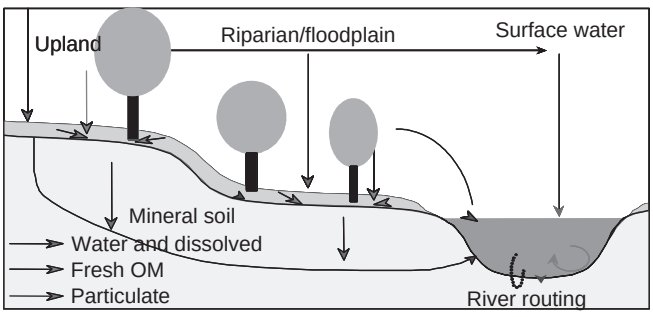

Figure 2 Grid-based view of land surface processes transferring water and its dissolved and particulate load to streams, where these constituents are subsequently routed downstream A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

their floodplains through human intervention fundamentally alters the nature of riverine ecosystems. The temporal scales of watersheds cover as much range as do the spatial scales. While the shape of the landscape itself (hills, valleys) will evolve (on geological timescales), these changes occur much more slowly than the seasonal and yearly evolution of the landcover and land use. These seasonal changes in turn occur much more slowly than a rainstorm, whose characteristic timescale is in the order of minutes to hours. The processes with which we are concerned, for example, the translation of rainfall into runoff across different types of landscapes, are themselves described differently at different space scales. The overall ensemble of these landscape features, which we can observe at multiple scales, can be thought of as the "physical template" upon which the more rapidly dynamic processes can operate.

Hence, the biogeochemistry of rivers is established as the interplay of terrestrial, biological, and geochemical weathering reactions that produce a suite of dissolved and particulate inorganic and organic compounds, via a series of pathways. The fundamental processes controlling the distributions of dissolved inorganic carbon (DIC) and the solute species in river waters are established initially by weathering within the watershed, and physical transport via runoff. Superimposed on the underlying geochemical and physical processes is production and mineralization by terrestrial and aquatic biota. These factors play out differentially across the world's river basins, producing chemical signatures that vary from river to river.

While matter transported by rivers ranges in size from molecules to trees, four broad size fractions are commonly used to characterize the bulk materials. Based operationally on filtration, the fractions include coarse particulate organic matter (CPOM, 63 microns to ~2 mm), fine particulate organic matter (FPOM, ~0.5 micron to 63 microns), dissolved organic matter (DOM, <0.5 microns) and dissolved nutrients, and dissolved gases (CO_2, CH_4, N_2O). As summarized (below) by Mayorga and Aufdenkampe (2002), these size classes exhibit very distinct transport dynamics, degradation patterns, and compositional characteristics (Figure 3).

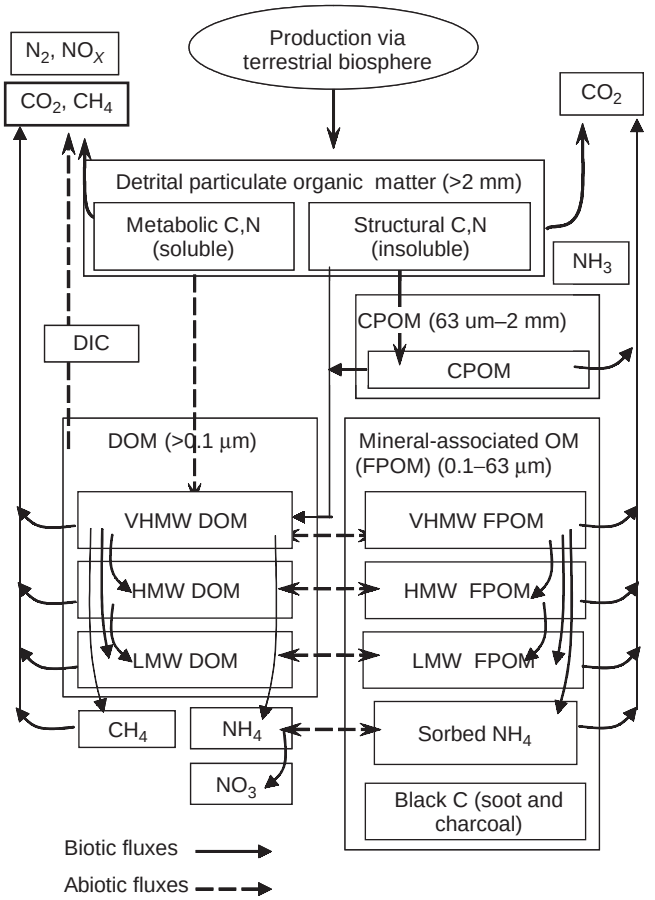

Figure 3 Fractions of the dissolved inorganic and organic components of the primary biogeochemical constituents of C and N in river water. Dissolved and particulate fractions can be sorted by molecular weight MW (V = very, H high, L low), VHMW DOC (>30 kDa), HMW DOC (1–30 kDa), LMW DOC (<1 kDa), VHMW DON (>30 kDa), LMW DON (200–1000 Da), and VLMW DON (<200 Da). The reason for such fractions is to break down bulk materials in a manner that can be related to system function

Dissolved Inorganic Species

Watersheds contain soils and rock that consist of a wide variety of different minerals. Weathering of the soil and rock minerals produces runoff containing the common ions (and many other ions in lesser concentration). The major inorganic ion composition of world rivers is controlled largely by geology and the weathering regime with minor inputs from precipitation (Stallard and Edmond, 1983, 1987). In general, weathering reactions can be characterized as a weak acid (carbonic acid) slowly dissolving basic minerals. Weathering reactions, such as sodium feldspar or calcite weathering, result in runoff containing dissolved ions, and commonly, undissolved particles of less soluble minerals such as clays. Many of the world's great rivers discharge water that can be characterized as rock-dominated (Gibbs, 1970). Water more or less in equilibrium with the materials in the drainage basin is characterized by higher concentrations of ions and an increased significance of Ca, Mg, and bicarbonate ions. Rivers that receive rainwater and snowmelt with little influence of rock weathering contain water with low concentrations of ions, reflecting rainwater that is (approximately) a dilute solution of carbonic acid with an admixture of a small amount of sea salt. Evaporation and fractional precipitation tend to dominate in more arid regions. The overall concentration of ions increases with evaporation until selected minerals begin to precipitate because their solubility product is exceeded.

The overall weathering regime in turn establishes the carbonate system, as the sum of the species of DIC, $DIC = [H_2CO_3^*] + [HCO_3^-] + [CO_3^{-2}]$. Natural waters are buffered with respect to pH mostly because of the content of inorganic carbon species. In turn, pH is an important controlling variable for many important geochemical reactions (e.g. solubility of carbonates). Many important biochemical reactions, such as photosynthesis and respiration, interact with pH and the carbonate system. Alkalinity, as the approximate imbalance of cations and anions, is a measure of the ability of a water system to resist changes in pH when acid is added to water. A stream that has a high alkalinity is well buffered so that large inputs of acid (from acid rain for instance) can be made with little effect on the stream pH. A stream that has a low alkalinity is poorly buffered and may undergo large, sudden drops in pH in response to acid inputs. Reduction/oxidation (redox) processes, which typically occur in oxygen-depleted zones near streams, will alter alkalinity. Examples of importance to rivers include oxidation of ammonia to nitrate (nitrification), oxidation of sulfide or reduction of sulfate and oxidation or reduction of iron. Precipitation or dissolution of minerals involving participating species will alter alkalinity. For example, the precipitation or dissolution of calcium carbonate can alter alkalinity. Other participating species, such as organic acids, may influence alkalinity, especially in low alkalinity environments. Dissolved inorganic nutrients are closely associated with the cycling of organic matter. Inorganic nitrogen compounds – NO_3^- and NH_4^+ – cycle rapidly via remineralization of organic matter and other microbial processes such as nitrification and denitrification. Of the bioactive compounds, PO_4^{3-} shows the least systematic variability, generally $0.4 - 2.0\,\mu M$ in turbid rivers as a result of buffering with larger mineral-bound reservoirs in the suspended sediments. On the other hand, NO_3^- and PO_4^{3-} are particularly subject to anthropogenic influences, via fertilizers and domestic and industrial wastes. Dynamics of dissolved gasses, such as O_2, CO_2, CH_4 are also largely controlled by the respiration of organic matter because river, floodplain, and lake waters are dominantly heterotrophic (Cole *et al.*, 1994; Cole and Caraco, 2001). Thus, the dissolved inorganic constituents of river waters are constantly evolving as a result of interactions with nondissolved phases within the river corridor.

Dissolved Organic Matter

Perhaps the most important characteristic of dissolved material is that it has the potential to be directly bioavailable. Microbial organisms, plant roots, and many animal tissues transport dissolved molecules across cellular membranes, both passively and actively. Likewise, contaminants exhibit their highest toxicity when in the dissolved phase. The dissolved fraction is particularly characterized by diversity and contrasts. Organics and inorganics exist in both truly dissolved and colloidal phases. DOM exists as a mixture of simple molecules, complex biomacromolecules, their partial degradation products and molecular assemblages or gels. This mixture contains the most labile material carried by the river (e.g. NH_4^+, free amino acids, etc.) and also relatively nonlabile weathering end-products (e.g. inorganic ions that determine alkalinity, low molecular weight (LMW), DOM, etc.). While the dissolved fraction is generally considered to be $<0.45\,\mu m$, to better understand the composition and dynamics of DOM, ultrafiltration techniques have employed membranes with pores as small as 1 nm to separate and concentrate DOM into various size fractions (Hedges *et al.*, 1994; Küchler *et al.*, 1994; Amon and Benner, 1996a,b; Mounier *et al.*, 1999; Patel *et al.*, 1999). Generally, ultrafiltered DOM (UDOM) refers to organic material with molecular weights $>1000\,g\,mol^{-1}$ or daltons (high molecular weight or HMW), including very high molecular weight subsets variously named very high molecular weight (VHMW) DOM or colloidal organic carbon (COC) by different research groups (1000 daltons is approximately equivalent to a molecule of 1-nm diameter).

Cumulative evidence suggests that DOM is produced largely from the degradation and/or leaching of leaf detritus similar to that in CPOM (Devol and Hedges, 2001). Once in solution, biomacromolecules such as proteins and carbohydrates are easily hydrolyzed (at least partially) by exoenzymes for subsequent microbial uptake. As a result, degradation tends to decrease both the size and bioavailability of HMW DOM to form the low molecular weight (LMW, 200–1000 daltons) fraction (Amon and Benner, 1996a). However, as all particulate and dissolved organic carbon fractions degrade, microbial activity and photochemistry can generate a pool of the smallest molecules (<200 daltons) – free amino acids, free sugars, and organic acids such as acetate and citrate (Amon and Benner, 1996b; Moran and Zepp, 1997). Despite the likelihood that this very low molecular weight (VLMW) DOM represents an exceedingly small proportion of total DOM in rivers, these compounds are generally extremely bioavailable and could drive significant biological fluxes. The relative proportions of VHMW, HMW, LMW, and VLMW DOM fractions would be expected to evolve down river as a result of their different degradation rates. Coagulation and disassociation of DOM in and out of colloidal gel phases or mineral surfaces complicates these size dynamics significantly however, as many of these processes respond to changes in pH and to ratios of polyvalent to monovalent ions in solution (such as Ca^{2+}/Na^+) (Chin *et al.*, 1998; Kaiser, 1998).

Particulate Organic Matter

Coarse suspended river sediments are a heterogeneous mixture of sand-sized mineral grains (coarse suspended sediments, (CSS)) and discrete plant fragments. Because CSS settles quickly to the streambed, suspended concentrations

are strongly dependent on streamflow velocities and increase substantially with depth in the river. Thus, CSS transport is highly episodic or seasonal, with most occurring during flood events. In large turbid rivers, the CPOM is a small but important portion of the CSS fraction, comprising only 0.6–3.3% by mass. CPOM is less dense than mineral grains of the same size, hence explaining its higher contribution to CSS in river channels under lowflow. Between 10 and 20% of CPOM can be identified biochemically as amino acids, carbohydrates, and lignins relative to 25–60% within biomass sources (Hedges *et al.*, 1986a; Hedges *et al.*, 1994; Hedges *et al.*, 2000). Biochemical source indicators, such as the carbon to nitrogen ratio and the ratio of cinamyl to vanilyl lignin phenols, all show that Amazon basin CPOM, for example, is primarily derived from tree leaves (Devol and Hedges, 2001). Biochemical indicators of degradation, such as the contribution of fucose and rhamnose sugars to total carbohydrates and acid to aldehyde ratios in lignin phenols, all support evidence from microscopic studies and major biochemical composition that CPOM is sparingly degraded and rather fresh. Radiocarbon analysis of CPOM and low density soil particulate organic matter confirms their recent origin (Hedges *et al.*, 1986b; Trumbore *et al.*, 1995). It is clear that CPOM is actively degrading and leaching, supplying microbes with substrate and releasing dissolved organic and inorganic compounds into the river. These rates have not been directly measured, but are likely to be quite high. Stream and river budgets suggest that CPOM continuously enters the river mostly from bank vegetation and detritus falling directly into the water (McClain *et al.*, 1997).

FPOM is essentially the product of diverse dissolved organic and inorganic compounds binding to fine suspended sediments (FSS, as clays and silt materials between 0.45 and 63 μm). The sorption of natural DOM to minerals is the primary pathway in which FPOM is formed (Mayer, 1994; Hedges and Keil, 1995), organic matter contributes only to a small fraction of FSS, generally. As FPOM is, typically, only a small weight-percent of FSS (typically 0.5–2.0% by weight), in the turbid rivers that transport most of the FPOM, the dynamics of FPOM have to start with an understanding of the sources and transport of FSS. FSS is mobilized initially into stream channels by erosion events (especially extreme events, resulting in hillslope failure). As a product of rock weathering, mineral diversity within FSS is very large and depends on the geology (source minerals) and climate (weathering rates) of the watershed. Clays and oxides are aggregated with the larger minerals in important quantities. The clay-size fraction (0.45–5 μm) is composed mostly of phyloalumino-silicate clay minerals, which are the weathering products of primary silicates. As a result, mineralogical compositions within large drainage basins are constantly evolving downstream, with inputs from tributary watersheds and from weathering during temporary storage on the floodplain. While maintained in suspension by the slightest turbulence, FSS is not transported conservatively downstream. Evidence suggests that within the Amazon, for example, a typical FSS particle passes through floodplain deposits several times between the Peruvian border and the Atlantic (Martinelli *et al.*, 1993; Dunne *et al.*, 1998). Given the patterns of channel migration, each cycle of floodplain deposition and resuspension requires a few thousand years (Mertes *et al.*, 1996). The presence of lakes and especially reservoirs created by dams trap sediment, thereby creating a very large anthropogenic impact on the downstream movement of suspended sediments.

From a biogeochemical perspective, the critical issue is, how does the FSS mineral particle acquire its organic matter composition? The major characteristics of FPOM, as tightly associated with the mineral phase, most likely form within soils prior to erosion into rivers. While mineralogically diverse, FSS is generally high in surface area and high in cation and anion exchange capacity. As such, significant quantities of certain inorganic ions (e.g. NH_4^+, PO_4^{3-}, and most metals) and organic compounds can potentially be adsorbed to the mineral surfaces of FSS. Thus, FSS actively interacts with the dissolved fraction, often acting as a buffer or reservoir for dissolved compounds. Sorbed organic matter affects mineral surface properties significantly by increasing cation exchange capacity and by offering hydrophobic phases into which organic contaminants (e.g. pesticides, petroleum products, etc.) and heavy metals readily sorb (Benedetti *et al.*, 1996). Biochemically, a smaller fraction of FPOM is identifiable as carbohydrates or lignins when compared to CPOM, but often a larger fraction is identifiable as amino acids. It appears that FPOM comes largely from leaf material as does CPOM, but often falls slightly outside of the biochemical range that is possible by mixing biomass alone, as might be expected of diagenetically altered material (Devol and Hedges, 2001). Specific degradation parameters show this clearly; however, riverine FPOM is still relatively fresh compared to riverine DOM or deep-sea sediments (Hedges *et al.*, 1994). Overall, 90% of the FPOM cannot be physically separated from the mineral material (Keil *et al.*, 1997; Mayer *et al.*, 1998). This appears to be the result of physical protection from microbial attack that is offered by the intimate association of FPOM with mineral surfaces (Keil *et al.*, 1994; Baldock and Skjemstad, 2000; Kaiser and Guggenberger, 2000). Whether an organic molecule sorbs or remains dissolved determines, in large part, its transport potential and susceptibility to degradation.

SCALE-DEPENDENT MODELING AND PROCESS DYNAMICS

Clearly, the biogeochemical signature of large-scale river systems is the composite of processes occurring across

multiple time and space scales. A parcel of river water passing a particular location in a network with a particular chemical signature represents the cumulative upstream history of that parcel. That chemical signal is the product of what occurred in the stream segment above that point (internal transformations, such as respiration or primary production, and lateral exchanges, such as riparian interactions or floodplains), plus the addition of mass from upstream segments. That is, the chemical signature at some point in a river is the product of both terrestrial and in-stream processes. To capture these dynamics, it is useful to organize our understanding into first heuristic, and ultimately, computer models. Ideally, we want to develop "first-principle" models, rather than the regression approaches commonly used, relating water flow across the landscape to river chemistry.

First, we must be able to describe the movement of water through the landscape, as a function of the specific physiochemical attributes of the landscape (as discussed qualitatively in the previous section). It is necessary to be able to explicitly represent infiltration, soil moisture, and runoff, and then the downstream routing of a water parcel. The emergence of geospatially explicit landscape and hydrology models is making it feasible to start developing coupled landscape/fluvial biogeochemistry models. At a macro scale, hydrology models such as the Variable Infiltration Capacity (VIC; Liang *et al.*, 1994; Liang *et al.*, 1996; Lohmann *et al.*, 1998) and others described elsewhere in this Encyclopedia describe a vegetation cover type (through parameters including leaf area index, stomatal resistance, root mass distribution with soil depth, and others) and soil attributes in multiple layers for each grid cell. The model solves for a water balance and energy balance simultaneously, producing fields of soil moisture and runoff, with the runoff routed down a river network. Models such as the Distributed Hydrology Soil Vegetation Model (DHSVM; Wigmosta *et al.*, 1994), can recognize the spatial heterogeneity of smaller watersheds (typically less than about 10 000 km^2), and compute cell-to-cell fluxes.

Such landscape/hydrology models can now be used to compute chemical properties, as the generation and routing of a chemical substance within the stream network. That is, a chemical substance can enter a river segment laterally or it can enter from an upstream reach (that previously had a lateral input). The combined inputs are then subject to advection (downstream flow) and chemical or physical reactions (respiration, sedimentation) during transport. Schematically, this is represented in Figure 4. Each discrete reach of the network can be represented by connected straight segments, where each segment lies within one of the grid cells used to run the hydrology model (e.g. VIC or DHSVM). The model is built in an Eulerian framework, where each model element is a stream segment.

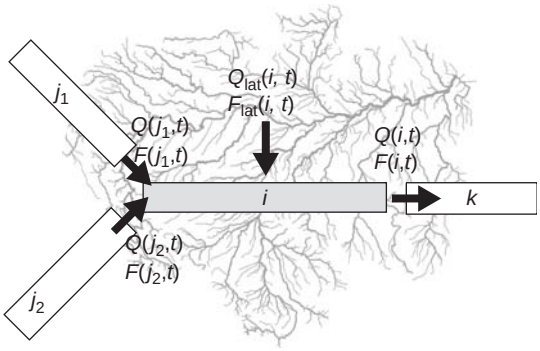

Figure 4 An overall river network (e.g. the Amazon), with the basic source/routing scheme superimposed. A representative segment i has two contributing segments, j_1 and j_2, and one outlet segment, k (Note that a segment can have anywhere from 0 to 7 input segments – more than 4 being rare – but it always has a single output segment). At time step t, input flows to i are $Q(j_1, t)$, $Q(j_2, t)$, and $Q_{lat}(i, t)$; and input mass fluxes are $F(j_1, t)$, $F(j_2, t)$, and $F_{lat}(i, t)$.$Q_{lat}(i, t)$ is the runoff rate entering segment i at time step t from the corresponding grid cell, and has previously been computed by a hydrology model. $F_{lat}(i, t)$ is the mass flux of species C entering segment i at time step t from the corresponding grid cell. At time step t, the output flow from i is $Q(i, t)$ and the output mass flux from i is $F(i, t)$. The travel time in i is $\Delta t(i)$. Input streamflows and mass fluxes at time t are used to compute the output streamflow and mass flux at time $t + \Delta t(i)$

Hence, there are as many model elements as there are stream segments and grid cells. Model elements are treated as control volumes with state variables that are updated at each model time step. There are only two state variables, $Q(i, t)$ (stream flow rate exiting element i at time step t, $m^3\ s^{-1}$) and $F(i, t)$ (mass flow rate of species C exiting element i at time step t, $\mu g\, s^{-1}$.

The first part of the problem is to compute the lateral inflow term. This is problematic, and depends very much on where in the drainage net the inflow is. The solute export module of a basin biogeochemistry model needs to estimate the amount and concentration of basin solutes (e.g. dissolved carbon and nitrogen species) exported to a stream via subsurface flow and in-stream concentrations (Figure 5). The control volumes in the basin are the soil solutions in each soil root zone and in the saturated lateral layer. The form of the specific equations can be derived from the relationships illustrated in Figure 3.

For the sake of illustration, let us now consider a hypothetical species C with concentration $[C]$ assumed to decay exponentially in time as it moves downstream, with decay constant k_1:

$$\frac{d[C]}{dt} = -k_1[C] \qquad (1)$$

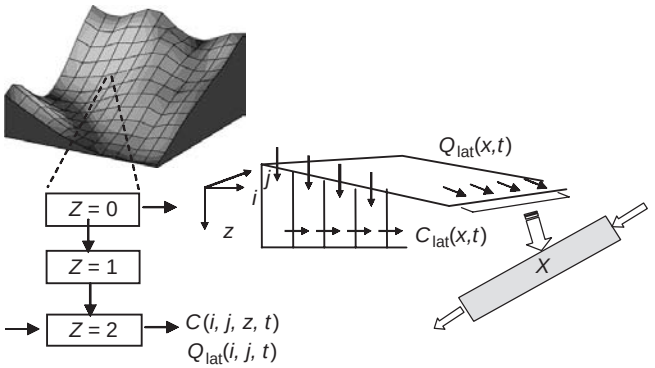

Figure 5 Schematic of lateral inflow (see Figure 4 for definitions) A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Integrating equation (1) from time $t = 0$ to $t = T$

$$[C](T) = [C](0)\mathrm{e}^{-k_1 T} \tag{2}$$

The concentration of species C (given in $\mu\mathrm{g\,m^{-3}}$) in the streamflow exiting a model element i at time step t is obtained from these state variables, as.

$$[C](i,t) = \frac{F(i,t)}{Q(i,t)} \tag{3}$$

The equations used to update the state variables are:

$$F_{\mathrm{lat}}(i,t) = k_2 Q_{\mathrm{lat}}(i,t)^{k3} \tag{4}$$

$$\Delta t(i) = \frac{length(i)}{velocity(i)} \tag{5}$$

$$Q(i, t + \Delta t(i)) = \Sigma_j Q(j,t) + Q_{\mathrm{lat}}(i,t) \tag{6}$$

$$F(i, t + \Delta t(i)) = [\Sigma_j F(j,t) + F_{\mathrm{lat}}(i,t)]\,\mathrm{d}t\mathrm{e}^{-k1\Delta t(i)} \tag{7}$$

where:

$\Delta t(i)$ is the travel time in segment i,

length(i) is the length of segment i,

velocity(i) is the streamflow velocity in segment i (In this first model version, *velocity(i)* is assumed to be independent of streamflow, making $\Delta t(i)$ constant in time for any segment i – an assumption that can later be relaxed),

$\mathrm{d}t$ is the model time step,

k_1 is the parameter in equations (1) and (2) (with units day^{-1}),

$Q_{\mathrm{lat}}(i,t)$ is the runoff rate entering stream segment i, a value previously computed by VIC for the grid cell corresponding to i,

$Flat(i,t)$ is the rate at which mass of species C is entering stream segment i at time step t from the corresponding grid cell (here assumed to be a function of $Q_{\mathrm{lat}}(i,t)$ according to (5)),

k_2 (units $\mu\mathrm{g\,m^{-3}}$) and k_3 (nondimensional) are model parameters, and $Q(*,*)$ and $F(*,*)$ are the state variables.

Equation (7) is directly obtained from equation (2), with the simplifying assumption that the travel distance (and time) for the lateral inputs is the same as for the inputs from tributaries.

Equations (5), (6), and (7) are computed for each model time step.

From equations (3) and (4), we obtain:

$$[C]_{\mathrm{lat}}(i,t) = k_2 Q_{\mathrm{lat}}(i,t)^{k3-1} \tag{8}$$

From equation (8) we see that the concentration of species C in the runoff entering segment i from its corresponding grid cell will increase with the runoff rate for $k_3 > 1$, and will decrease with runoff rate for $k_3 < 1$. For $k_3 = 1$, this concentration will be constant (and equal to k_2), regardless of runoff rate.

More specifically, the downstream advection and reaction for the different species can be represented as follows, where the exact form of the equation depends on the degree to which a specific parameter is dependent on its own concentration:

For conservative species (alkalinity, Ca, Si, O^{18}-H_2O) : $[C](i,t) = C_o$

Add a constant internal, nonconcentration dependent source S (FSS as function of erosion/deposition, production of nitrate): $[C](i,t) = C_o + S\ length(i)/\ velocity(i)$

Source + concentration dependent sink (e.g. PO_4 mineralization and adsorption) $[C](i,t) = s/k + (C_o\text{-}s/k)\ e^{(-k\ length(i)/velocity(i))}$

where S represents the aggregate of internal processes (erosion/deposition, mineralization, gas exchange, adsorption)

Gas Exchange: $[C](i,t) = (C_{\mathrm{eq}} \pm R/(D/\mu z)) - (C_{\mathrm{eq}}\text{-}]\ C_o \pm R/(D/\mu z))\mathrm{e}^{(-(D/\mu z)\ length(i)/velocity(i))}$

where

k = gain/loss from mineralization of dissolved organics (respiration/production)

z = thickness of hypothetical stagnant boundary layer.

C_{eq} = gas equilibrium with the atmosphere

D = molecular diffusion coefficient

While the above framework is still very much under development, it does represent the direction that basin biogeochemical modeling is developing.

RIVER BASIN MASS BALANCES OF CARBON

We will now evaluate the biogeochemical fluxes through global rivers, in terms of the box model of Figure 1. While the primary emphasis will be on carbon, the current export of nitrogen and phosphorus will also be examined. Evaluation of this model can only be approximate; the dynamics are complex, and multiple time constants are involved. Data are scarce, particularly in many of the most anthropogenically impacted systems. The distribution of the constituent processes varies dramatically across the face of the globe (with some of the most important regions being the least measured). This discussion is derived primarily from Richey (2004).

Mobilization from Land to Water and Riparian Zones

The modern terrestrial sediment cycle is not in equilibrium (Stallard, 1998). Meade *et al.* (1990) estimated that agricultural land use typically accelerates erosion 10- to 100-fold, via both fluvial and Aeolian processes. Multiple other reports in the literature support this conclusion. With the maturation of farmlands worldwide, and with the development of better soil conservation practices, it is probable that the human-induced erosion is less than it was several decades ago. Overall, however, there has been a significant anthropogenic increase in the mobilization of sediments (and associated POC) through fluvial processes. The global estimates of the quantities, however, vary dramatically. Stallard (1998) poses a range of scenarios, from 24 to 64 Pg year^{-1} of bulk sediments (from 0.4 to 1.2 Pg year^{-1} of POC). Smith *et al.* (2001) estimate that as much as 200 Pg year^{-1} of sediment is moving, resulting in about 1.4 Pg year^{-1} of POC (using a lower %C than Stallard, 1998).

Where does this material go? Does it all go downstream via big rivers, ultimately to the ocean, or is it stored inland? Stallard (1998) argues that between 0 and 40 Pg year^{-1} of sediments (0 to 0.8 Pg C year^{-1} POC) is stored as colluvium and alluvium, and never makes it downstream. Smith *et al.* (2001), using a different approach, estimate that about 1 Pg C year^{-1} of POC is stored this way. If this movement is merely transferring POC from one reservoir to another, with the same residence times, there is no net change in the C cycle. Then the issue is, to what degree can the (remaining) soils sequester carbon by sorption to the newly exposed mineral soils? Both Stallard (1998) and Smith *et al.* (2001) argue that carbon is removed from the upper portion of the soil horizon, where turnover times are relatively rapid (decades, or shorter), into either of the two classes of environments with longer turnover times; wetlands and smaller, deeper depositional zones, coupled with new carbon accumulation at either erosional or depositional sites. Both assume that oxidation of organic C in transit is minimal, and both use quite conservative values for total suspended sediment (TSS) export. If true, this sequence of processes would result in a significant C sink, on the order of 1 Pg C year^{-1}.

Within-river Transport and Reaction Processes

Within-river transport processes carry these eroded materials downstream through the river network. Transport is not passive; significant transformations occur along the way. Rivers exchange with their floodplains (depending on how canalized and diked a river is). A significant process within flowing water significantly affects organic matter (OM) – the mineralization to pCO_2. Most river and floodplain environments maintain pCO_2 levels that are supersaturated with respect to the atmosphere. High partial pressures of CO_2 translate to large gas evasion fluxes from water to atmosphere. Early measurements in the Amazon suggested that global CO_2 efflux (fluvial export plus respiration) from the world's rivers could be on the order of 1.0 Pg C year^{-1}. Recent measurements of temperate rivers lead to estimates of global river-to-atmosphere (outgassing) fluxes of $\sim$0.3 Pg C year^{-1}, which is nearly equivalent to riverine total organic carbon (TOC) or DIC export (Cole and Caraco, 2001). Richey *et al.* (2002) computed that outgassing from the Amazon alone was about 0.5 Pg C year^{-1}. Assuming that the fluxes computed for the Amazon are representative of fluvial environments of lowland humid tropical forests in general, surface water CO_2 evasion in the tropics would be on the order of roughly 0.9 Pg C year^{-1} (three times larger than previous estimates of global evasion). Factoring in the recent Amazon results, a global flux of at least 1 Pg C year^{-1} directly from river systems to the atmosphere is likely.

What is the source of the organic matter being respired? Is it labile contemporary organic matter, recently fixed in the water by plankton or nearshore vegetation, or is it some fraction of the allochthonous (terrestrial) matter in transport? The prevailing wisdom is that river-borne organic matter is already very refractory and not subject to oxidation (after centuries on land). The "age" of riverine organic matter yields some important insights.

Thus, preaging and degradation may alter significantly the structure, distribution, and quantity of terrestrial organic matter before its delivery to the oceans. As noted by Ludwig (2001), the OM that runs from rivers into the sea is not necessarily identical to the OM upstream in river catchments. Cole and Caraco (2001) observe that the apparent high rate of decomposition of terrestrial organic matter in rivers may resolve the enigma of why OM that leaves the land does not accumulate in the ocean (*sensu* Hedges *et al.*, 1997). Overall, this sequence of processes suggests that the OM that is being respired is translocated in space and time from its points of origin, such that, over long times and large spatial scales, the modern aquatic environment may be connected with terrestrial conditions of another time.

Input to Reservoirs

Just because dissolved and particulate materials enter a river it does not mean that they reach the ocean; modern reservoirs have had a tremendous impact on the hydrologic cycle. Starting about 50 years ago, large dams were seen as a solution to water resource issues, including flood control, hydroelectric power generation, and irrigation. Now there are more than 40 000 large dams worldwide (World Commission on Dams, 2000). This has resulted in a substantial distortion of freshwater runoff from the continents, raising the "age" of discharge through channels from a mean between 16 and 26 days to nearly 60 days (Vörösmarty *et al.*, 1997). While erosion has clearly increased the mobilization of sediment off the land, the proliferation of dams has acted to retain those sediments. Vörösmarty *et al.* (2003) estimates that the aggregate impact of all registered impoundments is on the order of 4 to 5 Pg year^{-1} of suspended sediments (of the 15–20 Pg year^{-1} total that he references). Stallard (1998) extrapolates from a more detailed analysis of the coterminous US to an estimate of about 10 Pg year^{-1} worldwide (versus 13 Pg year^{-1} efflux to the oceans), for a storage of about 0.2 Pg C year^{-1} (which he includes as part of his overall calculation of continental sedimentation.

Export to the Coastal Zone

The conventional wisdom is that the flux of POC and DOC are each about 0.2 Pg C year^{-1}, and DIC is 0.4 Pg C year^{-1} (e.g. Schlesinger and Melack, 1981; Degens, 1982, Meybeck, 1982, 1994; Ittekkot, 1988; Ittekkot and Laane, 1991; Ludwig *et al.*, 1996; Ver *et al.*, 1999). That these analyses converge is not terribly surprising. They are all based on much of the same (very sparse) field data, and use variations of the same statistically based interpolation schemes. Let us evaluate these numbers.

Because direct measurements are few, POC flux estimations are typically a product of the flux of total suspended sediments (TSS) and the (estimated) weight-percent organic C (w%C) associated with the sediment (because the bulk of POC is organic C sorbed to mineral grains). The first problem is an adequate resolution of the TSS flux. Data on TSS are frequently poor and of unknown quality. Many reported data are surface samples, and the depth integrations necessary to accurately characterize sediment flux are on the order of 2–3x higher. Additionally, much sediment moves during episodic storm events, when measurements are almost never made.

Estimates of TSS transport to the oceans have ranged from 9 Pg year^{-1} to more than 58 Pg year^{-1}, with more recent studies converging around 15 – 20 Pg year^{-1}. These estimates are generally based on extrapolations of existing data, which are weighted to the large rivers of passive margins and temperate regions. Milliman and Syvitski (1992) called attention to the much higher yield rates from steep mountainous environments (without directly computing a global total). More recently, Milliman *et al.* (1999) estimated that the total sediment flux from the East Indies alone (the islands of Sumatra, Borneo, New Guinea, Java, Sulawesi, and Timor), representing about 2% of the global land mass, is about 4 Pg year^{-1}, or 20–25% of the current global values. This type of environment (steep relief, draining directly to the oceans) is found elsewhere in the world, so the results are not likely to be unique. New data from Taiwan support these high levels, with isotopic analyses of the C showing that a significant part of the flux is human-driven (Kao and Liu, 2002).

Then, to obtain POC flux estimates, these values (and their uncertainties) must be multiplied by w%C. Meybeck (1991) divided particulate carbon into inorganic (PIC) and organic (POC) phases, and assumed that high sediment rivers have very low carbon fractions (0.5 w%C), representative of shale; he essentially does not consider the latter to be "atmospherically derived" and hence discounts it from estimates of fluxes to the ocean. More recent values for w%C tend to be in the 1–2% range, and higher for organic-rich systems (Richey *et al.*, 1990; Stallard, 1998; Gao *et al.*, 2002).

To account for this range, POC flux can be computed as an ensemble based on different combinations of w%C and TSS fluxes, resulting in a range of 0.3 – 0.8 Pg C year^{-1}, with a "more likely" value of about 0.5 Pg C year^{-1} (depending on assumptions used). Therefore, it is possible that the common estimate of 0.2 Pg C year^{-1} is low, and that the overall value lies in the range of 0.2–0.5 Pg C year^{-1}. The common estimate for PIC of 0.2 Pg C year^{-1} (Meybeck, 1991; Ver *et al.*, 1999) may also be underestimated if sediment fluxes are higher.

The value of 0.2 Pg C year^{-1} for DOC export may also be low. DOC is also subject to sparse (and questionable) measurements, without the availability of a proxy like TSS for POC. Aitkenhead and McDowell (2000) developed a model of riverine DOC flux as a function of soil C:N. Using this model, they computed a global flux of 0.4 Pg C year^{-1}, or twice the common estimate. That is, the total organic C output from fluvial systems may well be approximately double the original estimates, in the ~0.8 Pg C year^{-1} range.

Anthropogenic Transient

To what degree have these fluxes been influenced or impacted by human activities, that is, how much of this carbon is an anthropogenic transient? The consensus is that human-induced erosion has dramatically accelerated the movement of sediments (and POC). While some of this material "hangs up" on land (sedimentation, reservoirs), some of it likely escapes to the sea (some of the regions with highest sediment yields have very few dams). There

is evidence that anthropogenic processes have an affect on DIC. Raymond and Cole (2003) report an increase in the alkalinity of the Mississippi, that implies an increase in the consumption of atmospheric CO_2 through weathering. However, Jones *et al.* (2003) reported a systematic decrease in pCO_2 in rivers across the United States, which they attributed to large-scale declines in terrestrial CO_2 production and import into aquatic ecosystems, and not to terrestrial weathering or in-stream processes.

In the case of DOC, there is simply not enough information available to make conclusions. Clair *et al.* (1999) suggested that DOC export from basins in Canada might increase by 14% with a doubling in atmospheric CO_2. An additional factor rarely addressed in rivers is direct loading from urban and industrial sources (Ver *et al.*, 1999; Abril *et al.*, 2002). In evaluating the consequences of continental sedimentation and the potentially higher fluxes of POC, a net transient exported from land of roughly $1\,\mathrm{Pg\,C\,year^{-1}}$ is possible, with perhaps half of that going to the sea, and the other half divided equally between outgassing and sedimentation.

Overall Fluvial System – Atmosphere Exchange

Considerable uncertainty remains in the assessment of the carbon cycle of fluvial systems, including the actual magnitude of fluxes, how to include processes not previously considered, and delineation of anthropogenic and natural processes; all with an explicit recognition of geography. Estimates of the bulk transfer of atmospheric C through the land to fluvial systems (assuming a steady state summation of downstream processes, in a non–steady state environment) ranges from about $0.6\,\mathrm{Pg\,C\,year^{-1}}$ to $2.6\,\mathrm{Pg\,C\,year^{-1}}$. Continental sedimentation results in a significant sink, but that sink is reduced with CO_2 outgassing (because of the way the sedimentation was computed). The inclusion of continental sedimentation, and then the larger export of OM to the sea (about twice conventional assumptions, under +POC, DOC), yields net sinks of atmospheric CO_2 of up to $1.6\,\mathrm{Pg\,C\,year^{-1}}$. However, if outgassing is included, then the fluvial net sink is reduced to $0.2\,\mathrm{Pg\,C\,year^{-1}}$. While partitioning the total fluvial fluxes into natural conditions and anthropogenic transients is problematic at best, there is substantial evidence that there has been a dramatic increase in the mobilization of sediments. While much of this material is captured in reservoirs, it is reasonable to expect that a considerable amount escapes to the sea (especially in nondeltaic regions with steep slopes and few dams).

Summarizing all the components of the riverine carbon cycle, several images emerge. As a global steady state aggregate, there appears to be a sink (between continental sedimentation and marine sedimentation and dissolution) on the order of $1-1.5\,\mathrm{Pg\,C\,year^{-1}}$, with a significant anthropogenically enhanced component. A return flux to the atmosphere, on the order of $1\,\mathrm{Pg\,C\,year^{-1}}$, reduces the net sink to about 0.2 or $0.3\,\mathrm{Pg\,C\,year^{-1}}$. There are significant regional implications in this analysis. With its preponderance of land mass, extensive reservoirs, and agriculture, the bulk of continental sedimentation (and its implications for C sink), is focused in the Northern Hemisphere, between $30^\circ - 50^\circ\mathrm{N}$. The C sequestration in paddy lands would be closer to the equator. The greatest amount of sediment flux to the ocean (and the greatest uncertainty) is in South and Southeast Asia and Oceania. Outgassing is a function of both pCO_2 concentrations (driven by *in situ* oxidation) and surface area of water. It is likely the most significant in the humid tropics, particularly during the peak of the wet seasons. The highly canalized temperate areas have less area available. The northern latitudes, particularly with warming, are liable to have significant fluxes.

Dissolved N and P

While evaluation of the overall anthropogenic impact on river basin carbon is complex, there is little ambiguity about impacts on dissolved N and P. To establish a baseline for evaluation of the N cycle, Lewis *et al.* (1999) evaluated yields of total fixed nitrogen and nitrogen fractions for watersheds across the world, over a broad range of watershed areas, elevations, and vegetation types, in which anthropogenic disturbance was small. They found that yields were substantially lower than previously estimated for background conditions, and that yields can be predicted on the basis of general environmental variables such as drainage area or the amount of runoff. However, the production of food and energy has markedly increased the amount of newly fixed nitrogen entering terrestrial and aquatic ecosystems during the last century. As of 1990, the amount of newly fixed N entering terrestrial systems annually had about doubled (Galloway *et al.*, 1995; Galloway and Cowling, 2002). The fraction of this N that reaches rivers and ultimately the coastal oceans has led to the enrichment of coastal ecosystems (e.g. increased phytoplankton production, increased turbidity with subsequent loss of submerged aquatic vegetation, oxygen deficiency, and decrease in biodiversity, and so on (Nixon, 1995; Vitousek *et al.*, 1997; National Research Council, 2000; Cloern, 2001; Rabalais, 2002). Under a "business as usual" scenario, Seitzinger *et al.* (2002) computed that future DIN loadings to coastal systems could approximately double yet again, by 2050.

Similarly, Harrison *et al.* (in press) used a spatially explicit, global model of river dissolved inorganic phosphorus (DIP) export to evaluate the relative magnitudes of sewage, fertilizer, manure, and weathering P sources, and the inclusion of reservoir retention and consumptive water use terms. Their model computed that of the $34\,\mathrm{Tg\ of\ P\,year^{-1}}$ loaded on watersheds by human activity

globally, approximately 2% (0.71 Tg year^{-1}) reaches river mouths as DIP; of the total predicted annual DIP export (1.1 Tg P year^{-1}), anthropogenic sources account for 65%, with the remaining 35% (0.38 Tg year^{-1}) attributable to natural weathering processes.

SUMMARY STATEMENT

The overall biogeochemistry of river basins at large scales is fundamental in establishing the overall dynamics of the landscape, its linkages to the atmosphere, and ultimately to the oceans. Changes in land use and climate will significantly impact the critical water resources that these basins represent. New tools enable us to make more rapid progress than ever in our understanding. A cautionary note, however, is that the fact remains that there are far too few field studies on the actual state of a surprisingly large number of these basins.

PART 16

Land Use and Water Management

185: Integrated Land and Water Resources Management

IAN R CALDER

Centre for Land Use & Water Resources Research, University of Newcastle, Newcastle upon Tyne, UK

The need for Integrated Land and Water Resources Management (ILWRM), to meet and balance competing demands for food, timber and water, for conservation, amenity, recreation and the environment and for supporting people's livelihoods, is discussed. The principles of ILWRM including notions of sustainability, approaches to the economic valuation of land and water and demand management, are outlined. Also discussed are the differing public and science perceptions of the impacts of land use change, the interactions between land use, climate change, and water resources and how ILWRM can be implemented with stakeholder involvement.

THE NEED FOR INTEGRATED LAND AND WATER RESOURCES MANAGEMENT

There is increasing recognition for the need to better manage land use to meet and balance the competing demands being placed upon it. These demands can be in terms of production, for food, timber and water, for Conservation, Amenity, Recreation and Environment "products" (sometimes known as *CARE* products), and for supporting people's livelihoods. With projections of an increasing world population with increasing food requirements, there are concerns about where the extra water required to meet the increased agricultural production will come from (Falkenmark, 2003). There are also concerns that some of these increasing demands on land and water resources may be leading to degradations in quality and ecosystem function.

There is also the awareness that current land and water policies may not always be based on the best science, which may have led, in some instances, to perverse policy outcomes.

These are the drivers for improved integrated land and water resource management methodologies.

The Evolving Approach to Land and Water Management

The modern history of water resource and catchment management can be traced from its origins in the achievements of the nineteenth century engineers whose great civil engineering feats provided wholesome water to the world's growing and industrializing cities. Probably no other single factor contributed as much to the improved quality of life, and life expectancy, of city dwellers as this gift of safe water, literally available at the turn of a tap, and the provision of water-based sanitation systems, which then became possible. In those days, the surface water catchments or gathering grounds were managed to assure the pristine quality of water. Human occupation was regarded with distrust, at best a necessary evil, which had to be contained as far as possible. The success of the engineering approach was not just limited to water supply. The engineer had the ability to "tame the river". Through impoundments, barrages, and sluices, river flow from catchments could be regulated to reduce floods and to provide more water during times of drought.

More recently, the ethos of catchment and water resource management has shifted away from the tightly focused engineering viewpoint. At the same time, our perceptions of what we mean by a catchment have subtly changed. Originally, this may have meant just the headwaters where impoundments had been built to capture water for supply, irrigation, and hydropower purposes. Now, catchments are regarded more as the hydrological units that occupy the whole land surface of the globe.

As demands on water increase this has to be the case. Upland headwater catchments can no longer meet our

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

needs. The need to recycle water, together with the need to exploit groundwater means that more and more we regard every part of the land surface of the globe now as part of a catchment that can either supply water or receive our watery discharges.

The spatial linkages between upstream and downstream users and the "externalities" – the effect of one party's actions that impose a cost or benefit on another party without that cost or benefit being accounted for in the market – are becoming increasingly recognized. For example, land-based actions that alter catchment flows through alteration of the evaporative regime are now being considered and addressed through legislation. In South Africa, plantation forestry is designated as a "Stream Flow Reduction Activity". Soil water retention structures, ranging in scale from field bunds to check dams, farm dams, village dams through to large dams and reservoirs, may all have benefits in terms of storing or infiltrating water, but all have a cost in terms of increased evaporation from their water surfaces and their wet riparian zones. When soil water conservation measures are applied in excess within a catchment, they may have the same cumulative impact in terms of increased evaporation as that from a large reservoir. Together with high demands for irrigation water, the uncontrolled and unregulated implementation of such measures can contribute to the growing concern around the world arising from the phenomenon of "catchment closure", where, particularly in dry years, no flow emanates from a catchment.

The human and environmental dimension is achieving much greater prominence now in catchment and water resource management. Organizational and governance issues including institutional arrangements for collective action and community participation; decentralization of land and water management; laws, policies, and markets relating to watershed services and access to land and water; equity and poverty alleviation and are now central to what has been termed the "*Blue Revolution*" in land and integrated water resources management (Calder, 1999; Calder, 2005).

PRINCIPLES OF INTEGRATED LAND AND WATER RESOURCES MANAGEMENT

Concepts and Principles of Integrated Land and Water Resources Management

ILWRM involves the coordinated planning and management of land, water, and other environmental resources for their equitable, efficient, and sustainable use. ILWRM programs need to be developed alongside, and not in isolation from economic structural adjustment and other sectoral programs. For ILWRM strategies to be implemented, fragmentation of institutional responsibilities must be reduced.

ILWRM objectives encompass the United Nations Conference on Environment and Development (UNCED) principles:

- Water has multiple uses, and water and land must be managed in an integrated way.
- Water should be managed at the lowest appropriate level.
- Water allocation should take account of the interests of all who are affected.
- Water should be recognized and treated as an economic good.

ILWRM strategies seek to ensure

- a long-term viable economic future for basin dependants (both national and transnational);
- equitable access to water resources for basin dependants;
- the application of principles of demand management and appropriate pricing policies to encourage efficient usage of water between the agricultural, industrial, and urban supply sectors;
- in the short term, the prevention of further environmental degradation, and in the longer term, the restoration of degraded resources;
- the safeguarding of local cultural heritage and the local ecology as they relate to water management and the maintenance and encouragement of the potential for water-related tourism together with linkages between tourism and conservation.

ILWRM strategies should recognize that

- Solutions must focus on underlying causes not merely their symptoms;
- Issues must be approached in an integrated way;
- In general, development of sound resource management and collective responsibility for resources will take place at the subregional or village level.

History and the Dublin Principles

United Nations organizations have played a major role in the development of the new approach to water management. The United Nations Conference on the Human Environment in Stockholm in 1972 and the United Nations sponsored Conference on Water at Mar del Plata, Argentina, 1977 were instrumental in promoting the importance of water and water management to world governments. The delegates at the International Conference on Water and the Environment (ICWE) in Dublin, Ireland, in January 1992 called for a fundamental new approach to the assessment, development, and management of freshwater resources, which could only be brought about through political commitment and involvement from the highest levels of government to the smallest communities. They recognized that "commitment

will need to be backed by substantial and immediate investments, public awareness campaigns, legislative and institutional changes, technology development, and capacity building programmes. Underlying all these must be a greater recognition of the interdependence of all peoples, and of their place in the natural world".

The Dublin Conference Report, which was presented to the United Nations Conference on Environment and Development (UNCED) in Rio de Janeiro held in June 1992, sets out recommendations for action at local, national, and international levels based on four guiding principles (known now as the Dublin or UNCED principles).

Principle No. 1:

Freshwater is a finite and vulnerable resource, essential to sustain life, development, and the environment. Since water sustains life, effective management of water resources demands a holistic approach, linking social and economic development with protection of natural ecosystems. Effective management links land and water uses across the whole of a catchment area or groundwater aquifer.

Principle No. 2:

Water development and management should be based on a participatory approach, involving users, planners, and policy-makers at all levels. The participatory approach involves raising awareness of the importance of water among policy-makers and the general public. It means that decisions are taken at the lowest appropriate level, with full public consultation and involvement of users in the planning and implementation of water projects.

Principle No. 3:

Women play a central part in the provision, management, and safeguarding of water. This pivotal role of women as providers and users of water and guardians of the living environment has seldom been reflected in institutional arrangements for the development and management of water resources. Acceptance and implementation of this principle requires positive policies to address women's specific needs and to equip and empower women to participate at all levels in water resources programs, including decision making and implementation, in ways defined by them.

Principle No. 4:

Water has an economic value in all its competing uses and should be recognized as an economic good. Within this principle, it is vital to recognize first the basic right of all human beings to have access to clean water and sanitation at an affordable price. Past failure to recognize the economic value of water has led to wasteful and environmentally damaging uses of the resource. Managing water as an economic good is an important way of achieving efficient and equitable use, and of encouraging conservation and protection of water resources.

The Dublin Principles address questions of sustainability, equity, and economic efficiency. Originally, the term "sustainability" was used in the context of environmental and ecological sustainability, but more recently it has also been applied to peoples "livelihoods" and thereby includes the "equity" dimension.

NOTIONS OF SUSTAINABILITY

Tragedy of the Commons

Some of the early discussions and awareness of issues that we now conceptualize in terms of "sustainability" or "sustainable development" were provoked by Hardin (1968). Referring to the tradition of a community pasture, "the commons", Hardin gave the following example of a society that permitted freedom of action in activities that affected common property and was eventually doomed to failure.

> Picture a pasture open to all. It is to be expected that each herdsman will try to keep as many cattle as possible on the commons. Such an arrangement may work reasonably satisfactorily for centuries because tribal wars, poaching, and disease keep the numbers of both man and beast well below the carrying capacity of the land. Finally, however, comes the day of reckoning, that is, the day when the long desired goal of social stability becomes a reality. At that point the inherent logic of the commons remorselessly generates a tragedy. . . Ruin is the destination towards which all men rush, each pursuing his own best interest in a society that believes in the freedom of the commons.

The Limits to Growth

A team from MIT (Meadows *et al.*, 1972) presented in the book "The Limits to Growth", a crisis scenario of the depletion of the world's resources of fossil fuels, metals, timber, and fish and raised serious concerns about the sustainability of the world's ecosystem. It is now realized that many of the assumptions on which the computer predictions were based, particularly in relation to the extent of the reserves of fossil fuels and metals, were flawed, and consequently many of the dire forecasts that were made were erroneous. These failures have to some extent undermined the legitimacy of some very real concerns about the sustainability of land and water resources that are now faced in the twenty-first century.

The Brundtland Report

The United Nations World Commission on Environment and Development, chaired by Norwegian Prime Minister

Gro Harlem Brundtland, debated and investigated current concerns of the mid-1980s about the nature of development and the long-term consequences of certain development pathways. The report that was produced, titled "Our Common Future", but widely known as *the Brundtland Report* (United Nations World Commission on Environment and Development, 1987) reframed the environmental debate and laid the foundations for what was to become a new approach to development issues. The report provided a definition of sustainable development:

> Humanity has the ability to make development sustainable – to ensure that it meets the needs of the present without compromising the ability of future generations to meet their own needs.

Freshwater, together with food, energy, basic housing, and health are recognized as basic human needs. Sustainability introduces notions of sound management of the world's resources that leave them in as good a condition for the next generation as we find them today.

The report also advanced seven strategic imperatives and seven preconditions for sustainability to be achieved. The strategic imperatives advanced were as follows:

1. Growth be revived in the developing nations, to alleviate poverty and reduce pressure on the environment.
2. Notions of equity and nonmaterialistic values be included in the definition of growth.
3. Essential human needs for food, housing, and energy be met whilst accepting that this will necessitate changing patterns of consumption.
4. The issue of population growth be addressed particularly through reducing the economic pressures to have children.
5. The resource base be conserved and enhanced.
6. The necessary environmental risk-management technology be developed and also made available to the developing world.
7. Ecological as well as economic factors be taken into account in decision making.

Seven preconditions for these imperatives were identified as

1. responsive political decision making processes;
2. economic systems that make less resource demands;
3. responsive social systems that maintain union by redistributing both the costs and benefits of development;
4. production systems that can operate within ecological limits;
5. technology developments that support energy and resource efficient solutions;
6. international order that maintains cohesion globally;
7. responsive, flexible, self-correcting governments.

The report suggests that the shift to sustainable development must be powered by a continuous flow of wealth from industry but recognizes that future wealth creation will need to be much less environmentally damaging, more just, and more secure.

The report has been widely applauded for taking a long term and strategic, rather than piecemeal, approach to dealing with sustainability.

The Brundtland Report provided the stimulus for environmental organizations, industry, and development agencies to rethink their strategies and to develop the detail in the processes needed to address sustainability issues. Some of these detailed strategies, the "blueprints" for sustainability, have been defined, reflecting the needs of business, conservation, and development interests: The Natural Step, the Triple Bottom Line, Sustainable Livelihoods and the Pentagon, and Integrated Economic and Environmental Satellite Accounts.

The Natural Step

The concepts behind the Natural Step were originated by Dr Karl-Henrik Robert and are now being developed by the Natural Step Foundation (**www.naturalstep.org**). The Natural Step philosophy is based on four principles or "system conditions":

1. Substances from the earth's crust must not be extracted at a rate faster than their slow redeposit into the earth's crust.
2. Substances must not be produced by society faster than they can be broken down in nature or deposited into the earth's crust.
3. The physical basis for nature's productivity and diversity must not be allowed to deteriorate.
4. There must be fair and efficient use of energy and other resources to meet human needs.

The Natural Step Foundation claim that:

> The four system conditions provide a descriptive framework for a sustainable society. Participants on all levels – households, corporations, local authorities, nations – can systematically direct their activities to fit into this frame by requiring all secondary goals to function as natural steps in the process of achieving the four conditions of sustainability.

The World Business Council for Sustainable Development (WBCSD), a coalition of 125 international companies that claim a shared commitment to the environment and to the principles of economic growth and sustainable development, endorse the Natural Step approach. The approach is also supported by conservation organizations (IUCN, UNEP and WWF).

The Triple Bottom Line

Whereas the Natural Step focuses on the physical aspects of sustainability, the Triple Bottom-Line approach recognizes explicitly the social aspects. The ideas behind the Triple Bottom Line were developed by SustainAbility, (**www.sustainability.com**), a strategic management consultancy and think-tank concerned with foresight, agenda-setting, and change management. The elements of the "triple bottom line" are seen as representing society, the economy, and the environment (Elkington, 1997). Society is seen as dependent on the economy – and the economy dependent on the global ecosystem, whose health represents the ultimate "bottom line". The "bottom line" metaphor arose from business' use of the term to represent the profit figure in a company's earning-per-share statement. To arrive at this figure, accountants will, as part of standard accounting practice, collate, record, and analyze a wide range of numerical data that relates to economic performance. This approach is seen as the model for social and environmental accounting, to allow the calculation of the social and environmental "bottom lines".

The three bottom lines are not regarded as stable, but in constant flux, because of social, political, economic and environmental pressures, cycles, and conflicts. Elkington uses the example of plate tectonics to describe the movement of the lines:

> Think of each bottom line as a continental plate, often moving independently from the others. As the plates move under, over or against each other, 'shear zones' emerge where the social, economic, or ecological equivalents of tremors and earthquakes occur.

SustainAbility's Perceptions of the Shear Zone Interactions:

Economic/environmental

In the economic/environmental shear zone, some companies already promote eco-efficiency. But there are greater challenges ahead, for example, environmental economics and accounting, shadow pricing, and ecological tax reform.

Social/environmental

In the social/environmental shear zone, business is working on environmental literacy and training issues, but new challenges will be sparked by, for example, environmental justice, environmental refugees, and the intergenerational equity agenda.

Economic/social

In the economic/social shear zone, some companies are looking at the social impacts of proposed investment, but bubbling under are issues like business ethics, fair trade, human and minority rights, and stakeholder capitalism.

Sustainable Livelihoods and the Pentagon

The Department for International Development (DFID) White Paper on International Development (DFID, 1997), *Eliminating World Poverty: A Challenge for the twenty-first century*, presents the concept of the stewardship of natural resources so that the needs of both present and future generations can be met. Sustainability does not rely upon a "quick fix" solution becoming available in the future to reverse degradation. The White Paper also promotes the concept of "sustainable livelihoods" and this, together with the management of "the natural and physical environment" is expected to achieve the overall goal of poverty alleviation.

DFID provides the following definition for a sustainable livelihood:

> A livelihood comprises the capabilities, assets (including both material and social resources) and activities required for a means of living. A livelihood is sustainable when it can cope with and recover from stresses and shocks and maintain or enhance its capabilities and assets both now and in the future, while not undermining the natural resource base.

On the basis of the work of the Institute of Development Studies (Scoones, 1998), five types of assets, upon which individuals draw to build their livelihoods, are defined: natural capital, social capital, human capital, physical capital, and financial capital.

Capital Assets (Carney, 1998)
Natural capital

The natural resource stocks from which resource flows useful for livelihoods are derived (e.g. land, water, wildlife, biodiversity, environmental resources).

Social capital

The social resources (networks, membership of groups, relationships of trust, access to wider institutions of society) upon which people draw in pursuit of livelihoods.

Human capital

The skills, knowledge, ability to labor and good health, important to the ability to pursue different livelihood strategies.

Physical capital

The basic infrastructure (transport, shelter, water, energy, and communications), and the production equipment and means that enable people to pursue their livelihoods.

Financial capital

The financial resources that are available to people (whether savings, supplies of credit, or regular

remittance, or pensions), and that provide them with different livelihood options.

The consequences for natural resource management of applying this new "people-first" poverty-focused approach to sustainable development are not yet known. There are concerns that poverty-alleviation approaches focused at the microcatchment scale may result in "tragedy of the commons" type impacts at larger scales. Conversely, it could be argued that Integrated Water Resources Management (IWRM) approaches, although aiming to achieve net economic benefits to basin inhabitants, may not be taking sufficient account of the poorest in society.

Implementing the Ideals – the Blue Revolution

The different blueprints for obtaining sustainability objectives: the Natural Step, the Triple Bottom Line, the Pentagon, and Integrated Economic and Environmental Satellite Accounts (IEESAs), are not mutually exclusive. Nor are they definitive, and further efforts will be needed to achieve the Blue Revolution (Calder, 1999) in land use and integrated water resource management methodologies.

It is also recognized that successful implementation of integrated water resource management requires that the complementary elements of an effective water resources management system be developed and strengthened concurrently. These elements include

1. the enabling environment – the general framework of national policies, legislation and regulations, and information for water resources management stakeholders;
2. defined institutional roles and functions of the various institutions and stakeholders;
3. the management instruments, including operational instruments for effective regulation, monitoring, and enforcement that enable the decision-makers to make informed choices between alternative actions. These choices need to be based on agreed policies, available resources, environmental impacts, and the social and economic consequences.

The integrated water resource management process, which encompasses the ideals described above, has been defined by the Global Water Partnership as:

> "IWRM is a process which promotes the coordinated development and management of water, land and related resources in order to maximise the resultant economic and social welfare in an equitable manner, without compromising the sustainability of vital ecosystems" (GWP Technical Advisory Committee, 2000)

ECONOMICS OF LAND AND WATER

The Value of Water

Enshrined in the UNCED principles is the concept that water should be recognized and treated as an economic good, and economists are now able to devise methods for calculating the value of water as a commodity in its many uses.

The advantages to be gained by ascribing a value to water, and charging users a tariff related to this value include

1. provision of funds for water developments;
2. reducing demands on the public sector for the capital and recurrent cost of providing water;
3. releasing water for higher value use and assisting the prioritization of water allocation;
4. the resolution of resource conflicts between, for example, demands for water, power, fisheries, transport, and so on;
5. environmental benefits, through demand management, by releasing more water for environmental usage;
6. demand management, reducing the demand for water.

Provision of funds for water developments becomes increasingly important as cheaper sources of water become used up. The World Bank (Bhatia and Falkenmark, 1992) estimated that the cost of providing water from the "next" project was often two to three times that of providing water from the "current" project. Although US$10 billion was being spent each year on improving water supply and sanitation in the developing world in the early nineties, it was estimated by the World Bank that the investment would, even if costs were fixed, have to be five times this rate if reasonable water services were to be had by all by the year 2000. Cost recovery is, therefore, an important feature of a water pricing policy.

Reducing demands on the public sector and donor organizations as a result of cost recovery should, in theory, release funds for other forms of development. The World Bank estimated that in 1991, only 10% of the cost of water projects that it funded were financed by internal cash generation.

Releasing water for higher value uses will come about if water pricing is set at such a level that it discourages lower value uses. Water pricing can, therefore, be an effective instrument in water allocation.

The resolution of resource conflicts may be aided by realistic resource pricing instruments. Competition between agriculture, environmental, and hydropower requirements for water would be eased in many countries through water pricing, and agricultural demands for electric power for pumping groundwater for irrigation in countries such as India and China might be alleviated through realistic pricing of both water and electricity.

Environmental benefits. The environment as a valid user of water is becoming increasingly recognized. Also recognized is the increasing damage to the environment that comes through the growing supply and consumption of water. Abstractions for water supply, agriculture, and industry means less flow in rivers and the drawdown of water bodies. Lower flows in rivers also reduces the assimilative capacity and, with the discharge of pollutants, may lead to toxic conditions for wildlife and extra costs to public services for the treatment of water. Demand management, through curbing water use may have environmental benefits. In Australia, increasing charges for irrigation water is one of the instruments proposed to curb increasing salinization problems.

Demand management. Arguably, within the context of IWRM, the greatest benefits to be achieved from a pricing policy for water are in relation to controlling demands for water in situations where the water resource is close to being fully exploited.

DEMAND MANAGEMENT

> The equivalent of the Hippocratic Oath for water engineers is to promise to meet all reasonable needs for water without question by enlarging and improving supplies. – Winpenny (1992)

In many engineeringly developed countries, the ethos of the water engineer was to equate efficiency with maximum utilization of the water resource for the users. Taken to its limit, any residual flows in rivers were seen as wastage. With this ethos, environmental and ecological considerations and downstream users, especially if they were transnational users, were given little weight in the quest for "Development".

The trend away from supply-driven large water schemes toward greater demand management was well summarized by Arthur (1997); he recognized that "in the background of the differentiation between need and want, lies a much wider ideological conflict about the limits to growth".

In most countries, the accepted response to water supply shortages was to augment supplies. In the short-term demand management devices such as rationing, prohibited uses, public exhortation, and the use of standpipes, or the cutting off of supplies, are widely applied. But these nonprice devices, although often effective, are both costly and inconvenient to users and do not take account of the relative value of water to different consumers.

Where water is provided to users at a price less than the supply cost, a situation common in most parts of the world except the UK, the incentive for conservation and waste reduction is absent. This *negative* demand management leads to the paradox that in a situation when the water resource is already under stress, the subsidy is actually encouraging users to make additional demands upon it.

This situation is exemplified in India where subsidies to farmers in the form of free electricity encourages the pumping of irrigation water from boreholes from ever greater depths, leading to reduced environmental flows from catchments, and reduced access to water from downstream users.

The alternative approach, consistent with the concepts of IWRM, is to recognize that water resources are limited and new sources cannot be developed indefinitely. Demand management, in some form, must ultimately be applied, and the use of pricing is an instrument that can be both effective and can be defended by rational and objective arguments.

Although governments see many political hurdles in introducing water pricing policies, the principal concern being a short-term loss of votes, a secondary concern being the inflationary effect of charging for a commodity that is universally used, the benefits are increasingly being regarded as outweighing the disadvantages.

The development of a pricing policy for managing water demand does, however, require a methodology for deciding on the value of water to determine the price to be charged.

WATER AS AN ECONOMIC COMMODITY

Traditionally, water has been regarded as a "free" resource of unlimited supply with zero cost at the point of supply. Users have been charged for (often only a proportion of) the costs of transfer, treatment, and disposal. Opportunity costs for water are often ignored, and as a consequence, users have little incentive to ensure that water is used efficiently and not wasted.

The new (economic) approach to the allocation of water is to use prices and markets to ensure efficiency, and that water is supplied to its most valuable uses.

In an economic sense, efficiency requires that:

1. **Marginal Benefit of Use > Marginal Cost of Supply.** Which means that the users are able to derive greater economic benefit from the next unit of water supplied than the cost expended by the supplier in providing that extra unit of water.
2. **Marginal Benefit per unit of Resource is equal across all uses**. Where the supply of water is not unlimited, and the marginal units of supply have a positive cost, that is the supplier has to expend money to develop the next unit of supply water, the value of water consumption is maximized when net marginal benefits are equal in all uses. This implies that efficiency would be increased by transferring water between users until the marginal value of the water to the users is the same across all sectors. When equality of marginal values is achieved, further redistribution of water would make no sector better off without making another sector worse off.

In theory, it is possible to derive demand and supply curves that show both:

- the marginal benefit obtained from consumption and the willingness to pay; and
- the marginal cost of supply and the willingness to supply at given prices.

VALUING WATER

Various methods have been developed to determine the value of water in its many uses. Those, reviewed by Winpenny (1996) include

1. willingness to pay (WTP);
2. marginal cost analysis;
3. "netback";
4. WTP taking into account recycling and reuse costs;
5. in-stream value for pollution assimilation;
6. in-stream value for transport;
7. hydropower generation with and without capital costs included;
8. travel Cost and Contingent Valuation methods for amenity and recreational use.

For urban household consumers, the willingness-to-pay (WTP) approach has often been adopted to water pricing. This involves determining the demand curve, the relationship between the amount of water used by consumers and the charging price. This information can be obtained either by a survey, or from a knowledge of the change in consumption following a price change.

For agricultural use, the value of water is often determined in terms of marginal productivity. Here the economic benefits through increased yield or quality of the crop resulting from a unit addition of water are calculated under conditions when all other farm inputs are held constant. An alternative method *known as* "Netback" is related to the WTP principle. By taking the gross value of the crop per hectare and subtracting all production costs, and if required, a capital recovery cost and an acceptable profit margin, the remainder can be viewed as the maximum WTP for the water.

The same methodology can be applied to industrial water valuation, but as water is usually only a small part of total production costs, it would be misleading to attribute the whole of the remainder in the value and cost calculations to water valuation. For industrial use, another method is to regard the cost of recycling water, following water treatment as the upper limit on industrial WTP. The reasoning would be that if water pricing were greater than the treatment costs, industry would opt for treatment rather than buying water.

In-stream values for water arise through its natural capacity to assimilate waste and pollutants. This value can be compared with the alternative cost of reducing the pollutants at source or the additional costs incurred in water treatment. In-stream values for water for transport can be calculated as the cost advantage of water transport over the next cheapest form of transport (Winpenny, 1996).

Values of water for amenity and tourism have been calculated using the Travel Cost and Contingent Valuation methods. The travel cost method infers the amenity value from the travel costs of visitors to the site, which are then used to construct a hypothetical demand curve for the amenity or recreational value of the water-body. The Contingent Valuation method relies on opinion surveys to reveal the value that visitors derive from the water-body.

Winpenny (1996) has reviewed the values obtained for different uses of water in different parts of the world using the methods outlined earlier. Although he introduces the caveat that it is important to examine the fine print associated with each valuation before using the valuations as representative of the sector, there is a general picture that emerges: industrial uses are always high value, together with speciality crops and domestic uses (Table 1). Recreational uses can be high value whilst the majority of agricultural crops, often one of the largest overall consumers of water, are relatively low-value uses.

THE VALUE OF LAND USE

Whilst methods have been devised for valuing water in its many diverse uses including those for water supply, irrigation of crops, hydropower generation, industrial production, mining, amenity and recreational uses, and for the environment, there is also a need for methods for valuing land use. Within an IWRM context this is particularly true for land uses such as forests, which although having a high impact on water resources may have valuable multiple uses. These may include not only primary uses for timber production and other forest products but also secondary uses for recreation, conservation, and tourism. The valuation of land uses for primary production is inherently straightforward, although tax incentives and production subsidies may significantly effect the valuation. Valuation methods for secondary uses are less straightforward and more controversial but nevertheless important; in some circumstances, secondary land uses may be at least as valuable. Trade-offs need then to be considered between the value of water that may be forgone under a particular land use against the sum value of the different uses of the land.

Some of the methods that have been used for assessing the amenity and recreational value of land use are identical to those used for assessing the amenity and recreational value of water. Willis and Benson (1989) have discussed the use of travel cost and contingent valuation methods

Table 1 Estimated value of water for different uses, US$ per 1000 cubic meters

Use	USA Gibbons (1986)	China Dixon *et al.* (1994) Kutcher *et al.* (1992) Adams *et al.* (1994)	UK Rees *et al.* (1993) Bate and Dubourg (1994)	Zimbabwe Winpenny (1996)	South Africa Hassan *et al.* (1995)
Industrial process	180–800	500–4000		>230	
Speciality crop	100–800		80–140 (fruit) 1890 (potatoes)	100–150	
Domestic	20–360			>120	
Recreational	10–400				
Navigation	generally 0 but 370 in some stretches				
Intermediate value farm crops		average: 30 critical times: 90–100			100 (sugar)
Low value farm crops	10–60	<120	50–90 (field vegetables) 10–30 (cereals & grass)		100 (dryland crops) 0 (traditional livestock rearing)
Waste assimilation	0–20				
Industrial cooling	0–10				
Sediment prevention		0–20			
Power		20			

for assessing the recreational value of UK forests. They also discussed other "market related" methods including the Hedonic Price Method which links environmental assets with markets for private goods and services. The linkage of wages or house prices to environmental attributes were cited as examples that could be followed with this approach, but the practical difficulty in obtaining information on housing characteristics and sale prices of houses deterred the authors from pursuing this method for estimating the recreational value of forests. Using the travel cost method, Willis and Benson arrived at an average recreational value of UK £1.90 for one visit to a forest owned by the UK Forestry Commission. They estimated that the wildlife attributes of the forests contributed about 38% toward this value and showed that the total annual recreational benefit from the Forestry Commission's forests lay between £14 million and £45 million per year, later to be reassessed at £53 million (Benson and Willis, 1991).

Aylward and colleagues (Aylward *et al.*, 1998) have made an analysis of the use and nonuse values of different land uses on the catchment of Lake Arenal, the source area for Costa Rica's largest hydroelectric facility and irrigation scheme. This landmark study, entitled "Economic Incentives for Watershed Protection" takes into account both valuation, particularly non-use valuation related to watershed protection, and institutional analyses. Aware of modern research that has demonstrated that forests generally reduce water flows as compared with shorter crops, Aylward and colleagues state in their conclusions that "by examining the issue of externalities in detail the study shows that the crucial hydrological externality (water yield) and its relative direction (positive) are contrary to that expected by previous characterizations of the problem." They go on to say "while considerable variability can be expected in applying the valuation and institutional analyses to other sites and conditions, at a minimum this case study suggests the benefits of integrating the(se) two aspects of watershed analysis under a single framework. Additional case studies and more general theoretical work should assist in the development of a defensible consensus around rules of thumb, and shortcuts in such analyses that would contribute to better policy and project formulation. Such guidance is desperately needed given the current reliance on partial analyses and outdated conventional wisdom of what constitutes watershed protection, and watershed management in the humid tropics".

For the successful integration of land and water management, robust and accepted methods for valuing both water and land use will increasingly be required in the future. This is especially true where land and water are associated with environmental and recreational attributes, and where markets for environmental services are being developed (*see* **Chapter 193, Markets for Watershed Services, Volume 5**).

ENVIRONMENTAL ACCOUNTING

Environmental movements, including the IUCN, have long recognized that the System of National Accounts as defined by the United Nations, and implemented by governments worldwide does not accurately incorporate or take account the environment. National accounts are the economic data systems used to calculate familiar macroeconomic indicators such as gross national product (GNP), gross domestic product (GDP), savings rates, and income per capita. They are built and maintained by governments, following standard accounting practices defined largely through an international process coordinated by the United Nations.

Environmental accounting is seen as the mechanism by which national accounting systems can be modified to account for the economic role played by the natural environment. To increase international acceptance and implementation of environmental accounting, IUCN launched the first phase of its Green Accounting Initiative in 1996 (IUCN, 1998).

Several dozen countries have experimented with implementing environmental accounting methods to better understand economy-environment interactions and to test environmental strategies. Norway is one of the few countries to have institutionalized environmental accounting as a routine government activity.

Other countries have been active in developing environmental accounting methodologies. The US Bureau of Economic Analysis (BEA) has been responsible for developing the system of national economic accounts, which are used to produce the national income and product accounts, input–output accounts, and balance sheets for the US economy. Responding to the need for environmental accounting (Landefeld and Carson, 1994), the BEA produced a new accounting framework that covers the interactions of the economy and the environment.

It is expected that fully implemented IEESAs would allow the identification of the economic contribution of natural and environmental resources broken down by industry, by type of income, and by product.

A number of UK management agencies have commissioned and developed a variant of this approach as a basis for public participation. This approach was originally known as *Environmental Capital*, and more recently as "Quality of Life Capital". It is discussed more fully in **Chapter 192, Public Participation in River Basin Planning and Management: Quality-of-Life Capital as an Information Aid to Sustainable Decisions, Volume 5**.

IMPACTS OF LAND USE CHANGE, PUBLIC, AND SCIENCE PERCEPTIONS

Before we are in a position to devise and develop land and water policies that are aimed at improving either the water environment from the ecosystem perspective, water resources, economic returns, or for improving the livelihoods of poor people living within the catchment, it is important that we fully understand the biophysical impacts of any change in land use on the water regime. Arguably, the land use changes that have the largest impacts on water resources involve forestry and irrigated agriculture. It is clear that the "science" and "public" perceptions of the impacts of these activities are not always in agreement.

It is also important that the impacts of climate change, which may or may not occur at the same time as land use change, are also understood.

Forests and Hydrological Services

The conventional wisdom that forests are in all circumstances necessarily good for the water environment and, that they increase rainfall, increase runoff, regulate flows, reduce erosion, reduce floods, "sterilize" water supplies and improve water quality, has long been questioned by the scientific community. Although these issues have been debated since the nineteenth century (Saberwal, 1997), the "modern" science perception has been presented in a number of reviews by Bosch and Hewlett (1982), Hamilton and King (1983), Hamilton (1987), Bruijnzeel (1990), Calder (1992), particularly as regards tropical forests, and the more recent reviews, in the light of new studies by Calder (1999); Calder, 2000; Calder, 2005 and Bruijnzeel (2004), and the summary given in **Chapter 186, Water and Forests, Volume 5**.

On the basis of this conventional wisdom, in many countries of the world, forest and afforestation programs are still being promoted within watershed development programs on the basis of these "hydrological services" and "headwater conservation functions". In turn, the expectation is often that the increased "hydrological services" will benefit the livelihoods of poor people through increased access to water supplies. Planting trees to increase local rainfall and runoff are some of the misconceptions about water and land use that have influenced watershed development in India (KAWAD, 2001; Batchelor *et al.*, 2003; Calder and Gosain, 2003). It is believed that watershed management policies, which, together with increased afforestation, also promote increased irrigation from groundwater supplies as a means of improving the livelihoods of the poor, may be resulting in perverse outcomes (Calder and Gosain, 2003). In many Indian states, implementation of these policies has contributed to the lowering of groundwater tables to the extent that local people are now unable to access groundwater supplies through hand pumps and are having to purchase water from tanker deliveries.

Saberwal (1997) has reviewed the policy discourse in India, and traces the policy makers acceptance of the

positive link between water and forest to a "desiccationist" discourse promoted by Indian foresters since the middle of the twentieth century. The need to reconcile the public and science perceptions of forest and hydrological services has been outlined by Calder (2002), and is described in more detail in **Chapter 187, Land Use Impacts on Water Resources – Science, Social and Political Factors, Volume 5**.

Financing mechanisms designed to help conserve and protect indigenous forests, and to partly support the costs of reforestation programs have traditionally referred to, and are also often based on, this conventional wisdom. In Costa Rica, both the government led Payment for Environmental Services (PES) program, and all private agreements with the hydroelectric sector were initially based on this "universally accepted" knowledge, although currently it is defended as a "precautionary principle" in the absence of better – or more accepted – scientific knowledge. Further details on the development of markets for watershed services are given in **Chapter 193, Markets for Watershed Services, Volume 5**.

Land Use, Climate Change, and Water Resources

The interactions between land use, climate change, and water resources is an active research area, but one in which, as yet, there remains little consensus regarding the scale of the effects. Central to the research effort is the use of Global Circulation Models (GCMs) to represent the transfer of heat, water vapor, and momentum between the surface of the earth and the atmosphere. The GCMs require values for the parameters relating to the surface vegetation type and the availability of water to the vegetation, to allow the estimation of the heat and mass-transfer terms, under the atmospheric and rainfall conditions calculated by the GCM (*see* **Chapter 189, Land Use and Water Resources Under a Changing Climate, Volume 5**). Some of the limitations of the approach, particularly in relation to calculating the impacts of anthropogenic (greenhouse effect) climate change on water resources, have been identified by Bonell (1999). Bonell recognizes, quoting a recent International Hydrology Programme (IHP) expert group (Shiklomanov, 1999), that, even given the same initial starting conditions, different Global Climate Model (GCM)s lead to widely differing estimates of the extent of the climate change.

Nevertheless, at present GCMs represent the best technology available for predicting future climate change, and whilst it must be accepted that considerable uncertainty is attached to future GCM predictions, there is a need to understand how these climate change scenarios translate to future water resource scenarios. Further discussion on land use and water resource management under a changing climate are given in **Chapter 189, Land Use and Water Resources Under a Changing Climate, Volume 5**.

Agricultural Irrigation and Water Resources

To satisfy ambitions of food security and self-sufficiency, agricultural research for developing countries has traditionally focused, almost exclusively, on means of increasing productivity. As productivity and water use are intimately linked, agricultural and irrigation strategies, have often called for any remaining undeveloped water resources to be directed towards the agricultural sector. The requirements of other water users have not always been considered in these strategies. To support the water demands of this perceived priority user of water, Government Water Departments have placed great emphasis on developing the "supply side" infrastructure, activities associated with dam construction and the construction of transmission networks to irrigation schemes. For many years, the logic of this sequence of activities remained unquestioned. But with increasing support for the principles enunciated by the United Nations Conference on Environment and Development, which calls for greater recognition of equity, stakeholder involvement, the environment, and that water should be treated as an economic good, and with the publication of the report of the World Commission on Dams (2000), the past logic appears increasingly flawed.

Whereas in the past there would have been no doubt that agriculture should be regarded as the priority water user, questions regarding water priorities are now being posed in many countries. In Namibia, for example, although 43% of the country's water is used for irrigation, it contributes only 3% of GDP (Table 2).

The United Nations supported Consultative Group on International Agricultural Research (CGIAR) is now attempting to align strategies for increasing agricultural productivity within an environment of growing scarcity and competition for water through the System-Wide Initiative on Water Management (SWIM). The first paper produced under this initiative by Molden (1997) presents a conceptual framework for considering how water is used and recycled within a basin, and gives a useful definition of water accounting terms. Molden also makes the important point "that the portion of water diverted to an irrigation scheme that is not consumed, is not necessarily lost from

Table 2 Water use by sector and contribution to the Gross Domestic Product (GDP) in Namibia, from ''Sharing water in Southern Africa'', (Pallett, 1997)

Sector	Water used (%)	Contribution to GDP (%)
Irrigation	43.0	3
Cattle	25.3	8
Household + other	25.3	27
Mining	3.2	16
Tourism	0.4	4
Industry + Commerce	2.8	42

a river basin, because much of it may be reused downstream". An associated paper by Seckler (1996) discusses the concept of "dry" and "wet" water savings. Here "wet" savings are regarded as genuinely beneficial savings to the whole system that allow other, possibly downstream, users to make use of the savings. "Dry" savings occur if there are no "downstream" benefits from the savings, which might occur if the basin drained straight to the sea. Any texts such as these are surely valuable if they can introduce the ideas into the agricultural and, particularly, the irrigated agricultural community that there are downstream users that also need water, that allowing water to flow in a river and not use all of it for irrigated agriculture is not necessarily "a waste", and that there may, indeed, be valid environmental or downstream uses for that water.

There is no doubt that with an increasing world population and greater water requirements to produce the world's food needs, increasing efforts will be necessary to manage our land and water systems. To what extent the extra food needs should be met from increased irrigation or for the "horizontal expansion" of agricultural lands into grasslands and forests (Falkenmark, 2003) is the subject of current debates, and is also discussed in.

IMPLEMENTING INTEGRATED LAND AND WATER MANAGEMENT – STAKEHOLDER INVOLVEMENT

Increasingly, integrated land and water resources management is regarded as the philosophy, or process underlying the management of land and water resources. It is recognized that integrated land and water resources management must accommodate means of obtaining progressive commitments from stakeholders for new developments and initiatives.

Participatory Approaches

Principle number 2 of the Dublin Conference Report states:

> Water development and management should be based on a participatory approach, involving users, planners, and policymakers at all levels.

Whilst the participatory approach to water management and development was formalized in the Dublin Statement in 1992, participatory approaches had been advocated, and participatory methodologies had been developed, much earlier by social and management scientists in governmental and nongovernmental development organizations. The World Bank has compiled a sourcebook on participatory approaches that are outlined briefly below. The incorporation of vernacular knowledge in management approaches is also outlined below.

Glossary of Participatory Tools – from the World Bank Sourcebook on Participatory Approaches

- **Access to resources**. A series of participatory exercises that allows development practitioners to collect information and raises awareness among beneficiaries about the ways in which access to resources varies according to gender and other important social variables.
- **Analysis of tasks**. A gender analysis tool that raises community awareness about the distribution of domestic, market, and community activities according to gender, and familiarizes planners with the degree of role flexibility that is associated with different tasks.
- **Focus group meetings**. Relatively low-cost, semistructured, small group (4 to 12 participants plus a facilitator) consultations used to explore people's attitudes, feelings, or preferences, and to build consensus.
- **Force field analysis**. A tool similar to the one called "Story With a Gap," which engages people to define and classify goals and to make sustainable plans by working on thorough "before and after" scenarios.
- **Health-seeking behavior**. A culturally sensitive tool for generation of data about health care and health related activities.
- **Logical Framework or LogFRAME**. A matrix that illustrates a summary of project designs, emphasizing the results that are expected when a project is successfully completed. The logical framework approach to project planning, developed under that name by the US Agency for International Development has been adapted for use in participatory methods such as ZOPP and TeamUP. ZOPP, from the German term "Zielorientierte Projektplanung", is a project planning and management method that encourages participatory planning, and analysis throughout the project cycle. The TeamUP process assists stakeholders in planning and decision making and encourages stakeholders to collaborate as an effective working group.
- **Mapping.** A generic term for gathering in pictorial form, baseline data on a variety of indicators. This is an excellent starting point for participatory work because it gets people involved in creating a visual output that can be used immediately to bridge verbal communication gaps and to generate lively discussion.
- **Needs assessment**. A tool that draws out information about people's varied needs, raises participants' awareness of related issues, and provides a framework for prioritizing needs.
- **Participant observation** is a fieldwork technique used by anthropologists and sociologists to collect qualitative and quantitative data that leads to an in-depth understanding of people's practices, motivations, and attitudes.
- **Pocket charts**. Investigative tools that use pictures as stimuli to encourage people to assess and analyze a

given situation. Through a "voting" process, participants use the chart to draw attention to the complex elements of a development issue in an uncomplicated way.

- **Preference ranking**. Also called *direct matrix ranking*, an exercise in which people identify what they do and do not value about a class of objects. Ranking allows participants to understand the reasons for local preferences and to see how values differ among local groups.
- **Role playing**. Enables people to creatively remove themselves from their usual roles and perspectives to allow them to understand choices and decisions made by other people with other responsibilities.
- **Seasonal diagrams or seasonal calendars**. Show the major changes that affect a household, community, or region within a year, such as those associated with climate, crops, labor availability and demand, livestock, prices, and so on.
- **Secondary data review**. Also called *desk review*, an inexpensive, initial inquiry that provides necessary contextual background. Sources include academic theses and dissertations, annual reports, archival materials, census data, life histories, maps, project documents, and so on.
- **Semistructured interviews**. Also called *conversational interviews*, interviews that are partially structured by a flexible interview guide with a limited number of preset questions.
- **Sociocultural profiles**. Detailed descriptions of the social and cultural dimensions that in combination with technical, economic, and environmental dimensions serve as a basis for design and preparation of policy and project work.
- **Surveys**. A sequence of focused, predetermined questions in a fixed order, often with predetermined, limited options for responses.
- **Tree diagrams**. Multipurpose, visual tools for narrowing and prioritizing problems, objectives, or decisions. Information is organized into a treelike diagram that includes information on the main issue, relevant factors, and influences and outcomes of these factors.
- **Village meetings**. Meetings with many uses in participatory development, including information sharing and group consultation, consensus building, prioritization and sequencing of interventions, and collaborative monitoring and evaluation.
- **Wealth ranking**. Also known as *wellbeing ranking* or *vulnerability analysis*, this technique allows for the rapid collection and analysis of specific data on social stratification at the community level.
- **Workshops**. Structured group meetings at which a variety of key stakeholder groups, whose activities or influence affect a development issue or project, share knowledge, and work toward a common vision.

Indigenous and Vernacular Knowledge

For stakeholder involvement in environmental, land, and water management to be more than tokenism by planning and decision-making authorities, efforts are required to both structure the consultative process and incorporate stakeholder knowledge.

Newson *et al.* (1999) state:

> "Paradoxically, the planning ethos is open to all science, including "vernacular" science or the "common knowledge of ordinary folk". Adaptive planning, like public response to hazards, requires options and experience; whilst the scientist may set up the valid options, it remains the experience of (and "comfort" with) those options by the public which allow on-line adaptation of the plan to occur."

The incorporation of Indigenous Knowledge (IK) in development programs dealing with natural resource management is discussed by Barr (1998). Although the incorporation of IK is now becoming more common and methodological research on the incorporation of IK within natural resources research is now being developed, Barr warns of the difficulties associated with linking overlapping spheres of knowledge between local people at one end of a spectrum, with the applied and basic sciences at the other and with social scientists and anthropologists somewhere in the center. He argues that, in theory, natural resources IK has much to offer in tackling natural resource management problems, but the practical realities of operationalizing this type of interdisciplinary research are far from straightforward. Conflict, or at least disagreement, is recognized as a common feature of interdisciplinary research, especially where the disciplines are "closely guarded cabals".

The key importance of having appropriate and functioning links in place between the institutions involved in land and water management is discussed in **Chapter 194, Inter-Institutional Links in Land and Water Management, Volume 5**.

186: Water and Forests

GRAHAM JEWITT

School of Bioresources Engineering and Environmental Hydrology, University of KwaZulu-Natal, Pietermaritzburg, South Africa

Years of research in various parts of the world has highlighted the interaction between forests and water. Forests impact on the hydrological cycle affecting processes such as interception, transpiration, infiltration, groundwater recharge, and runoff. These inevitably manifest themselves as impacts on the water resource, both positive and negative. In this article, the role of forests in the hydrological cycle is described, and the potential impacts for water resources are considered.

INTRODUCTION

Approximately 70% of the Earth is covered by water and of the remaining land surface, over 30% by forest. Humans, forests, and water have a relationship that dates back for millennia. Throughout these times, both forest and water resources have been utilized by humans, often with a focus on one to the detriment of the other. Forests produce many goods and services that are utilized by humans. These include "traditional" commercial functions such as production of wood and other raw materials, as well as more difficult-to-value functions such as "biodiversity" that are fundamental to the to ecosystem integrity. Calder (1996) suggested that on a global scale, the largest land-cover change in terms of area, and "arguably also in terms of hydrologic effects, is from deforestation and afforestation".

It is well accepted that forests influence the hydrological cycle affecting both the quantity and quality of a catchment's water resources. The degree to which forests influence the hydrological cycle, the need to supply water resources to fulfill environmental and societal needs, and the associated management issues for both resources has evoked much controversy. The removal of forests for agricultural and industrial purposes has been blamed for both flood and drought, whilst in other regions, the establishment of commercial forestry has been blamed for reducing flow in rivers, and its establishment is controlled by water-specific legislation. Perhaps, because of the historical relationship between trees, forests, and humans, strong perceptions, both public and scientific exist (*see* **Chapter 187, Land Use Impacts on Water Resources – Science, Social and Political Factors, Volume 5**).

In essence, two broad schools of thought developed around the relationships between forests and water. A notion that has become entrenched in some quarters is that the complex of forest soil, roots, and litter acts as a "sponge" soaking up water during rainy spells and releasing it evenly during dry periods. The proponents emphasize that forests are "good" for water supplies and reinforce perceptions that forests "improve" water resources by recharging groundwater, maintaining baseflows, improving water quality, and moderating floods. Despite insufficient experimental data to support these perceptions, and the publication of many findings to the contrary, these are entrenched in policies and operational frameworks of many development agencies, foresters, and water managers.

The contradictory view is probably most effectively stated by Hamilton and King (1983) who suggested that "roots" may be more appropriately labelled a pump rather than a "sponge" and that "roots certainly do not release water in the dry season but rather remove it from the soil in order that the trees may transpire and grow". They added that "major floods occur because too much rain falls in too short a time, or over too long a time. In either case, the rainfall exceeds the capacity of the soil mantle to store it and the stream channel to convey it". In effect, they provided a thorough synthesis of issues that had been debated for over a 100 years, but were pioneers in an era of important advances in forest hydrology that have occurred over the past 25 years and which have improved

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

the state of hydrological knowledge in the field. However, contradictory results and difficulties in the measurement of some variables mean that a conclusive interpretation of how forests influence water resources is not always possible.

The strong perceptions and misconceptions that exist are symptomatic of problems in natural resource management, where the use of scientific information can degenerate into simple application of generalized values and a widespread belief is allowed to pass as fact. The result is that many aspects of land cover and water resource decision making are based more on perceived wisdom (myth) than scientifically established reality (Calder, 1999). These generalizations are seldom explicitly tested and are often applied inappropriately to address specific problems at local scales over short time periods. The consequence is that a body of "pseudo-fact" is generated in a self-reinforcing mode that seldom challenges theory, and eventually forms a barrier to effective, scientifically based management and perpetuates inappropriate paradigms or myths (Gunderson *et al.*, 1995). The failure of many individuals and organizations to understand the relationships between forest and water has led to the "misuse of both money and land" (Cossalter and Pye-Smith, 2003).

The subdiscipline of "forest hydrology" considers the scientific basis for these perceptions, whilst many of these misperceptions are explored in **Chapter 187, Land Use Impacts on Water Resources – Science, Social and Political Factors, Volume 5**.

Forests Around the World

A recent United Nations Environment Programme (UNEP) estimates that worldwide, there is approximately 40 million km^2 of forest, with just over 3 million km^2 in International Union for Conservation (IUCN) recognized areas (Table 1). This encompasses 25 different forest types, divided into tropical and nontropical, and includes both indigenous and exotic forest plantations, as well as "sparse trees and parkland", in which canopy cover ranges from only 10–30%.

Forest Plantations

There is an ongoing discussion worldwide of the potential environmental impacts of the large-scale establishment of forest plantations. The growing of trees to provide for industrial needs, in particular, pulp and fiber for paper production and charcoal for steel production, has become a major business over the past 30 years. The expansion of so-called fast-wood plantations has been particularly rapid in a few key countries in both the developed and the developing world (FAO, 2003; Cossalter and Pye-Smith, 2003). Fast-wood plantations are defined as intensively managed commercial plantations, set in blocks of a single species that produce industrial round wood at high growth rates (mean annual increment of no less than 15 m^3 per hectare), and that are harvested in less than 20 years (Cossalter and Pye-Smith, 2003). The rapid growth rates of such plantations imply high water use by them, and the typically short (6–12 year) crop rotations are intended to optimize this.

Table 1 Estimated extent (1996) of the global forest area (`http://www.unep-dwcmc.org/forest/homepage.htm`)

Region	1996 Forest area (km^2)	1996 Protected forest area (km^2)
Africa	5 683 130	496 927
Australasia	1 493 234	125 619
Caribbean	53 847	7899
Central America	901 984	88 096
Continental S and SE Asia	1 707 679	192 461
Europe	1815396	144 832
Far East	1 456 027	77 401
SE Asia	1 468 360	247 497
Middle East	167 661	6386
North America	8 453 988	699 956
Russia	8 257 159	150 637
South America	8 429 459	874 924
World	39 887 924	3 112 835

It is estimated that forest plantations cover approximately 10 million ha worldwide and that this area is growing at a rate in the order of 1 million ha per year (UNEP, 1996; Cossalter and Pye-Smith, 2003).

Invasive Alien Plants

Invasive Alien Plants (IAPs) have been identified as a major biodiversity and water resources problem worldwide. In the case of stands of IAPs made up of tree species, these may have similar characteristics to forests, and particularly in semiarid regions they have often been shown to use more water than the land cover they invade (Calder and Dye, 2001). For example, it has been suggested that IAPs are causing the loss of almost 7% of the annual flow in South Africa's rivers each year (Versfeld *et al.*, 1998). Water resources issues are especially highlighted in semiarid regions and much of the focus in this regard has been on IAPS growing in riparian zones, where it is believed that plants transpire more water than their counterparts elsewhere in the catchment (Mack and d'Antonio, 1998; Dye *et al.*, 2000), especially where dense stands develop (Sala *et al.*, 1996). This has reportedly led to reduction of flow levels in places by up to 50% (Higgins and Richardson, 1996; Mack and d'Antonio, 1998).

A Brief History of Forest Hydrology

Although most discussions around the topic of forests and water credit the work of European and American researchers with the first comprehensive studies of the

effects of forests on the water cycle, the history of forest hydrological research in China can be traced back to the mid-period of the Ming Dynasty (1368–1644)(Xinxiao, 1991). The earliest forest hydrology studies in Europe are reported to have been undertaken in Switzerland, reported by Engler (1919), and cited by McCulloch and Robinson, 1993). A major work by Zon (1927), in which the available literature on forest influences was summarized, preceded a period of "unparalleled research" (Lee, 1980; p. 16) not only in Europe and America, but also in East Africa (Blackie *et al.*, 1979), South Africa (Nänni, 1970; Scott *et al.*, 2000), and Australia (Best *et al.*, 2003). Kittredge, (1948) published his highly influential book "Forest Influences" that became a major reference work. Bruijnzeel (2004) reports that a heated debate on the hydrological role of forests took place in the 1930s and 1940s in the forestry journal of the former Dutch East Indies (Tectona). In the past 40 years, major text book contributions to the subject have been made by Hewlett and Nutter (1969), which were later revised by Hewlett (1982) and Lee (1980) and more recently by Chang (2002), as well as chapters and sections in the myriad hydrological text books that exist. However, the work by Hewlett – Principles of Forest Hydrology (Hewlett, 1982) probably remains the most prescribed forest hydrology text, and the review of forested catchment experiments by Bosch and Hewlett (1982) remains one of the most cited hydrological publications. Forest hydrology studies have been at the forefront of development of many hydrological theories. Perhaps, the most well known of these is the "variable source area" concept of runoff generation (Hewlett and Hibbert, 1967) proposed in 1965 at the International Forest Hydrology Symposium held at Penn State University.

Prior to 1980, the vast majority of forest hydrology studies were focused on water balance approaches such as paired catchment or split sample experiments. These studies were inevitably "input–output" type studies, with the result that critical processes such as transpiration and soil-water uptake had to be inferred, rather than measured. Arguably, the most significant advance in the studies of forest hydrology over the past 25 years have been allied with the advances in computing power and microcomputing techniques, which have provided the opportunities for the development of techniques and methodologies which allow the study of these processes representing internal catchment storages and fluxes and a more sophisticated study of "whole tree" water use. By 1993, at the "Water Issues in Forests Today" symposium held in Canberra, Australia, it was felt that the need for such process studies had been widely accepted as a new paradigm in forest hydrology (O'Loughlin and Dunin, 1993), and recent literature shows that researchers have undertaken detailed hydrological process studies in both forested and nonforested catchments as part of this new paradigm. Energy balance approaches using Bowen Ratio and Eddy Covariance, and more recently scintillation techniques has allowed more spatially and temporally detailed measurements of total evaporation, whilst sophisticated heat pulse and isotope studies have allowed for direct estimation of the transpiration component of the hydrological cycle. Advances with soil-water measurement instruments, such as neutron moisture meter and time domain reflectrometry have informed scientists about root uptake patterns and groundwater recharge beneath forests. Furthermore, advances in tracer studies are providing the impetus for the development on new theories of soil water and runoff generation (Bonell, 1998), whilst advances in remote sensing techniques provide opportunities for large-scale estimates of total evaporation.

Some argue that these process studies have been undertaken at a vast expense, resulting in many publications, but have done little to enhance the applicability of the science in a water resources management context and they at least need revisiting to address issues that are now relevant (e.g. DeWalle, 2003). In particular, the complexities of scaling results from detailed hydrological process studies at an experimental site to the catchment have slowed some of the expected progress in this regard. However, there have been notable cases where such process studies have had a direct influence on water resources planning decisions as highlighted in Section "Forests and water resources" below.

THE IMPACT OF FORESTS ON THE HYDROLOGICAL CYCLE

The influences of land cover on the hydrological cycle are well known (*see* **Chapter 117, Land Use and Land Cover Effects on Runoff Processes: Urban and Suburban Development, Volume 3**–**Chapter 120, Land Use and Land Cover Effects on Runoff Processes: Fire, Volume 3**). Forests, as a tall and often evergreen land cover, typically with deep root systems, litter layers, and secondary canopies occupy a particular niche in studies of land cover on hydrological functioning. The subdiscipline of forest hydrology has as its focus the way in which forests influence the hydrological cycle. As highlighted above, "modern" scientific understanding on forest hydrology has evolved from almost 100 years of research from forests based on paired catchment, water balance, and more recently detailed hydrological process studies. The vast majority of these studies indicate decreased runoff from areas under forests as compared with areas under shorter land covers. Furthermore, research has highlighted the potential for differences in water use between different forest and tree types, and the rapid increase in the area of forest plantations since the 1960s has highlighted the importance of different growth stages in tree water use.

Partitioning of Precipitation in Forests

Figure 1 provides a forest hydrology perspective of the hydrological cycle. In particular, the key water partitioning points of the hydrological cycle are highlighted, that is, the points where land cover in general, and forest in particular, are likely to impact on the hydrological processes that affect the way in which incoming precipitation is partitioned:

1. At the canopy level, incoming precipitation is partitioned into vertically orientated fluxes, that is, upward represented by evaporating water (interception loss and transpiration from the stomata) and downward represented by throughfall, stemflow, and canopy drip ultimately forming net precipitation once passing through the litter layer.
2. At the soil surface, net precipitation is partitioned horizontally into runoff and vertically into infiltration, as well as water vapor through direct evaporation from the soil or litter layer.
3. At the root zone, upward water fluxes are generated, that is, direct evaporation from the soil, but more importantly uptake of water by the root system for transpiration. In this zone, water is also partitioned both into downward percolation, ultimately providing groundwater recharge, and horizontally into "interflow", provided by unsaturated flow that moves downslope to eventually form runoff.

A perspective of the hydrological cycle that is becoming increasingly popular when considering water in the context of food and fiber production classifies water vapor and liquid water as green water and blue water respectively (Falkenmark *et al.*, 1999). Blue water is the runoff originating from the partitioning of precipitation at the plant canopy and land surface (eventually reaching the river network and forming streamflow), and the partitioning of soil water (forming baseflow and groundwater recharge). Green water is water vapor and is represented by the flow of water to the atmosphere as evaporation from soil, lakes, and water intercepted by canopy surfaces and transpiration by vegetation i.e. Total Evaporation (ET). As highlighted in Figure 2, which illustrates the expected differences in ET from grassland and forested catchments on the basis of equations derived from over 250 experimental catchments worldwide, in most forested catchments, green water flow greatly exceeds blue water flow (Zhang, 1999).

To the landowner, the benefits most commonly associated with green water use are the production of biomass resulting from the movement of water through agricultural crops and timber by transpiration. To others, forests offer attractive recreational areas and secondary products such as firewood or honey production. Such benefits can be considered "ecosystem goods and services", which foresters in particular, and society in general, derive from the land that is utilized (Jewitt, 2002a). The role of land cover in

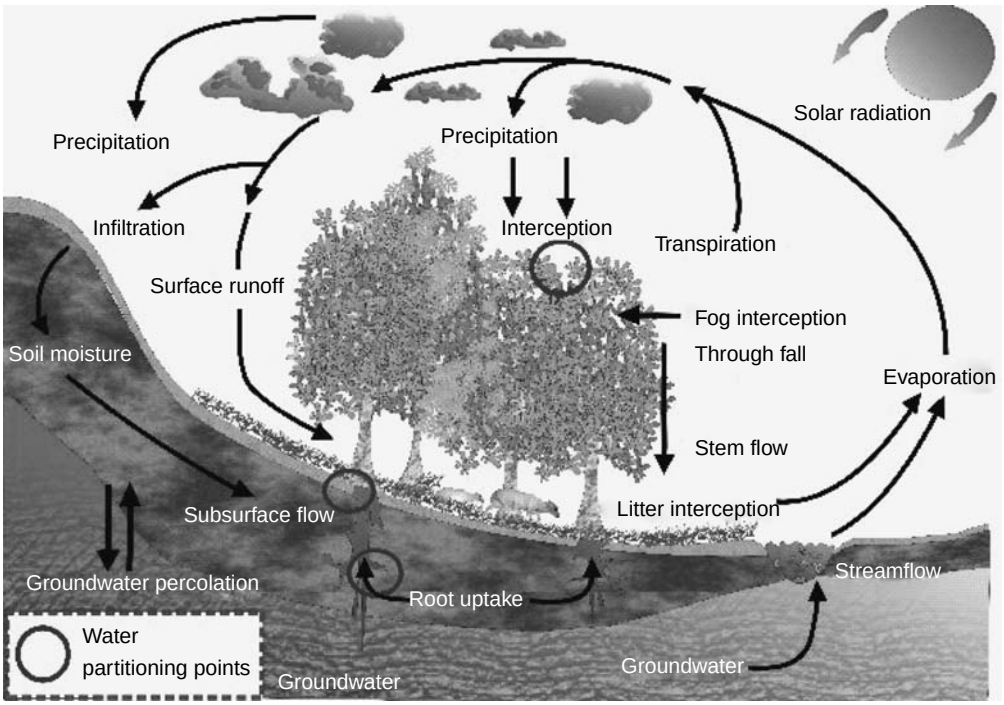

Figure 1 The key water partitioning points in the forest hydrology cycle. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

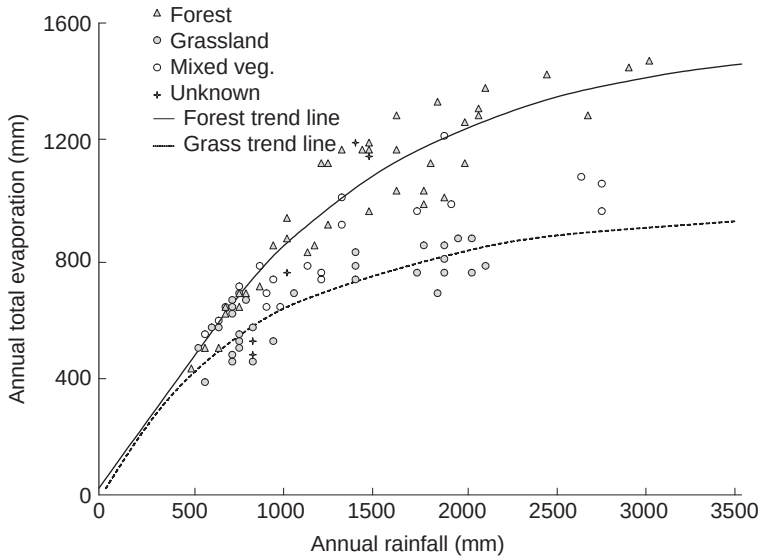

Figure 2 Relationship between annual total evaporation and rainfall for different vegetation (After Zhang, 1999, Reproduced by permission of the Cooperative Research Centre for Catchment Hydrology, CSIRO, Canberra, Australia). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

the catchment is of critical importance in this regard, as it partitions rainfall between water vapor flows to the atmosphere as evaporation and transpiration (green water), and the flow of water to rivers and groundwater (blue water). In arid and semiarid areas, runoff to rivers (i.e. blue water production) is generally less than 10%. Thus, a small change in the partitioning of rainfall by land cover, which is typically the case when forest plantations are established, can have a relatively large impact on runoff.

The Soil–Vegetation–Atmosphere Continuum

Forests and water cannot be considered in isolation, as the influences of forestry on water are largely dependent on the soil and climate conditions as well as the physiological characteristics of the tree itself. Although it may be useful to isolate different components of forest water use, it must always be recognized that these processes are part of a continuum. The fundamental importance of the soil–vegetation–atmosphere relationship and the hydrological role thereof has been increasingly highlighted in recent years, as process studies in forests have gained impetus, leading some to state that "Climate-Soil-Vegetation dynamics is the core of hydrology" (Rodriguez-Iturbe, 2000). Tree water use is driven by above (leaf area and pattern) and below ground (rooting depth and pattern) structure, and the rate at which water is used (interception and transpiration) that is further controlled by atmospheric and soil conditions. The role of soil properties in controlling infiltration, root water uptake, and evaporation from the soil as well as percolation of water through the soil and groundwater recharge coupled with an increase in studies of "whole tree water use" and water use efficiency is probably the most topical research aspect in forest hydrology today.

The main reasons for water use differences between forests and other land covers and different tree genera and species are related to physiological differences, that is, canopy and root structure. In assessing water use by different forest genera and species, a number of general points emerge:

- Different tree types have varying rates of transpiration under conditions of adequate available soil water (Bosch and Smith, 1989; Wullschleger *et al.*, 1998; Landsberg, 1999).
- Some trees maintain near-optimal rates of transpiration, even at relatively low soil-water content (Russel, 1973; Pryor, 1976; Landsberg, 1999). Others, however, are generally more conservative water users and reduce transpiration rates at higher soil-water contents and different atmospheric demands than other species.
- The distribution of roots differs with both age and tree type (Sherry, 1971) and in the case of man-made forestry plantations, will be affected by the method of site preparation used (Boden, 1984).
- The density of the trees' canopy will affect the amount of rainfall intercepted at the canopy level (Crockford and Richardson, 1990a).
- The thickness and nature of the litter layer on the forest floor will differ according to climatic conditions as well as tree type and age. The older the forest, the greater the build up of litter, and the higher the litter interception is likely to be.

Total Evaporation

Total Evaporation (ET) can be considered the consumptive use of water by a forest. It consists of the transpiration of water by plants and the evaporation of water from the soil and of the rain water intercepted by the forest canopy. ET depends on both climatic factors such as solar radiation, temperature, air humidity, and wind velocity as well as plant physiology factors, such as leaf characteristics (leaf area, evergreen versus deciduous), albedo, tree canopy, and rooting characteristics. Current scientific understanding indicates that in both wet and dry climates, evaporation from forests is likely to be higher than that from shorter crops (Calder, 1998) Trees form aerodynamically rough surfaces to the wind providing a high degree of turbulent mixing within the forest canopy. This results in the maintenance of high vapor pressure deficits and correspondingly high rates of transport of water vapor from the leaf surface to the atmosphere, and may result in evaporation from the canopy at rates in excess of reference potential evaporation during wet conditions (Calder, 1990). In the dry season and periods of drought, several studies have highlighted the fact that transpiration from forests is likely to be greater than other catchment land covers (Calder, 1990; Dye, 1996a), because of the generally greater depth and extent of their roots compared to other shorter land covers and the resulting greater access to soil water. Furthermore, litter is an important factor when considering the water balance of a forest, since it will both prevent a certain fraction of rainfall from entering the soil by intercepting it, and simultaneously will reduce soil-water evaporation losses and prevent overland flow.

Because of their size, longevity, and the deep rooting nature of trees and the fact that many forests grow in inaccessible areas, direct estimation of total evaporation from forests is particularly difficult. Typically, ET is either determined directly on the basis of microclimatic studies above the canopy, or indirectly by solving the water balance at tree, plot, or catchment scale. Conversely, in many studies, catchment runoff is calculated as the difference between precipitation and ET, or measured at the level of the streams coming from the upstream catchment area. Calder (1998) has suggested a "limits approach" to focus attention on the different processes that are hypothesized to control evaporation in temperate and tropical climates and wet and dry areas within these, and thus aid selection of which measurements are undertaken or which models should be used to estimate these. These limits are presented in Table 2.

Table 2 Principal limits and controls on evaporation for different land uses in different climates (After Calder, 1998)

Principal limits on evaporation		
	Temperate climate	
Land use	Dry	Wet
Tall crop	Physiology Soil moisture	Advection
Short crop	Soil moisture Radiation	Radiation Physiology
	Tropical climate	
Land use	Dry	Wet
Tall Crop	Soil moisture Tree size	Raindrop size Physiology
Short crop	Soil moisture	Radiation

Interception

When the forest canopy is closed, the interception of precipitation by forests is a major component of the influence that forests exert on the hydrological cycle. Interception by forest canopies has been considered to be one of the most thoroughly researched topics in hydrologic literature (Gray, 1970; Crockford and Richardson, 1990a). A detailed description of the interception process is found in **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1**.

Interception loss from forests depends upon the atmospheric condition driving the evaporation process and rainfall characteristics, but also on the density and nature of the forest stand. Usually, depending upon management practices, older trees have denser canopies, correspondingly higher canopy storage capacities, and higher interception loss from younger stands. It has also been noted that water droplet size affects the rate at which canopy storage capacity is reached. Thus, both raindrop size as well as canopy characteristics influence the drop size as it passes through the forest. In the case of forests with low leaf area, interception characteristics may be closely related to the drop size of the incident rain (Calder, 1996).

Significant differences in interception between evergreen and deciduous trees can be expected. For example, mature pines have a very dense canopy with high leaf area, are usually evergreen, have high surface tension between needles, and usually occur in temperate regions where rainfall of low intensity and small drop size is common and have been shown to have high values of interception loss (Crockford and Richardson, 1990b). Interception loss is estimated as 25–50% in conifer stands and 15–30% in deciduous forests. In semiarid regions and in forests of the tropical moist zone where high intensity convective storms are typical, the percentages of interception are variable, but are usually lower than in the temperate regions. In semiarid Mpumalanga, South Africa, Dye (1996a) believed that this reflects the less frequent, more intense rainfall characteristic of summer rainfall regions and concluded that transpiration, rather than interception from dry canopies was the dominant evaporation process in South African plantations. This conclusion can be extended to presume that the limit on ET in this situation is available soil moisture (Table 2).

Litter Interception Most forest stands have a forest floor of accumulated debris through which rainfall must pass before it enters the soil. Litter is usually regarded as beneficial to the forest system. Litter may play an important role in increasing infiltration rates in forest soils and may also protect the soil from temperature and moisture extremes as well as providing protection from erosional forces such as raindrop impact (Metz, 1958; Schutz, 1990). Litter also constitutes a critical source in the nutrient cycle and is a key to maintaining productivity in plantation systems. In many forests, but in particular in tropical and subtropical forests, tree roots use water and nutrients from the lower levels of the litter layer and as the forest stand matures, the importance of the litter layer in the nutrient cycle increases until it may eventually replace the mineral soil as the principal source of nutrients (Schutz, 1990).

As rainfall passes through the litter layer, some rainfall is retained and part later returned to the atmosphere by evaporation. The litter layer may have important effects on surface runoff, sediment yield and, as mentioned previously, infiltration into and evaporation from the soil. Researchers have shown that moisture intercepted by litter is governed primarily by moisture holding capacity and initial storage capacity of the litter, and by the evaporative demand following the rainfall event (Rowe, 1955; Helvey and Patric, 1965). Litter interception values range from 2% of mean annual precipitation (MAP) in temperate deciduous forests (Blow, 1955) to 4% in mature pine forests (Rowe, 1955; Bernard, 1963; Helvey, 1967). Pathak *et al.* (1985) estimated litter interception to be approximately 12% of MAP in a Himalayan forest.

Transpiration

The rate at which forests transpire is a function of the available radiant energy, atmospheric demand, windspeed, the nature of the rooting system, and the amount of water available in the soil as well as resistance imposed by the vegetation through stomatal conductance and the surface area of the leaves exposed to the atmosphere (Landsberg, 1999). In an undisturbed landscape, it is likely that the structure and leaf area of the vegetation will tend towards being optimal to utilize available water (Specht, 1972).

Essentially, transpiration is the process whereby water is evaporated through the stomata on the leaves of plants (*see* **Chapter 104, Satellite-Based Analysis of Ecological Controls for Land-Surface Evaporation Resistance, Volume 3**). Transpiration is both a result of, and a fundamental component of the photosynthesis process. In order to assimilate carbon, plants need to open their stomata. As the internal cells of the stomata are coated with water, the relative humidity within the stomata is assumed to be high, resulting in a vapor pressure deficit between the interior of the leaf and the surrounding atmosphere and thus, the movement of water from the leaf to the atmosphere. Thus, many of the tree and climatic characteristics that affect evaporation of water intercepted by the tree canopy also affect the transpiration process. Forest species vary considerably in physiological characteristics such as height, leaf area, stomatal resistance, whether deciduous or not, with the result that the amount of energy available to drive the evaporation and transpiration processes varies considerably between tree types. In this regard, researchers have highlighted the strong relationship that exists between leaf area and transpiration rates (Calder, 1998; Landsberg, 1999). Furthermore, the amount of water that is available for transpiration depends on the texture and depth of the soil and the ability of the plant to extract it. The drier the soil, the greater the tension between soil and water particles and the more difficult it is for trees to extract water resulting in reduced transpiration rates. The ability of plants to extract water from the soil varies according to root depth and pattern, as well as other physiological aspects, with the result that different tree types reduce their transpiration rates at different soil-water tensions (Russel, 1973; Pryor, 1976). Furthermore, the depth to which water is extracted corresponds to the rooting depth of the tree. In many circumstances, trees with deep roots can extract water that is unavailable to other plants. Initially, water is almost exclusively extracted from the surface layers; as the soil dries out, water is extracted from increasingly deeper levels of the soil profile (Richards and Caldwell, 1987).

Rates of transpiration from plants and the tree physiological factors that affect them are much debated. Coniferous vegetation has also been reported to close stomata when the surrounding atmosphere is dry, even if soil moisture is freely available. However, in the case of fast-growing eucalypt species, stomatal conductance and transpiration have been shown to be most strongly related to predawn leaf water potential and, thus, to soil moisture content (Mielke *et al.*, 1999; White *et al.*, 2000). Experiments and measurements based on porometer measurements of leaf conductance and rates of soil moisture depletion have highlighted differences in transpiration rates between species (Chang, 2002). In South Africa, Dye (Pers. Comm., 2003) have evidence that slow growing indigenous forest trees of the Podocarpus genus have much lower transpiration rates than commercially grown plantation species such as *Eucalyptis grandis*. However, although there may not be consensus regarding differences in stomatal conductance in trees, it is accepted that leaf area varies considerably and that these differences are likely to be more important than differences in stomatal responses (Landsberg, 1999). Periodic soil-water stress is also known to cause long-term adaptive reductions in leaf area, stomatal conductance, and sapwood structure and these may limit the rate of water use even in seasons when soil water is plentiful (Eamus *et al.*, 2000).

A phenomenon that has received some attention in recent years is that of "hydraulic lift", which is described as the movement of water from lower and wetter soil layers to upper drier layers. This results from the flow of water extracted from the deeper soil layers by the "trees" tap root, down the "trees" lateral roots, and extruded into the upper soil layers during the night when transpiration has ceased (Richards and Caldwell, 1987). This phenomenon is not typical of all tree types, but where it does occur, transpiration rates may increase as water becomes more readily available to the upper layers of the soil.

Infiltration, Drainage, and Recharge

Typically, forest soils have a high infiltration capacity. This is due both to the presence of above ground vegetation and litter that protect the soil from compaction caused by raindrop impact and because of the well-structured porous and highly permeable soils that are found to exist in forested areas. It is the forest floor rather than the canopy that is most important in controlling infiltration rates in forest stands (Hornberger *et al.*, 1997). However, it is also true that the forest canopy and litter reduce the mechanical effect of water drops that in turn protects and maintains the surface soil structure. High proportions of stemflow are common in many forest tree types and associated with this are high infiltration rates of the water flowing down the tree trunk to the soil surface.

In forest plantations, certain site preparation techniques, for example, deep soil ripping or the construction of terraces can substantially increase infiltration. However, the infiltration capacity can also be reduced by management practices associated with logging activities or fire.

Movement of Water in the Soil

The downslope movement of water in the unsaturated zone (often called *interflow*) is believed to play a very important role in the generation of both low flows and high flows (Rice and Hornberger, 1998; Lorentz *et al.*, 2003). It is clear from isotopic signatures that substantial portions of the storm hydrograph consist of pre-event water (Bonell, 1998). In addition, forest soils are often characterized by high levels of macropore development (Bonell, 1993; Lorentz *et al.*, 2003) and it is generally accepted among forest hydrologists that preferential flow within these macropores is a significant component of the hydrological functioning in forested catchments. Macropores form pathways where roots have rotted, or where cracks in the soil or animal burrows exist, and can form extensive networks, with the result that subsurface flow in these situations is transported in saturated form within these areas of the unsaturated soil matrix (*see* **Chapter 111, Rainfall Excess Overland Flow, Volume 3**–**Chapter 191, Environmental Flows: Managing Hydrological Environments, Volume 5**). Johnston (1987) reports that recharge of groundwater can also be positively affected by such preferential flow and provides evidence of recharge rates that increase from a range of 2.2–7.2 mm $year^{-1}$ to 50–100 mm $year^{-1}$.

Drainage and Groundwater Recharge

It is difficult to define the groundwater recharge component of the hydrological cycle, and often this perspective depends upon the scale at which associated processes are observed (Lorentz *et al.*, 2003). There has been much research on the hydrological functioning of the unsaturated zone, both in humid and arid regions. Important differences between them, such as the fact that the unsaturated zone is usually deeper in arid and semiarid areas lead to different interactions with land cover. Forests influence groundwater levels by direct abstraction of water from the phreatic surface where this is accessible to tree roots, but perhaps more importantly by impacting the rate of recharge of percolating water to the groundwater table, as tree roots abstract water from the unsaturated zone during the transpiration process. Whilst these two processes are probably most significant, the interaction of forests and groundwater is highly complex and depends upon the nature and type of vegetation, as well the position of the landscape as illustrated in Figure 3.

Forests are widely reported to have deep roots that can access groundwater directly. However, because hydrological studies tend to focus on the upper portion of the soil profile, there are very few studies that substantiate this perspective. Consequently, some authors believe that the ability of trees to dry out soil profiles to great depths or access groundwater directly is "not generally appreciated" (Le Maitre *et al.*, 1999).

FORESTS AND WATER RESOURCES

The processes associated with the key precipitation partitioning points highlighted above inevitably manifest themselves as impacts on the water resource. It is now generally accepted that forest cover has a negative impact on total water yield from a catchment. However, the impact of forests on low flows and on floods is highly controversial as has been highlighted by several authors (e.g. McCulloch and Robinson, 1993; DeWalle, 2003; Robinson *et al.*, 2003). The following sections serve to highlight the water resources impacts and benefits associated with forests.

Runoff and Catchment Yield

Many years of research in forested catchments worldwide has highlighted the major role that vegetative cover has on the total evaporation component of the hydrological cycle and the resulting catchment runoff. In some cases, this has resulted in the development of government policy specific to forests. For example, in South Africa, concern

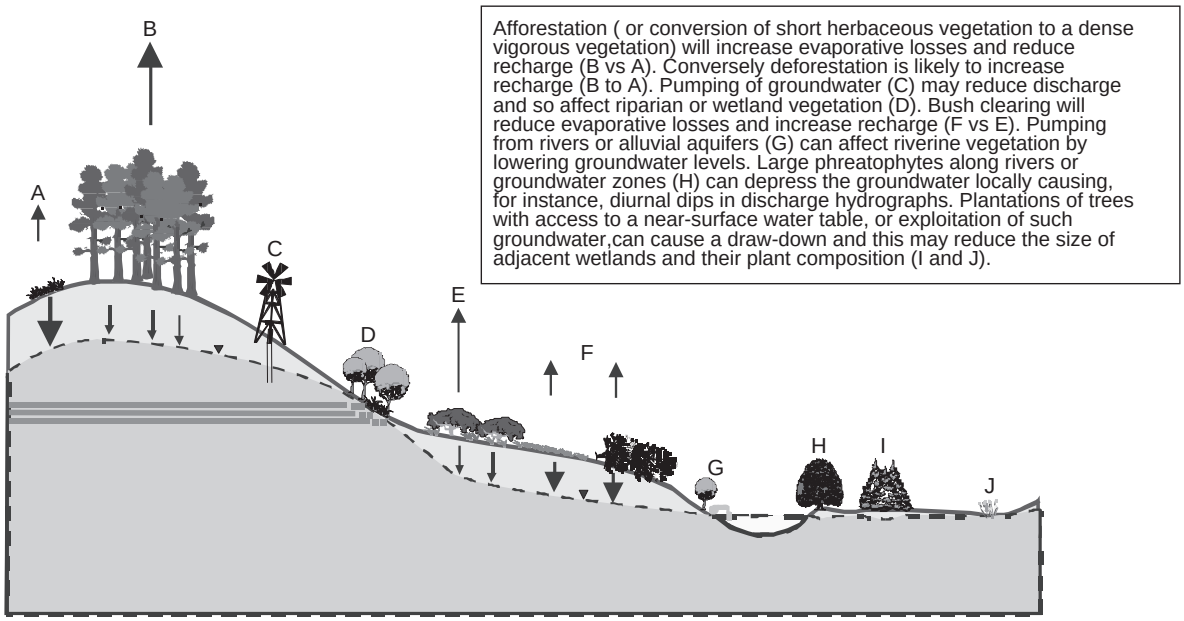

Figure 3 Some typical interactions between vegetation and groundwater (Drawing on ideas developed by Le Maitre *et al.,* 1999). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

regarding the impact of forest on available water resources has led to legislation controlling the establishment of commercial forest plantations since 1972. Under a new National Water Act promulgated in 1998, forest plantations have been declared "Stream Flow Reduction Activities", and as such landowners are required to apply for a water use licence before planting plantation forests. This legislation has been informed by many years of paired catchment and forest hydrology process studies, all of which have highlighted a reduction in runoff from areas converted to forest plantations, a summary of which is shown in Figure 4.

Peel *et al.* (2001) have highlighted the role that changes in ET may play in affecting variability in runoff. On the basis of an analysis of several catchments worldwide, they concluded that the variability of annual runoff is 1–9% higher for catchments with evergreen, as opposed to deciduous cover and presented the equation (for annual

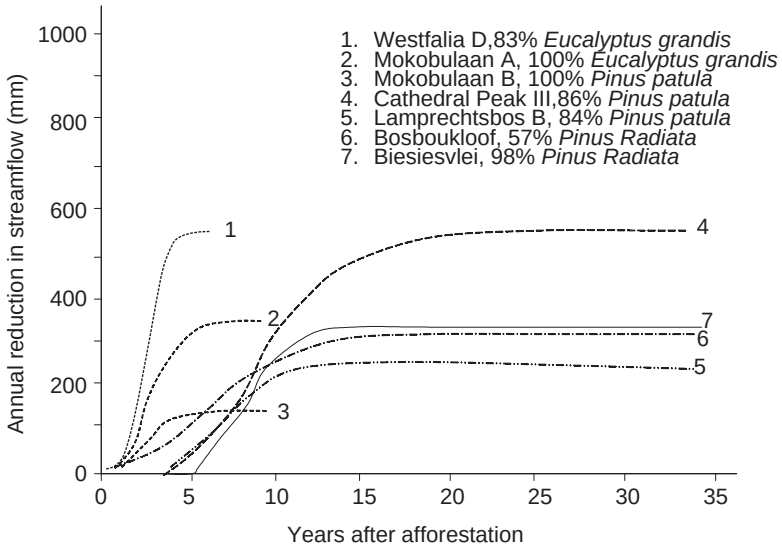

Figure 4 Streamflow reduction measured from six different paired catchment studies in South Africa with different extents of forest (Dye and Bosch, 2000, © South African Institute of Forestry)

values) below:

$$C_{vr} = C_{vp}\left(\frac{MAP}{MAP - AET}\right) \quad (1)$$

Where

C_{vr} – coefficient of variation of annual runoff,
C_{vp} – coefficient of variation of annual precipitation
MAP – mean annual precipitation
AET – annual total evaporation

The implications are that any change in ET in a catchment will alter the variability of runoff (assuming that precipitation is unchanged). Furthermore, if ET is increased, C_{vr} will also increase. As a change in land cover is the only significant change in ET that may be expected, Peel *et al.* (2001) concluded that any change in land cover that transpires more than the original will result in an increase in runoff variability, as well as a decrease in annual runoff. This is an issue of particular concern when tall evergreen tree plantations are planned in catchments with predominately grassland cover, and in addition to the well-known concerns in South Africa, which has led to calls for caution in the establishment of forest plantations elsewhere in the world (e.g. Vertessy *et al.*, 2003). The consideration of runoff reduction as well as increased variability is especially important when considering a potential reduction in water resources yield from a catchment. Peel *et al.* (2002) made use of the Gould–Gamma procedure to highlight the impact that such land-cover change could have on yield–storage relationships based on annual runoff from a catchment. According to this method, constant regulated yield (D), is a ratio of mean annual flow from a reservoir equal in size to the mean annual inflow into the reservoir with a reliability of 95% is defined as:

$$D = 1 - \frac{1.12}{1 - 1.67{C_{vr}}^{-2}} \quad (2)$$

Thus, storage yield is dependent upon both the amount and the variability of runoff with the implication that changes in catchment land cover that increase the variability of runoff must also reduce the yield and the reliability of that yield: a critical concern for water resources planners. In South Africa, the invasion of large areas of a catchment by forest species IAPs has been shown to reduce the yield from water supply systems considerably (Versfeld *et al.*, 1998; Gorgens and van Wilgen, 2004). Yield considerations provide a useful input to decision making. However, the provision of annual storage yield is only one of many considerations in water resources planning. In this regard, the consideration of periods of low flows when direct abstractions from a river, or when environmental minimum flows are specified, is critical.

Low Flows

Low flows are a normal, seasonal part of the natural hydrologic regime. Low flows are distinct from drought, though the effects are often similar (Smakhtin, 2001). In the absence of an adequate store of water, the low flow period is critical when considering competing water user needs, as it is in these periods that most conflict arises between different users, water supply schemes fail, river ecosystems are stressed, and water pollution issues are highlighted. As highlighted in the introduction to this article, it has often been suggested that forests behave as "sponges", retaining rainwater that is slowly released following a rainfall event or wet season and thus maintain or regulate river flows. However, recent advances in hydrological process studies, particular those which examine the interconnection between surface and ground water have highlighted the fallacy of this argument. Although many definitions of low flow exist, the key issue in the context of forest hydrology studies is an emerging body of work that highlights the role of accumulated soil moisture flow in the unsaturated zone, in addition to groundwater, in the generation of low flows (Kendall and McDonnell, 1998; Lorentz *et al.*, 2003). The basis for the assumption that forests "store water" is the high infiltration rate that is often found on forested soils, and the specific hydraulic properties of many organic rich forest soils. However, it is increasingly recognized that the transpiration demand of the forest and their deep roots that provide access to soil moisture deep in the profile mean that forests are more likely to have a negative, rather than positive impact on low flows from a catchment. Conversely, the most significant change following deforestation is an increase in "dry weather" streamflow (delayed flow) that arises from a decrease in total evaporation (Bonell, 1998).

Observations from South Africa and India indicate that increased dry period transpiration reduces low flows. Smith and Scott (1992), analyzing results from five of the South African catchment studies, concluded that percentage reductions in low (dry season) flow as a result of afforestation were actually greater than the reduction in annual flow. In South Africa, estimates of low flow reduction are considered more important in assessing applications for licences for commercial plantations than the estimated reduction in Mean Annual Runoff (MAR) (Jewitt, 2002b). In India, Sikka *et al.* (2003), focusing on the Nilgiri catchment in southern India, identified reductions in low flows in the driest months of the year when comparing streamflow from a grassland catchment with that from a catchment afforested with Eucalyptus globulus. In Fiji, the planting of Pinus radiata in a dry grassland area is reported to have resulted in a 65% reduction in dry season flows (Kammer and Raj, 1979) cited by FAO (1991). Conversely, observations from many parts of the world have highlighted the increase in dry season flows following deforestation (Bruijnzeel, 2004).

Authors such as Zadroga (1981) and Bruijnzeel (1990, 2001) have highlighted the hydrological significance of tropical montane cloud forests (TMCF) and their role in generating dry season flows through the interception of fog. However, Bruijnzeel (2001) concluded that it is the infiltration properties of the forest that are critical in determining how the available water is partitioned between runoff and recharge and that decreased dry season flows following deforestation in areas of TMCF may not necessarily result from the loss interception of fog, but possibly from decreased infiltration capacity of the soil once the forest cover has been removed. This highlights the importance of the partitioning points illustrated in Figure 1, and gives credence to Rodriguez-Iturbe's assertion that Climate-Soil-Vegetation dynamics is the core of hydrology (Rodriguez-Iturbe, 2000) with the recognition that different and often competing processes may dominate at different sites and that the direction, let alone the magnitude of the impact, may be difficult to predict for a particular site (Calder, 1998).

Groundwater Resources

Worldwide, forests have been reported to both increase and decrease groundwater depths (Chang, 2002). The combination of complex forest plant characteristics and subsurface stratigraphy and soil functioning mean that general statements in this regard are often not applicable at local scales. However, most reports on the influences of forests on groundwater suggest that the perception that forests are "good" for groundwater resources is false. Some authors have reported increases in available groundwater following deforestation (Hamilton, 1987; Ruprecht and Stoneman, 1993) whilst others, particularly in arid and semiarid regions, have reported a lowering in the groundwater surface following afforestation. Hamilton and King (1983) made a strong statement that "the overwhelming evidence from catchment research is that following reforestation, groundwater levels are lowered and stream yields are reduced, both effects being more pronounced during the dry season or growing season".

There is an extensive body of literature that highlights lowering of groundwater levels in response to afforestation (e.g. Bari and Schofield, 1992). In semiarid regions, most notably areas of Australia, there has been extensive research into the water resources problems associated with the rise of saline groundwater tables in response to removal of trees, particularly eucalyptus, to establish other forms of agriculture. In central England, a study by Calder (1999) showed there was no wetting of the soil profile beneath newly planted stands of Corsican pines, whereas wetting fronts were observed down the profile beneath stands of indigenous oak and heath vegetation. This suggests that large-scale establishment of Corsican pine in the area will have a detrimental affect on groundwater recharge, and thus water resources in the area.

Some forest species, by way of their deep roots are able to access the phreatic surface and directly abstract water, especially in cases where the groundwater table is shallow. Studies of the soil water use by trees of the Eucalyptus family under soil-water deficits in India (Calder *et al.*, 1993) and Australia (Ruprecht and Stoneman, 1993) have found that trees at some sites were obtaining most of their soil water from the groundwater, resulting in direct depletion of the groundwater. Conversely, there are many reports of rising water tables following the deforestation of parts of Australia, and reforestation is often seen as part of the solution to salinity problems that have arisen in these areas (Schofield, 1992.).

The issue of trees and groundwater in India has provoked much controversy. Many impoverished rural communities are dependent upon access to relatively shallow groundwater for their survival. However, a number of developments, including abstractions for irrigation and large-scale establishments of eucalypt plantations, have resulted in a lowering of the groundwater table, with concomitant impacts on rural livelihoods. Shiva and Bandyopadhyay (1983), focusing on the Karnataka region in southern India, described eucalyptus as a "disastrous tree for India" highlighting, *inter alia* the potential for the lowering of local groundwater tables through a reduction in the recharge of groundwater. The controversy has resulted in many publications, including reviews by the British Overseas Development Agency (ODA, now DFID) (Calder *et al.*, 1993; Calder, 1994) and the Food and Agriculture Organisation (FAO, 1989). Both reports confirm the potential for eucalypts to lower groundwater tables, but moderate many of the claims made by Shiva and Bandyopadhyay (1983). Calder *et al.* (1993) concluded that in three of the four sites studied eucalypts would not use more water than the indigenous vegetation, but would use more water than many of the locally produced crops. However, in one of the sites, water use was found to exceed rainfall, leading Calder *et al.* (1993) to conclude that it was possible that the trees were using groundwater directly. The FAO (1989) report recognized the potential for detrimental affects on local groundwater tables, but highlighted the water use efficiency by eucalypts suggesting that they consume less water for each ton of biomass produced compared to many other species.

Flood Peaks (Volume and Timing)

It is in analyzing the role of forest on floods that some of the most heated arguments surrounding water and forests arise. It is often claimed that forests prevent floods and that deforestation is a major cause of floods. A flood is the result of many complex catchment interactions. A catchment exhibits variable responses to similar magnitude rainfall events because of multiple interacting processes,

spatial variability in the susceptibility of the catchment to impacts, impacts of land cover and associated management practices, and amplification or suppression of response due to differing environmental conditions. With reference to Figure 1, it could be expected that interception of rainfall by forests may reduce the magnitude of flood peaks, delay their onset by intercepting a proportion of the storm rainfall and by creating soil moisture deficits prior to the event. Such effects would be most significant for small storms and least significant for the larger events. Furthermore, high infiltration rates under natural forests may also serve to reduce surface runoff and flood response.

However, forest hydrological studies carried out in many parts of the world: America (Hewlett and Helvey, 1970), South Africa (Hewlett and Bosch, 1984), United Kingdom (Kirby *et al.*, 1991), New Zealand (Taylor and Pearce, 1982), and Asia (Bruijnzeel and Bremmer, 1989) have all concluded that there is little linkage between land cover and storm flow. However, Fahey and Jackson (1997) have shown that significant decreases of 60% in mean flood peaks for different rainfall classes on small catchments in New Zealand, which were converted from indigenous tussock grasslands to pine plantations. More recently (La Marche and Lettenmair, 2001; Robinson *et al.*, 2003; Sikka *et al.*, 2003) have all concluded that the impacts of forest on floods are only likely to be noticeable for minor events and on small catchments. Bonell (1998) through a detailed study of catchment runoff mechanisms has shown that floods can occur from pristine forested drainage basins on the same scale as from disturbed areas. When unusually heavy storms form, floods are liable to occur whether forests are present or not.

However, field studies generally indicate that it is often the management activities associated with forestry such as cultivation, drainage, road construction (Jones and Grant, 1996), and soil compaction during logging that are more likely to influence, and may increase flood response, than the presence or absence of the forests themselves. Furthermore, Lee (1980) suggested that the most important influence of forest cover on floods and flood damage "has more to do with sedimentation and debris discharge than with absolute volume or rate of flow" (Lee, 1980 p. 280).

CONCLUDING REMARKS

Despite improved understanding of forest hydrology processes, there are still many calls for more research to address forest water use issues. Arguably, however, the area that needs most attention is the science-management interface. Too often, the complexities of the hydrological system have been simplified because of management approaches that cannot adequately consider complexity, and others whose goals are best served by promoting existing pseudofacts. The management of both water and forests requires a sound scientific underpinning. The investment in forest hydrology research worldwide has provided some of the best databases in the world in this regard. Ongoing innovations in hydrological process studies will continue to add value to this body of information. However, management of forests and water requires not only a sound scientific base, but also understanding, commitment, and collaboration of the responsible and affected organizations. As is the case in many aspects of natural resource management, scientists and researchers have failed to ensure that the results of their research are properly applied. The problems lie as much in scientists' reluctance to follow through to implementation of their research and present and promote their findings in management forums, as with the reluctance of management to deal with complexity. The interfaces between these stakeholders are still inadequate, and in particular, the satisfactory implementation of research findings into management operations is an area that needs much attention.

187: Land Use Impacts on Water Resources – Science, Social and Political Factors

TIM FORSYTH

Development Studies Institute, London School of Economics and Political Science, London, UK

Public perceptions of land-use impacts on water resources are important because they influence formal environmental policies and popular attitudes about land use. For example, upland agriculture and deforestation are commonly blamed for reducing rainfall levels and for causing lowland water shortages, and some governments have consequently passed logging bans or restrictions on upland agriculture. However, there is intense controversy concerning whether these public perceptions are supported by scientific evidence; whether these policies may actually address underlying problems; and how far hydrological science is itself influenced by social and political factors. This article draws upon debates in social science (rather than hydrological science alone) to discuss linkages between public perceptions and scientific explanations of hydrological change. As examples, the article discusses the cases of so-called Himalayan environmental degradation; dryland desiccation in the Sahel; and debates concerning the impacts of deforestation and reforestation in watersheds. The article argues that hydrologists should not categorize public perceptions and formal science separately, but see both as mutually evolving. Dominant perceptions, or "narratives", of hydrological change may occur from various coincidences of historical research and public concern, and reflect the viewpoints and experiences of only selected social groups. It is suggested that hydrologists can help overcome apparent conflicts between public perceptions and scientific explanations by increasing public participation in describing and framing complex environmental problems, and using this information to make existing narratives more diverse and flexible. There is also a need to understand the political and institutional factors that lead to the persistence of contested narratives within different national or organizational contexts.

INTRODUCTION

Human impacts on hydrological systems are a growing source of public concern. Few days seem to pass without some kind of public debate about society's impacts on water resources, which are usually seen as negative. In 2000, for example, Britain's Prince Charles once blamed a period of unusually high rainfall in Britain on "Mankind's arrogant disregard of the delicate balance of nature" ("Storms are Man's fault, says Prince" by Charles Clover, The Daily Telegraph, 7 November 2000, pp. 1). In other countries, many activists warn that excessive agriculture or deforestation will lead to desertification. Around the world, various policies and land-management schemes restrict human activities because of their presumed impacts on water resources.

But are these statements and policies justified? Can we really blame human activities for apparent problems such as water shortages or changes in rainfall? New research is suggesting that human impacts on water resources are highly varied, and that many common perceptions, or generalizations, about human impacts of land use are simplistic. These findings are fueling a debate about the origin of public perceptions of human impacts on water resources. The debate includes asking "how and why do public perceptions become seen as 'fact'?" Or, "how can we make public perceptions more accurate?"

This article of the Encyclopedia may be slightly different to others because it summarizes social and political debates rather than hydrological science alone. The article adopts a "science-studies" approach, or a focus on the political and social contexts that shape hydrological science. This

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

approach does not suggest that hydrological science cannot help explain environmental change, but instead shows how current and historic social concerns have influenced explanations of complex environmental problems. Understanding these social influences can help make hydrological science more effective and reduce apparent conflicts between public perceptions and science.

THE SOCIAL SCIENCE DEBATE ABOUT ENVIRONMENTAL ''MYTHS'' AND PERCEPTIONS

What are "perceptions", and why are they important? At the most basic level, all humans have their own perceptions – or experiences of – environmental events or changes. In this sense, a "perception" may be one person's individual experience of, say, a flood, or knowledge of how hydrological events occur, or what may cause them.

But "perceptions" may also include the tendency for large numbers of people to make assumptions about the nature or causes of environmental problems or hydrological events. In this sense, perceptions are no longer controlled by individuals' experiences, but are influenced by wide-scale discourses, or "received wisdom", and which are commonly reported in books, popular discussions, and media as though they are unquestioned "facts". Some examples of common perceptions concerning hydrology include:

- Forests increase rainfall (and hence deforestation decreases rainfall).
- Agriculture in upland areas reduces the downstream supply of water from those areas.
- Agriculture in dry lands leads to desiccation and irreversible degradation of land.
- Forests in upland areas reduce erosion and prevent lowland flooding (and hence deforestation may cause erosion and flooding).

Such views are frequently adopted as "factual" by many formal organizations such as state forestry departments or international development agencies. Yet, an increasing number of researchers are now questioning these statements because they are challenged by a variety of research and other evidence (e.g. Calder, 1999).

This kind of conflict between public perception and scientific research is, of course, not new, nor restricted to hydrology. Some authors have discussed the mismatches between orthodox perceptions of environmental problems and scientific research for years, and have called perceptions "myths" (see Leach and Mearns, 1996; Forsyth, 2003 for summaries). Some physical scientists have used the word "myths" to indicate scientific falsehoods, or the persistence of ideas after research should have falsified them. For example, Thomas and Middleton (1994) called desertification a "myth" because they claim recent research has made the traditional meanings attributed to "desertification" inapplicable to newer understandings of desiccation and drought (see the discussion of dryland desiccation below).

However, many social scientists have suggested that environmental "myths" should not be seen as falsehoods, but as "truths" that uphold some essence of cultural belief or knowledge (similar to ancient myths or folklore). This definition of "myth" throws the debate on its head: rather than asking why apparently false explanations still persist, we should ask why these explanations are still seen as "true" in certain contexts.

So, where do "myths" come from? For many analysts, the existence of environmental "myths" is explained by insufficient research or poor communication between scientists and the public and policymakers. Environmental problems are usually highly complex, and information is difficult to achieve for long time or space scales. Furthermore, it is not surprising that government agencies or the public cannot keep abreast of all research.

Researchers in science studies, however, consider these explanations insufficient. Instead of seeing a linear relationship – of science feeding public perceptions or policy – analysts seek each as coevolving and mutually enforcing. Under science studies, researchers look more at the social and political factors that lead to the identification and research of distinct environmental problems in the first place, and then at the social barriers to communication between different disciplines, social groups, or organizations. They argue that all scientific research reflects different social framings in what is researched, and how, and how policy circles see different knowledge claims as authoritative or legitimate. This approach does not ask "why doesn't the public or policymakers listen to science?" but, "what social factors lead to different scientific explanations being considered meaningful and true?"

It is worth reviewing the two main approaches to explaining environmental myths within science studies. The earliest approach (Cultural Theory is an approach influenced by British sociologist, Mary Douglas. It distinguishes itself from other cultural studies by using a capital C and T) argued that all societies inevitably contain four distinct social groups with specific worldviews (Schwarz and Thompson, 1990). *Individualists* are those seeking to maximize personal gain, and who see little social responsibilities for their actions (e.g. transnational corporations). *Egalitarians* are those most worried about the communal implications of social actions (e.g. nongovernmental organizations). *Hierarchists* are those seeking to impose rules on society in order to manage social actions and accommodate all perspectives (e.g. governments). And, *fatalists* are those who feel powerless to affect any change on how society works (e.g. poor farmers). According to Cultural Theory,

each group will explain environmental change in characteristically optimistic, pessimistic, managerial, or fatalist ways. Consequently, effective environmental governance would not rely upon deciding which of these worldviews was correct, but in devising a system of government that acknowledged all environmental claims were filtered in these ways. As Thompson *et al.* (1986) claimed, governors should not ask the public "what are the facts?" but "what would you like the facts to be?"

Later analysts, however, have questioned whether these four groups are too reductionist. The narrative, or storylines, approach focuses instead on the historical evolution of environmental explanations as linguistically and culturally embedded conventions (see Hajer, 1995). Under this approach, environmental myths emerge historically as the result of how different social groups and conflicts have defined them. Over time, narratives are seen to be factual or universal, but reflect only a limited knowledge of biophysical events, and limited perspectives on how such processes can be perceived by different groups. Two processes are especially influential on narratives. First, narratives usually reflect a selective "problem closure", or framing of how hydrological events are seen to be problematic to selected groups of people. For example, in Bengal, India during the nineteenth century, formal forest policies prioritized teak and sal production, and the practices of shifting cultivators were seen to be inimical to the objectives of the foresters. Hill forest areas were identified as less valuable for timber production and therefore, were burnt to encourage the cultivation of less valuable products such as sabai grass (Sivaramakrishnan, 2000). A second process is the formation of "discourse coalitions", or where political negotiations between different actors may serve to reinforce a narrative. For example, historians of environmentalism in North America have claimed that industrialization was associated with a growing perception of "wilderness" as threatened, and the urgent need to protect areas such as watersheds. This may lead to a discourse coalition when conservationist NGOs and governments may disagree about levels of logging versus conservation, but agree on narratives concerning the impacts of upland agriculture on watersheds even if these impacts are uncertain. This was perhaps illustrated when the Indonesian Forum for the Environment (Walhi) brought an action against the Indonesian government in 2004 for allegedly being responsible for flash flooding in Sumatra in 2003 by allowing logging to take place in upland watersheds.

Narratives, or storylines, therefore reflect the political debates of their day, and are partly controlled by the degree of public participation in formulating them. These, in turn, have political impacts and purposes. Hajer (1995, pp. 64–65) wrote, "Storylines are devices through which actors are positioned, and through which specific ideas of 'blame' and 'responsibility' and 'urgency' and 'responsible behavior' are attributed". Other authors have suggested that narratives allow actors such as governments or development agencies to foreclose scientific debate in order to support specific policies. "Development narratives tell scenarios not so much about what should happen as about what will happen according to their tellers – if the events or positions are carried out as described" (Roe, 1991, p. 288). Accordingly, it is important not to take a narrative at face value, and to ask, instead, on whose information and framings they are based.

The following examples illustrate some well-known narratives concerning land-use impacts on water resources. This article cannot hope to summarize all aspects of hydrological research on these important topics (see Bonell and Bruijnzeel, 2004; Bruijnzeel, 2004; Chomitz and Kumari, 1998), but the purpose here is to show the links between public perceptions and hydrological science, and how changing the framings and public participation has affected explanations.

HIMALAYAN ENVIRONMENTAL DEGRADATION THEORY

One of the most famous debates relating to public perceptions of land-use impacts on water resources is the so-called "Himalayan theory of environmental degradation". This narrative was used to describe processes of land degradation in the wet Middle Hills of Nepal resulting from the effects of rapid population growth and modernization. Eckholm (1976, p. 77) summarized the "theory" when he wrote:

> "Population growth in the context of a traditional agrarian technology is forcing farmers onto even steeper slopes, slopes unfit for sustained farming even with the astonishingly elaborate terracing practiced there. Meanwhile, villagers must roam further and further from their houses to gather fodder and firewood, thus surrounding villages with a widening circle of denuded hillsides."

In turn, these hillside processes have also been linked to a further vicious circle of deforestation and soil erosion that, in turn, enhance lowland floods and water shortages and sedimentation as far east as Bangladesh. Much of this narrative has been based upon the idea that forests form a "sponge" to hold water in the Middle Hills, and release this slowly throughout the year. This narrative has influenced environmental policy in various countries, and formed part of general watershed policies that link upland agriculture to lowland impacts (also see the discussion of watersheds). Indeed, the ecologist Norman Myers (1986, p. 2) wrote:

> "The Himalayan forests normally exert a sponge effect, soaking up abundant rainfall and storing it before releasing it in regular amounts over an extended period. When the forest is cleared, rivers turn muddy and swollen during the wet season, before shrinking during drier periods... Flood disasters are becoming more frequent and more severe."

Much research, however, has questioned many of the assumptions in the Himalayan theory (see Thompson *et al.*, 1986; Ives and Messerli, 1989; Ives, 2004). First, not all empirical work supported the basic premises that erosion and deforestation were occurring at unprecedented rates. One survey revealed that the estimations of deforestation rates in Nepal between 1965 and 1981 varied by a factor of 67, even after excluding some apparent typing errors (Donovan, 1981). This variety indicates that biophysical processes are more complex than commonly claimed. Moreover, it suggested that different actors and organizations represented environmental change in terms to suit their own perceptions and objectives.

Second, various research has questioned whether the metaphor of the forest as "sponge" is accurate, as trees form important sources of water demand. Some authors have suggested the metaphor of "pump" is better (Hamilton and Pearce, 1988; Bruijnzeel, 2004). In order to save space, the discussion of the impacts of upland land-use change on water supplies is discussed in the later section concerning deforestation and reforestation.

Third, research from anthropologists and cultural ecologists suggested that biophysical processes were not always experienced as problematic by farmers, who either knew how to lessen them, or who developed mechanisms to protect themselves against them. For example, one study found that some farmers triggered landslides themselves in order to revitalize soil fertility and facilitate the construction of terraces (Kienholz *et al.*, 1984). The assumption that population growth encouraged cultivation of steep slopes was also challenged by research in Nepal and Thailand, which indicated that upland farmers actually avoided steeper slopes because they knew this would accelerate erosion (Thapa and Weber, 1995; Forsyth, 1996). Studies like these showed the diversity of framings of environmental problems (or "problem closures"), and the need to consider both local evaluations of, and reactions to, biophysical changes.

And fourthly, geomorphologists argued that many processes of so-called degradation were probably more influenced by long-term geological or climatic factors that predated agriculture. For example, much mass wasting on steep Himalayan slopes can be attributed to tectonic uplift. Many deep gullies – or so-called *pahiros* – incising Himalayan slopes, reflect long-term erosion. Agricultural practices will inevitably have some impact on these processes, but it is unclear how far agriculture in itself is the sole cause of erosion (see also Gilmour *et al.*, 1987).

Of course, none of these criticisms suggest that there are no environmental problems in the Himalayas, or that upland agriculture and population pressure will have no impacts. But increasingly, analysts are arguing that we need to understand the social and political factors that led to the idea of "one" single model of environmental degradation, and how this reflected western concerns about the ecological crisis during the 1960s and 1970s, rather than acknowledging the diversity of local perceptions and the complexity of biophysical processes (Gyawali, 2000; Ives, 2004).

DRYLANDS AND WATER SCARCITY: DESICCATION IN THE SAHEL

Desiccation in the context of land use refers to the drying out of land, including the possible reduction in rainfall, resulting from human actions (see Saberwal, 1997). It is usually related to the similar concept of desertification, which is land degradation in drylands. Public perceptions of desiccation and desertification usually include images of fragile land being rapidly degraded by cultivation, grazing, and urbanization. The cofounder of the Worldwatch Institute, and well-known environmentalist, Brown (2001, p. 8) wrote:

> "Easily a third of the world's cropland is losing topsoil at a rate that is undermining its long-term productivity. Fully 50% of the world's rangeland is overgrazed and deteriorating into desert."

Public perceptions of human despoliation of dryland ecosystems are not new. Scholars in the eighteenth century, for example, considered the Sahara desert to have been created by the Romans and Phoenicians as the result of deforestation, overgrazing, and overcultivation (Goudie, 2000). Such beliefs were strengthened by the apparent collapse of local empires in North Africa. In 1324, it was reported that the Emperor of Mali, Mansu Musa crossed the Sahara to Mecca with 500 slaves and 100 camels laden with gold (Bass, 1990, p. 13). The caravan's arrival en route in Egypt depreciated the precious metals market there by 12%, and spread rumors of the fabulous wealth of the empire's capital in Timbuktu. The empire declined, however, as the result of competition from new Portuguese and Spanish empires, and in 1738 half the population of Timbuktu died of famine. When the city was visited in 1828 by a French traveler, he wrote graphically of his shock at finding apparent evidence of human failure in a barren land:

> "I looked around and found that the sight before me did not answer my expectations… [The city] presented, at first view, nothing but a mass of ill-looking houses, built of earth. Nothing was to be seen in all directions but immense plains of quicksand of a yellowish-white color. The sky was a pale red as far as the horizon, all nature wore a dreary aspect; and the most profound silence prevailed; not even the warbling of a bird was to be heard" (Caillié, 1830, in Bass, 1990, p. 13).

In time, such views led to the narrative that local land uses, and particularly agricultural intensification and grazing, were responsible for desertification. This was especially true in the Sahel, or the strip of land immediately south

of the Sahara, and comprising some of Africa's poorest countries such as Chad and Burkina Faso, and which has experienced sever drought since the 1970s. One British colonial administrator wrote about East Africa in 1937:

> "Anyone possessing some knowledge of the desert-country types can come and study the stages, quite sufficiently clear-cut once the eye is attuned to discerning them, by which the desert has through the centuries, assisted by man (sic), advanced over rich and fertile regions" (Stebbing, 1937, p. 1).

And consequently, many land-management policies have sought to control the physical processes of desiccation – such as by using fences to restrict sand movement – or restrict activities such as grazing. But again, the narrative linking desiccation to land use alone has been questioned. As with Himalayan degradation, criticisms have highlighted the role of human impacts vis-à-vis preexisting long-term biophysical processes. At the most fundamental level, land uses have not caused the existence of deserts, but these have developed because of long-term climate patterns influenced by large volumes of rising hot air (Goudie, 2000). Other studies have pointed out that many dryland zones – such as the Namib Desert of southwest Africa – are subject to cycles of relative wet and dry periods of precipitation, and consequently these cycles need to be considered before any analysis of land-use impacts (Thomas and Middleton, 1994). Other biophysical changes are difficult to estimate. Some analysts have sought to model impacts of land use–cover change on desiccation (for example, see Sud and Fennessy, 1982; Nicholson, 1988; Xue, 1997). But these models may be questioned too. For example, it may be reasonable to propose – as some of these models do – that rainfall may decrease by 25% if (say) an acacia savanna ecosystem was replaced by grassland used for pastoralism. But there are (at present) insufficient measurements, for the critical times, to indicate whether such changes took place. Plus, such changes are reversible, and are constantly in flux (Hulme, 2001, p. 26).

Critics have also questioned the public perception of drought itself. Hulme (2001) argues that the primary problem concerning public perceptions about the Sahel is the belief in the concept of a uniform climate that is in equilibrium. Instead, the climate – and associated drought – is highly variable over space and time. This implies that different localities have diverse experiences of climatic change. Furthermore, the concept that there is necessarily a problem of drought in the Sahel implies that the region has departed from some "normal" level of precipitation that is clearly identifiable. The so-called Sahel drought became a topic of international concern in 1972 and 1973, which were the region's driest years on record. At this time, analysts tried to predict the length of the drought according to past periods of dryness. But, counter to expectations, the years 1983 to 1985 were then even drier. The long-term trend suggested further desiccation. For the period 1931 to 1960, the 30-year average Sahel rainfall was 520 mm. Between 1941 and 1970, it was 512 mm. 1951 to 1980 was measured at 488 mm and 1961 to 1990 was measured at 428 mm. The predicted level for 1970 to 2000 was 410 mm (Hulme, 2001 p. 24). On this basis, perhaps it is more important to see the current "drought" as normal, and instead seek to explain how the decades of the 1920s, 1930s, and 1950s were comparatively wet.

The implications of these concerns is to place less emphasis on "desertification" or "desiccation" as identifiable processes with known causes and effects, and instead to see each as more varied and governable in different ways. For example, recent research has suggested that increasing land use, combined with dust storms, may be responsible for maintaining high levels of atmospheric dust over the Sahel, which may be responsible for reducing rainfall. Indeed, the growth in off-road vehicles may disrupt surface crusts and lichens and hence release dust to the air (Goudie, 2004). Similarly, social science researchers have urged more attention to the socioeconomic causes of vulnerability to drought within Sahel communities (Batterbury and Warren, 2001). For example, it may be more effective to encourage local technologies of rainwater harvesting as a response to drought, rather than to address only the broad causes of drought. In both these physical and socioeconomic cases, the approaches allow more flexibility in explaining environmental problems in the Sahel, and allow research to identify both the causes and responses to desiccation in more locally grounded ways. This does not mean suggesting drought or desiccation do not occur, or that they are not problematic. But it means we should replace simple narratives focusing on single causes with those that incorporate greater awareness of the narrative's history, and more local participation about current experiences and exposures to risk.

DEFORESTATION AND REFORESTATION IN WATERSHED ZONES

The examples of Himalayan degradation and desiccation in the Sahel are examples of narratives linked to specific locations. But the impacts of deforestation and reforestation in watershed areas are equally controversial and more general. Public perceptions in various countries attribute various land-use impacts on water resources, notably that deforestation will decrease levels of rainfall, or that upland agriculture will cause lowland water shortages, especially during dry seasons. In turn, it is commonly believed that reforestation is an adequate solution to these problems.

Yet, these views are also questioned. Sometimes, critics include those who oppose forest protection in order to allow logging. But other critics instead ask whether these explanations of hydrological impacts are simplistic, and whether the proposed solutions will be effective, or whether they would unnecessarily interfere in farmers' livelihoods.

Again, this article cannot hope to discuss all aspects of these hydrological debates (see Bruijnzeel, 2004), but seeks to illustrate the coevolution of perceptions and scientific narratives. Four themes are discussed: the meanings and extent of deforestation and the impacts of deforestation or upland agriculture on rainfall, lowland water flows, and erosion.

Defining ''Deforestation''

For many analysts, "deforestation" is a narrative in itself (Fairhead and Leach, 1998). Public perceptions usually state that deforestation is universally damaging, even though the term comprises great diversity. The impacts of deforestation on hydrological resources depend on its extent, and on the local socioeconomic needs attributed to those resources.

First, public perceptions often consider deforestation a wide-scale and uniform phenomenon. Undoubtedly, in many locations, deforestation has occurred at alarming rates, and continues to do so. But our knowledge of deforestation rates is highly varied. Comparisons of satellite data and ground surveys of forests, for example, suggest that some estimates based upon satellite imagery alone exaggerate rates of forest loss because of the simplifications and assumptions used in making estimates at different spatial scales. For example, Fairhead and Leach (1998, p. 183) estimated that total forest loss in six West African countries since 1900 may reach 9.5 to 10.5 million hectares, rather than commonly discussed estimates of 25.5 to 30.2 million hectares. (Indeed, some agencies, such as the World Conservation Monitoring Center, have placed deforestation in this region even higher, at 48.6 million hectares). As with Himalayan environmental degradation, we need to acknowledge the diversity of these estimations and ask why statistical uncertainties are often not acknowledged, and, accordingly, become seen as "fact".

Moreover, there are diverse framings or classifications of "deforestation". The term often conjures images of clearfell logging, such as in the Amazon. But widespread deforestation for commercial logging should not be confused with selective logging, the harvesting of nontimber forest products, or the cyclical burning and regrowth under forms of shifting cultivation (sometimes known in more extreme forms as "slash and burn" agriculture). Under these diverse forms of forest usage, it is crucial to consider what is meant by "deforestation". Each will have different impacts on resources. As two critics wrote:

> "The generic term "deforestation" is used so ambiguously that it is virtually meaningless as a description of land-use change... It is our contention that the use of the term "deforestation" must be discontinued, if scientists, forestland managers, government planners, and environmentalists are to have meaningful dialogue on the various human activities that affect forests and the biophysical consequences of those actions" (Hamilton and Pearce, 1988, p. 75).

Similarly, there are various meanings of the word "reforestation". Afforestation is commonly meant to imply planting trees where there were previously no forests, whereas "reforestation" is planting trees in sites of previous forest. Yet, of course, it is important to distinguish between monoculture forest plantations, and carefully reseeded, long-term reconstructions of diverse ecosystems. Some outspoken public perceptions are strongly for or against plantations, either because they are seen to be effective ways of replacing forests (including for the purpose of carbon sequestration) or because they are seen to be ineffective for hydrological or biodiversity problems, and may also exclude local land users from agricultural land. Eucalyptus plantations have especially been criticized because they have been associated with commercial forestry with little impacts on local economic growth, yet their fast growth rates usually absorb much water from local fields. A full investigation into the nature and impacts of reforestation/deforestation is beyond this article, but it is important to note that these terms evoke important, and historical, meanings, and are highly varied.

Do Forests Increase Rainfall?

Many public perceptions assume that deforestation reduces rainfall. For example, a magazine for tourists in Thailand carried an article entitled "*There's no doubt – it's a drought!*" by Thammasak Thinnsawat and David Hardy, *Good Morning Chiang Mai*, vol. 4 no. 3, pp. 12–23. March 1999 which claimed: "the bottom line is forests decimated by excessive tree felling and land denuded by slash and burn agriculture severely reduce cloud formations – and thus rainfall, the main cause of Thailand's drought". Similarly, the leader of the Chipko environmental movement in India once claimed that cutting forest results in drought (World Water, 1981). The link between forests and rainfall is easy to make, because so many forests exist in rainy areas – notably rainforests and mountainous zones.

Research, however, has sought to redefine these narratives. At one level, the presence of forests will usually influence cloud formation because of higher levels of evapotranspiration and humidity than experienced under other land uses. But much research has suggested, instead, that many forest areas follow, rather than cause rainfall, and that long-term patterns of climate and topography have more influence on precipitation than forests. Moreover, the impacts of deforestation on albedo (or atmospheric reflectivity) are also considered less dramatic than originally thought because most replacement vegetation has similar reflective values.

Research into the impacts of deforestation on rainfall is usually hard to achieve because a temporally monitored experiment, using a large land area, is infeasible. Furthermore, these studies do not always use the same baseline or extent of "deforestation", or acknowledge the impacts of other climatological factors such as the El Nino

Southern Oscillation. But various studies using time-series data or simulations have suggested that there is little statistical evidence for forests causing rainfall. There are many examples. One of the earliest studies (Bernard, 1953) found no evidence for forests influencing rainfall in the Central Congo Basin (estimated one million km^2). Research in Russia, reviewed by Shpak (1968) indicated that forestland produces approximately 10% more rainfall than land without forest (in Hamilton, 1988, p. 103). In southern India, annual rainfall over the last 100 years has not decreased, even despite the general conversion of the dry deciduous forest to agriculture, although evidence suggests a decline in the number of rainy days (Meher-Homji, 1980). Tangtham and Sutthipibul (1989) found a negative correlation between 10-year moving averages of annual rainfall and remaining forest area in northern Thailand, 1951 to 1984, but a positive correlation between forest area and number of rainy days. A further study found no changes in rainfall totals or patterns on the 12 100 km^2 Nam Pong basin in northeastern Thailand between 1957 and 1995, despite a decrease in areas classified as forest from 80% to 27% since the 1970s (Wilk *et al.*, 2001). And in the Amazon basin, Global Circulation Models have suggested that removing even the entire Amazon basin would result in reduced rainfall, especially in the dry northeast of Brazil, of only an average of about 0.5 mm per day (Rowntree, 1988).

But, of course, these studies do not suggest that forests have no influence on rainfall. Some simulation studies suggest forest conversion over areas between 1000 and 10 000 km^2 may cause delays in the formation of clouds. This result was found, for example, in deforested areas of southwestern Amazonia (Cutrim *et al.*, 1995). Similarly, reductions in clouds was observed over deforested parts of Costa Rica during the dry season, but these reductions were not observed in neighboring Nicaragua in regions with good forest cover (Lawton *et al.*, 2001). Most importantly, there is strong evidence that some forests do influence rainfall in specific locations such as coastal or montane regions, where fog may coincide with tall vegetation. In such "cloud forests", cloud-water interception may account for some 5% to 20% of ordinary rainfall, and even more in exposed sites (Bruijnzeel, 2004, p. 194). In these locations, deforestation is likely to have notable impacts on local levels of precipitation and lowland supply of water.

The public perception that forests cause rainfall reflect a general trend to see deforestation as damaging to water resources, and is supplemented by popular beliefs about water supply and erosion.

Do Forests Increase Runoff?

A further public perception is that deforestation – and associated activities such as upland agriculture – may disrupt water supplies to the lowlands, notably by reducing supplies during dry seasons or by increasing flooding during peak flows. Linked to this, some organizations have called for reforestation in upland areas to prevent water shortages. Countries such as Thailand and China have also implemented logging bans partly for these reasons. One of the common beliefs underpinning these interpretations is that forests act as a "sponge" in watersheds, which hold water throughout the year. Converting the forests to agriculture may result in losing this sponge effect, and hence damage the water-holding properties of watersheds.

A variety of public experiences have confirmed or contradicted these statements. There are numerous reports within lowland sites of springs drying up after deforestation. But there are similar reports following reforestation. Some researchers have consequently argued that we need to distinguish more closely between total water yields, and the seasonal distribution of flows (Bruijnzeel, 1990). Similarly, it is difficult to generalize about land-use impacts on the basis of information from various sites, which vary in terms of underlying geology and climate, and, again, in terms of how deforestation is defined and experienced.

That said, many hydrologists agree that removing forest cover by a third or more results in significant increases in streamflow because of reductions in evapotranspiration. In effect, this is to suggest that forests do not necessarily act as "sponges" in watersheds, but as "pumps". As Bruijnzeel (1990, p. 84) wrote:

> "Removal of forest cover leads to higher streamflow totals and reforestation of open lands generally leads to a decline in overall streamflow."

And similarly, various studies suggest that upland agriculture, or limited forms of deforestation, may impact only marginally on lowland water supplies. Alford (1992) in Thailand, for example, concluded that there was no apparent connection between net runoff from river basins and shifting cultivation between 1976 and 1987 (although it is worth noting that much deforestation from shifting cultivation started in the nineteenth century, and so these results may not be fully representative). In Africa, two studies estimated the increase in water supply following the conversion of forests to crops was an estimated 140 mm per year in Nigeria (Lal, 1983) and 410 mm per year in Tanzania (Edwards, 1979). No declines in annual streamflow have been reported following lowland tropical forest removal (Bruijnzeel, 2004, p. 199). Such results have also been applied in reverse in relation to the impacts of reforestation. For example, Bosch (1979) found that afforestation of former grasslands with pine resulted in reductions in both annual streamflow (of 440 mm) and during the dry season (of 15 mm). These were supported by later research in South Africa by Scott and Smith (1997) who also found that the reduction in dry season flows were actually greater than the reduction in annual flow rates. In Kenya, water yields have been reported to return to original levels within

eight years where pine plantations replaced forests (Blackie, 1979). Bruijnzeel (2004, p. 209) wrote:

> "The conclusion that already diminished dry seas flows in degraded tropical areas may decrease even further upon reforestation with fast-growing tree species seems inescapable."

Yet, these findings are contingent upon a variety of local contexts, and particularly the protection of soils under and around forests. The case of tropical montane cloud forests generally experience low evapotranspiration, and removing these forests may also reduce the impacts of this vegetation on channeling water to the ground (see discussion of rainfall and deforestation). Different geological zones have varying runoff efficiencies (or the ratio between water input as precipitation and output as streamflow). Alford (1992), for example, estimated basins in Thailand to have a comparatively low efficiency of just 20%. This low efficiency, and the observed lack of responsiveness from rainfalls to lowland flows were attributed to the extraction of water by local irrigation and dams before they reached the main river channels (Walker, 2003). Different soil conservation measures may also enhance or reduce the ability for soils to hold water. (The topic of erosion is discussed in the Section "Do forests reduce erosion?").

Similarly, the influence of land-use changes on flooding is also controlled by local topographical and climatic factors such as rainfall events, hydraulic conductivity of soil, and slope morphology. It is therefore difficult to find clear relationships between simple criteria and flooding. In Nepal, for example, Hofer (1993) found no statistically significant relationships between river discharge, precipitation, and flooding in large watersheds between Nepal and the Gangetic plain. After analyzing some 40 years of data, he later wrote of the Ganga–Brahmaputra–Megha river system:

> "It can be inferred that floods are a normal process in the Ganga-Brahmaputra-Megha lowlands. Neither the frequency nor the magnitude of flooding has increased over the last few decades. Consequently there is no reason to believe that floods in the lowlands have intensified as a result of human impact in the highlands" (Hofer, 1998).

Earlier research in the Nepal Himalayan produced similar results at a smaller scale. Marston *et al.* (1996, p. 1) studied data at 22 stream crossings together with drainage basin morphometric data and information about forest cover to identify the controls on bank-full discharge from monsoon storms. They claimed: "results demonstrate that 82% of the variation in bank-full discharge can be explained as a function of drainage area alone; forest cover did not add explanatory power" (see also Calder and Aylward, 2002).

As with other biophysical events, the framing and perceived frequency of floods may reflect socioeconomic trends. The dramatic impacts associated with flooding may frequently be linked to the increased financial valuation of flood damage, and the trend towards locating housing and economic activities on floodplains, rather than a universal increase in the size and frequency of floods. Hamilton and Pearce (1988, p. 87) warned that public perceptions often misplace the causes of flooding:

> "These stormflow effects must not be extrapolated to support statements that appear in the press (and the misconception commonly held) that logging in upper watershed is the principle cause of serious and widespread flooding in the lower reaches of major river basins."

This article cannot hope to summarize the diverse and large literature concerning land-use impacts on water flows. Instead, the purpose is to illustrate the strength of public perceptions despite various hydrological studies that question them. These differences are discussed further after the final exploration of deforestation and erosion.

Do Forests Reduce Erosion?

It is generally agreed that severe soil erosion can seriously damage the ability of soils to hold water. Erosion also restricts the supply of nutrients and water to plants. Cultivation of steep slopes usually accelerates erosion, and the removal of tree canopies can accelerate splash erosion, at least in the short term. Many policy statements therefore state that upland cultivation is a primary cause of erosion, and that reforestation can help reduce erosion. Indeed, much statistical information about different rates of soil erosion show that sheet (or surface) erosion occurring under forests is much less than under agricultural plots.

Hydrological research does not question the general perception that erosion is problematic, or that agriculture can accelerate erosion. But there are various questions about how far upland agriculture is the primary cause of erosion, or how far reforestation is a solution. First, many authors have pointed out that much debate about erosion and watershed degradation overlooks the role of naturally occurring erosion, which can also occur under forests, although mainly in hilly areas. As discussed under Himalayan degradation, many deep gullies (called *pahiros* in Nepal) predate agriculture, and can occur in forestland. Similarly, gullies on agricultural plots in South Africa and Thailand should not be blamed on agriculture, but should instead be seen as characteristic of granite weathering (Twidale, 1982; Froehlich, and Starkel, 1993; Forsyth, 1996). A further category of erosion is mass wasting, or landslips, which have generally been linked more to climatic and geological factors (including tectonic uplift) rather than the impacts of agriculture or deforestation. Statistics that show less erosion under forests than on agricultural land are usually based on the measurement of sheet (or surface) erosion. Sheet erosion is still an important form of erosion and does reduce agricultural productivity and water-holding properties of soils. But full

measurements of erosion should also include other forms of erosion.

Second, some studies have also suggested that reforestation using plantations can accelerate erosion. Teak (*Tectona grandis*), for example, has been shown to increase splash erosion because of its large-sized leaves, and hence reforesting land with teak plantations in order to reduce erosion may have surprisingly counterresults (Calder, 1999, p. 30). Trees exposed to fire may also find that litter layers burn quickly, thus exposing soil to erosion.

Thirdly, various studies show that hill farmers have acknowledged the problem of erosion and taken steps to reduce it or avoid it. This topic also implies asking how different land users frame the problem of erosion, and this has been controversial. For example, many studies of farmers' perceptions of soil erosion have produced results that erosion is not perceived to be a problem by farmers, and this has occasionally reinforced narratives that farmers do not care about the impacts of upland agriculture on environmental problems. It is indeed likely that many farmers do not perceive impacts of erosion on watershed properties, and this may be especially true for the so-called "pioneer" form of shifting cultivators who historically relocated villages every 10 to 20 years in search of fertile ground (Harper and El-Swaify, 1988). But various social scientists have pointed out that the word "erosion" usually means different forms of degradation to different users, and that farmers are certainly more likely to perceive problems of declining soil fertility, of which erosion is a part, rather than erosion *per se*. On this basis, various studies have shown how farmers may avoid overall problems of soil degradation by adopting soil conservation measures, or organizing agriculture to avoid steep slopes (for example in Amazonia: Nortcliffe and Dias, 1988; in Papua New Guinea: Sillitoe, 1993; and in Sarawak: Hatch, 1983; Douglas *et al.*, 1993.)

Local land-use patterns and vegetation may also have an impact on how far soil erosion on slopes may result in sediment yields in rivers. Alford (1992) in Thailand, for example, found that suspended sediment transport in northern Thailand is comparable to the lowest values measured in river systems of the world to be between 44 t km^{-2} (Ping river) and 256 t km^{-2} (Nan river). For comparison, the more arid and tectonically active Hunza river of Pakistan has a sediment load of 13 200 t km^{-2}, while the Tamur river in eastern Nepal carries 5500 t km^{-2}. Moreover, the relationship between streamflow and sediment transport in Thailand was observed to be more constant on a year-to-year basis than streamflow and precipitation. Alford argued that these findings suggest that the sediment in Thailand's rivers is more likely to come from sources within the stream channel rather than erosion from slopes. This again suggests that local dams and rice fields trap both water and sediment from higher slopes, and hence that eroded material may not travel very far. Indeed, these results have been found in other cultivated slopes (Trimble, 1983).

Some studies have shown increases in sediment yield when farmers have removed logs or other barriers that act as barriers for soil movement (e.g. in West Java: Bons, 1990). The construction of roads, however, has been blamed for accelerating erosion. In Indonesia, one study suggested that rural roads were just 3% of the study area, but contributed disproportionately to the total basin sediment yield (Rijsdijk and Bruijnzeel, 1991). Similar results have also been found in Africa and South America (see Ziegler and Giambelluca, 1997).

Again, of course, the purpose of this discussion is not to suggest erosion is unproblematic or that upland agriculture does not cause erosion. The purpose is to challenge simplistic narratives that blame erosion on agriculture alone, or which suggest that reforestation is an adequate response. Frequently, actions by the state such as road construction or plantation forestry may even increase erosion. Reducing erosion from agricultural land is clearly necessary, but considering different framings and the variety of hydrological research on this theme will inevitably result in more complex and more effective explanations and policy responses.

Linking Public Perceptions and Science

Of course, there is insufficient space in this article to review all debates and information about watershed degradation. But it is clear that there are many differences between common public perceptions of environmental problems in watershed areas and scientific explanations. Why do these differences exist? What do they tell us about the relationship of science and public concern?

As discussed in the section on environmental "myths", environmental narratives arise from the unquestioned adoption of existing explanations for phenomena based on historic framings of events and partial public participation in the formulation of explanations. Some watershed narratives have clearly been constructed from the viewpoints and experiences of some, rather than all, social groups. For example, the perception that upland agriculture may cause lowland water shortages may reflect the experiences of many lowlanders that water shortages are increasing, and the framing that watershed zones should be managed to increase water supplies to the lowlands. But shortages may also occur because of growing lowland demand for water, and an alternative framing of watershed areas may also acknowledge the potential impacts of reforestation and resettlement on upland livelihoods. If a narrative is a succinct summary of cause, effect, blame, and responsibility, then it is not surprising, perhaps, that some actors may seek to find solutions for problems that do not involve changes to their activities, but instead seek to attribute causes elsewhere.

Similarly, dominant public perceptions or narratives may also emerge because of the great uncertainty and contestation of environmental policy in many locations, and the relative absence of inclusive and critical arenas for environmental policy formulation. Universal hydrological "laws", or statements of cause and effect, are difficult to achieve because of the variety of contexts in which land-use changes occur, and the diversity with which different users evaluate or frame impacts. It is difficult to generalize conclusions between different scales because of the growth in complicating factors and concurrent changes at larger scales. Furthermore, words such as "deforestation" and "upland agriculture" are often used without acknowledging the diversity they contain. Debates may be dominated by actors who fear that "deforestation" means logging, or that "agriculture" implies the most destructive forms of slash and burn, when in fact there are various less damaging forms of cultivation in-between.

The nascent character of many environmental policy-making arenas, and a relative lack of participation in the application formal expertise, may also contribute to the evolution and persistence of narratives. In rapidly developing countries such as Thailand or Nepal, environmental politics may also be dominated by new political allegiances between the state and domestic activists (see Ives, 2004). As discussed above, classically this trend has been associated with a desire of urban middle classes to perceive "wilderness" as threatened, and hence to protect forests or watersheds from the impacts of modernization or population growth. These desires may coincide with those of the state to assert ownership over forestland, or to place controls on mountainous or watershed zones for other reasons such as national security. As discussed in the section on "myths", these alliances may "discourse coalitions" in favor of reforestation and restrictions on agriculture, despite evidence questioning the hydrological assumptions of these policies. The lack of local arenas for discursive governance (where both local experiences and framings of environmental problems can occur), or the domination of scientific discourse by state agencies, may strengthen narratives.

But it is important to note that criticizing these narratives is not the same as suggesting that there should be no concern about watersheds, or that upland agriculture has no impact. As with debates about Himalayan degradation and dryland desiccation, the objective has been to assist scientific explanation by showing the simplicity of the narratives, and identifying more relevant and locally determined targets of research. This involves diversifying public participation in research and policymaking. Bruijnzeel (2004), for example, suggests that the debate about tropical forests and hydrology risks focusing too much on questions concerning forest protection, rather than highlighting the important supplemental role of soil protection. This suggestion is clearly justified for the purposes of securing lowland water supplies because evidence suggests that soils may be more accurately described as a "sponge" than forests. But protecting soils may also address upland framings of environmental problems by protecting agricultural productivity. Reframing environmental narratives to focus on new targets may allow the creation of more holistic and equitable forms of environmental policy. Protecting upland livelihoods as well as watershed properties may also reduce the socioeconomic driving forces behind some forms of agricultural expansion and deforestation. Furthermore, policymakers should investigate other explanations for water shortages, such as the role of increased water demand in the lowlands, or introducing ways to make lowland settlements less vulnerable to events such as floods.

CONCLUSION

Public perceptions of land-use impacts on water resources are often dramatic and simplistic. But it is wrong to see perceptions as "separate" from science. Instead, both public perceptions and scientific explanations coevolve historically, and many expert bodies such as government agencies or scientific organizations share these perceptions. Consequently, it may be better to call public perceptions "narratives" because they are succinct summaries of complex events that are taken as true by various actors. Certain narratives can dominate, or be seen as unquestioned "facts", when there are sufficient supporters of the explanation, or when alternative explanations are less publicized or seen to be less applicable by the people currently involved in the policymaking process.

This article has summarized three debates where such narratives exist: "Himalayan" environmental degradation, dryland desiccation in the Sahel, and impacts of deforestation and reforestation in watersheds. In these cases, complex biophysical processes involving various elements of serious land degradation have been linked to public perceptions – or narratives – of change that have been questioned by various types of hydrological research. Many physical scientists have suggested that the way to improve the accuracy of these narratives is to conduct more research, and to enhance communication between scientists, the public, and policymakers. While these actions are, of course, welcome, many social scientists suggest such strategies are insufficient because they do not acknowledge the social and political origins of narratives and their persistence. As an alternative, social scientists, and particularly science-studies scholars, argue that we should look at the mutual dependencies of science and public perceptions, and to use this knowledge to enhance hydrological research.

The first, and most important, point made under a narrative approach is that narratives serve to foreclose scientific and political debate. Believing, for example, that

upland agriculture always causes lowland water shortages (and that, consequently, upland reforestation will solve this problem) may be used to legitimize reforestation or the relocation of villages without public debate. A more critical approach would question the hydrological evidence for this presumed relationship of agriculture and water shortages, plus how far this relationship reflects framings of specific social groups (see sections above). For example, in Thailand, many government agencies, environmental activists, and media repeat the narrative that upland agriculture has to be restricted or partly replaced by upland reforestation in order to regulate dry season water flows and avoid lowland water shortages. Yet, much research suggests that reforestation (if done on a widespread level) may actually reduce flows, and that water shortages may be better addressed by managing lowland water demand. A more holistic approach might ask how far lowland water supplies, reforestation, and upland agricultural livelihoods can be enhanced concurrently. Diversifying the framing of problems – by seeing problems as both in lowland and uplands, rather than simply for the viewpoint of lowlanders – may therefore lead to more effective and more equitable solutions. Indeed, this approach may result in scientific progress by rejecting explanations that have been questioned by research, and instead refocusing research on topics that are considered more relevant. As discussed above, it may be necessary to see upland soil protection, rather than forests alone, as a means of protecting both upland livelihoods and lowland water supply.

Foreclosing of debate may also take place through the unquestioned used of language. For example, Blaikie and Brookfield (1987, p. 4) famously remarked that "one farmer's soil erosion is another's soil fertility". Of course, this statement does not suggest that erosion (or sedimentation) is unproblematic. But it shows how words such as "erosion", "deforestation", or "wilderness" evoke images of environmental cause and effect, or of the status of a particular problem. Adopting a narrative approach requires seeing the implicit meanings in these words, and the specific histories of how these meanings were identified, and with whose participation. A narrative approach acknowledges the cultural embeddedness of supposedly "factual" words and explanations in order to show how alternative framings and experiences may lead to different explanatory conclusions. There is also a need to see much more diversity – and contestation – within terms such as "deforestation" in order to indicate that this does not always imply "logging", or similarly that "upland agriculture" or "shifting cultivation" need not necessarily mean the most stereotypically destructive forms of "slash and burn".

The existence and persistence of narratives reflect the degree of public participation in formulating scientific explanations. Enhancing participation increases the range of information about biophysical events, and diversifies how events are framed. Many environmental "myths" remain unchallenged because alternative framings are not seen to be necessary, and because existing narratives do not interfere with current socioeconomic activities. For example, the old "myth" that the Sun rotates around the Earth has been challenged by science for centuries, and would make some activities – such as space travel – untenable. But for the majority of humans, there is no practical need to challenge this myth, and most people still say "the Sun rises in the morning", even though this statement is clearly inaccurate. In similar ways, many narratives of watershed degradation are unchallenged by lowlanders because they have not yet considered alternative framings of watershed policies from people living in highlands. But the increasing consideration of alternative framings, and the realization that old narratives do not explain growing problems such as water shortages, may gradually lead to a reevaluation of popular explanations. Indeed, some countries such as South Africa and New Zealand have replaced the old narratives of watershed degradation within water policies, and have adopted more diverse and holistic approaches to integrated forest and water management (Calder, 1999). It is worth asking why some countries have adopted this approach when others have not.

Of course, there are some important caveats. Adopting a narrative approach does not imply replacing one simplistic narrative with another. Bruijnzeel (2004), for example, has suggested that debates about upland watershed degradation are commonly divided between narratives for or against forest protection, and consequently, criticizing orthodox watershed explanations may enhance logging. This statement is misplaced. As discussed above, a narrative approach aims to show the social or political influences on any scientific explanation, and does not seek to dismiss forest protection or any other choice as policy options. Moreover, Bruijnzeel's statement confuses normative positions and statements of causality. Forest protection can be justified normatively on various social, political, or ecological reasons. But it is becoming increasingly difficult to justify forest protection on behalf of many of the watershed narratives discussed above. As Hamilton and Pearce (1988, pp. 92–93) noted some years ago, "Banning forest product harvesting on the basis of the basis of the harmful soil and water consequences of 'deforestation' is aiming at the wrong target". Rather than clinging onto such scientific explanations as justifications for normative positions, policymakers should ask how they can still achieve forest protection in more diverse and transparent ways.

That said, the analysis of narratives remains a politicized activity. The political implications of adopting or opposing environmental narratives need to be acknowledged. Many authors have argued that narratives persist for self-interested reasons, and some critics have suggested that criticizing narratives may also be to legitimize agendas. Roe

(1991), for example, claimed narratives allow development agencies to predefine "problems" in order to demonstrate "successful" aid work. Similarly, Thomas and Middleton (1994) suggested the government of Chad used narratives of desertification during the 1980s to avoid implementing democratization. Others have suggested state forestry departments also enforce narratives as ways to maintain control over forests (e.g. Fairhead and Leach, 1998). Pereira (1989, p. 1), for example, wrote:

> "The worldwide evidence that high hills and mountains usually have more rainfall and more natural forests than do the adjacent lowlands has historically led to confusion of cause and effect. Although the physical explanations have been known for more than 50 years, the idea that forests cause or attract rainfall has persisted. The myth was created more than a century ago by foresters in defense of their trees... The myth was written into the textbooks and became an article of faith for early generations of foresters."

Allegations like these should be made with are: they should not be interpreted as personal attacks on individuals, and many professionals acknowledge the controversies associated with some of these narratives. Yet, there is still a need to understand how narratives may persist despite the accumulating scientific evidence against them. In turn, this requires analyzing the relationships between public perceptions and scientific advice within specific networks or institutional contexts. For example, some critics have questioned whether the "Alternatives to Slash and Burn" (ASB) initiative of the Consultative Group on International Agricultural Research (CGIAR) may – by its very name – repeat narratives and foreclose scientific debate about the impacts of this kind of agriculture (see Forsyth, 2003, p. 146). According to the ASB: "the consequences of (slash and burn) are devastating, in terms of climate change, soil erosion and degradation, watershed degradation, and loss of biodiversity" (ICRAF, 1999). As discussed above, many studies have suggested these criticisms cannot be applied to all forms of shifting cultivation. Moreover, this statement seems to frame problems of climate change and biodiversity loss within debates about agricultural smallholdings, and hence may allocate notions of "blame" and "responsibility" for these problems in ways that some critics suggest should be applied primarily to more obvious targets such as industry or cities. More research is needed on how formal expert organizations frame and help shape public perceptions of hydrological problems, and why some countries and organizations persist in using narratives and others have stopped.

188: Land Use and Water Quality

ANDY BAKER

School of Geography, Earth and Environmental Sciences, The University of Birmingham, Birmingham, UK

The literature investigating the relationship between land use and water quality is synthesized. It is demonstrated that although some general correlations between land use and water quality can be observed, in general the relationship is complex with correlations in individual watersheds likely to be site or regionally specific. Land cover measurements discussed include land use, land cover, ecotone, buffer strip, and indices of landscape metrics, whereas water quality issues include spatial and temporal sampling strategies and the use of nonconservative tracers. Examples of land use–water quality relationships are given for both the impacts of urbanization and the intensification of agriculture. A paucity of studies in developing countries and the need to advance models of land use–water quality relationships are highlighted.

INTRODUCTION

Water quality is affected by a combination of natural and anthropogenic factors, whose relative influence changes with both time and space. Natural factors affecting water quality include precipitation intensity and amount, river discharge, geology, and soil type, topography (slope length and gradient), and vegetation cover. Meybeck *et al.* (1989) and **Chapter 91, Water Quality, Volume 3**, **Chapter 93, Effects of Human Activities on Water Quality, Volume 3**, **Chapter 94, Point and NonPoint Source Pollution, Volume 3**, **Chapter 96, Nutrient Cycling, Volume 3**, **Chapter 97, Urban Water Quality, Volume 3**, **Chapter 98, Pathogens, Volume 3**, and **Chapter 100, Water Quality Modeling, Volume 3** in the Water Quality and Biogeochemistry section in this Encyclopedia provide detailed reviews. Most of these factors can, and have, been affected by humans; for example, changes in river discharge due to abstraction, urbanization or impounding; polluted discharges from industry, agriculture, sewerage, and so on. Many of these anthropogenic influences are part of the larger process of catchment land use or land cover change that can affect water quality in rivers and lakes, as well as downstream estuarine and coastal waters. Investigation of the relationship between land cover and water quality is particularly useful when considering diffuse source pollution. Diffuse sources of suspended sediments, pathogens, nutrients, and pesticides in agricultural land uses; and suspended sediments, pathogens, nutrients, oxygen demanders, heavy metals, oil, and road salt in urban areas are often difficult to measure. One aim of understanding land use–water quality relationships would be to be able to use land use as a proxy for water quality in rivers suffering from diffuse pollution. Another would be to use satellite-derived land cover to predict water quality in unmonitored catchments; as for example, 80% of stream miles go unassessed in the United States with respect to the requirements for Section 305(b) of the Clean Water Act (GAO, 2000; cited in Griffith, 2002).

For a relationship between land use and water quality to be observed, a number of criteria have to be met. As in any water quality investigation, the determinand has to be relatively conservative, such that an upstream land-use fingerprint is preserved at the sampling location. For example, many studies have shown that chloride concentration correlates with urbanization at all scales and at all stages of urban development, and although natural chloride inputs need to be understood from sea spray/precipitation and in some cases geology (Smart *et al.*, 2001), this has the potential to be an excellent and easily measured fingerprint of human impact in part due to its conservative nature. Sampling location and frequency have

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

to be appropriate to the size of the catchment and the land-use impact to be monitored. For example, a baseflow survey of dissolved organic matter will not obtain much useful land use–water quality information for phosphorous which is less mobile in this form and more often associated with suspended sediments, but would be appropriate for an investigation of land use–water quality trends for nitrate. Similarly, the land use has to be determined for the catchment, and this is not necessarily a trivial task. For small catchments, this can often be obtained by ground survey or map data. However, for large catchments satellite imagery such as the Landsat TM has to be used to obtain the necessary spatial coverage, and classification schemes such as the Normalized Difference Vegetation Index (NDVI) used to allocate land-use classes (see review by Griffith, 2002). However, these normally contain some significant amount of error: this is a particular issue when trying to ascertain the source of errors in models of land use and water quality during their validation.

Given these requirements, it is useful to observe that the majority of studies have occurred on low order streams in small catchments with a wide variety of land uses; few are on large catchments with a similar variety of land use. Similarly, the largest body of research is on the temperate zone in the United States and European rivers, in predominantly agricultural and/or forested regions, and with relatively stable land uses. Fewer studies have been undertaken in tropical and developing countries with rapidly changing land use. The former regions also have, in general, moved through the transition from having predominantly point source pollution problems to a situation where diffuse pollution is more important; also where fertilizers are more common and frequently overapplied compared to developing countries; and finally, where land use is substantially different.

LAND-USE AND WATER QUALITY ISSUES

Land-use Pattern and Water Quality

The location of different types of land use within a catchment is the focus of considerable research, primarily driven by the buffer strip concept. However, the impact of buffer strips (riparian zones, land-water ecotones) on water quality appears unclear (Johnson *et al.*, 1997; Sliva and Williams, 2001; Jones *et al.*, 2001; Griffith, 2002). It is not always clear when, if, or how riparian vegetation maintains water quality, or whether the land use of the entire catchment has a greater effect. For example, Johnson *et al.* (1997) show that landscape characteristics explain some water quality variations in some seasons, but that catchment land use was just as important in predicting water quality. Similarly, too few studies have investigated the relationship between landscape pattern metrics and water quality. Wear *et al.* (1998) looked at a rural–urban gradient and suggested that the most remote portion of watershed and the outer edge of urban development have disproportionate influences on water quality. Other studies, however, have found little or no importance of landscape pattern metrics. As for the general relationship between catchment land use and water quality, different landscape pattern metrics and buffer strips will work in different catchments depending on land use, topography, climate, catchment size and soil, and geology. A comprehensive review can be found in Griffith (2002).

Water Quality Sampling Strategy

Sampling location and frequency have to be appropriate to the size of the catchment and the land-use impact to be monitored. Many studies have focused on simplified experimental conditions to test the land use–water quality relationship: low order streams in small catchments with a wide variety of land uses sampled over short time periods (<1 year). However land use–water quality issues of practical concern often occur in larger catchments, which are harder to sample at an appropriate spatial and temporal resolution. Land use–water quality relationships observed at the subcatchment scale may not be up scaleable, and any compromises in spatial and temporal sampling strategy means that the land use–water quality relationship obtained will be in part a function of the sampling strategy. For example, Johnson *et al.* (1997), in the 16 317 km^2 Saginaw basin in the United States, monitored 62 sites over two years with summer and autumn sampling. Summer water quality samples showed good positive correlations between row crop land cover and nutrients, total dissolved solids and alkalinity, but autumn water quality was poorly correlated with land use in comparison and a lack of relationship between phosphorous and row crop probably due to the limited sampling strategy.

Effect of Increased Urbanization on Water Quality

The effects of increasing urban land cover can be observed on a wide range of water quality determinands. Probably the most well known spatial study is the relationship between population density and annual nitrate concentration observed by Peierls *et al.* (1991) in a review of published data for 42 globally significant rivers that accounted for 37% of freshwater input to the ocean. A log–log regression of population density against mean annual nitrate concentration was shown to have an R^2 of 76%, with no differences between tropical and other rivers. One of the best historical records of the land use–water quality relationship is that of the River Seine, where river water quality data has been measured at Paris since 1886 (Meybeck, 1998). Here sodium, chloride, potassium, sulfate, and total dissolved solids were all observed to have increased

moderately, in part from urbanization (from increased industrialization, domestic wastes and deicers). Phosphate, ammonia, and total coliforms have all increased significantly from increasing sewerage inputs. A comparison with forested headwaters of the Seine demonstrated that peri-urban streams have a two times increase in sulfate, five times increase in sodium, chlorine and potassium, and a 100 times increase in ammonia compared to the headwaters. Ren *et al.* (2003) published a 49 year record that also demonstrated a long-term trend of decreasing water quality with increased urban land cover in the Shanghai region.

On a smaller scale, similar relationships can be observed. Within urbanized catchments correlations have been observed between percentage urban land use and fecal coliforms, dissolved copper, chloride, and ammonia (Sliva and Williams, 2001), and between population density and mean *Escherichia Coli* and *Faecal Coli* (Frenzel and Couvillion, 2002) – see Figure 1. In a review of water quality data from 56 catchments in Scotland with 0–40% urban land cover, Ferrier *et al.* (2001) demonstrated significant correlations between the percentage urban area and ammonia concentration ($R^2 = 44\%$), phosphate ($R^2 = 47\%$), suspended sediments ($R^2 = 50\%$), and biochemical oxygen demand ($R^2 = 38\%$). In diverse New England watersheds, correlations between dissolved nitrate concentration and percentage urban land use ($R^2 = 68\%$) and between dissolved chloride concentration increases and road density ($R^2 = 87\%$) have been observed (Rhodes *et al.*, 2001). However, what is still unclear is the percentage urban land cover necessary such that urbanization determines water quality over all other land-use types. For example, in an investigation of the 1295 km^2 Salt Fork watershed of eastcentral Illinois, two major urban areas (5% of cover) determined the majority of soluble reactive phosphate in all seasons and explained 50% of the variance of nitrate concentration, despite a 90% row crop land cover (Osborne and Wiley, 1988).

Agricultural Intensification and Water Quality

There is a clear relationship between agricultural land use and water quality (for a review see Hooda *et al.*, 2000), especially when urban land cover percentage is low (<5%) and the agricultural activity is intensive. Nitrate is the most common water quality determinand correlating with agricultural land cover, suspended solids, and pesticides are also frequently reported to correlate with agricultural land cover. At the smallest scale (40 sites in a 7.3 km^2 watershed that is 45% forested and 52% cropped), it has been demonstrated that dissolved nitrate concentration could be predicted from land use (in rank importance): percentage area of confined animals > percentage pasture > percentage corn > percentage rotation > percentage forest (Gburek and Folmar, 1999). At a watershed scale, the Chesapeake Bay region of the United States total dissolved nitrate correlated with the percentage cropland ($R^2 = 85\%$; Jordan *et al.*, 1997) with the calculation that only 10 – 30% of the nitrogen inputs in the catchments were discharged, and that the rest must be either stored in the catchment or evolved. Ferrier *et al.* (2001) demonstrated in their Scottish catchments study that arable land cover correlated with nitrate concentration ($R^2 = 44\%$), and that improved grassland land cover correlated primarily with

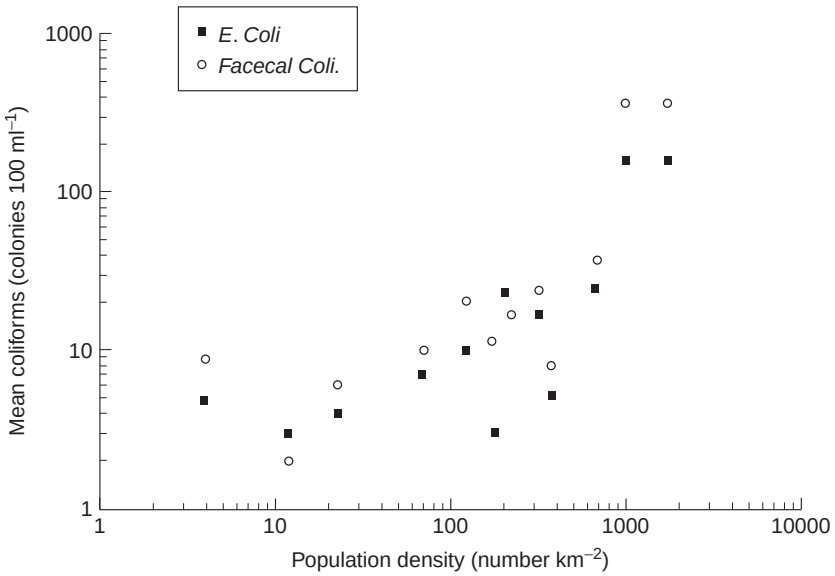

Figure 1 Graph of mean *E. Coli* and *Faecal Coli* against population density ($R^2 = 60\%$ and $R^2 = 64\%$ respectively). (After Frenzel and Couvillion (2002))

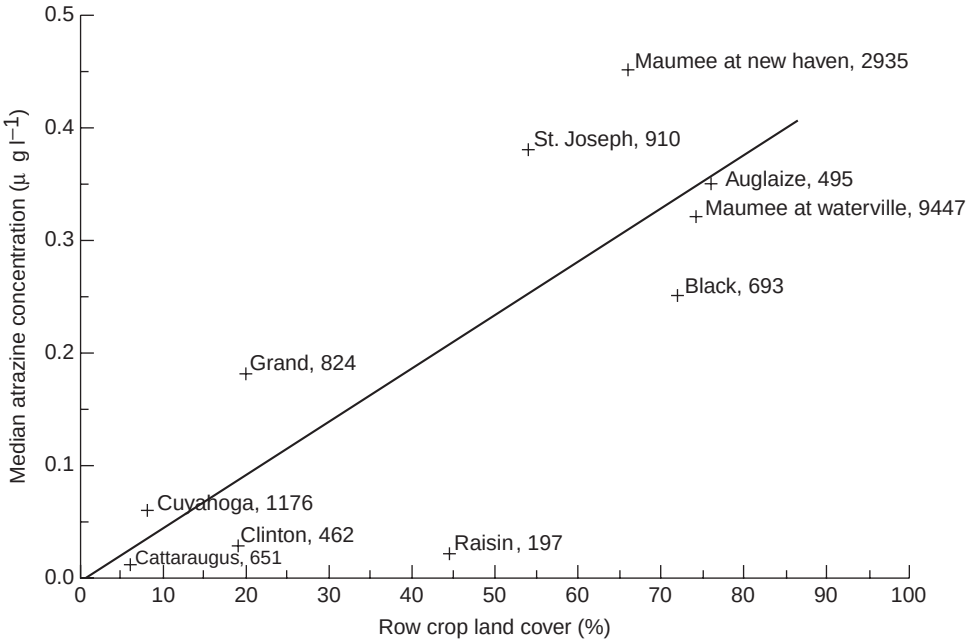

Figure 2 Relationship between atrazine and row crop percentage cover, adapted from Frey (2001). Data was collected in 1996–1998 as part of the US National Water Quality Assessment Program. Median concentrations are based on 24–36 samples per site over a wide range of flow conditions. Figures are the drainage areas in km^2

phosphate ($R^2 = 44\%$), and with weaker correlations with biochemical oxygen demand ($R^2 = 27\%$) and suspended solids ($R^2 = 27\%$). An example of the pesticide–land use relationship is given in Figure 2, from the Maumee River in Northeast United States. With subcatchments from 342 to 16 400 km^2, and where the primary land use is row crop (soybean and corn; 74%), herbicide concentrations were highest where land use was row crop, then next highest where land use was mixed-use and urban land, and finally lowest where there was pasture or forest (Myers *et al.*, 2000; Frey, 2001).

The relationship between water quality and agricultural land use, particularly as agricultural intensification occurs, are less well understood. In two small relatively unimproved agricultural catchments in upland United Kingdom, improved grassland was shown to correlate positively with mean fecal indicators at high discharge, whereas there was a negative correlation between fecal indicators and percentage unimproved land cover (moor land and rough grazing) (Crowther *et al.*, 2002). However, a paucity of published studies in developing countries (see Section "Land use–water quality studies in developing countries") limits our understanding of temporal trends in the agriculture land use–water quality relationship during intensification in these countries. Any shift towards organic farming, leading to a less intensive form of production, is likely to increase investigations of the water quality–organically farmed land cover relationship.

Land Use–Water Quality Studies in Developing Countries

The land use–water quality relationship needs investigation over a wider range of land uses and climate zones. A large body of research exists on temperate zone North American and European rivers, in predominantly agricultural and/or forested regions, the combination of which are by implication regions of relatively stable land uses. Fewer studies have been undertaken in tropical and developing countries, often with more rapidly changing land use. North American and European regions also have in general moved through the transition from having predominantly point source pollution problems to a situation where diffuse pollution is more important; fertilizer use is more common and frequently overapplied when compared to developing countries; and have land uses that are substantially different from tropical and arctic regions. Studies in temperate regions suggest that nitrate export has increased by 3 times to 20 times since industrialization owing to increased animal and human wastes and increased runoff (Peierls *et al.*, 1991). Large-scale land-use changes are occurring in tropical countries; will tropical deforestation lead to a similar phenomenon when tropical rivers are naturally high nitrate transport environments (Downing *et al.*, 1999)?

Two studies highlight the land use–water quality relationships observed in South America. Ometo *et al.* (2000) investigated 10–57 km^2 subcatchments in southeast Brazil that had been deforested in the 1850s and replaced by coffee

plantations and subsequently pasture and sugar cane. Strong correlations between land use and most water chemistry parameters were observed, probably due to the strong contrasts between catchments dominated by pasture or sugar cane agricultural land use, and urban versus nonurban areas. Dissolved calcium and magnesium ions, alkalinity and pH, all correlated with the addition of lime to leached soils in the catchments to improve agricultural productivity. Dissolved sodium and chloride concentrations correlated with urban land cover: given the lack of road salt used this is postulated to be from sewage sources. Nitrate showed no correlations with land use due to a lack of fertilizer use. Biggs *et al.* (2002) investigated part of the Amazon basin where 22% has been deforested with ~50% of deforested area currently in regrowth. A sampling strategy of sampling once at each of high and low flow at 49 sites from watersheds ranging in area from 19 to 12 500 km^2 was used. Sodium, chloride, and sulfate were all observed to increase with urbanization, with 40–58% of dry season and 83–89% of wet season chloride determined to be from urban sources when population is >250 per square kilometer. The effect of deforestation on water quality was shown to depend on soil type and geology, due to long hill slopes and thick soils which buffer the effects of this land-use change and a sampling strategy too long after deforestation and with inadequate temporal sampling.

CONCLUSION

The land use–water quality relationship is complex and, in general, any correlation observed in one catchment is likely to be site or region specific. However, some water quality determinands and land covers do show reproducible trends. Human influence in general, often determines chloride concentration (for example, see Herlihy *et al.*, 1998). Agricultural land use often determines nutrient concentrations in intensive agricultural regions, and if liming is widespread then lime-derived anions and cations can be observed to correlate with land use in both intensive and extensive agriculture. In general, as soon as urban land use increases beyond a small percentage of total land cover (~5%; the precise amount requires further research), then urban land use impacts on water quality dominate over agricultural. Undisturbed forest cover in all cases appears to have relatively little impact on river water quality compared to other land uses, despite the demonstration of enhanced nitrogen loss from some forests. However, land use is forever changing, and future land cover changes will be driven by the interplay between population growth, climate change, and policy makers, which will vary in different parts of the world. Understanding human land use and natural vegetation adaptations to climate change, together with river response, are essential; for example, see the assessment of the relative influences of land use, climate, and discharge changes on water quality in a Pennsylvanian river (Interlandi and Crockett, 2003). This will be achieved by improved understanding, and modeling, of the processes driving the observed land use–water quality relationships. Current models typically have a strong empirical component, either (i) using land use to calibrate empirically derived rating curves of water quality versus discharge to a mechanistic river flow model (such as SPARROW; Alexander *et al.*, 2004) or (ii) using Bayesian neural networks (such as Ha and Stenstrom (2003) who classify land use from water quality data). Both modeling approaches are limited to the watershed conditions for which they were calibrated or trained. Modeling approaches such as BASINS (Tong and Chen, 2002) have greater potential to improve our understanding of land use–water quality relationships under changing land use and climate conditions, due to its physical-process-based core, its incorporated point and nonpoint source models, and a GIS interface that permits simple input of land-use data.

189: Land Use and Water Resources Under a Changing Climate

THOMAS W GIAMBELLUCA

Geography Department, University of Hawaii at Manoa, Honolulu, HI, US

Water resources are becoming increasingly scarce because of the mounting demand for water associated with population growth and economic development. The availability of and need for water resources are strongly influenced by land use. Land use and land cover change can alter the regional hydrologic cycle by changing evapotranspiration (ET), runoff, soil moisture, and perhaps even precipitation, resulting in changes in water supply and demand. In addition to changes associated with land use, climate warming may significantly influence the global hydrological cycle, leading to a variety of regional hydrological changes. Higher atmospheric CO_2 levels and changing climate will influence land cover in various ways. Conversely, many types of land cover change disrupt the global carbon cycle, contributing to changes in atmospheric greenhouse gases. The drivers of climate and land cover change will be subject to complex feedbacks involving the hydrological cycle and water resources. Hence, it is important to consider the web of interacting factors affecting water resources in the context of climate and land use change. This article reviews the effects of land cover and land use change on water supply and demand, the predicted effects of global warming on water resources, the interaction between climate change and land cover change, and the combined effects of land use and climate change on water resources.

INTRODUCTION

Water resources are becoming increasingly scarce because of the mounting demand for water associated with population growth and economic development. Global water withdrawals are projected to increase by about 35% between 1995 and 2025 (Shiklomanov *et al.*, 2000) on the basis of population growth and changes in per capita usage.

The availability of and need for water resources are strongly influenced by land use. Land use and land cover change can alter the regional hydrologic cycle by changing evapotranspiration (ET), runoff, soil moisture, and perhaps even precipitation, resulting in changes in water supply and demand. In addition to changes associated with land use, climate warming may significantly influence the global hydrological cycle, leading to a variety of regional hydrological changes. Higher atmospheric CO_2 levels and changing climate will influence land cover in various ways. Conversely, many types of land cover change disrupt the global carbon cycle, contributing to changes in atmospheric greenhouse gases. The drivers of climate and land cover change will be subject to complex feedbacks involving the hydrological cycle and water resources. Hence, it is important to consider the web of interacting factors affecting water resources in the context of climate and land use change (Figure 1). This article will review the effects of land cover and land use change on water supply and demand, the predicted effects of global warming on water resources, the interaction between climate change and land cover change, and the combined effects of land use and climate change on water resources.

LAND USE AND LAND COVER EFFECTS ON WATER RESOURCES

Land Cover Effects on Supply

As Lettenmaier *et al.* (1999) emphasize, it is important to distinguish between water resources systems and hydrological systems when examining sensitivity to change. Nevertheless, the ultimate limits to water supply are determined by the rate and steadiness with which water flows through

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

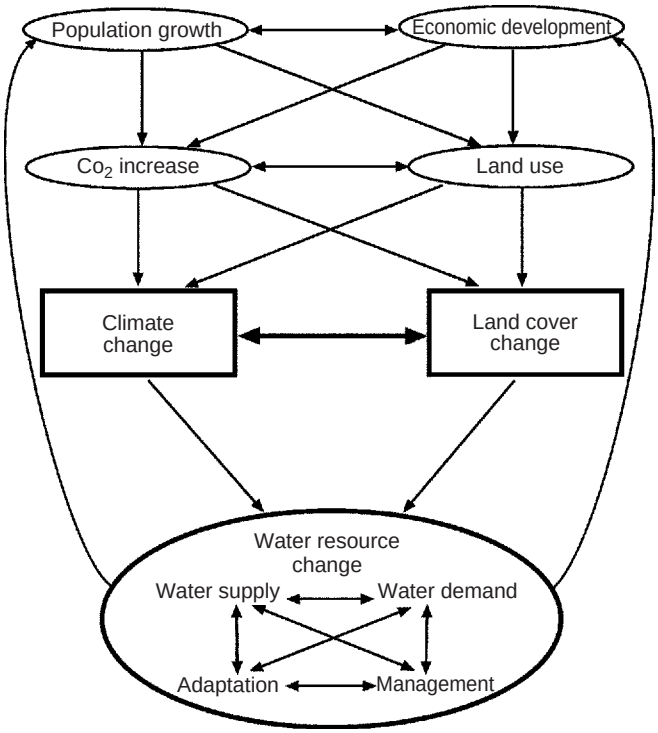

Figure 1 The effects of climate and land cover change on water resources are embedded within a web of interacting drivers. Feedbacks involving water resources may alter the drivers of change and influence future climate and land use

the hydrological cycle. Water cycling over land areas is influenced by soil and vegetation characteristics, and, therefore, is subject to modification from human activities that influence land cover (*see* **Chapter 117, Land Use and Land Cover Effects on Runoff Processes: Urban and Suburban Development, Volume 3**; **Chapter 118, Land Use and Land Cover Effects on Runoff Processes: Agricultural Effects, Volume 3**; **Chapter 119, Land Use and Landcover Effects on Runoff Processes: Forest Harvesting and Road Construction, Volume 3**; and **Chapter 187, Land Use Impacts on Water Resources – Science, Social and Political Factors, Volume 5**). Forest clearing, agriculture, and urbanization change the land surface characteristics and influence hydrological processes by changing energy and water flows between the surface and the atmosphere. Land cover affects how much incoming energy from the sun is absorbed by the surface, which is very important in determining how much water returns to the atmosphere via ET. Land cover change, therefore, changes the energy balance of the surface, affecting the water cycle. Deforestation, for example, alters the disposition of radiant energy by increasing surface albedo (the proportion of solar radiation reflected by the surface) and daytime long-wave radiation emission (loss of thermal infrared radiation) by the surface, resulting in lower net radiation, that is, less radiant energy retained by the surface (e.g. Bastable *et al.*, 1993; Culf *et al.*, 1995; Giambelluca *et al.*, 1997, 1999; Larkin, 2002). The characteristics and variable state of the land surface also control the proportions of net radiation used for ET and heating of the air. Replacing forest with other land covers changes energy partitioning because of differences in leaf area, aerodynamic roughness, root depth, and stomatal behavior. Field studies have verified that replacement of forest by pasture or nonirrigated crops reduces ET (Wright *et al.*, 1992; Jipp *et al.*, 1998, Giambelluca *et al.*, 2000), which results in more streamflow.

Land cover change can also alter soil hydraulic properties, resulting in reduced infiltration rates (e.g. Ziegler and Giambelluca, 1997). In drier climates, intermittent streamflow is often mainly dependent on overland flow produced when rainfall intensity exceeds infiltration capacity (e.g. Loague *et al.*, 1996), a process known as *Horton overland flow* (HOF). Reduced infiltration (increased HOF) can increase mean annual streamflow and lower the amount of water available for ET. In these environments, land cover change directly influences the water cycle that, in turn, affects the energy balance.

As Bruijnzeel (2000) emphasizes, the effects of land cover change on ET and streamflow are not uniform, and depend on the original vegetation type, characteristics of replacement land cover, climate, exposure, and soil depth. Much of the uncertainty regarding the hydrological impacts of deforestation stems from a failure to develop and use realistic land cover projections in climate simulations (Giambelluca *et al.*, 1996b), and a relative shortage of information about the hydrological characteristics of replacement land covers other than crops and pasture/grassland, especially secondary vegetation (Giambelluca, 2002).

In addition to local effects described above, land-atmosphere feedbacks may lead to regional changes in climate including rainfall. As much as 25 to 56% of the Amazon Basin rainfall is estimated to be derived from "recycling" of water evaporated within the basin (Eltahir and Bras, 1996). Basin rainfall, therefore, may decrease if evaporation is reduced by deforestation. A series of General Circulation Models (GCM) simulations (e.g. Nobre *et al.*, 1991; Henderson-Sellers *et al.*, 1996; Polcher and Laval, 1994; McGuffie *et al.*, 1995; Xue *et al.*, 1996) suggests that replacement of the entire Amazon rainforest with pasture could reduce evaporation and alter atmospheric circulation, decreasing basin rainfall by as much as 20%.

Past studies using GCMs (e.g. Henderson-Sellers *et al.*, 1993; McGuffie *et al.*, 1995) and Regional Climate Models (e.g. Kanae *et al.*, 2001; Sen *et al.*, 2004) suggest that land cover change in Southeast Asia has significant local and remote effects on the regional climate. Sen *et al.* (2004) found that the deforestation in the Indochina Peninsula increases rainfall downstream of the deforested area and

reduces it upstream during the summer months when the whole region is under the influence of the East Asia summer monsoon (EASM). Further, they find that deforestation on the peninsula causes significant changes in the EASM flow, which is the main moisture supplier to the higher latitudes over China, and thus, in its rainfall over eastern China. These findings are supported by observations of regional precipitation made during the second half of the 20th century.

Urbanization has profound effects on hydrological processes (*see* **Chapter 117, Land Use and Land Cover Effects on Runoff Processes: Urban and Suburban Development, Volume 3**) and, hence, water supply. Urban development generally involves the reduction of vegetation coverage, construction of impervious structures such as buildings and roads, compaction or removal of surface soil, and channelization of river and stream systems. These urban effects generally reduce infiltration of water and increase rates of overland flow, resulting in higher flood frequency, and increased sediment transport. Even in cases where urbanization increases groundwater recharge rates by concentrating water into pervious areas (Giambelluca, 1986), industry, transportation, and other human activities increase the risk of chemical and biological contamination, and water supply is usually negatively impacted.

Land Cover Effects on Demand

Water use is strongly tied to land use. Urban and agricultural development carry specific water demands, and are associated with certain land use changes. Therefore, we can associate land use changes with changes in water demand. Land use planning in some regions is increasingly concerned with the water demand implications of land use change. In parts of Hawaii, for example, private land development is constrained by limited water supply (Giambelluca *et al.*, 1996a). Recent expansion of residential development there was facilitated in part by demand savings from shifts of large land tracts out of irrigated sugar cultivation.

Globally, 66% of water withdrawals and 83% of consumptive use go to agriculture, mostly irrigation (Shiklomanov, 1997). As land use changes in response to continued population growth and economic development, the accompanying demands for freshwater will increase. Growth projections suggest that irrigated agriculture will have to expand in area by 20 to 30% between 1995 and 2025 to meet increasing food needs, although slowing rates of dam construction and irrigation development may limit increases in irrigated area to 5 to 10% (Cosgrove and Rijsberman, 2000). Estimations of future water withdrawal increases, taking into account likely land use changes accompanying population growth and economic development (but not the effects of climate change), range from 10.5% (Cosgrove and Rijsberman, 2000) to between 23 and 49% (Raskin *et al.*, 1997) for the period 1995 to 2025.

CLIMATE CHANGE EFFECTS ON WATER RESOURCES

Impacts on water resources may be the most important potential effect of global warming. Changes in land surface hydrology due to changing climate, such as changes in the discharge of large continental rivers, have potentially far-reaching implications for human populations. Many studies on climate change impacts on water resources have been reported (e.g. Gleick, 1999). Warming is expected to intensify the global hydrological cycle, that is, to increase global ET and precipitation (*see* **Chapter 195, Acceleration of the Global Hydrologic Cycle, Volume 5**). But increases in precipitation will be unevenly distributed with some regions projected to receive lower amounts as the climate warms. As a result, water supply and demand will change in different ways in different parts of the world. Some areas will experience improvements in water supply in relation to demand as a result of climate change. Other areas will see additional degradation of water resources because of warming.

Climate Change Effects on Supply

Climate change can affect water supply through changes in precipitation and ET. Changes in atmospheric circulation are predicted to result in changes in precipitation amounts, intensities, and patterns (e.g. Felzer and Heard, 1999). Trends in precipitation have been detected through analysis of historical data. In general, precipitation is increasing in the middle and higher latitudes of the Northern Hemisphere and decreasing in the lower latitudes of both hemispheres (Folland and Karl, 2001). Climate models predict that future global warming will be accompanied by an increase in global mean precipitation. Regional precipitation increases are predicted for the mid- and high-latitude land areas of the Northern Hemisphere, and over Antarctica and Africa. Regional precipitation is generally predicted to decrease in subtropical regions (Giorgi and Hewitson, 2001).

ET is affected by atmospheric demand, or potential evapotranspiration (PE), and moisture availability. Atmospheric demand is controlled by net radiation, air temperature, humidity, and wind speed. Projected air-temperature increases would generally result in higher PE, if other variables were unchanged. However, temperature changes might bring about shifts in other variables that could compensate for warming. For example, water vapor content of the air could increase, offsetting the effect of higher temperature. Cloud cover could increase, thus reducing net radiation. Studies do predict higher PE for some regions. Even where PE increases, ET will increase only if sufficient moisture is available. However, models consistently predict increases in mean global ET with greenhouse warming.

Because of increased ET, drought occurrence is predicted to increase in many regions, especially in summer, in some

cases even where precipitation will increase. Lower soil moisture and streamflows in those regions will stress water resource systems by reducing supply and increasing the demand for water.

Numerous studies have been done on the possible impacts of global warming on streamflow. Most of these studies have been based on output from GCM simulations of steady-state climate at some future condition of elevated greenhouse gases, usually double the preindustrial level. Predictions of precipitation and temperature from the model are downscaled to river basins, for which river discharge is estimated using hydrological models. More recently, several studies have been done using output from transient GCM runs, that is, estimates done using a projection of time-dependent change in greenhouse gas levels over the next 50 to 100 years. Arnell (1998) investigated how projected climate changes will affect streamflow on the European continent. The climate model output he used indicated that precipitation would increase in northern Europe and decrease in the south. Streamflow changes mirrored this regional pattern. Lettenmaier *et al.* (1999) also found that, in general, precipitation changes dominated projected streamflow changes in their study of six basins in the United States. In some basins, though, ET increases offset precipitation increases or amplified precipitation decreases. Nijssen *et al.* (2001) studied climate change implications for nine global rivers. They found that while precipitation was generally higher with warming, annual streamflow did not necessarily increase. For most tropical and midlatitude river basins, they projected annual streamflow declines because of higher ET.

The most unequivocal projections of streamflow change are seen in the middle and higher latitudes, where warming will influence both the proportion of precipitation falling as snow and the timing of snow melt. In general, these changes will result in greater flows during the winter and less in the spring.

Climate Change Effects on Demand

Climate change may influence the demand for water resources in several ways. Changes in either precipitation or ET will alter regional water budgets, affecting the demand for water, especially for agriculture. Perhaps most significant in this regard are projected changes in ET, especially in light of consistent model projections of global increases in ET rates. Many types of water use are linked to ET, especially irrigation. Because precipitation is forecast to increase in many regions, some of the effects of increased ET on water demand will be offset. Nevertheless, irrigation requirements are expected to be higher because of warming. Döll (2002) analyzed the effects of climate- change-induced shifts in growing season and changes in ET, finding that global net irrigation requirements will increase by 3 to 5% by the 2020s and 5 to 8% by the 2070s, over and above the increases due to population growth. Most climate projections suggest greater climate variability under global warming, with a higher frequency of extreme events including droughts. Long dry spells usually correspond with increases in demand, putting pressure on water resource systems. In Honolulu, Hawaii, for example, water shortages during droughts are primarily the result of increased demand, rather than reduced supply.

EFFECTS OF CLIMATE CHANGE ON FUTURE LAND COVER

Natural vegetation and agriculture will be altered by higher CO_2 levels and climatic changes. This may include both shifts in ecosystem range boundaries and structural changes within existing ecosystems. Observations and experiments show potential for climate change to disrupt natural and managed ecosystems, especially at high latitudes (Gitay, *et al.*, 2001).

Climate change effects on natural ecosystems may be difficult to distinguish from changes brought by other human influences, such as land use change. However, global warming will inevitably cause changes in vegetation in existing rangelands, forests, wetlands, and arctic and alpine systems; some of these changes are already being seen. CO_2 increases, for example, may favor C_3 plants over C_4 plants, which could give woody plants a competitive advantage over grasses in areas near current forest-grassland ecotones (Noble and Gitay, 1996). Forests will be affected by CO_2-concentration- and warming-related changes in productivity, with some regions gaining and others losing. Forests and other ecosystems may be impacted by changes in disturbance regimes, including fire, disease, and insects. Invasive species are likely to get a boost from the combined influences of climate change and increased disturbance (Loope and Giambelluca, 1998; Dukes and Mooney, 1999). Recent experience has demonstrated the importance of the interacting effects of climate and human activities in determining the impacts on natural vegetation.

The effects of global-warming-induced changes in natural ecosystems on water supply are likely to vary regionally. In areas where vegetative cover decreases, streamflow may increase because of ET reduction. However, increased sedimentation might negate such gains by lowering water quality. Conversely, where vegetative cover increases, water yield may suffer because of higher ET. Calder and Dye (2001) give evidence that invasive species tend to increase stand ET, which would reduce water supply in affected areas.

Climate change can also influence water demand through its effects on land use. For example, warming may influence crop selection that in turn may affect irrigation requirements. Higher CO_2 concentrations can influence crop water use by increasing water use efficiency

(WUE). Because plants regulate their stomata to optimize water loss and carbon uptake, increased CO_2 may translate into higher photosynthetic rates and lower transpiration for crops, that is, higher WUE (Field *et al.*, 1995; Morison, 1987). However, increases in plant growth may offset the WUE increases (Arnell and Liu, 2001), so that the impacts of higher WUE on water demand may be negligible.

HOW WILL LAND COVER–WATER RESOURCES RELATIONSHIP CHANGE WITH GLOBAL WARMING?

Given our knowledge of (i) the interactions between land cover and the hydrological cycle and the effects of those interactions on water resources, and (ii) the potential impacts of climate change on land cover and water resources, there arises a need to consider these two issues together. Most research to this point has been directed at either land use change impacts or climate change impacts. It seems obvious that we should now look at combined effects and ask questions such as: how will global warming affect the land cover–water resources relationship? Below are some issues that may be considered in this context.

Deforestation continues to be a dominant cause of land cover change, especially in developing countries in the tropics (FAO, 2003). Deforestation profoundly affects water supply by reducing ET and increasing overland flow and sedimentation. Much of the deforested land in the tropics is not permanently converted to alternative land uses, especially where land is cleared for shifting agriculture. Once abandoned, this deforested land experiences secondary vegetation succession leading eventually, in the absence of repeated clearing or other disturbances, to the development of vegetative cover resembling forest (see e.g. Moran *et al.*, 1994). The hydrologically sensitive land cover characteristics of deforested areas gradually revert back to those of forest as secondary vegetation matures (Giambelluca, 2002). The productivity of natural vegetation is forecast to increase in some regions because of increasing atmospheric CO_2 concentrations and warming (see e.g. Bugmann, 1997). We might infer, therefore, that the growth of secondary vegetation in some deforested areas will be faster, and, hence, deforestation-related ET reduction will be shorter lived. This would reduce the overall impacts of deforestation on water resources. However, in many regions, water and nutrient availability limits may actually result in lower productivity under warmer, higher CO_2 conditions. Even if deforested areas do recover faster, farmers might adapt to this change by cycling land more frequently in shifting cultivation systems.

Higher CO_2 concentrations and warming are also predicted to increase agricultural productivity in some areas (Gitay *et al.*, 2001). If this effect is realized, it may have implications for the amount of land devoted to agriculture in the future. Reduced land requirements for agriculture could have beneficial effects on water resources by reducing impacts on water supply and demand. Any gains in this regard, however, are likely to be overwhelmed by an increasing demand for agricultural products as the global population grows.

Adaptations by farmers to the changing environment will have important consequences for water resources. As mentioned, shifting cultivators might reduce the fallow period in response to higher growth rates. In areas where climate becomes drier, because of precipitation and ET changes, farmers may have to choose between using more irrigation and adopting drought resistant crops. Each of these choices would impact regional water resources.

Land management will certainly be affected in many ways by the problems of increasing greenhouse gases and global warming. Governments and industry are likely to invest heavily in afforestation and reforestation efforts as a means of sequestering atmospheric carbon. International negotiations on reducing emissions and stabilizing atmospheric levels of greenhouse gases make clear that future agreements will involve a large role for carbon credits through increasing terrestrial biomass. By increasing the forest cover, however, water resources may be negatively impacted (Calder, 1999). It is virtually certain that afforestation/reforestation will result in higher ET and reduced streamflow in the affected areas. This impact is often not considered in assessments of the costs and benefits of such efforts.

Consideration of land use change effects on water supply and demand may increasingly affect future land use policy (Giambelluca *et al.*, 1996a). Municipal water agencies are increasingly using integrated land and water management approaches for long-range planning (Calder, 1999; also *see* **Chapter 185, Integrated Land and Water Resources Management, Volume 5**). Adaptations by water and land managers and water users will strongly influence the effects of future climate on water resources (Arnell and Liu, 2001).

CONCLUSION

Climate change will affect water resources on a global scale. Regional-scale effects will be variable and will often be less important than effects of land cover change. Land cover change effects can be very important at smaller spatial scales. Studies of hydrologic impacts of land cover change and climate change have largely been done separately. Clearly, both sources of hydrologic change will be important in this century, and progress in understanding and predicting impacts requires that land cover and climate change be considered together.

190: Hydromorphological Quality – A Policy Template for Channel Design in River Restoration

ANDREW RG LARGE[1] AND MALCOLM D NEWSON[2]

[1]Centre for Land Use and Water Resources Research, University of Newcastle, Newcastle upon Tyne, UK
[2]School of Geography, Politics and Sociology, University of Newcastle, Newcastle upon Tyne, UK

The European Union's Water Framework Directive (WFD) is the most substantial piece of European water legislation to date and will have a profound effect on how water is managed in Europe over the next 25 years. The term "hydromorphological" was introduced by the WFD to describe the quality of water bodies in addition to physicochemical and ecological elements, and has rapidly become a prominent descriptor. Reference conditions are described as "having no or only very minor alterations" resulting from human activity yet, at the same time, there is considerable confusion as to how far back we have to go to approximate such conditions. A core uncertainty or ambiguity concerns the possible differences between structural definitions of a reference condition and those that relate to processes, or "functionality". Whilst ecohydrology and hydroecology are clearly critical in the provision of a science foundation for the WFD, the introduction of hydromorphological quality as a measure of the condition of fresh waters requires new (or, at least, innovative) thinking.

A momentous challenge for those involved with the concept and realization of "good ecological quality" is to assess it, monitor it, and restore it within a basin-wide strategy, considering also the element of land use and management. The potential role of fluvial geomorphology in understanding, assessing, monitoring, and restoring hydromorphological quality in river systems is stressed.

BACKGROUND

The practical application of the strategic principles of sustainable development to river basin management requires a broad range of public and private policies, including regulatory and economic instruments. It also makes heavy demands upon new forms, sources and applications of scientific knowledge and information (Newson, 2000). A key element of a more integrated approach to the development of river basin resources is "catchment consciousness", the view that land and water must be considered together, the whole basin comprising an ecosystem capable, when intact, of supporting sustainable solutions to human needs (Newson, 1997; Calder, 1999).

The European Union (EU)'s Water Framework Directive (WFD) is the most substantial piece of European water legislation to date. With the exception of heavily modified water bodies, the WFD requires all inland and coastal waters to reach "good ecological status" by 2015, and will have a profound effect on how water is managed in Europe over the next 25 years. It seeks to do this by introducing a "river basin" scale management system, within which demanding environmental objectives will be set. This Directive includes ecological targets for surface waters, came into force on 22 December 2000 (European Commission, 2000), and Member States have had three years from that date to transpose it into national law. The process is being assisted by intensive scientific, technical and legal efforts at "Common Implementation Strategies": uniformity but including subsidiarity. Of the core environmental elements of the Directive, which address surface water, groundwater, inland waters, lakes, and transitional (estuarine) waters, coastal waters, and aquifers – coverage is restricted here to rivers. Overall, the legislation is

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

innovative in that it reflects a move from human health, already legislated for in earlier European legislation (e.g. Bathing Water Directive, 76/160/EEEC, and the Dangerous Substances Directive, 76/464/EEC) to *ecosystem health* as the driver.

New Terminology – ''Hydromorphology''

The term *hydromorphological* was introduced by the WFD to describe the quality of water bodies in addition to physicochemical and ecological elements, and has rapidly become a prominent descriptor. It does not yet figure in any recognized English dictionaries (unlike the words "fluvial" and "geomorphology", which together describe the most likely scientific discipline capable of describing the hydromorphological quality of rivers). The term is defined by NTNU (2002) as "the hydrological characteristics of rivers together with the physical structure that they create". A semantic extension from "morphology" (of river channels) to "hydromorphology" has occurred because of the need to consider the many natural and anthropogenic variants of river *flow regime* as well as *fluvial geomorphology* (both processes and landforms) in the description of river physical habitat (Figure 1).

The broad interest in river physical habitat (now virtually forced upon river basin planners and managers) has been brought about by the widespread achievements in controlling chemical pollution in rivers of the developed world. Much effort has been spent in defining river "health", and Europe is no exception, as evidenced by the range of EU Directives prior to the WFD. These achievements in water quality management coincided with the early period of incorporating the ideals of *sustainable development and integrated water resources* management into basin strategies and operations (Newson, 1997; Calder, 1999). Almost independently, a third dimension, the growth and early success of a widespread *river restoration* movement, has restarted the long-running debate in ecology about what structures and/or processes constitute "natural" conditions

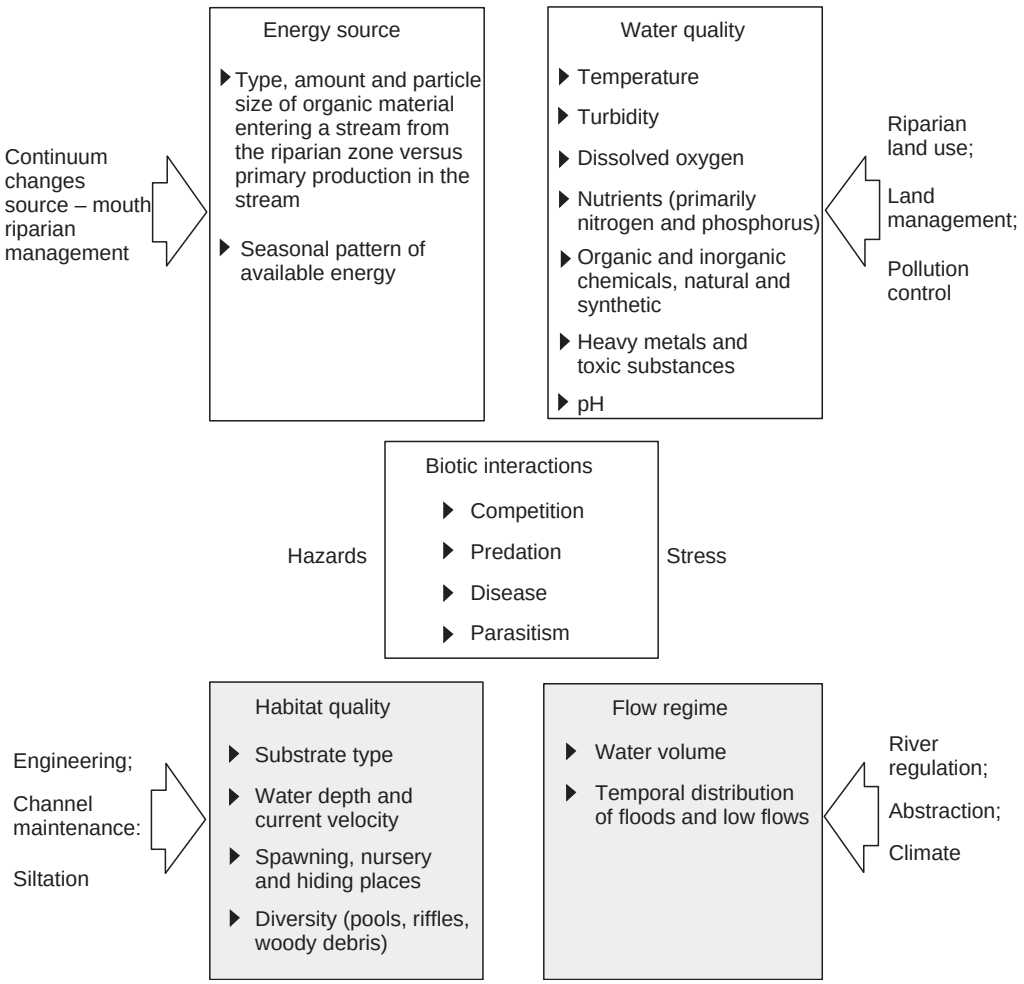

Figure 1 How river flow, sediment systems, and anthropogenic influences interact to create channel physical habitat (Reproduced from Newson and Newson, 2000 by permission of Edward Arnold)

in an ecosystem. To an extent, this debate has become one of many crises of inadequate or uncoordinated scientific support frustrating the common implementation of the WFD. Reference conditions are described as "having no or only very minor alterations" resulting from human activity yet, at the same time, there is considerable confusion as to how far back we have to go to approximate such conditions. In practice, there are extremely few such examples in existence today, and Wilby (1999) has concluded that there are few if any aquatic environments that have not been "marked by the human fingerprint".

Ecology, Hydrology, and Morphology: Interrelationships

Among the relevant scientific disciplines contributing to the hydromorphological discourse are hydrology (particularly hydraulics) and ecology. Over the last two decades, however, hydrologists have paid ever-increasing attention to the relationships between water and sediment in the catchment landscape and the ecological processes driven by its distribution and movement. In a similar way, ecologists have become more sophisticated in their appreciation of water storage and transfer processes in ecosystems. Ward *et al.* (2001) have summarized the evolution of our conceptual understanding of river systems over this period; the result of this process has been the development of two new subdisciplines termed *ecohydrology* and *hydroecology* respectively. *Ecohydrology* concerns the understanding of hydrological factors determining the natural development of wet ecosystems (Wassen and Grootjans, 1996) and river environments. For example, Large and Prach (1999) have described the ways in which plants exert a considerable influence on the hydraulic properties of channels, principally through their effect on channel roughness or friction to flow. At the same time, there is a growing belief that a deeper understanding of the functioning and significance of ecohydrological relations (e.g. Brunke and Gonser, 1997) can aid the rehabilitation or restoration of degraded riverine ecosystems.

Hydroecology, on the other hand (e.g. Amoros and Petts, 1993; Petts *et al.*, 1995), has as its basis the study of ecological and hydrological processes in rivers *and floodplains* and the development of models to simulate these interrelationships. In following this approach, hydrologists no longer regard ecological processes and the biota inhabiting fluvial hydrosystems to be static and reactive components of the hydrological landscape. For example, an increasing number of hydrologists are concerned with how flow velocities affect plant growth in channels and the relationship between flow regimes and ecological processes within channel and riparian habitats (Large and Prach, 1999).

Whilst ecohydrology and hydroecology are clearly critical in the provision of a science foundation for the WFD, the introduction of hydromorphological quality as a measure of the condition of fresh waters requires new (or, at least, innovative) thinking. This includes the deployment of all available knowledge about the flora and fauna of the water column and boundary layer, the geomorphology of bed, banks, floodplain, and the hydraulics of the full "natural" range of flows. The emerging field of *ecohydraulics* seeks to support the characterization, monitoring, and restoration of hydromorphological quality (Newson and Newson, 2000).

The WFD takes a brave political stance in setting an ecosystem concept for river basin management. The corollary is that ecosystem quality forms the basis of scaling existing conditions, monitoring change, and progressing improvements, including the broad group of activities manifesting river restoration (Figure 2). The sheer breadth of the freshwater restoration ideal creates semantic and legislative controversies; some hard choices now need to be made in the adoption by member nations of the WFD's stated objectives. The WFD required Member States to report on the impacts of human activity on all waters by the end of 2004, and much effort is

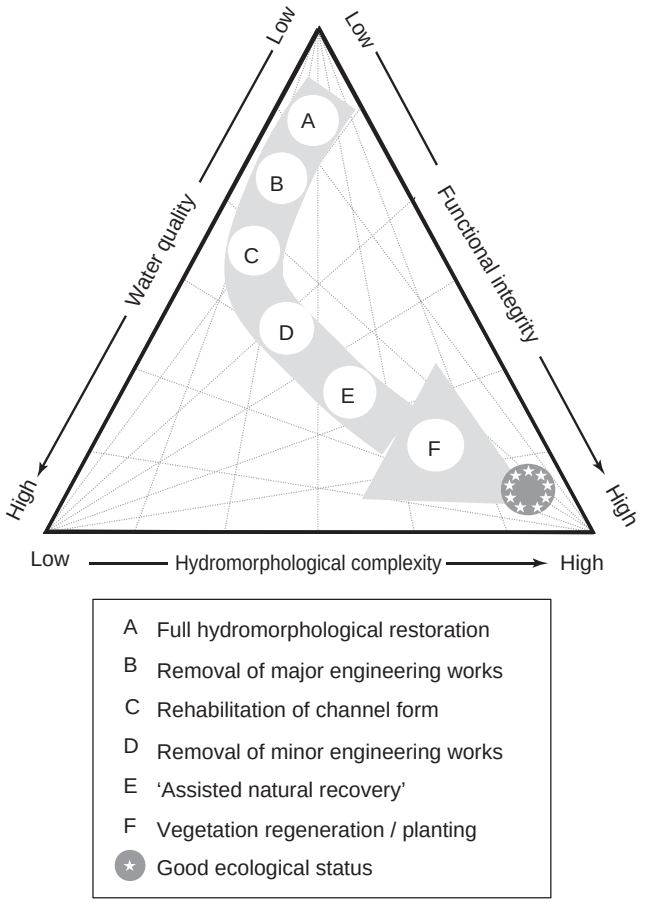

Figure 2 The ''arc of restoration'' approaches aimed towards good ecological status as defined by the EU water framework directive. Scenario A will also equate to HMWB condition

currently being directed at developing tools to measure the impact of hydromorphological changes on the ecological status of freshwaters. In order to measure and mitigate human impact, however, the notion of a natural state or other near-natural reference condition must first be defined.

DEBATES CONCERNING "NATURAL" HYDROMORPHOLOGY: REFERENCE CONDITIONS AND THEIR RESTORATION

Considerable uncertainty pervades the issues, but, in essence, the WFD judges hydromorphological quality against reference conditions that are deemed to be typical of a natural (or "little altered") river. Two definitions within Article 2 of the WFD are important in the context of water status (Chave, 2001): *artificial water body* means a body of surface water created by human activity, while *heavily modified water body* (HMWB) means a naturally occurring body of water that has been substantially changed from its natural condition as a result of *physical alterations* by human activity. As such, the latter situation has clear implications for the integration of hydromorphology into river restoration approaches.

A core uncertainty or ambiguity concerns the possible differences between *structural* definitions of a reference condition and those that relate to *processes*, or "functionality". There is also debate as to whether the definitions used should begin with *pristine* conditions, admit that *seminatural* conditions should be the starting point, or measure modifications in order to select "least modified". There are also metaethical views that advocate "natural" as meaning only the richly varied results of natural processes; Elliot (1997) uses the term *faking nature* for our often-partial attempts to keep faith with this fundamental meaning. There are clear dangers in a philosophy based simplistically upon putting river engineering into reverse gear. Geomorphologists have used the less disparaging term "mimicking" for the construction of river channel features, such as "riffles", that have the architecture of the naturally occurring form but which are designed to be stable and therefore have no function in the fluvial sediment system (e.g. Petersen *et al.*, 1992 for an example of this type of approach to stream rehabilitation). For a variety of reasons, therefore, including uncertainty about the outcome of our designs, *assisted natural recovery* has begun to gain ground as a compromise restoration strategy.

Under the WFD, the huge spatial scale of the desire to recover good ecological quality demands low-cost (or, in its place, low-maintenance) approaches. This philosophy, which intervenes only to encourage restorative fluvial processes (such as sedimentation to narrow over widened sections, and thus rehabilitate in terms of hydromorphology), has resonance with the longer timescales of concern inherent in the drive for sustainability. As Parker and Pickett (1997) suggest:

> *The goal of ecological restoration ostensibly is to return ecosystems to a state or condition from which they can be self-sustaining thereafter."* (p17)

Whatever the criteria used to classify (i) reference attributes of river systems and (ii) the success of measures put in place to rehabilitate these, the fact remains that the methodology and terminology of river protection and restoration have long been challenging and contentious. The reason, as Kentula (2000) points out, is that "success" in projects is an imprecise term that means different things to different audiences and in different situations. Kentula (2000) distinguishes between two sorts of success: *compliance success* and *functional success*. The former is determined by evaluating compliance with the terms of a regulatory framework such as the WFD, while the latter is determined by evaluating whether the "reference" ecological functions of the system have been restored (often extremely difficult to ascertain over short time periods). Realists suggest the need to consider contemporary reference conditions, chosen to view human action more inclusively because humans are bound to have an interest and involvement in restoration; few believe we are in the business of creating new wilderness! In the case of rivers, adherence to Parker and Pickett (1997) criterion may, however, still mean that catchment-scale processes remain heavily anthropogenic and the combination of modified flows and sediment supplies from upstream will create sustainable but "heavily modified" forms and hence habitats. Sear (1994) deals with the essential space/time relationships that may frustrate river restoration schemes that do not incorporate an appreciation of catchment-scale fluvial dynamics.

Selecting Reference Conditions for Hydromorphological Quality

The search for reference conditions of channel morphology and structure is frustrated by the rapidity and extent of human modifications to rivers throughout Europe. As Nienhuis and Leuven (1998) put it:

"good descriptions of pristine European rivers do not exist".

Thus, the most obvious route to achieving improved hydromorphological conditions is in mitigating the most obviously damaging impacts of basin development to date. Such an approach offers options to tackle both causative processes and their structural outcomes in river channel morphology. The process approach has the ability to cope with aspirations for "man-inclusive nature", or "nature

Table 1 The variety of terms used to describe works used to improve or maintain the hydromorphological quality of rivers and their associated habitats

Terms	Definition
Restoration	Complete structural and functional return to a predisturbance state (Perrow and Wightman, 1993)
	Return of a system to a close approximation of its condition prior to disturbance (National Research Council, 1992)
	Return to a system which closely resembles unstressed surrounding areas (Gore, 1985)
	Full, structural and functional return to a previous, natural, state (Wade *et al.*, 1993)
	The act of bringing back to a former state (Hayward and Sparks, 1990; Hawkins, 1991)
Rehabilitation	The partial return of some physical and biological components to achieve an incomplete functional return to an earlier condition (Wade *et al.*, 1993)
	Used primarily to indicate improvements of a visual nature to a natural resource: putting back into good condition or working order (National Research Council, 1992)
	Partial structural and functional return to a predisturbance state or putting back to good order (Perrow and Wightman, 1993)
	Reestablishment of character, bringing back to a good condition (Hayward and Sparks, 1990; Hawkins, 1991)
Enhancement	Any improvement of a structural or functional attribute (National Research Council, 1992; Perrow and Wightman, 1993)
	To increase in importance, quality (Hayward and Sparks, 1990; Hawkins, 1991)
	Improvements with no particular reference to a previous state (Wade *et al.*, 1993)
Creation	The birth or bringing into being new ecosystems that previously did not exist on the site (National Research Council, 1992; Perrow and Wightman, 1993)
	That which is brought into existence (Hayward and Sparks, 1990; Hawkins, 1991)
Mitigation	Actions taken to avoid, reduce or compensate for the effects of environmental damage, either potential or real (Perrow and Wightman, 1993). Among the broad spectrum of actions are those that restore, enhance, create or replace damaged ecosystems (National Research Council, 1992)
Amelioration	Avoiding damage and implies improvement is made (Perrow and Wightman, 1993)
	The act of making better, improvement (Hayward and Sparks, 1990; Hawkins, 1991)
Reclamation	The adaptation of a resource to fulfill a utilitarian human need (Perrow and Wightman, 1993)
	Putting a natural resource to a new or altered use. Often used to refer to processes that destroy natural ecosystems and convert them to agricultural or urban uses (National Research Council, 1992)
	The act of bringing back from error, to make usable (Hayward and Sparks, 1990; Hawkins, 1991)

in balance" (Lenders *et al.*, 1998), or design for "man-exclusive nature" or "nature in flux".

Table 1 summarizes commonly used definitions and the variety of terms used to describe works used to improve or maintain the hydromorphological quality of rivers and their associated habitats. All of these terms can have slightly different meanings to different people and user groups and have been interchangeable in the literature. Whisenant (1999) highlights the potential for confusion by means of a table defining 11 different descriptions for the act of "improving ecological conditions in damaged wildlands". Brooks (1995) and Brookes and Sear (1996) explore these semantic problems further, and echo the modeling approach of Cairns (1987) who advocates that, in a pure sense, the principal objective of river channel (hydromorphological) restoration should be for ecological improvement. Distinction between definitions of "restoration" and "rehabilitation" is essential, and there is little scope for supporters of "enhancement" because of its anthropocentric focus (Tapsell, 1995). Nevertheless, community-based schemes to improve the ambience of rivers and their corridors are growing in frequency, perhaps partly because of the commercial support they receive in return for adjacent investment opportunities.

Structure and Process, Catchment and Site – Further Debates

The core division of approaches to defining "natural" or excellent hydromorphological quality is that between reference conditions and the definition of natural process mechanisms. In practice, the separation is artificial. For example, physical processes of fluvial dynamics may be universal but are heavily influenced by local boundary conditions, that is, structure. However, there are also distinctions of detail between the two approaches, in that approaches *via* structural reference images tend to ignore present conditions (including anthropogenic influences on process and form). Kern (1992), in stating that rehabilitation must be based on a thorough knowledge of a river history and present condition, has outlined a number of key topics for consideration and espouses a conceptual approach representing the ideal solution for the river in question and for contemporary conditions (Table 2). This approach takes into account contemporary conditions and constraints (water rights, flood defence etc.), with the result being an optimal – not ideal – solution, as there are always political and economic aspects that influence the realization of any scheme. Lenders *et al.* (1998) suggest that reference conditions can emerge as

Table 2 Essential topics to be considered in river rehabilitation and desirable stream properties relating to the natural potential for restoration (after Kern, 1992)

Topic	Description
Land use	• Historical land use and former extend of floodplain • Present land use and future prospects • Flood defence
Floodplain habitats	• Valuable habitats (oxbows, forested wetlands etc.) • Natural capital (soil properties, groundwater levels, flora and fauna etc.)
Channel morphology and stream type	• Condition/stability of stream bed and bank • Sediment transport characteristics • Hydraulic properties
Hydrological and hydraulic data	• Alterations in discharge due to land use • Historical and present bankfull discharge
Limnology	• Physical and chemical properties • Pollution sources • Recolonization sources
Elements	**Description**
Natural stream properties	• River pattern • Morphodynamics • Natural flood dynamics • Floodplain morphology
Irreversible changes	• Abiotic and biotic factors • Changes in run-off regime • Changes in sediment transport regime • Mining of alluvial sediments • Species and habitat loss
Cultural ecology	• Loss of species diversity due to historical land use • Encouragement of biodiversity under traditional management

"palaeoreferences" (from past evidence), "actuoreferences" (from other similar sites before modification), or "system-theoretical references" (effectively, the process approach). System-theoretical or process approaches will tend to take as their conceptual base our best approximations of how the river flow and sediment systems interact to create channel physical habitat (Figure 3).

The process approach finds favor in both ecology and geomorphology because the integrity of process dynamics creates resilience and, hence, a sustainable project outcome. The concept is not far removed from *ecosystem health* (Rapport, 1995) in which ecosystem processes deliver environmental services (*sense stricto* Jewitt, 2002) such as flood protection, water supply, and water purification. Woodley *et al.* (1993) suggest that "integrity" corresponds with "self-correcting capability"; they hypothesize, however, that as ecosystems have both structural and functional integrity, the latter may not always be lost or damaged with the former because they are arranged in parallel, and, thus, resilience to all but catastrophic (or chaotic) processes is assured. The process approach also allows for *assisted natural recovery* of the system, a much cheaper form of restoration or rehabilitation.

Assessment and Monitoring "Towards Good Ecological Quality"

A final, momentous challenge for those involved with the concept and realization of "good ecological quality" is to assess it, monitor it, and restore it within a basin-wide strategy, considering also the element of land use and management. This is not the challenge faced by most community-based projects for enhancement or rehabilitation but is crucial to the river basin scale government institutions charged with sustainable development practice and implementation of the WFD. As Chave (2001) highlights, the four most important and innovative aspects of the WFD legislation are that it aims to:

- manage water as a whole *on a river basin basis*.
- use a combined approach for the control of pollution, setting both emission limits and water quality objectives.
- reflect the true cost of water, ensuring the user bears the cost of provision and use.
- involve the public in making decisions on water management.

Such an approach has been advocated for some time. Doppelt *et al.* (1993) discuss options available for the assessment of ecosystem status and suggest priorities for action at the basin scale, highlighting a prime need for data at the basin scale from which to select spatial, system-driven aspects of rehabilitation, and arguing for "a new synthesis of conservation biology, ecosystem science, and geomorphic knowledge". Key elements of the spatially planned approach include securing existing populations of desirable species, maintaining critical areas/functions, constructing functional recovery measures, and ensuring well-distributed biotic response.

In Europe, the catchment (watershed) approach is also implicit in the demands made by the EU WFD. Here, the need is for systems capable of assessing the ecological and hydromorphological quality of freshwaters. Article 8 of the WFD requires the establishment of monitoring and sampling programmes within six years of the date of entry into force of the Directive. Three types of monitoring activity are envisaged (Chave, 2001): surveillance, operational, and investigative (Table 5). Such systems must be

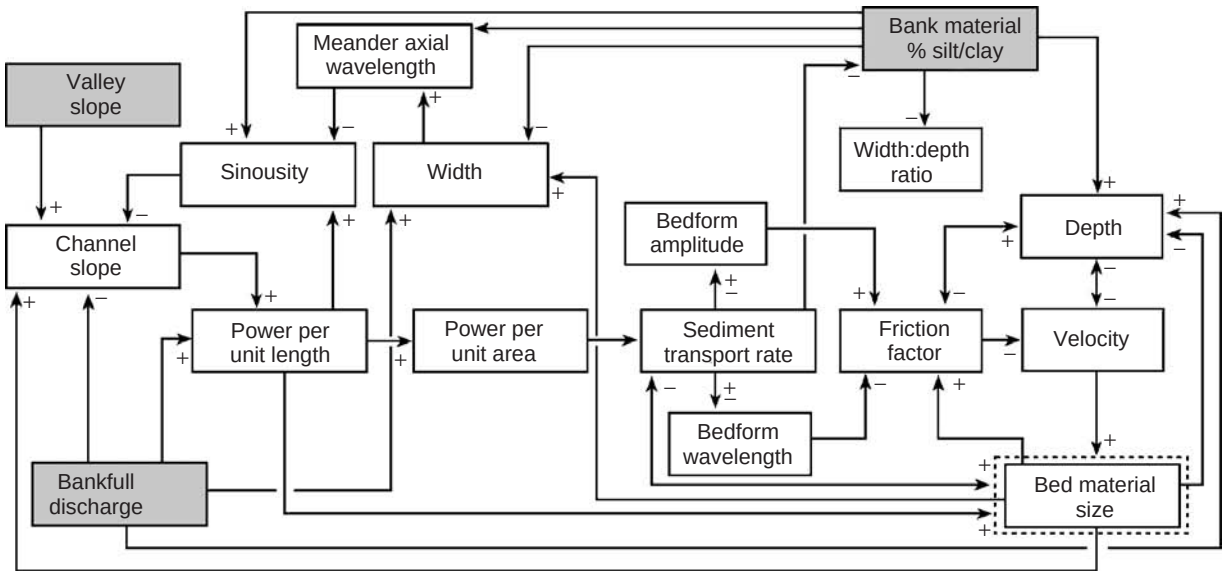

Figure 3 Systems approach to modeling the fluvial system. Independent variables are shaded, direct relationships are shown by +, inverse relationships by −. Reversible linkages are signified by double-headed arrows (From Richards, 1982, by permission of Methuen)

robust, repeatable, and harmonized; in the United Kingdom, a lead towards surveillance monitoring has been provided through the development of the River Habitat Surveys (RHS) methodology to describe and evaluate the physical characteristics of rivers (Raven *et al.*, 1997; Fox *et al.*, 1998, p458). Many European nations have analogous systems because all were aware of the impending and impressive database requirements of the WFD (Raven *et al.*, 2002). The RHS system uses survey lengths of 500 m, chosen by stratified random sampling, and including both transect-based and "sweep-up" (whole length) observations. The "hydromorphological" dimension is respected by the inclusion of both geomorphological features/dimensions and flow types (map data, valley form, channel features, bed and bank materials, vegetation, land use, profiles, dimensions, biotopes, and land management are addressed by the methodology). To date, 6000 sites have been covered by RHS for the 85 000 km of channel in England and Wales. Whilst the RHS include geomorphological variables sufficient to describe the main framework of physical habitat and the impacts thereon of channel and riparian development, the fact remains that a functional appreciation of the ecosystem in hydromorphological terms is beyond the present Survey methodology. Existing River Habitat Survey techniques have not, for example, covered the floodplain environment and physical aspects of the hydromorphology of rivers. The GeoRHS programme in the United Kingdom is aimed at enhancing RHS to develop appropriate indices to support a wide range of functional operations (e.g. flood defence, WFD, conservation, and restoration). Other innovative remote sensing techniques also offer potential in this regard (e.g. LiDAR as described by, among others, Charlton *et al.*, 2003).

Finally, into the vacuum between RHS and the preceding neglect of channel dynamics by river managers has come a range of geomorphological survey techniques, or "geomorphological audit" that allow a much greater emphasis on the often quite local processes of channel "stability" or adjustment (Newson, 2002).

THE GEOMORPHOLOGICAL BASIS FOR ''REFERENCE'' AND ''RESTORATION''

The potential role of fluvial geomorphology in understanding, assessing, monitoring, and restoring hydromorphological quality in river systems has already been stressed. There are, however, considerable limitations to the exploitation of this potential, notably in the relative lack of empirical data about channel form and process (compared, e.g. with hydrological data) and the relatively high levels of influence on channel forms and dynamics operated by site factors and the historical dimension. Accordingly, geomorphologists have been forced to adopt survey procedures and local calibrations for "universal" models in their applications to both the modified channel forms of flood-prone regions and the modified flows characteristic of dryland regions (Newson *et al.*, 2002).

Table 3 highlights the traditional preoccupation of fluvial geomorphologists with processes, centering on the composite process of "adjustment". A river channel slowly or episodically adjusts to the major drivers of river discharge (dominantly high flows, around bankfull) and fluvial

Table 3 Geomorphological description of terminology commonly used for UK rivers (after Newson, 2002)

Terminology	Suggested geomorphological description for UK rivers
Reach	Length of river in which channel dimensions and features relate characteristically to identifiable sediment sources and sinks. Reaches may be demarcated by tributary inputs under certain conditions of climate, river regulation and land use.
Stable (i.e. channel planform/elevation)	Essential to differentiate between engineering concepts of stability, legal/popular interpretation and natural resilience or ''robust'' behavior. Geomorphological stability incorporates adjustments, short of threshold behavior, that can be predicted from assessment of channel ''styles''.
Reference conditions (or ''natural'')	Rivers with planform/sectional geometry and features that represent the full interplay of water and sediment fluxes with local boundary conditions. ''Natural'' rivers are free to adjust their form and features (by aggradation/degradation and lateral migration across floodplain/valley floor) to both system-scale drivers and local conditions. ''Natural'' rivers, therefore, provide a diverse physical habitat in both space and time.
Heavily modified rivers	Rivers that, through human modification or repeated actions, are constrained in their direction/rate of adjustment and diversity of features, frequently to the extent that they create a geomorphological hiatus in the flow/sediment system, causing upstream or downstream impacts or both. Depending on system location and conditions they may recover if human action is ceased or modified.

sediment fluxes (supplied from catchment or the upstream channel). In engineering terms, adjustment is "instability", and so its constituent processes have been heavily controlled throughout the history of anthropogenic influences on rivers. In England and Wales, for example, two-thirds of all river channels sampled by the RHS have been modified in form or boundary conditions, mainly to control flooding or to reduce the risk of "instability". Many of the modifications of river channel cross sections carried out in the name of flood protection also modify the geomorphological effectiveness and work rate of the flow in that section, for example, by increasing channel depth and, hence, stream power. The flow regime, by contrast, is most heavily impacted by impoundment, regulation, and abstraction, although catchment land use, land cover, and land management are now also seen to have a subtle but important influence, especially on flow extremes.

The limitations posed to the application of geomorphological "tools" (Newson, 2002; Kondolf and Piegay, 2003a,b) by the need to conduct local surveys and calibrations is further complicated by the disparate scale of the demand for practical assessment, monitoring, and design: that is, the catchment scale. The procedures adopted by the Environment Agency in England and Wales are progressively scaled by level of detail (Newson *et al.*, 2002), but approaches elsewhere include geomorphic classification (e.g. Rosgen, 1996), hierarchical channel classification (Frissell *et al.*, 1986), and "river styles", an Australian approach also scaled through a spatial hierarchy (Brierley and Fryirs, 2000; Thomson *et al.*, 2001). River classifications attract scepticism (e.g. Wadeson, 1994; Kondolf, 1995), but Thomson *et al.* (2001) advocate the typology represented by "river styles" on the basis that it proceeds downwards in spatial scale from basin to hydraulic units, thus encapsulating system-scale information and a basin-wide long-term strategy in its local guidance. Similar approaches have been independently advocated by Van Niekerk *et al.* (1995) for South African rivers. By contrast, the Rosgen classification is of individual channel cross sections, perhaps more relevant to an engineering approach to local dynamics.

THE POLICY TEMPLATE: IMPLEMENTING AND COMPLYING WITH THE WFD

The WFD designates five classes of water body (in the case under discussion, these are typed river lengths, excluding those considered "heavily modified"), labeled as being of "high", "good", "moderate", "poor", or "bad" ecological status. These labels are based upon a comparison between actual and reference conditions for (i) biological quality elements, (ii) hydromorphological quality elements, and (iii) physicochemical quality elements. Only "high" ecological status requires reference conditions to exist for hydromorphological quality, whereas biological quality enters the description of each status. "By definition, rivers with undisturbed physical structure, and, therefore, of high hydromorphological status should, given good water quality, support aquatic communities of high ecological status" (Raven *et al.*, 2002). River Basin Management Plans are to form the strategic guidance to the achievement of "good" ecological status for all relevant water bodies by 2015. The environmental objective for heavily modified water bodies (HMWB) is to realize *good ecological potential* subject to the limitations posed by their use as a socioeconomic priority. HMWB, by definition therefore, are bodies of water that, as a result of physical alteration by human activity, are

Table 4 Hydromorphological reference conditions as specified by the WFD (after NTNU, 2002)

Component	Reference condition
Bed and bank character	Lacking any artificial in-stream and bank structures that disrupt natural hydromorphological processes and/or unaffected by any such structures outside the site Bed and banks composed of natural materials
Planform and river profile	Planform and river profile unmodified by human activities
Lateral connectivity and freedom of lateral movement	Lacking any structural modifications that hinder the flow of water between the channel and the floodplain, or prevent the migration of the river channel across the floodplain
Free flow of water and sediment in the channel	Lacking any structural modifications that affect the natural movement of sediment, water, and biota
Vegetation in the riparian zone	Having natural vegetation appropriate to the type and geographical location of the river

substantially changed in character and *cannot* meet "good ecological status".

Measurement of river ecosystem functioning requires integration of a wide variety of parameters (Lorenz, 1997), and of particular relevance here are stream water quality, hydrology (discharge and stream velocity), and geomorphology (describing the structure of the river channel, riparian zone, and floodplain), along with ecological information on species diversity and abundance. In addition to measurement of these parameters, it will be necessary to develop systems that allow for the definition of pristine (reference) conditions for rivers (Table 4), as well as defining "high", "good", and "moderate" status for hydromorphological elements insofar as they support the biotic components dependant on the parameters listed above (EPA, 2002a; NTNU, 2002). The latter is a requirement of the WFD allowing the quality of rivers to be compared in an equitable and ecologically meaningful way.

Each State is required to establish programmes for river monitoring in order to determine "water status" with River Basin Districts (EPA, 2002a). The identification of hydromorphological reference conditions is thus an essential prerequisite for assessing hydromorphological quality, and is a specific requirement of the WFD to enable adequate classification of other (i.e. high, moderate, and good) status levels. Furthermore, the Directive states that the objective of achieving good water status should be pursued in an integrated manner for each river basin, so that measures in respect of surface water and groundwaters belonging to the same ecological, hydrological, and hydrogeological system are coordinated. The WFD specifies a nested programme of surveillance (Table 5) with additional monitoring required for protected areas.

Biological Integrity

In many countries of the EU, there has been much attention paid recently in devising practical methodologies and evaluating ecological integrity. In the United States, the concept of "biological integrity" has been a basis for much legislation in relation to river environments over the last 20 years (Karr and Chu, 2000). In the United Kingdom and Europe, however, there has been considerable discussion but little practical progress in development of methods for assessing "integrity" as opposed to "quality" (Table 6) in running waters (Harper *et al.*, 2000) and, as Karr (1993) has pointed out, the concepts of biotic integrity *per se* are not new. As far back as 1949, Aldo Leopold argued that:

Table 5 Monitoring requirements of the water framework directive (after EPA, 2002b)

Operation	Objectives
Surveillance monitoring	• To assess overall surface water status within each catchment or subcatchment • To validate assessment of potential impacts on waters, assist in optimization of future monitoring, and aid detection of long-term changes • To include all of the biological, physicochemical and hydromorphological elements (see Table 6)
Operational monitoring	• To establish the status of waters that the surveillance monitoring indicates to be in danger of failing to meet quality objectives • To determine changes arising from remedial measures
Investigative monitoring	• Required in cases where the reason for failure to meet water quality objectives is unclear or unknown • Where surveillance monitoring indicates objectives are unlikely to be achieved, to determine the causes why • To assess the impact of accidental pollution

Table 6 Quality elements for the classification of ecological status in rivers under the WFD

Quality element	Description
Biological elements	• Composition and abundance of aquatic flora • Composition and abundance of benthic invertebrate fauna • Composition, abundance, and age structure of fish fauna
Hydromorphological elements supporting the biological elements	• Hydrological regime • Quantity and dynamics of water flow • Connection to groundwater bodies • River continuity • Morphological conditions • River depth and width variation • Structure and substrate of the river bed • Structure of the riparian zone
Chemical and physicochemical elements supporting the biological elements	• Thermal conditions • Oxygenation conditions • Salinity • Acidification status • Nutrient conditions • Specific pollutants • Pollution by all priority substances identified as being discharged into the body of water • Pollution by other substances identified as being discharged into the body of water

> "a thing is right when it tends to preserve the integrity, stability and beauty of the biotic community"

In the United States, the phrase "biological integrity" first appeared in a policy context under the Water Quality Amendments of 1972 (PL-92-500) where the legislation called for the restoration and maintenance of "the chemical, physical and biological integrity of the nation's waters" (Karr, 1993). Overall, the development of methods to assess the ecological integrity of running waters requires the integration of physical and chemical parameters, as well as their effects on biological diversity, structure, and process (Harper *et al.*, 2000).

Walker *et al.* (2002) take the practical, administrative, and consultative burdens of the WFD a stage further by describing a system of Physical Quality Objectives for rivers in England and Wales. The existence of the very large database from the RHS allows experimentation with scoring systems involving habitat quality and habitat modification (both judged against "reference sites" in the database). The system goes further by classifying river survey sites in England and Wales along the axes formed by the Habitat Quality Assessment and the Habitat Modification Score in order to indicate how progress in meeting the demands of WFD compliance might be publicized and restoration strategies debated.

FLOW RESTORATION

The above account has shown considerable bias away from "hydro-" towards "morphological" in the definition of supporting conditions for freshwater biodiversity; this is understandable in England and Wales where, as mentioned, two-thirds of all channel lengths surveyed by RHS have been structurally modified. Nevertheless, a high proportion of rivers also experience a flow regime that is regulated (Gustard *et al.*, 1987) by reservoir impoundment, abstractions (Petts, 1996), or wastewater discharges (more than 70% of gauged rivers, according to Petts, 1988). A pertinent example of the issues raised by the pending application of the WFD in Scotland is the highly (perhaps "heavily") modified flow regime necessitated by hydroelectric power generation that dominates the hydromorphological quality of otherwise little directly altered channels (Walker, 2002).

Assessment of the ecological impacts of regulated flow regimes in England and Wales has been driven more by episodes of drought or by poorly assessed and regulated abstraction volumes than by reservoir operation. It is very clear that there have been considerable geomorphological impacts from reservoir operations (Petts, 1984) and that subtle, progressive impacts may follow (e.g. Sear, 1992 for the effects of reservoir releases on riffle-pool structures). Reservoir construction has now abated in the United Kingdom, in favor of demand management and other water supply strategies; however, in future projects, the flow assessment technologies developed for conditions of drought and over-abstraction (e.g. Bragg *et al.*, 1999) are likely to be deployed as part of environmental impact assessment and as part of compliance with the WFD – if only to confirm a "heavily modified" status. A simple physical assessment is already part of the Environment Agency's Catchment Abstraction Management System (Dunbar *et al.*, 2002).

CONCLUSIONS AND REFLECTION

This article commenced with discussion of the hydromorphological quality of freshwaters (in support of ecological quality) with reference to the considerable progress made in solving problems of chemical water quality. The methods of assessment, monitoring, and regulation applied to water

pollution perhaps offer us, in view of their apparent success, a model (or at least an analogue) for the application of similar controls on hydromorphology.

In fact, at least two different schemes of water quality management existed in Europe prior to the WFD, the Water Quality Objectives (or ambient) approach of the United Kingdom and the continental model of emission controls (without reference to the capacity of the receiving environment). The WFD unites these two models, which, despite their differences, have relied on:

- Toxicological evidence for system degradation – the central concept of pollution impacts;
- Appropriately independent authorities capable of regulation within nation states;
- Legal registration of the problem sites and surveillance to assess compliance and permit public accountability;
- Legal sanctions to prevent degradation;
- Derivation of indices of water quality and monitoring to indicate improvement/deterioration.

Several major areas of contrast in the new policy drive to rehabilitate freshwater ecosystems in the interests of sustainable development through environmental protection have been outlined. In terms of a regulatory role for hydromorphological elements, it can be shown that:

- The equivalent "exact" definitions (*cf.* toxicology) do not yet exist;
- Available data and tools for river morphology are scarce compared to the (basin) scale of the demand;
- The most profound causes of harmful impacts (channelization, excessive flow regulation, hydropower) may persist unregulated because of their socioeconomic importance (cf. chemical pollution controls where "the polluter pays").

Despite optimism that the appropriate authorities are largely in place and that public pressures become part of participation in the WFD, there remain the considerable contextual and academic problems of moving from limits imposed by chemistry to those imposed by physics and biology. Implicit, therefore, in the contemporary approach to ecosystem dynamics is a requirement to understand process and context; a requirement emphasized by the approaching deadline for implementation of the WFD. Process here refers to system dynamics and the mechanisms underlying them, while context refers to both the "spatial influences on the system" (e.g. Parker and Pickett, 1997 p. 22) and the timescales across which they operate.

191: Environmental Flows: Managing Hydrological Environments

CHRISTOPHER J GIPPEL

Fluvial Systems Pty Ltd, Stockton, Australia

Environmental flows refer to the facets of natural flow regimes that are required to sustain riparian and aquatic life in a healthy condition, plus provide for the needs of those human uses that rely on, and do not compromise, stream health values. Environmental flow assessments are required for regulated rivers, where the flow regime has been modified, or flow volumes significantly reduced. The methodological trend has been from narrow studies that catered for a single fish species at one critical life phase to a holistic approach that aims to restore natural river processes. Consideration has also been given to the specific issues of flood flows required for wetland inundation and channel formation, needs of groundwater-dependent ecosystems, the needs of estuarine ecosystems, and flows required for recreational activities. Holistic methodologies are particularly appropriate in developing countries with strong livelihood dependencies on the goods and services provided by aquatic ecosystems. The number of studies worldwide that report environmental flow recommendations greatly outweighs the number of studies that report scientific evaluation of the results of implementation of these recommendations. However, where implemented environmental flow regimes have been monitored, the results have generally been positive.

INTRODUCTION

Many studies conducted over the past two decades throughout the world have cited flow regulation (by dams, diversions, and direct pumping) as a major cause of degradation across the spectrum of river health (Gordon *et al.*, 2004, p. 286). It is often difficult to isolate observed changes in the aquatic environment that are due to flow regulation from those that are due to changes in other factors such as catchment land use, fishing pressure, introduced species, riparian vegetation cover, large woody debris distribution, and natural variations in flow regime (i.e. the pattern of floods, droughts, and seasonal flow variability). The difficulty arises from the fact that changes to these factors can produce similar ecological responses, and the changes in these factors are often overlapping or simultaneous with flow regulation. While data are often available to quantify the hydrological impact of regulation, in most situations, regulation began well before ecological monitoring programs were initiated.

Identification of flow regulation as one of the major causes of stream health degradation has led river managers to seek ways of reversing this effect, to the extent that this is currently one of the priority issues in stream management throughout the world (Gordon *et al.*, 2004, p. 287). Modifying regulated flow regimes and returning diverted water back to rivers to benefit wildlife is a highly contentious and controversial issue. Conflicts over water use are common, especially where water supplies are limited, as in arid and semiarid areas, where demands for water supplies are increasing, and where there are other in-stream uses such as navigation and recreation. It is necessary then to determine a satisfactory balance between competing uses. The process of achieving this balance is the topic of this article.

In-stream and Environmental Flows Defined

The term *in-stream flow* is used, particularly in the United States, to refer to a specific stream flow that is identified for the purposes of planning or management of a stream or river. In-stream flows are those that are retained in their natural setting, as opposed to those waters that are diverted for offstream users such as industry, agriculture, and town water supply. Flows influence adjacent groundwater levels,

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

as well as the hydrological status of foodplain wetlands. The level of flow in a stream also conditions aesthetic and scenic values. Navigation is affected by flows. For example, kayakers in mountain streams require high flows, while in large rivers like the Columbia River in Washington State, if flows are below a certain level, the river becomes impassable to commercial barges, tugs, and other watercraft because of the lack of draft (Rushton, 2000). In-stream flows are also used for the production of hydroelectricity and waste disposal. In some places, indigenous people live close to the river and their livelihoods depend on the river's resources, both clean water and biological resources (Quinn, 1991). Some rivers have valuable commercial and recreational fishing industries that depend on in-stream flows. The intrinsic wildlife values of rivers are also sustained by in-stream flows. The flows required to maintain or rehabilitate the habitat for riparian and aquatic life are the most difficult to quantify, and this is the main focus of the rest of this article. This subset of in-stream flows is known, particularly in Australia and southern Africa, as *environmental flows*, although in recent times, this term has been used more broadly to also include other related uses.

Brown and King's (2003) definition of environmental flows encompassed aesthetic, recreational, and cultural values as well as biophysical ones, and they also placed social and economic issues within the realm of environmental flows. In-stream flows for hydropower releases, irrigation releases, navigation, dilution of pollution, release of wastewater, and interbasin transfers were excluded from Brown and King's (2003) definition of environmental flows, because these uses traditionally work against achievement of their defined ecological and human needs goals. So, for the remainder of this article, the term environmental flows is used to refer to in-stream flows required to sustain riparian and aquatic life in a healthy condition, plus those human uses that rely on, and do not compromise, stream health values.

Three Basic Assumptions of Environmental Flows Assessment

Gordon *et al.* (2004, p. 288–290) stated three basic assumptions that underlie most environmental flow assessments:

- assessments are generally grounded on the natural flow paradigm, even though the final regime is likely to be a compromise on this;
- less than all the natural flow will maintain stream integrity (stream health); and
- stream health exists on a continuum

The natural flow paradigm states that discharge variability is central to sustaining and conserving biodiversity and ecological integrity (e.g. Poff *et al.*, 1997; Richter *et al.*, 1997; Puckridge *et al.*, 1998; Tharme and King, 1998). Given the currently limited understanding of flow-ecology relationships, and the improbability of ever being able to fully define the needs of the whole biological community, the conservative alternative is to assume that the natural flow regime is the best indicator of environmental needs. The idea of mimicking a natural system, also known as *physiomimesis* (Katopodis, 2003), appears as an objective in numerous publications in the environmental flow literature (e.g. Environment Protection Authority of NSW, 1997; Arthington, 1998; Tharme and King, 1998; Snowy Water Inquiry, 1998). While the natural flow regime paradigm has merit, translating it into practical recommendations for environmental flows can be problematic. In practice, the process of determining environmental flows does not involve attempting to devise a regulated flow regime that has a statistically defined variability (across all timescales) identical to that of the natural flow regime. For example, all of the environmental flow projects listed by Poff *et al.* (1997) involved only partial restoration of the natural flow regime. Under conditions of limited water resources, competing demands, and constraints on flow control imposed by river structures, some flow variability targets will be low priority and others will be impossible to implement.

There is an implicit understanding that environmental flow assessment is not about recommending the full natural flow regime as the ideal. Rather, it is about determining what lesser amount will maintain stream health in the desired condition. For streams regulated by dams and major diversions, the objective of environmental flow assessment is to set maintenance or rehabilitation targets (Gippel *et al.*, 2002), while for other streams, the objective is to set a sustainable limit to current and/or future pumping and diversions (Nathan *et al.*, 2002). The biotic and abiotic components of stream ecosystems can range in their sensitivity to water resource development (Figure 1). Estimates of how much flow must remain in a river before its health is impaired range from about 65% to 95% of natural flow, provided the natural pattern of flow is also retained (Dyson, 2003). The range of values for an acceptable level of hydrological modification given in the literature partly reflects the enormous variation in sensitivity and importance of the systems that have been assessed (Gordon *et al.*, 2004, p. 290).

When stream health is defined as ecosystem integrity (Karr and Dudley, 1981) it could be construed as an absolute term that cannot have degrees, that is, ecosystem integrity is intact (stream is healthy) or it is not (stream is not healthy). A healthy working river is one that is managed to provide a compromise, agreed to by the community, between the condition of the river and the level of human use (Gordon *et al.*, 2004, p. 239). This concept is implicit in stream health assessment methodologies that rate stream condition against a reference condition, but along a

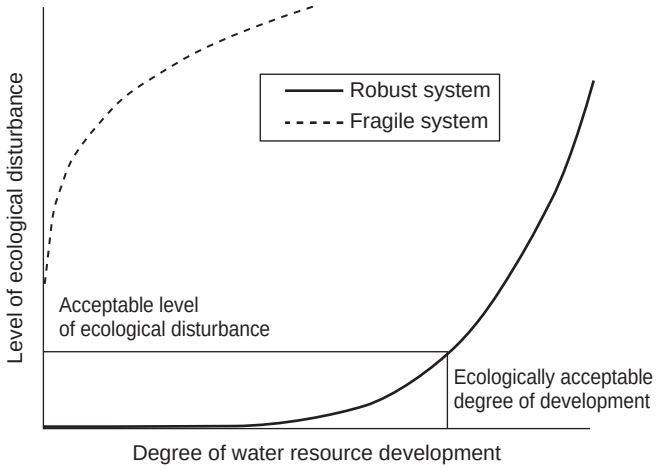

Figure 1 Conceptual diagram of the relation between the degree of water resource development and the level of disturbance. Source: Stewardson and Gippel (1997), Hydro Tasmania

grade, such as expressed by a range of observed/expected scores, or as a range of index scores compared against the highest possible score (Gordon *et al.*, 2004, p. 239–262). Also, grades of stream health are allocated to rivers in classification schemes (Gordon *et al.*, 2004, p. 262–286). In situations where the vision for the river, and hence the management goal, is a departure from the reference condition, the environmental flows assessment process seeks to find the balance between the desired ecosystem condition and other social and economic needs for water (Dyson, 2003). The flows allocated to achieve the chosen condition are the environmental flows.

FORMS OF ENVIRONMENTAL FLOW ASSESSMENT

Environmental flow assessments vary across a wide range of complexity and depth, as dictated by the level of funding, availability of data, technical capacity, time frame, priority of the site, or expected level of controversy. Environmental flows may be specified at several levels of resolution, from a single annual flow volume or a minimum flow limit below which diversions are not permitted, through to a comprehensive flow regime that specifies the distribution of a range of flows throughout the year. A comprehensive study might specify flows necessary to allow the passage of fish, flows to provide sufficient living space for biota or to ensure acceptable levels of temperature, dissolved oxygen or salinity, and higher flows (flushing flows or channel maintenance flows) to remove fine materials from the streambed, scour out encroaching vegetation, or flush anoxic or highly saline waters from stratified pools. The spatial scale of environmental flows assessment also varies widely, from whole of catchment to the river reach. Methodologies range from relatively simplistic, reconnaissance-level approaches to resource-intensive methodologies for detailed studies.

There have been numerous reviews and evaluations of environmental flows methodologies (e.g. Arthington and Zalucki, 1998; Espegren, 1998; Jowett, 1997; King *et al.*, 1999; Annear *et al.*, 2002; Caissie and El–Jabi, 2003; Tharme, 2003; Scatena, 2004), and a comprehensive bibliography is provided in Gordon *et al.* (2004, p. 291). Tharme's (2003) recent global review of the present status of environmental flow methodologies revealed the existence of some 207 individual methodologies, recorded for 44 countries within six world regions. A database of these methodologies is available online at **`www.lk.iwmi.org/ehdb/EFM/efm.asp`** (International Water Management Institute, 2003). This article provides only a sketch of the main methods currently in use. There is a vast literature on the topic of relationships between flow and ecological responses (e.g. Pusey *et al.*, 2000; Ward *et al.*, 2001; Bunn and Arthington, 2002), and while this knowledge forms the empirical basis of much of the environmental flow assessment process, it is not reviewed here. Some key river ecosystem processes are discussed in the article on river ecosystems (river continuum concept, flood-pulse dynamics, hyporheic zone processes). The focus of this article is environmental flow methodologies, with an emphasis on the hydrological, hydraulic, and geomorphological aspects.

Hydrological Methods

Hydrological methodologies use simple rules based on flow duration or mean discharge to scale down the natural flow regime. The Tennant method (Tennant, 1976), also referred to as the *Montana method*, is the most commonly applied hydrological methodology worldwide (Tharme, 2003). Recommended minimum flows are based on percentages of the average annual flow, with different percentages for winter and summer months. The Hoppe (1975) regional rule-of-thumb method utilizes flow duration curves ideally based on daily discharge data.

The main attraction of hydrological techniques is the fact that an answer can be obtained rapidly if gauged flow records are available, eliminating the time and cost of field data collection. The techniques tend to be site- and species-specific, and for them to be applicable in other situations, the relationship between habitat and discharge must be similar. Orth and Leonard (1990), Pusey (1998), Dunbar *et al.* (1998), and Tharme (2003) concluded that simple hydrological methods requiring little or no fieldwork are most appropriate for basin-wide planning purposes, or for providing preliminary estimates in uncontroversial situations. A number of studies have compared hydrological methods with more sophisticated approaches (e.g. Orth and Maughan, 1981; Orth and Leonard, 1990; Caissie *et al.*,

1998; Bureau of Reclamation, 1999). These comparisons generally found that there was no consistent or reliable pattern in the relative magnitude of flows recommended by these methods.

Hydraulic Rating Methods

Hydraulic rating methods utilize a quantifiable relationship between the quantity and quality of an in-stream resource, such as fishery habitat, and discharge, to calculate flow recommendations. Most emphasis has been placed on the passage, spawning, rearing, and other flow-related maintenance requirements of individual, economically or recreationally important fish species. This approach is sometimes known as a *transect method* or *wetted-perimeter method* because it involves measuring and interpolating changes in simple hydraulic variables, such as wetted perimeter, mean velocity, or maximum depth, usually measured across single river cross sections, as a surrogate for habitat factors known or assumed to be limiting to target biota (Figure 2). Simple wetted-perimeter methods (Nelson, 1980) (Figure 3) have been widely applied for many years (Tharme, 2003), and are still being used to make important environmental flow determinations (e.g. McCarthy, 2003). Gippel and Stewardson (1998) provided an application and evaluation of the hydraulic rating method for headwater streams in Victoria, Australia, and compared the results with those of hydrological methods, and macroinvertebrate and fish data. In that case, the wetted-perimeter breakpoints occurred at flows considered too low to adequately protect the biota.

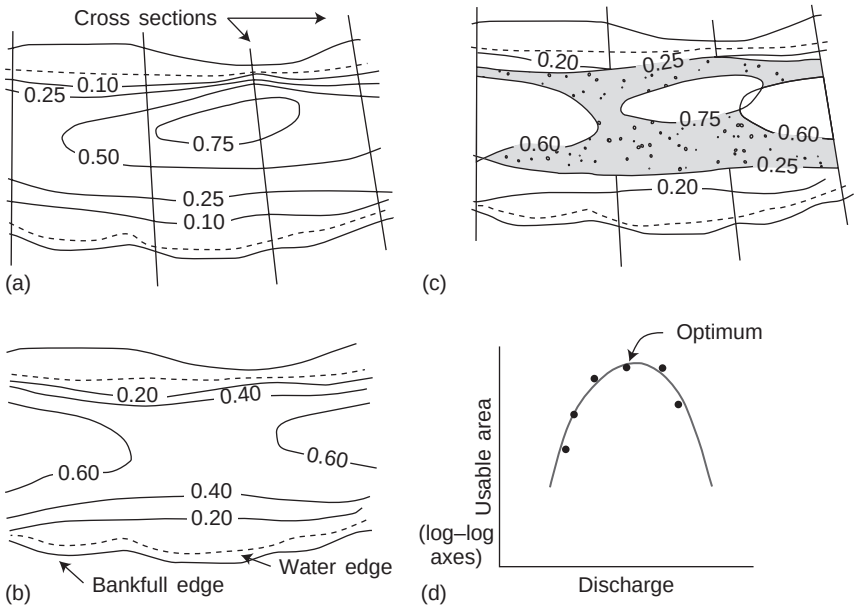

Figure 2 Washington method for determining preferred discharge. For this theoretical example, ''preferred habitat'' is: depth 0.25–0.75 m and velocity 0.20–0.60 m s^{-1}. Figures display: (a) depth contours in meters, (b) velocity contours in m s^{-1}, (c) a combination of maps (a) and (b) with shaded region showing usable area, and (d) trend-fitted curve derived from measurements (point shown) taken at several discharges. The ''optimum'' discharge corresponds with the greatest usable area. (Adapted from Collings (1972) © Washington State Department of Ecology)

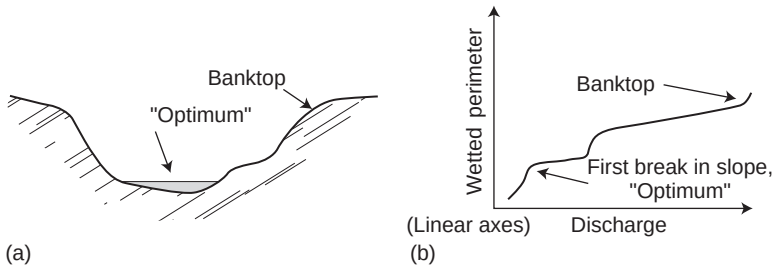

Figure 3 Wetted-perimeter method: (a) hypothetical channel cross section and (b) graph of wetted perimeter versus discharge. The first breakpoint in slope is used as an index of optimum available water (Reproduced from Gordon *et al.* (2004) by permissions of John Wiley & Sons.)

Habitat Rating Methods

Hydraulic rating methodologies were the precursors of more sophisticated habitat rating or simulation methodologies, also referred to as microhabitat or habitat modeling methodologies (Tharme, 2003). Habitat rating methods not only consider how physical habitat changes with stream flow but also combine this information with continuous habitat preference functions for given species to determine the amount of suitable habitat available over a range of stream flows. Results are normally in the form of a curve showing the relationship between suitable available habitat area and stream discharge. From this curve, the optimum stream flows for a number of individual species can be ascertained and the results used as a guide for recommending environmental flows. The most well known of the habitat rating methods is contained within the In-stream Flow Incremental Methodology (IFIM) (Bovee, 1982).

IFIM is the most commonly used flow assessment method worldwide (Tharme, 2003; King and Brown, 2003). In many States of the USA, IFIM is regarded as the most scientifically legally defensible method, so it has become the standard for large rivers, with hydraulic rating methods used on smaller streams (Espegren, 1998). There has been considerable development of IFIM since its introduction over 20 years ago (Bovee, 1982), with some of the earlier concepts becoming redundant. King and Tharme (1993) presented an updated step-by-step guide to applying the IFIM, including a review of the process.

The IFIM is much more than a habitat rating method. It is a problem-solving tool made up of a collection of analytical procedures and computer models. It was designed as a communication link between fishery biologists, hydrologists, and hydraulic engineers. "Incremental" means the slight or incremental modification of the problem or the perspective or view of the problem until a solution is found. It also refers to the ability to look at the effects of incremental changes in a variable (e.g. discharge) on available habitat. Rather than generating a single answer, the methodology produces a range of solutions that permit the evaluation of different alternatives.

The IFIM is grounded in the ecological niche concept of explaining community distribution, incorporating both macrohabitat and microhabitat concepts. Macrohabitat applies to large-scale longitudinal gradients in habitat characteristics along streams, and microhabitat is the precise location where an individual species is normally found. The microhabitat approach was originally justified by reference to two studies showing that competition between fish species was reduced by physical habitat isolation (Bovee and Milhous, 1978). The Weighted Useable Area (WUA) microhabitat model is the core habitat rating component of the IFIM. WUA is an indicator of the net suitability of use of a given reach by a certain life stage of a certain species. PHABSIM (Physical HABitat SIMulation) is a collection of computer programs used to model WUA. The IFIM habitat modeling process is conceptualized in Figure 4.

The IFIM/PHABSIM approach is not without its critics (Castleberry *et al.*, 1996; Van Winkle *et al.*, 1997; Pusey, 1998), with claims that its misuse has actually hastened the decline of rivers in the western United States, particularly the large alluvial rivers (Woo, 1999). Two major criticisms of PHABSIM are that it promotes the application of flows that are too low for sediment mobilization, and that it promotes relatively constant flows. Much of the criticism relates to the earlier applications of IFIM, when the focus was on a single species of fish, or on studies where PHABSIM was enthusiastically applied outside of the more

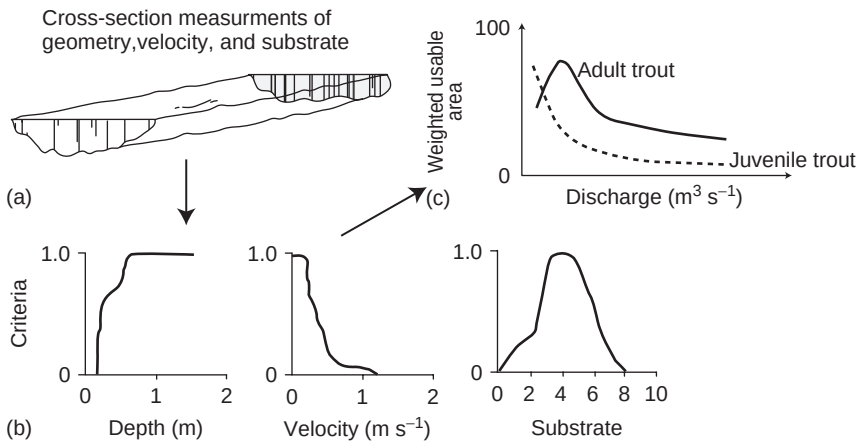

Figure 4 A conceptualization of the procedures in PHABSIM: a stream reach is selected and surveyed at a particular discharge (a), and the information is combined with habitat-Suitability Index (SI) curves defined for a particular species and life stage (b). The procedure is repeated for several discharges (using measured or modeled data) to obtain a curve describing the suitability of use of that reach as a function of discharge (c) (Reproduced from Gore and Nestler (1988) by permission of John Wiley & Sons, Ltd.)

holistic IFIM framework, and channel forming flows were ignored (Barinaga, 1996).

A critical limitation on the use of habitat-simulation models is the lack of well-defined habitat-suitability curves. As these curves are essentially empirical correlations, some authors (e.g. Nestler *et al.*, 1989) warn that the curves may not be transferable from one stream to another. The strongest criticism of PHABSIM has centered on the ecological interpretation of the WUA index. Gore and Nestler (1988) reviewed and commented on the criticisms put forward by a number of authors. The assumption is made in in-stream flow uses of PHABSIM that if the habitat is maintained, the fish population will be maintained. Some studies found evidence to support this assumption (Orth and Maughan, 1982; Stalnaker, 1979), while others did not (Irvine *et al.*, 1987; Mathur *et al.*, 1985; Scott and Shirvell, 1987). Other factors such as food supply, biological interactions (e.g. competition, predation), nutrients, dissolved oxygen, presence of ice cover, temperature, and flow regime (including the effect of floods) may be of greater importance than physical habitat in limiting species biomass or abundance (e.g. Pusey, 1998). Orth and Maughan (1982) concluded that IFIM is a useful framework for managing streams with altered flow regimes but it is not a panacea. Biological expertise is still needed in the interpretation of results. However, the model can provide a basis upon which a biologist may apply professional judgment (Mosley and Jowett, 1985) and a methodology for comparing the relative effects of different management decisions.

Stewardson and Gippel (2003) noted that because IFIM in its original form is grounded in ecological niche theory, it does not adequately account for disturbance, which is an important determinant of community structure. Their Flow Events Method extends the hydrological variability (Range of Variability Approach, or RVA) idea of Richter *et al.* (1996) to also consider temporal changes in physical habitat conditions at the appropriate spatial scales. The method characterizes flow variations for environmental flow studies using knowledge of the influence of flow events on biological and geomorphic processes. The Flow Events Method is not a new method, but an analytical tool that can be used within any framework, such as IFIM or various holistic approaches.

Holistic Methodologies

Holistic approaches are essentially frameworks for organizing and using flow-related data and knowledge (Arthington *et al.*, 1992; Brown and King, 2003; King *et al.*, 2003). Holistic approaches cover a wide range of related "methodologies", all listed in Gordon *et al.* (2004, p. 299) and online at **www.lk.iwmi.org/ehdb/EFM/efm.asp** (International Water Management Institute, 2003). Several holistic methodologies have been developed, primarily in Australia and South Africa, with the same fundamental characteristics, but different approaches to development of quantitative or semiquantitative relationships between flow modifications and geomorphological/ecological responses. All are reviewed in Tharme (2003) and Arthington and Pusey (2003). The holistic approaches are not constrained by the available analytical tools, and it is not unusual for these approaches to make use of several different techniques. The full IFIM process also falls within the realm of a holistic approach. While the hydrological, hydraulic rating, and habitat rating methods usually focus on key sport fish such as salmonids, or fish with a very high conservation value, the holistic approaches attempt to consider the entire ecosystem, using all available information, much of which may be little more than personal experience and working hypotheses.

Proponents of holistic methodologies take the view that, where possible, management strategies for rivers should be aimed at maintaining or rehabilitating as much as possible of the original, functional aquatic ecosystem (Arthington and Pusey, 1993; Arthington and Pusey, 2003). Holistic approaches are based on the natural hydrological regime and are intended to provide water required for the complete ecosystem, including the river channel, riparian zone, floodplain, groundwater, wetlands, and estuary. Explicit numerical models that relate discharge to aspects of the river's geomorphology, water quality, or ecology (i.e. hydraulic or habitat rating models) may be available, or even developed through the course of the investigation, but they are usually used as an aid to decision making, rather than as a numerical solution to the problem of defining a suitable regulated flow regime.

An important advance in holistic methodology has been the establishment, in Queensland, Australia, of the Benchmarking methodology, which undertakes basin-scale evaluation of the potential environmental impacts of future scenarios of water resource management (Arthington, 1998; Brizga *et al.*, 2002). Another significant development has been the incorporation of social, cultural, and economic components into environmental flow assessments. For example, the DRIFT (Downstream Response to Imposed Flow Transformation) method developed for use in southern Africa (Brown and King, 2000; King *et al.*, 2003) evaluates links between flow modifications, geomorphological and ecological responses and social consequences for subsistence users of river resources, and economic implications in terms of mitigation and compensation. Another example is The Living Murray initiative (**www.thelivingmurray.mdbc.gov.au**), which is an ongoing process that is examining the ecological, cultural, social, and economic consequences of flow scenarios for the entire 2530 km long River Murray, Australia (Gippel *et al.*, 2002).

A holistic approach may adopt a bottom-up philosophy (Arthington, 1998), whereby the regime is built up

from hydrological facets (usually a pattern of baseflows combined with various sized floods) that is assumed from experience or research to be the minimum combination required to achieve ecological sustainability. The BBM (Building Block Methodology) (King and Louw, 1998) builds the regime from three main groups of flow facets (Figure 5). The alternative is the top-down philosophy, whereby it is assumed that the entire natural flow regime is ecologically important, but that some facets of it can be modified or omitted without threatening ecological sustainability (Arthington, 1998). The top-down DRIFT process (Figure 6), which emerged from the foundations of the BBM, was developed for the assessment of environmental flows for the Lesotho Highlands Water Project (King and Brown, 2003; Arthington *et al.*, 2003).

Holistic approaches share four main assumptions regarding achievement, or maintenance, of ecological sustainability:

- some facets of the natural flow regime cannot be scaled down, and must be retained in their entirety
- some facets of the natural flow regime can be scaled down
- some facets of the natural flow regime can be omitted altogether
- variability of the regulated flow regime should mimic that of the natural flow regime, in certain respects

These assumptions arise from the notion that high- and low-flow events are more important than in-between conditions because of the stresses and opportunities they present to the biota (Poff *et al.*, 1997). Also, many geomorphic and ecological processes show nonlinear responses to flow, requiring a threshold to be exceeded before the process

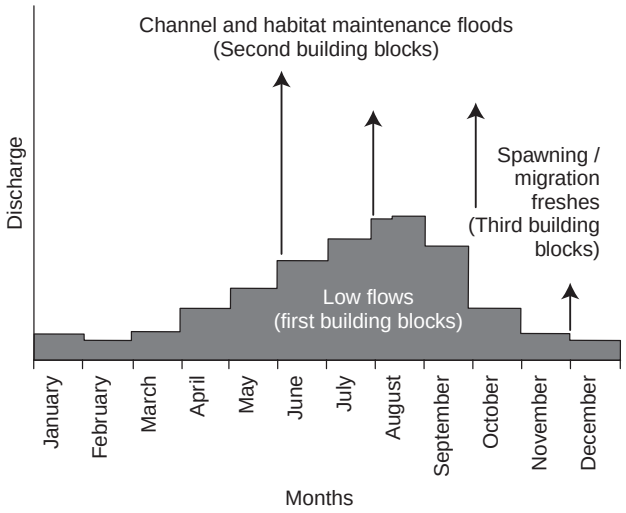

Figure 5 The ''building blocks'' of a hypothetical environmental flow regime created using the BBM approach. Source: Tharme and King (1998)

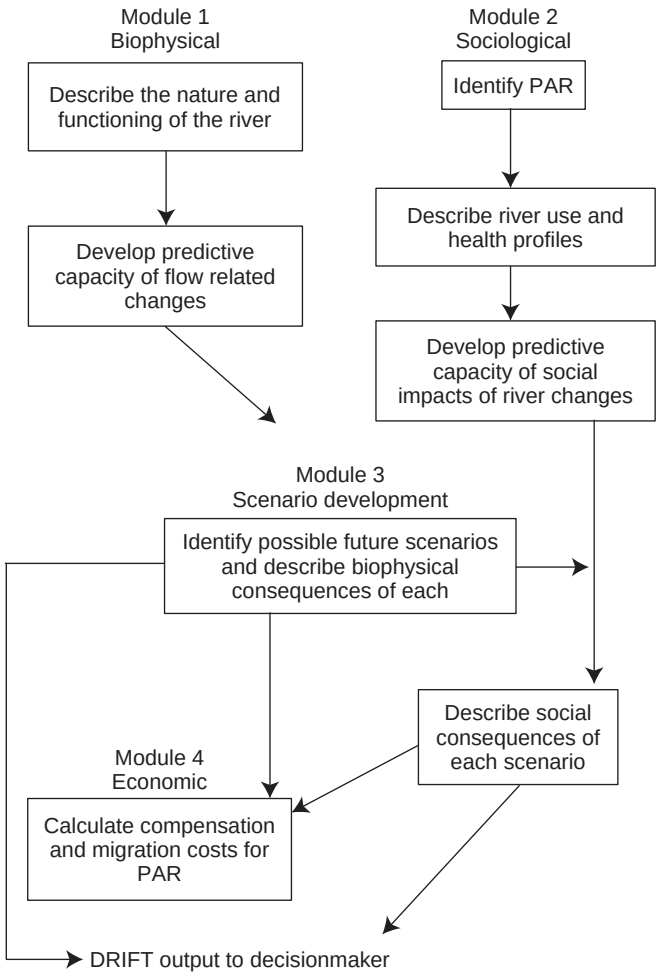

Figure 6 The four modules used in a DRIFT assessment. PAR is human ''populations at risk''. Source: King and Brown (2003), The World Bank, Washington DC

is activated (i.e. they cannot be scaled down) (Poff *et al.*, 1997). This approach attributes lower ecological importance to medium to high-level baseflows, and repeated small and medium-sized flood events, so they are sacrificed in the environmental flow regime. Drought events are normally retained in their entirety by adding the proviso that prevailing natural flows (e.g. as defined by unregulated dam inlet discharge) are applied when they fall below the baseflow level set for that month. Very large floods, although their ecological and geomorphological importance has been acknowledged, are not usually considered in environmental flow assessment because in most situations they cannot be managed and are likely to occur regardless of water infrastructure. Central to the holistic approach of addressing biophysical aspects is the idea of assembling a team of specialists from various disciplines to combine their expert knowledge to recommend a flow regime that satisfies objectives for the particular site or river system. The outcomes of

expert panel deliberations are conditioned by interpersonal dynamics, the potential for groupings to arise within the panel, the impact of a single dominant personality, and the possibility that consensus can be a product of collective bias (rather than independent assessments). For reviews of these issues, see Cottingham *et al.* (2002) and Arthington *et al.* (2004). Bishop (1996) statistically analyzed the results of a study of two expert panels that independently rated a range of flows for their suitability for native fish, invertebrates, and habitat quality at the same six sites (see Swales and Harris, 1995). Of the 18 assessments made, the two panels agreed on only one of them. It was suggested that the differences in the ratings were derived from differences in expertise, from the subjective nature of the assessment, and conflicts between the experts' knowledge of a system and the supplied data (Bishop, 1996; Pusey, 1998). An expert panel assembled to examine the flow needs of the Snowy River, Australia attempted to overcome a number of the typical shortcomings of the expert panel approach by (i) integrating available data with expert opinion in its assessments, and (ii) developing a composite River Condition Index underpinned by a conceptual framework that links habitat and biotic condition and consists of several subindices that translate qualitative assessments (relative to a predisturbance reference condition) into numeric values in a transparent and repeatable manner (Young *et al.*, 2004).

The little use of structured risk assessment procedures in the field of environmental flow assessment has been remarked by Arthington and Pusey (2003). The DRIFT process handles uncertainty in knowledge and data through the use of severity ratings, which allow scientists to indicate, within a coarse range, the likely biophysical response to a change in a single aspect of the hydrological regime. Environmental flow scenarios are thus illustrated as risk envelopes of predicted changes, with wider envelopes indicating greater uncertainty (King and Brown, 2003; King *et al.*, 2003). The Benchmarking methodology attempts to employ a risk assessment framework based on past evidence of the impacts of certain forms of flow regulation (Brizga *et al.*, 2002). The problem of uncertainty can also be handled by adopting a conservative "precautionary principle", and by recommending ongoing monitoring and adaptive management (e.g. Poff *et al.*, 1997; Richter *et al.*, 1997; Environment Protection Authority of NSW, 1997; Arthington and Pusey, 2003).

Prescriptive Versus Interactive Approaches

Brown and King (2003) placed all environmental flow assessment methods into two categories: prescriptive and interactive (Table 1). The prescriptive approach involves the study team spending considerable effort in justifying their derivation of the "best answer" to specific project objectives. The team does not necessarily examine alternative scenarios, and the outputs do not include functions that inform the process of compromise. Interactive approaches, on the other hand, develop relationships between changes in river flow and one or more aspects of the river, allowing multiple interpretations of possible future river health. Brown and King (2003) illustrated the characteristics of the interactive approach by comparing the IFIM and DRIFT methods. Both are essentially problem-solving tools with similar approaches. The output is a set of options, termed "alternatives" in IFIM terminology, and "scenarios" in DRIFT terminology.

SOFTWARE TO ASSIST ENVIRONMENTAL FLOW ASSESSMENTS

In detailed environmental flow assessments, relationships between discharge and certain thresholds, often morphologically defined, which have known or assumed ecological significance, are usually developed with the aid of a one-dimensional (1-D) hydraulic model (for detailed discussions on the use of numerical models in hydrology, *see* **Chapter 17, Hydrological and Environmental Modeling of Transport Processes in Rivers and Estuaries, Volume 1**, **Chapter 18, Shallow Water Models with Porosity for Urban Flood Modeling, Volume 1**). An example of a 1-D model is HEC-RAS, which is public domain software that can be downloaded free of charge from The Hydrologic Engineering Center, US Army Corps of Engineers (`http://www.hec.usace.army.mil/`) or via a link at the Scientific Software Group (`www.scisoftware.com`). The Hydraulic Analysis (HA) module of the Cooperative Research Centre for Catchment Hydrology River

Table 1 Relative data and time requirements of selected flow assessment methods. Source: Brown and King (2003)

Output	Method	Data and time requirements	Approximate duration of assessment	Relative confidence in output
Prescriptive	Tennant method	Moderate to low	2 weeks	Low
	Wetted- perimeter method	Moderate	2–4 months	Low
	Expert panel	Moderate to low	1–2 months	Medium
	Holistic method	Moderate to high	6–18 months	Medium
Interactive	IFIM	Very high	2–5 years	High
	DRIFT	High to very high	1–3 years	High

Analysis Package (RAP), which can be downloaded free of charge (**www.toolkit.net.au/rap**), also has 1-D hydraulic modeling capability, and it can be used to define habitat criteria and calculate the area of habitat at a range of discharges. The HA module can read HEC-RAS output files or users can enter their own channel geometry data. The hydrodynamic module of the DHI Water & Environment MIKE 11 software (**http://www.dhisoftware.com/mike11/**) can also be used to perform the hydraulic modeling for environmental flow assessment. The formulations can be applied to branched and looped networks and quasi 2-D flow simulation on floodplains. MIKE 11 also has advanced cohesive and noncohesive sediment transport modules that can be used in the geomorphological assessment. The Surface-Water Modeling System (SMS) software, available from the Scientific Software Group (**www.scisoftware.com**), provides a high quality graphical user interface for HEC-RAS (also for a number of 2-D models); it has tools for extracting cross sections from digital elevation data, defining and referencing stream reaches using digital maps, generating the HEC-RAS input file, running HEC-RAS directly within the interface, and integrating the HEC-RAS results with floodplain delineation or 2-D hydraulic analysis. Additional SMS modules that may be useful in environmental flows assessment include the modeling of contaminant migration, salinity intrusion, and sediment transport (scour and deposition).

The PHABSIM software and manual (Waddle, 2001), which is used with IFIM, can be downloaded free of charge from the United States Geological Survey (**http://www.fort.usgs.gov/products/software/PHABSIM/PHABSIM.asp**). A number of alternative software systems with the same or similar components as PHABSIM have been developed for use with IFIM. Details of these alternatives, plus other potentially useful software, are provided in Gordon *et al.* (2004, p. 298).

The HA module of the RAP (**www.toolkit.net.au/rap**) is based on the Flow Events Method of allocating environmental flows and can be downloaded free of charge. The Time Series Analysis (TSA) module of RAP has been developed to produce a graphical user interface that allows users to investigate time series data. TSA is especially useful as an interactive tool to assist the deliberations of environmental flow expert panels. A further two modules are under development for inclusion in RAP: the Rules Based Models (RBM) module and Quantitative Models (QM) module will allow prediction of biological responses to alternate flow scenarios.

The Index of Hydrological Alteration (IHA) software calculates a suite of more than 60 ecologically relevant statistics from a daily hydrologic data series. The software can be downloaded free of charge from The Nature Conservancy's Sustainable Waters Program (**http://www.freshwaters.org/tools/**). In an environmental flow assessment of a regulated river, these statistics can be used in the preliminary stages to measure the degree of hydrological change (Richter *et al.*, 1996). The IHA software also includes the Range of Variability Approach (RVA) to support ecologically based management of hydrological systems. This method can be used to help design adaptive management programs that use the quantified natural variation of a hydrological system as an interim management target (Richter *et al.*, 1997).

SOME SPECIFIC ENVIRONMENTAL FLOW ISSUES

The environmental flow issues discussed below are not presented as alternatives to the methodologies discussed previously. Rather, they can be integral components of holistic approaches. There are numerous specific issues that could be included in a discussion of environmental flow methodologies. Assessments of the in-channel flows required for maintenance of fish, macroinvertebrates, plants, and adequate water quality feature in most environmental flow studies – the issues discussed below will also require consideration in many cases. This is not meant to be an exhaustive list, and each case is likely to present some site-specific issues.

Managed Floods for Riparian, Floodplain, and Wetland Inundation

Acreman (2003a) described the concept of reinstatement of flood releases from reservoirs for floodplain inundation, and emphasized the need to ensure that managed floods are compatible with the livelihood strategies of the floodplain communities. Objectives of managed floods include flood recession agriculture, fishing, animal husbandry, groundwater recharge, or conservation of biodiversity and bioproductivity. Managed floods have been demonstrated to result in stimulation of fish breeding, provided they occur during the normal flood period (Welcomme, 1989). One of the main limitations of managed floods is technical feasibility. Many dams do not have adequate outlet structures or sufficient storage capacity, and water quality can be poor due to stratification. Another reality is that the practice of managed flood releases for wetland flooding will mostly involve enhancement (or boosting) of the peak magnitude or duration of naturally occurring floods, rather than generating the entire flood from a dam release (Gordon *et al.*, 2004, p. 303). This is simply a matter of the large volume of water required to achieve overbank flows.

While the flood-pulse concept emphasizes the ecological importance of floods, in practice it may be difficult to identify thresholds of flooding below which floodplain ecosystems cease to function adequately (Welcomme,

1976). Acreman (2003a) suggested that the alternative to attempting to recommend how much water the floodplain ecosystem requires is to set managed flood objectives in terms of specific targets, such as fish production, for which sufficient data may be available to develop a tentative predictive relationship. In other cases, flows necessary to maintain specific floodplain and riparian plant and animal communities are reasonably well known (e.g. Stromberg and Richter, 1991; Blanch *et al.*, 1999; Roberts *et al.*, 2000; Leslie, 2001; Hughes *et al.*, 2001). In some cases, lack of flood flows for plant recruitment is not the problem; rather it is lack of flows to keep riparian plant growth in check (Johnson, 1999).

Managed Flows for Channel Formation

There is overwhelming evidence in the literature that marked alteration of channel forming flow processes is associated with declining ecological health, or degradation of the physical channel attributes required for normal ecological functioning (e.g. Gippel and Collier, 1998; Tharme and King, 1998; Petts and Maddock, 1996; Gippel, 2000; Reiser *et al.*, 1989a,b; Rutherfurd, 2000). Channel forming flows include any flows that have a role in shaping the physical form of the channel, maintaining habitat forms, prevention of vegetation encroachment, and removal of fine sediment and detritus from the surface of the substrate (Reiser *et al.*, 1985, 1989a,b; Brookes, 1995). In environmental flow literature, the terms "flushing flows" and "channel maintenance flows" are also used to describe some of these processes (Reiser *et al.*, 1985; Reiser *et al.*, 1989a,b; Kondolf and Wilcock, 1996; Milhous, 1996; Milhous, 1998; Texas Parks and Wildlife Department, 2003). Channel forming flows can be specified in terms of magnitude, frequency, duration, and timing. Like many aspects of environmental flow assessment, the idea of providing special flows that maintain channel morphology has attracted some criticism. This in part reflects gaps in the knowledge of the way channels form, regional and site-specific differences in the way channels form, and indeterminacy of channel form (Gippel, 2002). Where flows for geomorphic processes have been recommended (e.g. Gippel and Stewardson, 1995; Wilcock *et al.*, 1996; Snowy Water Inquiry, 1998; Kondolf, 1998), they invariably represent only a small part of the natural medium and high flow regime. There is currently only limited understanding of how specific bed and bank features form and are maintained. Low flows can transport sand-sized sediment and cause in-fill of scour pools, so there is a need to also consider the impacts of the duration of low-flow events on river geomorphology (Brizga, 1998).

Reiser *et al.* (1985, 1989a,b), Milhous (1996), Brizga (1998), and Gippel (2002) reviewed the literature on channel forming flows as a component of environmental flow assessment. The approaches generally fell into three categories:

1. *Hydrological* – These methods use an index obtained from runoff records, such as the Tennant and Hoppe Methods.
2. *Morphological* – Channel characteristics such as some percentage of bankfull flow are used to obtain a flushing flow.
3. *Sedimentological* – A channel forming flow is determined by using a sediment transport equation to find the flow level needed to move particles of a given size.

Gippel (2002) suggested that geomorphologists should be prepared to apply a range of methods to the problem of understanding channel forming flows, and not expect a simple and consistent explanation to emerge from the analysis. Natural flow regimes are composed of numerous facets, or components, occurring as a complex time series, and not as discrete, predictable, and independent events. Scaled-down flow regimes, or regimes with certain components culled from the natural regime, should not be expected to produce the same morphology as a natural flow regime. Environmental (regulated) flows will nearly always be simpler and less variable than natural flow regimes, so the resulting geomorphology will probably be less complex (Gippel, 2002).

Assessing Water Requirements of Groundwater-dependent Ecosystems

Nearly all rivers have some level of groundwater interaction. Arthington *et al.* (1992) included groundwater in the original holistic approach and King *et al.* (2000) recognized the need to consider groundwater when doing surface water environmental flow assessments in South Africa, especially for nonperennial rivers, although only a few studies have done so. Cook and Lamontagne (2002) noted that while methods are available for assessing the groundwater dependency of ecosystems, water requirements are much more difficult to determine.

Recognition of the need to consider the water requirements of groundwater-dependent ecosystems is relatively recent (Hatton and Evans, 1998; Petts *et al.*, 1999). Clifton and Evans (2001) developed a conceptual framework for assessing the water requirements for groundwater-dependent ecosystems. The framework is divided into three main components. The first concerns determining the level of groundwater dependency of the ecosystem, which involves identifying the dependent elements of the ecosystem. Next, the key groundwater elements are described in terms of flux (rate of surface or subsurface discharge), level (depth of water table), pressure (applies to confined aquifers), and quality (salinity, nutrients, and contaminants). The second main component of the framework is to assess

the water regime in which the dependency operates. Like surface water assessments, this step involves studies of the ecology, habitat, consumptive use, and hydrological characterization in terms of timing, frequency, and duration. These models are used in the third component of the framework, which is to determine the environmental water requirements.

Assessing Water Requirements of Estuarine Ecosystems

Most of the research and application of environmental flows has been limited to the freshwater reaches of rivers. However, there is a reasonable basis of understanding of the role of freshwater in maintaining estuarine ecosystems [see papers in Montagna *et al.* (2002)]. The conceptual models of Kimmerer (2002) describe the consequences of freshwater inflows to estuaries in terms of physical, chemical, and biological components, or resources. The model of Sklar and Browder (1998) also included the effects of landscape modifications, tidal actions, and solar activity.

Freshwater inflow is known to be a strong determinant of fish abundance or fish catches (Loneragan and Bunn, 1999), and numerical modeling tools for maximizing estuarine fish harvest have been devised on this basis (Bao and Mays, 1994a,b). Salinity is an important variable used to define estuarine processes. The limits of oceanic saline influence have traditionally been defined by the 1 ppt (parts per thousand) salinity isohaline, because this is the upper limit for many agricultural and industrial applications, but a higher limit of 2 ppt (termed "X2"), measured 1 m from the bottom of the water column, is more useful as an ecological indicator (e.g. Kimmerer *et al.*, 1998; Kimmerer and Schubel, 1994; Jassby *et al.*, 1995; Gordon *et al.*, 2004, p. 308–309). In San Francisco Bay, the X2 index was found to be easy to measure, meaningful to non-scientists, and therefore, a good communication tool, it could be directly related to management actions, a historical record was available, and it was correlated with habitat conditions and ecosystem responses (Jassby *et al.*, 1995).

Coastal fisheries production appears to have strong potential as an indicator of freshwater flows and ecosystem health in estuaries (Loneragan and Bunn, 1999; Coastal, 2002). It is considered important by the general public, it has tangible economic value in the form of recreational and commercial fisheries, and time series of data are usually available (i.e. through commercial catch or landing records). Even though habitat availability and fishing pressure also affect fish catch, providing environmental flows to sustain fisheries production has become a key feature of many water management plans in Queensland, Australia (Arthington *et al.*, 2000).

One of the first frameworks for assessing the freshwater flow needs of estuaries was devised by Fruh and Lambert (1976) and Lambert and Fruh (1978) for the Corpus Christi Bay, Texas. In the United Kingdom, Binnie, Black, and Veath Engineering Consultants (1998) provided a systematic procedure for assessing the freshwater flow requirement for estuaries. Estuaries have had little attention compared to rivers when it comes to environmental flow assessments. One problem is that there is often a jurisdictional boundary at the tidal limit, so more attention could be directed to estuaries if they were made a compliance point in riverine environmental flow assessments. A general approach to determining the flow requirements of estuaries (based on a risk framework) has been proposed by Peirson *et al.* (2002). In the Republic of South Africa, the recommended framework for assessing the freshwater flow needs of estuaries is based on the same approach used for freshwater parts of rivers (Department of Water Affairs and Forestry, 1999). Alber (2002) suggested that the management approach can be inflow-based (i.e. there is a limit to which inflows can depart from the hydrologically natural inflows, under the assumption that too much alteration will result in decline in the resources), condition-based (inflow standards are set in order to maintain specified conditions in the estuary), or resource-based (inflow standards are set based on the requirements of specific resources), but each of these is carried out by regulating inflow. Montagna *et al.* (2002) contains several papers that detail methods to assess the freshwater inflow requirements of estuaries in the United States and South Africa.

Assessing Flow Needs for Recreation

Rivers are used for a range of water-based recreational activities, including fishing, kayaking/canoeing/rafting, boating/waterskiing, and associated land-based activities including sightseeing, walking/jogging, camping, picnicking, hunting, and bicycle riding. Recreational flow requirements have been largely ignored outside of the USA where, in certain states, laws specifically designate recreation or aesthetics as beneficial uses for which in-stream flows are protected (Shelby *et al.*, 1992a). The peak in recreational activities usually occurs in the warmer months, which coincides with the period of irrigation demand, potentially creating conflicts in resource management. Each recreation activity has different requirements, and recreation is an experience, not just an activity (Merrill and O'Laughlin, 1993). Thus, recreational users desire protection of natural stream values (namely, water quality, riparian vegetation, natural channel features, adjacent wetlands, and the opportunity to see and hear moving water), as well as provision of the hydraulic conditions that facilitate the particular activities of interest (Merrill and O'Laughlin, 1993; Brown, 2003).

Whittaker *et al.* (1993) evaluated the relationship between stream flows and recreational values, and concluded that one of the most effective methods for evaluating flows for recreation was surveys of users. Brown

and Daniel (1991) and Brown *et al.* (1991) found that recreational quality and positive reactions to scenic beauty increased with discharge up to a point, and then decreased with further flow increases. Suitability for paddling can be assessed by consulting river guides, seeking the opinion of recognized local expert kayakers and rafters, or by conducting a survey using a dedicated crew of paddlers (Shelby *et al.*, 1992b; Rood and Tymensen, 2001; Rood *et al.*, 2003).

Tennant (1976) and Corbett (1990) suggested particular proportions of mean annual flow that would offer suitable conditions for recreational boating and other uses, but this method is relatively crude (Whittaker *et al.*, 1993; Burley, 1990). The transect survey method can be used to identify the flow that will limit any particular recreational activity, which usually requires a minimum depth of water. Bureau of Reclamation (1999) suggested four classes of suitability of flow depth for general recreational uses: 0–45 cm (poor); 45–75 cm (fair); 75–105 cm (good); and 105–135 cm (excellent). For kayaking/canoeing/rafting, Rood and Tymensen (2001) suggested a minimum depth of 60 cm was required to immerse a paddle blade, and depths of 75 cm to 100 cm progressively improved the appeal of many hydraulic features, reduced the chances of hitting rocks, permitted the kayaker to perform a roll, and provided less obstructed conditions for a paddler who swims following a capsize.

IMPLEMENTATION AND EVALUATION OF ENVIRONMENTAL FLOWS

Methods of environmental flow assessment are at best indicative of the flow required to meet the environmental needs of rivers. The best way to test hypotheses regarding environmental flows is to trial full-scale implementation. Acreman (2003b) recommended that three types of responses be monitored: the river flow, the response of the ecosystem, and the social response to ecosystem change. The number of studies worldwide that report environmental flow recommendations greatly outweighs the number of studies that report scientific evaluation of the results of implementation of these recommendations. In fact, very few such studies can be found in the international literature (Annear *et al.*, 2002, p. 309). This is partly explained by the fact that most environmental flows have been implemented relatively recently, and there has been insufficient time to evaluate their effect. Another reality is that some implemented flows are not well monitored, or the results are not published in a readily accessible form. A recent review of cases of scientifically monitored environmental flow implementation (Gordon *et al.*, 2004, p. 315–318) revealed generally positive results. Where the ecological response was negative, neutral, or unexpected, the results of the studies allowed refinement of the environmental flow regimes.

Although adaptive management (Holling, 1978; Walters, 1997) has been used in resource management for around 30 years, it is now being widely promoted as a suitable model for management of river resources (e.g. Annear *et al.*, 2002, p. 309; Ontario Ministry of Natural Resources and Watershed Science Centre, 2001; Newson, 2002). Because it is scientifically based, includes stakeholders, requires attention to documentation, and is based on the idea of implementing interventions as field-scale experiments that generate knowledge useful to management, adaptive management offers a possible framework for implementing and evaluating environmental flows (e.g. Castleberry *et al.*, 1996; McBain and Trush, 1997; Reid and Brooks, 2000; U.S. Fish and Wildlife Service, 2000; Irwin and Freeman, 2002; Freeman, 2002; Arthington *et al.*, 2003; Poff *et al.*, 2003). Gippel (2003) undertook a comprehensive review of all implemented environmental flow-related actions on the River Murray, Australia. Overall, there was a high level of awareness of adaptive management, but no examples could be found where a formal adaptive management framework had been explicitly followed from inception to implementation and adjustment (Gordon *et al.*, 2004, p. 315).

FUTURE DIRECTIONS

The choice of environmental flow method depends on time and budget allocations, data availability, and the level of competition between in-stream and offstream water users. Answers will only be as good as the quality of information examined and the skill of the user in applying the method and interpreting the results. The major trend in in-stream-environmental flow assessment over the past 30 years has been a shift from narrow studies that catered for a single fish species at one critical life phase to a holistic approach that aims to restore natural river processes. For complex and controversial projects on large river systems, there has been a shift from prescriptive to interactive approaches and from bottom-up to top-down approaches

Proponents of the habitat-simulation methods feel that these are more attuned to biological principles than the hydrological index and hydraulic rating techniques, and are thus superior for evaluating biological impacts resulting from flow alterations. Whatever tools are used, it would appear that they are best applied within a holistic framework. None of the methods can, as yet, directly address the potential changes in biomass or populations resulting from altered flow regimes. Many scientists and practitioners recognize the need for more research on the effects of flow regimes on biota because of resultant changes in physical habitat as well as changes in water quality and biological interactions.

The field of in-stream flow assessment is still a dynamic, controversial, and evolving area, with plenty of scope for testing and refinement of methods. The well-established IFIM and the new DRIFT holistic frameworks can be considered the present "state-of-the-art" methods for decision making on large-scale, complex, and controversial projects, but other methods are more than adequate for simpler situations, especially where resources and time are limited. Tharme (2003) noted a widespread move towards hierarchical application of environmental flow methodologies, with at least two stages to the framework: (ii) reconnaissance-level assessment, primarily using hydrological methodologies; and (ii) comprehensive assessment, using either habitat-simulation or holistic methodologies. Holistic methodologies are particularly appropriate in developing countries, where the focus is on protection of the resource at an ecosystem scale, as well as the strong livelihood dependencies on the goods and services provided by aquatic ecosystems (Tharme, 2003).

Rivers often support economically significant industries (i.e. they are "working" rivers) and are important for recreation and navigation. A "healthy working river" is one that is managed to provide a compromise, agreed to by the community, between the condition of the river and the level of human use (Jones *et al.*, 2002; Gordon *et al.*, 2004, p. 239). This definition acknowledges the need for negotiation and compromise between the often-competing values and uses of the river. In situations where river management is based primarily on agreed human uses, the role of scientists would be to work out how to achieve the highest possible level of stream health for the designated class of stream use (Gordon *et al.*, 2004, p. 285). This is an alternative to the approach of determining the minimum flow regime required to maintain the ideal of ecological integrity, with an acceptable level of risk.

The search for an "ideal" universal flow allocation technique may be fruitless, as the practical reality is that environmental flow problems are highly diverse, in terms of the characteristics of the environment, the funds available, the time available, the scope of the study, and the potential cost of making an error in the allocation. Thus, while the importance of developing methods and testing hypotheses cannot be understated, there is a need to ensure that the industry develops the capacity to make prudent use of the outcomes of environmental flows research (Gippel, 2000). At the same time, it is vital that the stakeholders and wider community are informed of, and involved in, developments in the environmental flows field (this has not been a strong feature of progress to date). Lack of understanding can disempower community advisors and stakeholders – a problem that could threaten successful implementation of environmental flows (Gippel, 2001). Poff *et al.* (2003) called for innovative funding partnerships between government agencies, not-for-profit foundations, and the private sector in order to advance the scientific basis of water management. The weakest area of environmental flows endeavors is not the science of assessment, but in the transformation of recommendations into implemented flow regimes (Gordon *et al.*, 2004, p. 315–318). In an extreme example, it took fifty years of research and negotiation to agree on a flow regime that would restore fish populations in the Trinity River (U.S. Fish and Wildlife Service and Hoopa Valley Tribe, 1999; U.S. Fish and Wildlife Service, 2000). Implemented environmental flows require performance evaluation, ideally within an adaptive management framework, which encourages refinement of the flow recommendations and the flow assessment methodologies.

192: Public Participation in River Basin Planning and Management: Quality-of-Life Capital as an Information Aid to Sustainable Decisions

MALCOLM NEWSON[1] AND LIZ CHALK[2]

[1]*School of Geography, Politics and Sociology, University of Newcastle, Newcastle upon Tyne, UK*
[2]*Environment Agency, North East Region, York, UK*

The long-term benefits conveyed by intact ecosystems to human development can be considered as an innate "natural" capital investment. A number of UK environmental management agencies have commissioned a practical realization of this concept, partly as a basis for public participation, successively titled "Environmental Capital" and "Quality of Life Capital". Hydrological concepts are particularly appropriate to an evaluation of natural goods and services; intact natural systems provide flood and pollution controls which need costly artificial replacement when lost or damaged. There are obvious opportunities, therefore, to incorporate assessments of environmental capital as part of the public participation in river basin planning demanded by the European Water Framework Directive. This contribution examines the effectiveness of "Quality of Life Capital" as an information pool and decision-support mechanism in two catchment-scale initiatives (sponsored by the European Union), aimed at community involvement in integrated land and water management. Firstly the conceptual and practical justifications for considering river basins as "multistakeholder platforms" are reviewed, followed by a comparison of the two trial applications in the north of England – to the headwater catchments of the rivers Wharfe and Coquet. What emerges from the comparison and from evaluations of other integrated river basin and coastal zone projects is the importance of information (and its management), continuity and facilitation by project management and a lasting system of monitoring to support adaptive management. The spatial scale of most river basin units defined under the Water Framework Directive is possibly the biggest barrier to widespread adoption of the approach.

INTRODUCTION

Variants of the "natural capital" theme are popular amongst those environmentalists who see an effective dialogue between ecology and economics as a major contributor to sustainable development. Practically, sustainable development is also in need of innovative delivery mechanisms for two other vital planning/management components:

- deriving strategic visions and principles that act as enduring (but flexible) *templates for specific actions* and
- achieving *stakeholder participation* in both strategies and operations.

These components are vital in practical, community-based schemes ("multiple stakeholder platforms") which have become popular for promoting best practice in integrated (land and water) management of river basin units. Despite the reservations of some authors (see below), the scale of river basin management units in most of Europe makes it feasible to contemplate basin-scale authorities, using holistic approaches (with Germany a notable exception). The EU Water Framework Directive (WFD) renders integration of ecology and economics in the difficult arena of public participation a statutory requirement. A final practical need, implied but not stated in the WFD, is for communities and professionals to move towards adaptive

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

management through monitoring ever-changing physical and social contexts.

Implementation of sustainable development has come to rely on three main elements: ecosystem understanding (including the use of indigenous knowledge), economic evaluation of environmental assets, and widespread public participation. The WFD is an example of a policy resting on these three elements (European Commission, 2000). However, despite the EU's Common Implementation Strategy for public participation there is clearly much greater urgency in national policies to implement technical, biophysical aspects in Programmes of Measures.

Semantics are important as one seeks to detect the strength of commitment in the WFD. Article 14, dealing with this matter states that public information and consultation must be "ensured", whilst active involvement is to be "encouraged".

In interpreting the Directive for UK water industry readers, Chave (2001) variously lists the requirements as:

> "*to involve the public in making decisions on water management*" (p. 11);
> "*to consult with the local population*" (p. 13).

These statements clearly ignore the heroic challenge framed by Holzwarth (2002) who states the Directive will be the basis of:

> "*catchment-based governance*" (p. 105) and
> "*getting the citizen involved*" (p. 108).

Clearly, there are considerable doubts in this piece of legislation (and in the minds of many specialists who support integrated water resource management) about the "why, when, where, and how" of public participation and what levels are required. However, debates about *levels* of participation (see e.g. Arnstein, 1969; Priscoli, 1989) have now been joined by almost frantic attempts to evaluate empirical examples to discover *processes and outcomes* (e.g. Connick and Innes, 2003) of planning and management. In this context, that is the separation of strategy and operations, or planning and management, it is also worthy of note that the WFD reserves public participation mainly for the River Basin District *planning* process, rather than seeing a role for public participation in the more technical measures.

RIVER BASINS AND THEIR STAKEHOLDERS: A CONTEXT FOR QUALITY OF LIFE CAPITAL

A frequently neglected element of debate about public participation in environmental decision making is the scale and political identity of the geographical unit or polity upon which the "multiplestakeholder platform" is to be constructed.

The "closure" of open systems to form geographical units for environmental management makes many environmental scientists nervous. However, the "fitting" of sustainable management systems onto system-defined spatial units has become a major policy dimension in the last decade. Politicians, seeking to interpret the rise of new policies and forms of governance, find the concept of bioregions (McGinnis, 1999) both convenient and attractive (e.g. Gore, 1992; Taylor, 1992). However, there remain huge problems of mapping of environmental problems on to a coherent and active community to form the basis for multistakeholder platforms.

To hydrologist readers, the "catchment", "watershed", or "basin" may be a familiar and unchallenged (except in the case of groundwater) scale for research and management but the "fit" of the responsible agencies with their geographical territories and the "interplay" between the administrative functions of integrated management cannot be taken for granted (Moss, 2003).

Rhoades (1998) is explicitly skeptical:

> "*The assumption that a precisely defined geophysical unit also serves as a socio-political or economic unit for planning and management is clearly flawed. Watersheds as closed human management units are external bureaucratic or researcher fantasies, not indigenous ones*" (p. 5).

This skepticism is important because the indigenous perception is vital to successful public participation.

However, other authors, for example Clark and Richards (2002), suggest that at least some contribution to the failure of sustainable river basin management ideals comes from fissures within and between management institutions and styles. If we reform the *management*, the management *unit* becomes effective; there are many other arguments in favor of sustainable management units structured around river basins. Large basins may not correspond to the world's "bioregions", often incorporating many such zones from source to mouth, but the coherence of the freshwater ecosystem (land *and* water), the obvious global value of that system, and a general public/professional resonance with rivers, give river basins a considerable boost as planning and management units.

In terms of employing techniques to aid public involvement such as natural capital, a number of authors have tabulated the financial value of both the goods and services provided by intact river basin ecosystems (Costanza *et al.*, 1997) and their astonishing rate of loss (see Newson, 1997, for the United Kingdom). Certain elements of natural capital only become valued because they have been lost (Daily, 1997): "*Interestingly, the nature and value of Earth's life-support systems have been illuminated primarily by their disruption and loss*" (p. 5).

Perhaps the single most successful argument in favor of river basin units as "bioregional" units is that provided by the success of the science of hydrology in the last 50 years

and its transformation into a basis for decisions concerning large-scale land use and land management (Newson, 1997; Calder, 1999). In the engineered river basin system of dams, transfers, supplies, and discharges the disciplines of law and finance can (in theory – see Winpenny, 1994) structure a sustainable use of *water* resources. However, far more than 95% of the area of most basins comprises land, not water, and can therefore experience profound changes of use and management during conventional development processes. Basin land use seldom exercises as obvious a control on water quantity and quality as for example a major dam, but at the very least has an influence on the resilience of the river ecosystem as a whole and its sensitivity to climate variability.

Table 1(a) shows the elements of the hydrological and geomorphological systems within river basins that might be considered as natural capital, based on the composite outputs of international research. Table 1(b) demonstrates, for the United Kingdom, the spectacular reduction in this capital during the last century, or rather its substitution by human capital for example intensive food production systems.

In the formation of the Environment Agency in England and Wales, river basin or watershed ("catchment" in the UK terminology) units "won" over the claims of others that, local government boundaries are the best spatial unit for particular regulatory policies for example waste control. The EU has taken the concept further with the WFD which requires nation states to submit river basin plans by 2009, based upon full ecosystem appraisal and the setting of targets based upon shortfalls between actual conditions and ecosystem "quality" (European Commission, 2000; Williams, 2001; Holzwarth, 2002).

The Directive makes implicit demands on sciences (e.g. hydrology, ecology, geomorphology, economics) which admit their uncertain predictive power, especially under conditions of rapid environmental change. Public participation does not merely fulfill a democratic ideal but helps by configuring the risks resulting from predictive uncertainties (Clark, 2002). Public participation is also timely because of:

- changes in environmental science (a stronger attempt to couch predictions in terms of risk);
- changes in governance (particularly within new bureaucratic territories such as river basins, and through popular processes of localization) and
- changes in the philosophy of public agencies towards adaptive management as a means of coping with the very long timescales inherent in the sustainability vision.

Viable techniques of implementation *via* decision support must therefore deliver: "*the alluring prospect of combining the rigor of the scientific method with the contingent realities of policy and politics*" (Dovers and Mobbs, 1997). In a sense this reveals a considerable information agenda, confirmed by what follows, and demands that the information base facilitates a combination of traditional "top–down" (technocratic) approaches with reliance on the now questioned "bottom–up" strategies (Rockstrom, 2003). Sociopolitical analysis of such partnerships is a fast-growing field in planning (e.g. Davies, 2002), but here we concentrate on the simpler, empirical evaluation of an information core to the "social learning" element of river-basin scale public participation projects.

This contribution outlines justifications and practical experiences in applying the "Environmental Capital" (now

Table 1(a) River basin system ''natural capital''

''Spontaneous regulator'' (terminology: Marchand and Toornstra, 1986)	Environmental goods and services under ''capital'' scenarios
''Natural'' river channels	Regulation of sedimentation
Undeveloped floodplains	Ditto, plus attenuation of peak flows
''Natural'' forests	Ditto, plus contributions to snowmelt
Deep soils (not eroded by bad practices)	''Natural'' reservoir and flood control
Wetlands throughout the basin	Ditto, plus water quality benefits

Based upon (from Newson, 1997).

Table 1(b) Losses of ''spontaneous regulators'' in the United Kingdom during development

Element of loss	Extent of loss
Soil moisture storage	60.9% of agricultural land drained
Ponds	75% lost
Natural channels	35 000 km of channel modified/''maintained''
Floodplain loss	$>3000\,km^2$
Transformation to urban	1/3 of all recent land-use change

Based upon (from Newson, 1997).

"Quality of Life Capital": **www.qualityoflifecapital.org**) approach to two schemes of integrated land and water management in a general framework of restoring ecological quality (a WFD objective) to headwater catchments. We use a comparison of the relative success and failure of Quality-of-Life Capital (QoLC) in the two basins to derive general guidance for effective stakeholder participation.

"CAPITAL" ASSESSMENTS OF ECOSYSTEM ATTRIBUTES

It has frequently been argued that, whilst moral persuasion, regulation, and economic instruments are the major conventional tools available to national governments to achieve sustainable development through environmental protection, an holistic framework for both strategic planning and operations might best be provided by the concept of nature (and its anthropogenic transformations) as "capital" (Table 2(a)). This approach is much wider than the resource economics paradigm that dominated our concept of environmental limits for the second half of last century, driven partly by the strictures of classical economics. The major focus has now shifted from simple resource conservation to limits posed by environmental degradation and loss of biodiversity. Natural processes are seen as counteracting these anthropogenic impacts and are delivered to human societies as "services" by intact ecosystems. As Daily (1997) puts it:

> "*In addition to the production of goods, ecosystem services are the actual life-support functions, such as cleansing, recycling and renewal and they confer many intangible aesthetic and cultural benefits as well*" (p. 3).

Clearly, the concept has much resonance with definitions of sustainable resource use; Costanza *et al.*, (1991) have stated "*a useful definition is the amount of consumption that can be continued indefinitely without degrading capital stocks – including 'natural capital stocks'. This natural capital stock uses primary inputs (sunlight) to produce the range of ecosystem services and physical natural resource flows*" (p. 8).

Better management of complex ecosystems inevitably demands understanding at the system scale as well as requiring a myriad of local details. An inconvenient paradox of applying "systems thinking" to environmental management is the complexity inherent in our understanding of the system being managed. Whilst fundamental to the approach (Clayton and Radcliffe, 1997), its outputs require translation into "useable knowledge" by the assignment of values and risks to the management options it offers and the selection of priorities, before practical applications are possible. With this in mind, the concept of natural capital (later operationalized as Environmental Capital and finally QoLC in the United Kingdom) was introduced as a bridge between scientific assessments of environmental problems and the emerging body of economic techniques to aid decision making.

The basic analogue is between environmental assets and the economists' notion of capital; assets are deemed to be well used if they continue to supply "interest" income. Natural capital is not substituted into other forms of, for example, man-made capital without debate on the long-term significance of this trade-off; in this way the polity decides the relative "strength" of the sustainability model it adopts (Turner, 1993 and Table 2(b)). The central position of trade-offs in the natural capital argument makes stakeholder participation vital (Clark, 2002).

The vital question, however, remains that of whether such conceptually elegant procedures can be translated into simple, robust, and accessible public procedures, without preempting or replacing decision-making procedures. In 1997, four public agencies in England and Wales funded the development of a survey and appraisal technique known as

Table 2(a) "Natural Capital" and other relevant forms

Form of capital	Definition
Natural	Natural resources, living systems, ecosystem services. Enlarged by Pearce and Barbier as: • renewable/nonrenewable resources; • assimilation of waste; • amenity; • biogeochemical cycles – stabilization; • genetic blueprints, behavior.
Human	Labor, intelligence, culture, and organization. Includes social capital: • Membership of groups; • Relationships of trust; • Access to institutions.
Manufactured (or physical)	Infrastructure, machines, tools, factories, vehicles.
Financial	Cash, investments, economic instruments

Based upon (after Pearce and Barbier, 2000; Hawken *et al.*, 2000).

Table 2(b) Substitution of capital: defining the ''strength'' of sustainability (after Pearce and Barbier, 2000; Clayton and Radcliffe, 1997)

''Strength'', criticality	Substitution of capital between forms
Weak sustainability	Essentially no inherent difference is assumed between natural capital and other forms and substitution occurs if it moves the capital to more valuable human/physical forms
Strong sustainability	Environmental resources and ecological services that are essential for human welfare and cannot easily be substituted should be protected
Critical natural capital	Applied to attributes that are irreplaceable or irreparable and currently scarce; also applied to those attributes whose loss would promote further significant loss.

Based upon (after Pearce and Barbier, 2000; Clayton and Radcliffe, 1997).

"*Environmental Capital*". It was avowedly scientific, based on natural systems guidance (Clayton and Radcliffe, 1997) for sustainable development (CAG/LUC, 1997). However, the change of name from "Natural Capital" to "Environmental Capital" was based upon the inclusion, within the proposed survey technique, of all elements of environmental capital (Table 2), as well as natural capital. In this way, the ecosystem is seen as inclusive of anthropogenic processes rather than a separate pristine ideal. The technique set out to emphasize *functions*, as well as features, of a given geographical unit and the main themes of sustainable development were promoted by the pattern of the environmental capital enquiry: from attributes to importance and thence to trends/sufficiency and substitution or trade-offs (between forms and features of environmental capital).

A subsequent change to Quality-of-Life Capital or QoLC sought to widen its public appeal. An Overview Report (CAG/LUC, 2001a,b) suggests, *inter alia* that:

> "*Quality of life can be understood in terms of having a wide range of human needs satisfied*".
> "*A decision support tool that considered all these stocks or capitals in an explicit, transparent, coherent and integrated way might reasonably be hoped to help us reach better decisions than the current ramshackle, piecemeal, inconsistent and often disguised treatment of environmental, social and economic issues in decision and planning processes*" (p. 14).

The CAG/LUC report came too early to be matched to a growing orthodoxy of "multistakeholder processes" (Hemmati, 2002) and gives much of the responsibility for steering the technique to officers of the participating agencies. Yet, the ability to produce a shared understanding of environmental (river basin) needs by multiple stakeholder communities is a strength of QoLC; it is able to provide a cohesive look at catchment attributes, thus overcoming the current fragmented approach to management which does not mimic complex catchment-scale system interactions. However, the approach also has aspirations to become the basis of public participation (in e.g. Environmental Impact Assessment, planning, and within sectorial policy development):

> "*Professional judgement should be supported by assessment of public perceptions of the characteristics of the environment*" (CAG/LUC, 1997; p. 22).

The inclusion of the public voice at every stage of environmental decision-making has become a hall-mark of the ecological restoration movement, but now has powerful support within integrated water resource management as central to resource development projects, river/wetland restoration projects and projects to develop and encourage best practice in land/water management. Given proper attention to issues of subsidiarity and translation into a commonplace language, QoLC has the potential to deliver these ideals.

INTRODUCTION TO UK CASE STUDIES: UPPER WHARFEDALE AND UPPER COQUETDALE

It is currently useful to evaluate the few available reports of public participation in river basin management to elucidate any general principles lying behind the site-specific problem orientation and unique sociopolitical contexts of each case study; generally, failures of consultation and participation are not reported. We here report from two integrated (land and water) management projects in the north of England. In one QoLC, techniques were used as an information platform with apparent success, and in the other, the approach largely failed (but not because of technical weaknesses – see following text).

Common elements of the Upper Wharfedale and Upper Coquetdale projects were their EU funding *via* the "Objective 5b" rural development (Agricultural Adjustment) route (hence their socioeconomic core purpose) and their integrated land/water approach to restoring some of the environmental goods and services provided by in tact catchments. Another common thread was the prominent involvement of the Environment Agency, the statutory body for river management in England and Wales. However, the manner of that involvement, and finer details of project orientation and management, differed between the two projects, providing the basis of an experimental comparison.

An essential question surrounding the ecosystems approach to management is that of the costs surrounding data collection (Clark, 2002). A holistic survey system such

as QoLC is particularly demanding in this respect; environmental management professionals have gained a rather negative impression of survey costs from the scoping of Environmental Impact Assessments. In fact, our experience in both Upper Wharfedale and Coquetdale is that much of the essential information is already available in a developed country and therefore the basic requirement is for collation, within a new conceptual framework, rather than primary survey, even though the technique reveals some survey gaps. In addition, a major value of stakeholder involvement derives from the "indigenous knowledge", or "vernacular science" (Wynne, 1992) which becomes a genuinely interactive element of the social learning experience between experts and the community (Rolling, 2000).

The QoLC framework offers considerable opportunities to access the experiential knowledge of local people; however, this exposes managers to the need to reconcile popular impression with scientific "fact", for example concerning the seriousness of river erosion. This may ultimately enhance stakeholder understanding of catchment processes leading to a higher potential for adaptive community decisions in the longer term.

The Upper Wharfedale "Best Practice" Project The Upper Wharfedale Best Practice Project (UWBPP) was carried out between 1998 and 2002 in an upland river catchment area within the Yorkshire Dales National Park, with the highest point approximately 670 m above sea level. It is 100 km^2 in area and has a population of 5600, heavily inflated by visitor pressure in summer. The initial positive response from local organizations and the community to the idea of project on water and land management, was stimulated by brainstorming sessions of both interested professionals and local stakeholders, the latter at a public community meeting.

An initial Feasibility Study which accessed local opinion at its core stages (RKL-ARUP, 1998) listed the "main programme elements" which might feature in the Project as:

- river bank erosion;
- regeneration of "gill" (headwater valley-side stream) habitats;
- flood defence strategy;
- pollution control;
- biodiversity;
- moorland drainage;
- livestock farming practice;
- education.

The consultants also suggested delivery mechanisms for a "Best Practice" project in Upper Wharfedale:

- agricultural reforms and demonstrations;
- forestry restructuring
- fluvial management as a holistic concept;
- ecological improvements;
- recreational management;
- archaeological and landscape conservation;
- socioeconomic support.

The Project was developed and implemented through a partnership, led by the Environment Agency, and managed by a Steering Group. Day to day management on the ground was coordinated by a Project Officer with overall management coordinated by a Project Manager. Some issues were progressed using subgroups with themes such as sustainability, education, and habitats. Workshops, public meetings in the Parish Hall, individual meetings at the farmhouses, walk events at locations in the Dale and the production by local artists and the community of a floor-scale river game (We Have A River For Everyone) were some of the other methods used to disseminate information and seek public input to the core Environmental Capital survey, to which we now turn. Whilst exact, linear management principles are often inappropriate for participatory approaches, some choreography of the Environmental Capital approach is vital for all concerned (Table 3); the working "capital" features identified by professionals and the public in Upper Wharfedale are identified in Table 4 and Figure 1.

A series of Project leaflets have formed a principal information outlet; they cover sheep dip treatment, river erosion and the uplands, moorland gripping, river gravel management, the Environmental Capital Approach (its title at that time) and sustainable river management techniques (Environment Agency, 2003).

The River Coquet drains the southern flanks of the Cheviot Hills in Northumberland, UK; its upper part, known as *Upper Coquetdale*, has an area of 358 km^2, a population of 3200 and is similar in relief, climate, and land-use to Upper Wharfedale. The river has the status of an SSSI, part of the area is in the Northumbrian National Park and a number of agri-environment "Best Practice" policies have been executed in the catchment. The application of QoLC surveys did not, however, commence until the

Table 3 Steps involving public participation, worked around QoLC assessments in the Upper Wharfedale Best Practice Project

Step	Aims/objectives
1	Establish study area
2	Determine features
3	Understand features, their functions
4	Identify benefits and evaluate features
5	Produce management principles
6	Produce short-term objectives
7	Implement and monitor success of short-term objectives
8	Fill long-term information gaps
9	Produce long-term objectives
10	Implement and monitor success of long-term objectives

Table 4 Upper Wharfedale – evaluation of quality of life capital elements within the Upper Wharfe catchment

Feature	Attributes/ services	Why it matters	Scale which matters	Substitutability	Impor- tance	Trend	Management/ monitoring
Blanket peat **moorland**	Stores carbon from atmospheric pollution, stores water, key habitat	Environmental control (stores water, carbon) – vital to all	Global/catchment/ Wharfedale valley floor	Impossible to substitute: peat growth rates very slow	High	Eroding and thinning due to grazing/ gripping	Block drains, ''assisted recovery'', low intensity use. Monitor hydrological recovery, monitor access, grouse, cover/stocking etc.
Native **woodland**	Absorbs carbon from atmospheric pollution, ground stabilizer, habitat	Amenity, nature conservation, local economy	Local and regional/ catchment	Impossible to substitute, existing woodland can be managed/ extended	Medium/ high	Undermanaged – area below critical threshold	Proof against stock, regenerate, extend in upper catchment and riparian zone
Plantation **woodland**	Economic services, absorbs carbon from polluted air	Local economy and Conservation potential	Local/catchment	Restore where past practices unsustainable	Medium	Mitigation (e.g. habitat, runoff) welcome	Forestry Commission ''guidelines'' retroactive for existing plantations. Stream sampling and wildlife monitoring
Limestone features	Pavements, caves scientifically import, attract visitors	Part of ''spirit of place'' of the Dales, biodiversity/ tourism	Local (river regime, tourism, water supply) national, biodiversity	Impossible to recreate. Can be lost through quarrying etc	High	Pavement needs protection, caves: access, pollution protection	Related to peat moorland, but also to recreation management/pressure and farm pollution (cave ecosystems)
River channel and gills	Oxygenation, sediment storage, aesthetic attraction, angling, biota	Central to the catchment and to the identity of place. Local water supplies	Local, regional/ catchment	Enhancement of past flood works (e.g. gravel trap) to assist recovery	High	Works in the past created erosion and deposition problems	Research on past and present sediment and flow regime of the channel followed by restoration including flood protection

(continued overleaf)

Table 4 *(continued)*

Feature	Attributes/ services	Why it matters	Scale which matters	Substitutability	Impor- tance	Trend	Management/ monitoring
River floodplain: Hay meadows, wetland pastures, flood deposited material	Economic core, visitor focus, flood storage, wildlife habitat	Key element of farming economy but some services are to communities downstream	Local and regional/ catchment	We may make publicly funded substitutes (e.g. agri-environment incentives)	High	Flood defence and drainage schemes led to damage. Aims now are natural rivers	Hydraulic modeling and geomorphological/ ecological studies to plan sustainable floodplain environment – e.g. flood areas v improved areas
Farmland in general excluding moorland and floodplain (see below)	Basic natural resource for human occupancy, fabric of landscape	Provides food for farm stock and a habitat for wildlife	Local, national and international. Essential to livestock economy, landscape	Potentially improvable but intensification may be unsustainable or damaging	High	May degrade if farming income falls, best practice conservation strategy essential	Manage according to stocking density/ fertilizer in relation to ecology but in tune with farm finance. Monitor cover/ stocking
Built environment: villages, farmsteads, field barns, walls	Homes, fabric of the landscape, habitat, economic core. Major aesthetic appeal	Provides cultural, aesthetic and economic services to humans	Local, national and international	None, except *via* new livelihoods for locals – e.g. high technology cottage industries	Critical	House prices, loss of services, visitor pressure may threaten farm economy in crisis	Basic economic structure must be retained but perhaps subtly modified in response to changing agricultural activity/ roles
Routes: roads, lanes, tracks, paths	Add high value to landscape, limits and diversifies human exploitation	Cultural, aesthetic and economic services, set ''carrying capacity'' for dale	Local, national: access to care, accessibility to delivery vehicles and to scenery	Techno, substitutes for mobility make no impact yet in this economy and culture	Critical	Maintenance essential to sustainability at all scales	Conditions and status of infrastructure must be recognized, pressures must be monitored on a regular basis
Archaeology Prehistoric to industrial & agricultural	Context to human occupation, attractive to visitors	Provides cultural setting and sense of renewal, educational values	Local, national. Greater in the context of landscape	None	High	Limit visitor pressure, protect against vandalism, make accessible	Full survey, designation, sustainable exploitation, restoration where appropriate

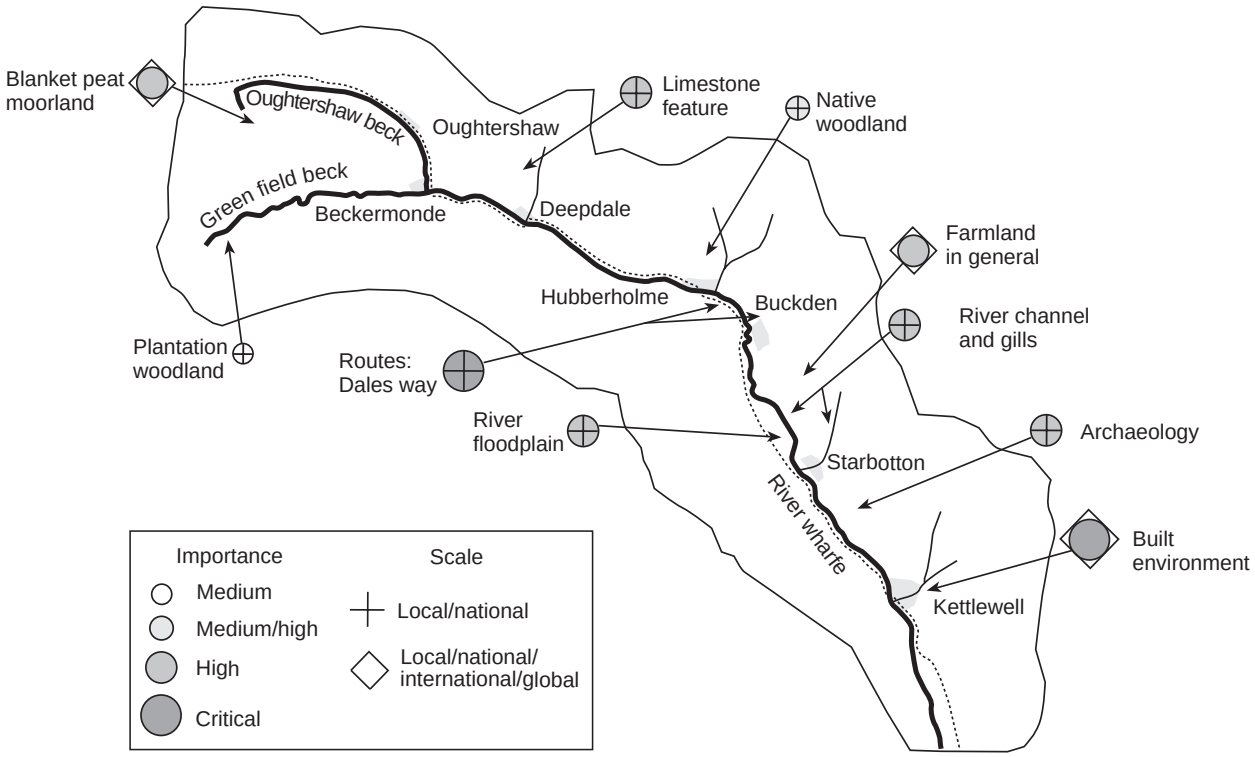

Figure 1 Upper Wharfedale – examples of QoLC mapped in the catchment

Northumbrian Rivers Project, also an EU "Objective 5b" scheme, chose the Coquet as one of its target catchments in 1997.

The Northumbrian Rivers Project's main targets were to improve riparian land management in order to conserve and extend the fishery interest, thus supporting both the farming community through grant aid and attracting important income from tourism. The Environment Agency, concerned that riparian initiatives did not conflict with their Flood Defence function, commissioned Newcastle University to apply QoLC to the river and its geomorphology (Newson, 1999); community issues and wider public participation did not occur until later (Fox, 2002). Fox gained access to a wide sample of Upper Coquetdale residents during a very detailed survey of QoLC attributes, revealing a number of tensions in the relationship between environmental managers and the assessment of environmental values based on indigenous perceptions. Broadly, local people viewed the "natural" environment of the valley as heavily anthropogenic and placed meaning and identity in relation to the degree to which the landscape is "worked". They did not lack insights into natural capital and some of the goods and services provided by intact ecosystems but they generally refused to participate in financial or trade-off exercises. There was a dominant popular impression that environmental management should be a means of representing indigenous pride in their "worked" landscape to institutions outside (to increase the financial support for its infrastructure), rather than as a delivery mechanism for national and transnational policies on sustainability, that is bringing the "outside" in.

LESSONS FROM EVALUATION: A COMPARATIVE ANALYSIS OF ''CAPITAL'' AS A PARTICIPATORY DEVICE

Whilst the two projects described briefly above (for more detail see Newson and Chalk, 2004) were not selected to provide an analytical comparison, they exhibit contrasting characteristics worthy of consideration in reforming and adapting the use of QoLC in the much broader application now sought for public consultation in river management.

However, before making the analysis, it is possible to gain further insights on other exercises in public participation from the small sample of published evaluations (e.g. Edwards-Jones, 1997a,b; Hillman *et al.*, 2003; Connick and Innes, 2003; King, 2003 – the latter example being from Integrated Coastal Zone Management).

Almost unanimously these evaluations assert the central role of decisions based upon a broad but systematic body of information whose compilation and shared value becomes part of the "social capital" of the participatory venture (Hillman *et al.*, 2003, p. 221).

King (2003) suggests that:

> "*An information strategy is vital for participation and the two aspects should be conceived together*" (p. 142).

Another common thread is to put emphasis on quality of process rather than on mechanistic measures of outcome; "collaborative practices are more fluid and less predictable than traditional forms of policy making" (Connick and Innes, 2003, p. 178). Perhaps this realization faced Professor Kader Asmal in his role as Chair of the World Commission on Dams (Asmal, 2000):

> "*the process becomes a messy, loose-knit, exasperating, sprawling cacophony. Like pluralist democracy, it is the absolute worst form of consensus-building except for all the others*."

This quotation underlines the complexity arising from flexibility but emphasizes a core need for structure! Information provides a neutral structure for participation, but this neutrality is, paradoxically, best delivered by firm, very energetic, project management (Edwards-Jones, 2003).

Thus, it is vital for the following comparison between our experiences in Upper Wharfedale and Upper Coquetdale to consider QoLC as a contender for structuring the vital information core of a participation exercise, but with the contexts for its success set by attitudes and social processes. Table 5 draws up a list of contrasts that have impinged upon the delivery of stakeholder participation through QoLC in the two small UK catchments. Virtually none relates to the technical proficiency of the QoLC technique; the openings into community views potentially provided by QoLC are undoubted, but the method's "success" is likely to be judged as that of the project itself.

Clearly, the prime contributors to success or failure were the spatial and temporal focus (and clarity!) of the project objectives, activity rates in both consultation and operations, coordination and facilitation by clearly identifiable leaders use of knowledge and information. There is considerable resonance with a list of criteria for collaborative dialogue presented by Connick and Innes (2003):

- includes representatives of all relevant interests;
- is driven by a practical purpose and task shared in the group;
- is self-organizing;

Table 5 Comparative elements of the UWBPP and the Upper Coquetdale applications of QoLC assessment techniques

Element	UWBPP	Upper Coquetdale
Spatial focus	Catchment wide, with prominent moorland and valley-side as well as riparian activities. Sole focus for financial aid.	Channel obstructions, bank erosion and riparian support to river ecosystem. Finance shared with three other rivers.
Temporal focus	Five-year Project lifetime followed by landowner responsibility for maintenance but with monitoring continuing.	Five-year Project lifetime followed by landowner responsibilities for maintenance.
Public consultation – timing and context	Began at feasibility stage and integral throughout. Project set in a geographical context of heavy visitor pressure and a plethora of institutional consultations.	Expert-led until quite late in Project lifetime. Experience of environmental consultation developed only by National Park and Catchment Management Plans.
Coordination and project management	''Expert'' and voluntary members of Steering Group in close coordination with community representatives. Clear responsibility of Project staff (from Environment Agency); no staff changes.	Identical ''expert'' (institutional) bodies represented on Steering Group but closest voluntary linkage to fishing community. Project officers from FFWAG. Several staff changes.
Operations	EA able to facilitate aspects of river management (machinery) and monitoring (e.g. hydrology), although majority undertaken by local contractors, landowners, tenants, and angling clubs.	Landowner responsibility – no Project labor force.
Knowledge and information management	Indigenous knowledge sought from feasibility, collated with ''expert'' knowledge in QoLC attributes and valuation. Dissemination at all levels including schools and events linked to best practice leaflets.	Catchment Management Plan and knowledge of anglers used to guide priorities (largely also fixed by *modus operandi* of Project). Public information events and river geomorphology training courses. Project followed, rather than led, best practice.
Dissemination and continuity postproject	Trials of best practice a specific aim – hence dissemination by variety of media: education and training. Monitoring and research tasks set for longer term.	Relatively little innovation: survey directed to problem sites, funding guided by opportunity. Publicity, not publications a project aim since heavy links to tourism economy (fishing).

- is encouraging to participants as they learn and interact;
- encourages challenges to assumptions and fosters creativity;
- incorporates many kinds of high-quality information;
- seeks consensus only after discussions have fully explored issues and interests and significant effort has been made to find creative responses to difference.

WIDER ISSUES: MAINTAINING/UPDATING THE "STAKEHOLDER PLATFORM" AND APPLYING ECONOMIC VALUATION

One of the major costs attending truly sustainable development is monitoring, demanded both by the uncertainties of the knowledge base applied to current management operations and by the needs of adaptive management systems to be aware of environmental changes. Following exercises in public consultation of the type described here, it is tempting for the appropriate agencies to return the task of monitoring to professional cadres in the sole interest of addressing legislative necessities. The UWBPP intends to leave the community in Upper Wharfedale with both a role and an interest in monitoring the "best practices" established during the life of the project. The example of the Australian "Catchment Health" project (Walker and Reuter, 1996) has been copied informally for future activity by for example schools, voluntary groups, and farming families; women and children have played particularly significant roles in adoption.

Additionally, the Project has identified longer-term research tasks for the academic community and these have been adopted and funded (McDonald *et al.*, 2003). Longer-term strategic options identified included the radical option of reconnecting the river with its floodplain. Current information was inadequate to achieve an integrated understanding of how the land is linked to the river and answer questions like how to manage gravels in the river and what is the impact downstream. The impacts of wider, less certain influences, such as climate change, also need to be factored in. Clearly, however, at significant points in the collection of new and relevant information it must be disseminated to allow the reconstruction of the basic QoLC matrices.

If longevity and community-based schemes of monitoring are an indicator of success in participatory schemes of river basin management, the QoLC attracts a further test – that of whether it is feasible to convert stakeholder values for environmental attributes from an ordinal scale to an interval, financial one. The apparent unwillingness of those surveyed in Upper Coquetdale to consider formal valuation of their QoLC matrix is a set-back, but it may be that in projects where there is a genuine chance of economic changes (gain) as variation to national or regional practice local people may be persuaded by the seriousness of the possible outcomes for their own interests.

A technique that helps to create multistakeholder platforms by incorporating the concept of capital should be capable of interfacing with the world of classical economics or at least with existing local manipulations of the macroeconomic framework (e.g. agricultural subsidies under the Common Agricultural Policy (CAP)). The early fiscal manifestations of "environmental economics", for example *via* the use of specific economic instruments to promote environmental values, would benefit from such a linkage. It would clearly be a considerable additional burden of survey to the existing QoLC techniques to undertake separate analysis of the multidimensional "values" of the "natural" and anthropogenic assets of a river basin. Techniques abound for such surveys and, indeed, have been applied to the Upper Wharfedale area (Yorkshire Dales) in exercises predating the UWBPP (Garrod and Willis, 1999).

However, these conventional valuation techniques do not directly embrace (because public questionnaire survey alone is inadequate as a basis) the concept of environmental services. Here QoLC should be capable, *via* its natural systems analytical approach, of introducing "hard" economic values by "parallel accounting". For example, if the volume of water passing through a specific floodplain wetland can be estimated and the flood protection or water quality benefits of this passage can be inferred from the hydrological literature, then the costs foregone to the local or regional or global economy from the environmental services provided by the wetland can be calculated (e.g. Bockstael *et al.*, 1997). Given a wider uptake for QoLC and similar techniques, the application of valuation techniques should now be attempted: "*All we need to do now is to apply accounting to environmental capital . . .attempting to bring measurable elements into the process as our knowledge improves. But to wait until everything falls properly into place will mean that we shall have to wait for ever.*" (El Sefary, 1991).

CONCLUSIONS

The QoLC methodology addresses many of the practical problems raised by those with empirical experience of integrated river basin planning and management (e.g. Edwards-Jones, 1997a,b, 2003) who converge on information, and its management through to decisions, as the core of successful projects. Whilst it is currently a less formal manifestation of a decision-support system for river management than the model SURCoMES, also calibrated to run in Upper Wharfedale (Clark and Richards, 2002), future opportunities afforded by minor reforms of the basic technique and the addition of improved communication technologies (e.g. Kingston *et al.*, 2000) may give it a prominent position as a foundation for multistakeholder platforms. Rule-based models with "fuzzy" decision-making circuits, such as SURCoMES, will inevitably play a part in future adaptive management scenarios. As Clark (2002) puts it:

"*decision support itself strengthens sustainability, which may be unachievable without it, and enables informed and aware stakeholder participation*" (Clark, 2002, p. 349).

The EU Water Framework Directive makes heavy demands for, but is currently in a learning phase for, both stakeholder participation and economic evaluation. QoLC techniques are certainly a potential for delivering a framework for both these innovative contributions to sustainable development. They act as "formal ways of integrating stakeholders and science" (Osidele *et al.*, 2000) even if they do not create multistakeholder platforms, defined by Rolling and Maarleveld (1999) as "devices or procedures for social learning and negotiation about effective collective action". To the authors, it is doubtful whether multistakeholder processes can be universally "designed" (as by Hemmati, 2002, who gives 15 design principles) but the characteristics of the two Projects used as case studies here, offer signposts about the general characteristics of "collective action to reduce a collective impact" (Rolling, 2000).

Most importantly Environmental (QoLC) Capital has been a successful way to involve a wide range of interests and provoke debate between specialists and people in the community and thus provide a catalyst for some visionary longer-term thinking and initiatives to further understanding. It has placed professional judgement alongside the concerns of local people, helping everybody to be aware of and own change.

Perhaps the most daunting barrier to the widespread use of information "hubs" to participatory approaches under the EU WFD, is the large spatial scale of the river basin districts to be planned. A possible remedy already adopted in Scotland is subdivision of the basin districts for the specific purpose of stakeholder analysis followed by participation.

Acknowledgments

Clearly, in studies of this type those who contributed are too many to name, in both professional and stakeholder camps. However, our colleagues Ivan Ingles (Environment Agency: Upper Wharfedale Project) and Helen Fox (Upper Coquetdale surveys) made prolonged contributions. We would also like to thank Ann Rooke for drawing Figure 1.

Increasing degradation of watersheds has led to increased recognition of the services they provide in various forms of support for livelihoods and general well-being, as well as to a greater willingness to pay for them and to cooperate in initiatives to protect them. This is reflected in numerous initiatives, in which market-based instruments and other supporting institutional arrangements are used as a way to create incentives and to recover the costs of watershed protection, as well as to allocate water more efficiently among various uses. Many of these payment initiatives have focused narrowly on the role of forests in the hydrological regime as a way to justify funding for their conservation, but should be developed in the context of basin-wide management objectives, which provide a framework for considering the full range of interests that share a common river basin in the context of specific ecosystem functions that support them, and for identifying and quantifying trade-offs associated with various management options. In addition to forests, this would include consideration of the relative values of all types of land cover and land uses such as wetlands, riparian areas, steep slopes, roads, and management practices. It also requires an accounting for the role of human consumption in the modification of the hydrological cycle, so that these changes can be distinguished from natural variation, and so as to be able to distinguish biophysical from economic causes of scarcity. Economic justification for an initiative may also require that initiatives aimed at protection of freshwater supplies be part of a package of approaches designed to capture the value of multiple ecosystem services found in landscapes, and to resolve conflict among various uses. Given the heterogeneity of landscapes and the site-specific nature of ecosystem services, a key challenge is to develop the capacity for place-based approaches to monitoring and assessment. This article provides an overview of the types of economic instruments and institutional arrangements used to capture the value of watershed services, the assumptions on which they are based, institutional challenges faced in implementing them, and the kinds of scientific information needed to identify economic trade-offs, inform stakeholder negotiations, and support decision-making.

INTRODUCTION

The general decline in the capacity of watershed ecosystems to provide essential goods and services has led to an increased recognition of the ways in which they support human well-being. These include direct and indirect economic benefits, ranging from provision of freshwater for various consumptive and nonconsumptive uses, to those associated with regulation of the flow of water and sediment, and support for ways of life that have cultural value and that involve land use practices consistent with continued provision of services. However, unless those asked to pay the costs of practices necessary to insure continued provision of these services are also assured of benefits, there is little incentive for them to do so.

Regulation of land use practices alone is often ineffective because they tend to place a disproportionate share of the burden on upstream land users without giving them a corresponding access to benefits. For example, it is common for states to claim ownership of forested areas, and to protect watersheds through policies that exclude local populations from access to resources on which they have traditionally relied, which may lead them to occupy more marginal land areas (Tomich *et al.*, 2004). Those who

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

do practice farming in upland areas may barely be able to recover their costs of production even in the absence of conservation measures.

This situation has led to an increased interest in the use of market-based mechanisms as a way for upstream land users to recover the costs of protecting watershed services. A recent review by IIED identified 287 initiatives of payments for ecosystem services of forests, of which 61 were specifically for those associated with watersheds. The main concerns addressed in these initiatives have been maintenance of dry season flows, protection of water quality, and control of sedimentation (Landell-Mills and Porras, 2002).

In theory, market-based approaches can lead to more efficient allocation of resources and to more cost-effective solutions to the problem of watershed degradation. In practice, there are a number of scientific and institutional challenges encountered in their implementation, and little evaluation of the transaction costs of addressing these challenges. However, in evaluating these costs, it should be kept in mind that the development of institutional capacity needed to effectively respond to watershed degradation can also have other benefits. For example, it can lead to social cooperation in other matters, development of skills, opportunities for clarification of land titles, and increase of scientific understanding, and environmental education (Landell-Mills and Porras, 2002). It should also be kept in mind that regulatory and market-based approaches are not mutually exclusive, and often complement one another. Given also that ecosystem services tend to be very site-specific, there may be no clear-cut answer regarding *the* most efficient approach.

To the extent that there is rivalry over access to a limited supply of watershed services, a central challenge is to develop institutions or enforceable rules through which access can be limited to those who are entitled to them, and which also define responsibilities for actions needed to insure they are provided (Ostrom, 1990). To the extent that watershed goods and services have characteristics of public goods, which makes it difficult or expensive to limit access, the willingness of potential beneficiaries to pay for them, depends not only on demand but also on whether they have confidence in the effectiveness of proposed management actions needed to ensure that the service is actually delivered and that they will have access to the stream of benefits. In other words, the value of watershed services will depend on

- the integrity of ecosystem functions or processes that support service provision;
- the scale at which impacts or benefits have economic significance; and
- the effectiveness of institutional arrangements needed to insure provision and access.

All of the above are often assumed rather than assessed.

A fundamental paradox is that, given the complexity, natural variability, and stochastic nature of multiple interdependent and site-specific factors that ultimately determine outcomes, and the spatial and temporal separation of causes and effects between upstream and downstream, and between the present and the future, complete information is unobtainable and uncertainty is inherent. Market mechanisms, on the other hand, tend to be more effective when uncertainty is low, because buyers like to know if they are getting what they pay for. A precise determination of costs and benefits and their distribution, for purposes of establishing market values, presumes the ability to link actions and outcomes, so as to be able to demonstrate this. Making uncertainty explicit may be a harder sell, but is critical to managing buyer expectations and maintaining their cooperation in the long term. It is also a critical consideration in negotiating an equitable distribution of costs and benefits.

In the absence of an independent and transparent process of assessment, initiatives have often been based on myths about land and water relationships that can lead to inappropriate or partial solutions and also to placing a disproportionate share of the blame on marginal groups in remote upper watershed areas. Equally misleading are notions that science can provide certainty and that markets can solve all problems. However, science can allow a better approximation as to the magnitude and direction of impacts, monitoring, and more informed decision-making, while market-based instruments are critical to finding ways to cover the costs of providing valued services. Because of uncertainty, which is inherent in complex problems, to some extent, myths may be unavoidable and even useful as plausible scenarios, but need to be continuously questioned as new knowledge becomes available, and replaced when they are found to be implausible or irrelevant in a particular context.

This article provides an overview of the various kinds of potential watershed services, their biophysical characteristics, the kinds of instruments that have been used to create incentives for their provision, and the information used to support them. This is followed by discussion of their inherent assumptions, and challenges faced in implementing them. The article concludes by identifying the kinds of scientific information needed to identify economic trade-offs, to inform stakeholder negotiations, and to support decision-making.

DEFINING WATERSHED SERVICES

The ability to link payments to the level of service provision requires an identification and quantification of benefits actually provided, in a specific context so as to be able to determine their economic significance. This section outlines

the various types of watershed services and biophysical characteristics that need to be considered in doing this.

Watershed services are products of ecosystem functions or processes that provide different kinds of direct and indirect streams of benefits to humans in the following general categories:

1. Provision of freshwater for
   (a) consumptive uses (drinking, domestic, agricultural, and industrial),
   (b) nonconsumptive uses (hydropower generation, cooling water, and navigation).
2. Flow regulation and filtration, key aspects of which are the control of mean surface runoff, peak or flood flows, base or dry season flow, and erosion and sediment load, as well as recharge of groundwater and soil moisture (UN FAO, 2002). Benefits of these may include the following:
   (a) Water storage in soils, wetlands, and floodplains, which can buffer flood flows and drought.
   (b) Control of erosion and sedimentation which, in excess, can have adverse effects on aquatic life, irrigation canals, dams, and navigation. Below normal flows of sediment downstream from dams can have adverse effects on coastal areas where it provides protection from erosion and nourishes the development of mangroves, both of which can reduce storm damage.
   (c) Maintenance of river channels, wetlands, riparian habitats, fisheries, and other wildlife habitat that may be important for hunting, migratory birds, rice cultivation, and fertilization of floodplains.
   (d) Maintenance of mangroves, estuaries, and coastal zone processes, which often rely on seasonal pulses of freshwater inputs, and are critical habitats for fisheries as well as for other marine life.
   (e) Control of the level of groundwater tables that may have adverse effects on agriculture by bringing salinity to the surface.
   (f) Maintenance of water quality, which may be impacted by inputs of nutrients and organic matter, pathogens, pesticides, and other persistent organic pollutants, salinity, heavy metals, and changes in the thermal regime.
3. Supporting services that may include the following:
   (a) The maintenance of natural flow and disturbance regimes as drivers of ecosystem processes and which support ecosystem resilience. Resilience, in turn, provides some measure of insurance against uncertain effects of a change in conditions, for which thresholds are generally uncertain.
   (b) Support for cultural values which may include aesthetic qualities that support tourism and recreational uses, and support for ways of life.

These various kinds of services are interdependent, in that there is a trade-off between provision of freshwater for direct uses, and on the regulatory and supporting services that insure continued provision. Therefore, a fundamental objective should be to achieve an acceptable or optimal balance between these trade-offs.

The above list only represents the kinds of benefits that watersheds may provide. However, benefits cannot be considered "services" unless they also have economic significance. Therefore, site-specific assessments are necessary to identify benefits that are provided in a specific context, and the scale at which they can be detected. This then provides a basis for identifying the economic significance to various stakeholders, so as to be able to identify potential "buyers", actions required to insure that benefits continue to be provided, and the levels of compensation needed to create an economic incentive for potential "sellers". This is further discussed in the section on challenges to implementation.

In the absence of an independent, transparent, and place-based process of assessment, payment initiatives are often based on myths or general beliefs regarding watershed services and their values. These can, in turn, lead to ineffective or partial actions, inefficient allocation of resources, and often to placing an inappropriate share of the blame for watershed degradation and water scarcity on marginal groups in remote upland areas – all of which can exacerbate rather than solve problems, or create entirely new ones (Kaimowitz, 2001). Myths regarding land and water relationships fall into three general categories:

- *Inappropriate generalizations* – from one site to another, and, in particular, application of knowledge from wet temperate to arid and tropical zones.
- *Forests and water myths* – for example, that forests significantly reduce or prevent flooding and increase dry season flows. Whether or not either of these occur depends on numerous site-specific factors that determine the levels of evapotranspiration and infiltration, and, therefore, the quantity of water that is available to stream flow, and the scale at which increased or decreased flows of water are significant. For example, forests may significantly reduce flooding in a localized area, but tend to have an insignificant impact or to be averaged out at larger scales, where runoff is received at different rates from many different sources in the upper watershed. The types of vegetation that occur, the depth of roots relative to water tables, and whether there is ground cover will also play a significant role in the amount of evapotranspiration that occurs, and in the levels of stream flow. Soil that has been compacted as a result of previous management activities, the presence of roads, and other construction associated with development, can also reduce infiltration and

change drainage patterns, regardless of whether trees are planted (Calder, 1999).

- *Erosion myths* – that soil conservation practices in limited areas upstream can have a significant impact on downstream areas, particularly in arid areas with naturally high rates of erosion. For example, modifying land use practices in areas where erosion is naturally high will not prevent sedimentation of dams, though it may have on-site benefits for the farmers (UN FAO, 2002). Another fallacy regarding erosion at a landscape level is that it can be determined from plot level measurements, which assumes that all eroded soil has a negative impact, regardless of where it is deposited, and that agriculture is the main culprit (Swallow *et al.*, 2001). There is considerable evidence that erosion rates are significantly higher on roads and foot paths and marginal areas such as forest margins and steep slopes (Bruijnzeel, 2004). A recent study in an upper catchment in northern Thailand found that unpaved roads produce as much sediment as agricultural land despite the fact that these roads occupy less than one-tenth of the area occupied by agriculture (Ziegler and Giambelluca *et al.*, 2004).

In sum, land use and hydrology interact in complex ways, in which forests are one of several factors that should be considered in the context of the entire flow regime. Even in small subbasins, there may be complex interactions between various biophysical aspects and between them and human management systems that make it difficult to predict management outcomes. Whether any of the above presumptions hold therefore depends on the outcome of multiple interactions, and is therefore highly contextual or site-specific.

Not to be overlooked are increases in water scarcity brought about by increases in demand, both upstream and downstream. For example, a case study in Thailand suggests that dry season flows have diminished primarily because of a dramatic increase, both downstream and upstream, in dry season cultivation and irrigation of soybeans by those who own paddy fields. However, the focus of regulation intended to address the problem has been on the more vulnerable farmers who are dependent on rain-fed slopes in areas where significant forest cover remains, who have the least significant impacts on hydrology, and who are generally regarded as guardians of resources rather than as legitimate users (Walker, 2003).

Even when land and water links can be demonstrated and quantified, a recent literature review on the subject raises questions about whether the magnitude of damages or benefits is likely to be economically significant, when considering just the relationship between land use and hydrology. This will largely depend on downstream economic interests that rely on water, and the scale at which impacts are significant (Aylward, 2004). However, there are other off-site values associated with land use practices, in addition to those associated with freshwater flows that may have significance when combined (e.g. biodiversity protection, carbon storage, recreational values). Therefore, it is important to consider how watershed protection contributes to basin-wide management objectives.

TYPES OF MARKET-BASED INSTRUMENTS USED TO CREATE INCENTIVES FOR PROTECTING WATERSHED SERVICES

As mentioned above, initiatives to develop market-based incentives for the provision of ecosystem services associated with freshwater have been made possible by a general recognition that regulations alone are inadequate for achieving this. Also, the increased threats or the increased perception of threats has led to an increase in willingness to pay by beneficiaries of these services (Landell-Mills and Porras, 2002). The main concerns addressed in the initiatives reviewed by IIED have been maintenance of dry season flows, protection of water quality, and control of sedimentation (Landell-Mills and Porras, 2002). However, in the absence of the use of appropriate economic instruments and supporting institutional arrangements among beneficiaries and providers, that is, buyers and sellers of services, these values are hypothetical. This section describes the various kinds of economic instruments used to protect watershed services, discusses factors that need to be considered in their selection, and provides examples of their use.

Payment arrangements for watershed services may take various forms depending on the nature of the service, what is required to provide it, whether and how it is possible to limit access to benefits to those who pay the costs of provision, the scale of relevant ecosystem processes that support it, and, more generally, on the geographical and historical context. They may range from informal, community-based initiatives, to more formal contracts between individual parties, and to complex arrangements among multiple parties facilitated by intermediary organizations. They may also include a mix of complementary market-based, regulatory and policy incentives that are more likely to become necessary at larger scales, when threats are beyond the response capacity of individual communities (Rose, 2002), and when multiple services are involved. The government may play different kinds of roles depending on the type of arrangement, ranging from the enforcement of contractual agreements, to the creation of regulatory incentives, monitoring compliance, contracting with service providers, providing technical assistance, and identification of priority conservation areas. Some of these roles may also be filled by nongovernmental organizations, which often have the advantage of greater flexibility, and the ability to act more expediently. NGOs may also play the role of advocates on behalf of less powerful constituencies, so as to create

political pressure that may be necessary for governments to recognize their rights and respond to their concerns.

Actual design of payment arrangements will also reflect policy decisions as to who should pay costs and who is entitled to benefits. An example of a policy decision would be whether or not farmers should be entitled to the value of farmland when it is converted to urban uses, when this is driven by public investments in infrastructure, and the extent to which they should be compensated for any restrictions on land use conversion (Buist *et al.*, 1995).

Individual economic instruments can roughly be placed in the following general categories, and are often used in combination:

Voluntary Contractual Arrangements (VCA) – These typically involve the negotiation and agreement of a contract in which resource users, who benefit from watershed services, compensate upstream landowners for the costs of adopting management actions needed to insure provision. Intermediary organizations, such as landowner associations, are often necessary as a way to reduce transaction costs associated with the need for agreement and collaboration among numerous downstream beneficiaries and landowners dispersed over large upper watershed areas. An important consideration is the relative power of stakeholders at the bargaining table, what information is available to them, and whether any significant stakeholders have been excluded. Another is whether land users have some form of property right or tenure security, without which they may not have authority to enter into contractual agreements and therefore have access to the benefits. VCAs are more straightforward when negotiated among individual parties, such as the case of an agreement between the La Esperanza Hydropower Company and the Monteverde Conservation League in Costa Rica, which is the sole owner of the forested area upstream from the plant (Rojas and Aylward, 2002). Agreements among numerous parties will also require that more consideration be given to the establishment of decision-making entities for purposes of allocating funds to priority conservation measures. This may take the form of a trust fund, such as FONAG (Fondo del Agua), a trust fund established in Quito Ecuador to protect 2 upstream ecological reserves. This fund is overseen by a stakeholder board, and allocates pooled funds and in kind support received from municipal entities that provide water and electric services, from NGOs, and from private sources (Echavarria, 2002a; Echavarria, 2003).

Transfer Payments (TP) – These are payments made to land owners as compensation for the costs of adhering to specified management practices. This is a hybrid approach, in that payments are usually made on the basis of VCAs with landowners, but differ in that the contract is normally made between landowners and the government, for purposes of achieving broader policy objectives rather than directly with downstream users, in response to their specific concerns. When voluntary, landowner participation will depend on whether payments are sufficient to offset their opportunity costs, which may be revealed by allocating them on the basis of bidding systems. It is also a mechanism often used to allocate funds collected through various sources, which may include User Fees, conservation donors, and general tax revenues. Transfer Payments may also be funded through the sale of marketable permits (described below) to those who have higher costs of regulatory compliance. The best-known examples of TPs are the United States Conservation Reserve Program and similar initiatives in some countries in the European Union, in which farmers are compensated for conservation measures based on a number of criteria that include water quality (USDA, 2000). An arrangement established by irrigation farmers in the Cauca Valley in Colombia, in which they voluntarily pay additional water-use fees to support watershed conservation, could also be considered a system of transfer payments. This is because the farmers themselves do not have the authority to directly fund watershed management activities. Instead, the fees are paid to a governmental entity – the Corporación Autonóma Regional del Valle del Cauca – which uses them to implement existing watershed management plans (Echavarria, 2002b).

Acquisition – This approach encompasses many forms, ranging from the acquisition of rights to water and land parcels, to the acquisition of partial rights through easements that restrict uses, and leasing, in which rights are acquired for a specific period of time. In the context of watershed protection, it is common for governments or nongovernmental entities, such as land trusts, to acquire development rights on particular parcels of land so as to prevent their conversion to other uses, while owners may retain rights to occupancy and/or other specified uses. An example is the purchase of land and conservation easements in critical areas that cover the Edwards Aquifer, which supplies drinking water to 1.5 million people in Austin and San Antonio Texas (US) (Trust for Public Land, 2001). It is also one of the instruments used to implement the New York City Watershed Agreement, in which the city invests in upstream watershed protection measures (Perrot-Maître and Davis, 2001; Catskill Corporation, 2001; New York Department of Environmental Protection, 2001).

Tradable Development Rights (TDRs) – This is a form of acquisition that shifts the cost of acquiring development rights to developers and future residents. Using this approach, developers who acquire the rights from areas designated for conservation are granted permits to build at higher densities than would otherwise be allowed, in areas specifically designated for development. The more successful initiatives are generally part of a comprehensive regional plan that justifies the designation of conservation and development areas. The best-known example of the

use of TDRs for the purpose of insuring the provision of freshwater may be the New Jersey Pinelands Development Credit Program in the United States. A key concern is that the Pinelands occupy an area of sandy soil that covers a very large aquifer, and where massive development is otherwise expected (Collins and Russell, 1988) (New Jersey Pinelands Commission, 2004). A related approach is the US Wetland Mitigation Banking program, in which wetland restoration may be funded through the sale of credits to developers, who may be required to purchase these as compensation for development impacts on wetlands that cannot be mitigated. The sale of credits also provides a way of concentrating wetlands restoration efforts in areas where they can be most beneficial (Liebesman and Plott, 1998; Salzman and Ruhl, 2002). A survey conducted in 2000 identified over 230 operating wetland mitigation banks, over half of which were commercial, and which involved the restoration of 16 500 ha in exchange for the development of 9500 ha (IWR, 2000; National Research Council, 2001).

Marketable Permit Systems (MPS) – These are similar in concept to TDRs, but, in this context, are applied to trades between point and nonpoint sources of pollution. Once allowable levels of pollution and resource use have been established as a matter of policy and regulation, MPSs provide a way to reduce the overall costs of compliance by allowing those who have higher compliance costs to purchase credits from those whose costs are lower, usually through intermediary organizations that register and verify credits. They may also be structured such that proceeds from the sale of permits are used to fund transfer payments, thereby shifting the cost of payments from the public to the private sector. They may be in the form of a cap-and-trade or credit programs. The first requires establishing an aggregate limit on resource use or emission of pollutants. The second instead offers credits to those who reduce emissions or resource use beyond legal requirements or engage in specific conservation practices. Among the key policy issues is the choice of method for allocating initial rights to shares of the total allowable emissions, and rules regarding the transfer of those rights (Tietenberg, 2002). For example, rights may be allocated on the basis of existing uses, lotteries, auctions, or rules that define who is eligible. Limits on transferability may be used to prevent concentration of rights in the hands of a few, or to maintain rights within a particular community, but may also reduce efficiency by reducing the pool of buyers and sellers. A third policy issue is for stakeholders to reach an agreement as to what constitutes an equitable allocation of the burden of emissions reduction among point and nonpoint sources, so as to avoid violating the "polluter pays" principle (King, 2003).

In the context of watersheds, several programs are under development in the United States, though very few trades have actually taken place to date. Those few include one among nonpoint sources in the Dillon Reservoir, and one in Minnesota, in which the Minnesota Pollution Control Agency permitted the Rahr Malting Company to construct a downstream facility that would increase biological oxygen demand, in exchange for funding reductions of upstream nonpoint sources of phosphorus. However, trades are expected in a number of other basins as estimates of Total Maximum Daily Loads (TMDLs) are completed (Nutrient Net, 2004). TMDLs define permissible levels of emissions that are consistent with achieving water quality standards, and provide a basis for allocation of the burden of emission reductions. In the Tar Pamlico basin in the state of North Carolina, an association of point source dischargers has purchased credits from the state that have been banked for use when their cap is exceeded, and that are intended for future use in funding Best Management Practices (NC NPSMP, 2004). A credit-trading program is also being used for salinity reduction in New South Wales in Australia. In this case, an association of farmers purchases salinity credits from the State Forests agency of NSW, which, in turn, contracts with upstream landholders to plant trees, which also provide carbon storage benefits (Perrot-Maître and Davis, 2001; State Forests of New South Wales, 2001; Sundstrom, 2001).

Certification and Labeling (CL) – This creates an incentive to adhere to specified management practices by providing consumers with the information necessary to make their choices of products more consistent with the values they place on ecosystem services. This may increase the market share of a product, and/or result in a price premium. However, producers are not always the ones who benefit from price premiums, given the number of actors between them and those who ultimately purchase the products. This arrangement requires intermediary organizations to establish standards for labeling and to certify practices, all of which has a cost. An example is the Salmon Safe initiative, which certifies and promotes wines and other agricultural products from Oregon farms and vineyards that have adhered to management practices designed to protect water quality and salmon populations (Salmon Safe, 2003).

In addition to the sale of permits and voluntary payments based on contractual agreements are a number of different kinds of sources of funds, ranging from user fees, to taxes, donations, and earmarked proceeds from sales of specific products. The appropriateness of particular sources will depend on whether or not it is possible to limit benefits to those who pay for them, and the scale at which benefits are detectable and significant.

For example, *User Fees* (UF) involve charges to users of a resource, based on the principle of "User Pays", which is only feasible when it is possible to limit benefits to those who pay for them. To be considered an instrument for protecting services, funds must also be specifically designated for conservation purposes. Intermediaries usually play a

role in the collection of funds and their disbursement to landowners. These are often added to the fees already paid by users for delivery of water. Examples of this approach include the cases of New York City, Quito Ecuador, Cauca Valley Colombia, where charges are added to existing water charges, and are designated specifically for funding upstream conservation measures (New York Department of Environmental Protection, 2001; Perrot-Maître and Davis, 2001; Echavarria, 2002b; Echavarria, 2002a). Fees may also be differentiated so as to support policy objectives of giving priorities to particular uses. For example, under the South African water law, water licensing charges vary by sector and do not apply to a certain amount of water that is reserved for basic human and ecosystem needs (DWAF, 1999a).

When it is not possible to limit access to benefits to specific users, *taxes* may be more appropriate. Transfer payments, such as the United States Conservation Reserve program, tend to be funded through general tax revenue. In Costa Rica, the National Fund for Forest Financing (FONAFIFO), a program of payments for ecosystem services that includes protection of watersheds, is in part funded by a fuel tax, in addition to payments from beneficiaries. In Colombia, watershed management is in part funded through a 6% tax on the revenue of large hydroelectric plants. This tax also supports political decentralization, as it is a key source of funding for regional authorities, which have the primary authority for watershed management. This revenue is divided among the autonomous regional corporations and municipal governments. A portion of the allocation to the autonomous regional corporations goes to a general fund that supports management of watersheds in which there is no hydropower facility. In addition, 1% of funds invested by towns in water projects must be invested in watershed protection.

Donations from external sources may be important for addressing impacts associated with actions of external actors, such as those associated with timber concessions and other uses of government owned land, and with macroeconomic policies. Funding from external donors may also be necessary to finance the high transaction costs faced up front, in the beginning stages of an initiative, associated with feasibility studies, assessment activities, and capacity building, generally done through intermediary organizations.

Earmarked proceeds from the sale of specific products that are associated with special places and symbols may simply be designated for the support of conservation objectives that have broad benefits, which may also influence consumer purchase decisions and have other benefits for the company or organization. For example, in the state of Maryland (in the United States), for an additional fee, car owners have an option of obtaining Chesapeake Bay license plates, which supports the Chesapeake Bay Trust – an entity created by the state legislature to support Bay restoration. The University of Maryland also recently began to designate 2% of the proceeds from the sale of items associated with the "Fear the Turtle" slogan toward the protection of the terrapin – the school mascot and official state reptile (Hsieh, 2003). The terrapin is generally regarded as an "ambassador" for the Chesapeake Bay ecosystem, as it relies on its water quality, shorelines, salt marshes, and tidal rivers, and has provided the basis for extensive public education and outreach regarding comprehensive approaches to conservation (Dunlap, 2003; Golder *et al.*, 2000).

Most arrangements will consist of a package of various instruments. For example, TPs may be made through VCAs with sellers, using funds derived from UFs. Individual arrangements may also be part of a comprehensive plan intended to protect multiple services, which, in addition to those associated with freshwater, may include other benefits of forests, such as carbon storage, aesthetic values, and biodiversity. These are the four services for which forest owners who adhere to approved management plans are compensated in Costa Rica's FONAFIFO program, which is then able to sell them to different kinds of buyers. For example, hydroelectric companies and municipalities may pay for watershed benefits, tourism agencies for landscape beauty, and foreign energy companies may purchase carbon offsets. State Forests of New South Wales has also initiated an Environmental Services Scheme in which landowners are to be compensated through a credit scheme for multiple benefits of forests, including carbon sequestration, biodiversity, soil conservation, in addition to protection of water quality and offsetting the rise in salinity levels (State Forests of New South Wales, 2004). This approach may also be necessary when watershed benefits alone are not sufficient to offset the opportunity costs of forgone land uses (Landell-Mills and Porras, 2002).

Fundamental to all of these instruments is the need for a consistent set of criteria and a transparent process for decision-making with respect to the establishment of priorities for allocation of the funds. It is also important to keep in mind that market-based mechanisms are not a substitute for regulations, which are often necessary to create an incentive to find more cost-effective ways of achieving compliance through the use of market mechanisms. For example, in the well-known case of New York City, the incentive for the city to negotiate with upper watershed communities and to pay for upper watershed conservation measures was created by new regulations that would have otherwise required much higher expenditures to construct a filtration plant (Perrot-Maître and Davis, 2001). Trading schemes rely directly on regulatory standards or caps, without which there would be no incentive for using market-based approaches.

In general, benefits will be more tangible, and contractual agreements more feasible, at smaller scales, where links between causes and effects can be more readily established, and where property rights and stakeholders can be better defined. At larger scales, where it is harder to link causes and effects, and rights and responsibilities are harder to define because of public good or common pool characteristics of the service, or of multiple services, there will be a greater need for government involvement. Larger scales also offer a larger pool of buyers and sellers, but are harder to tailor to local conditions (Rose, 2002).

CHALLENGES TO IMPLEMENTATION

Implementation of market-based payment arrangements for watershed services will be difficult unless beneficiaries are both able and willing to pay for them. Willingness to pay will generally depend on perceptions and beliefs regarding the benefits of ecosystem services. In the long if not the short term, this may require a demonstration that there are measurable benefits that support livelihoods and overall well-being. It will also require the development of institutional arrangements that insure access to benefits by those who pay for them, over the relevant period of time. By providing compensation for inevitable trade-offs among conflicting interests and objectives, market-based instruments will often be one element in a more comprehensive management strategy. This section begins with an overview of the difficulties of demonstrating measurable benefits, and the use of scientific and other information to evaluate trade-offs. It concludes with a discussion of the various kinds of institutional arrangements needed to support payment initiatives.

Demonstrating Measurable Benefits

Assessment and verification of the benefits of ecosystem services, and the effectiveness of management actions taken to insure continued provision, are critical to building and maintaining stakeholder confidence and willingness to pay for them. In general, this aspect has received less attention than the identification of able buyers and systems for collecting payments (Pagiola *et al.*, 2002). However, it can require gathering of data over time and significant commitments of funding and expertise that are not available until an initiative is well established. Rules of thumb may be sufficient in the initial phase, provided initiatives are designed to include monitoring and assessment that allows them to be improved over time.

Key questions that should be answered in assessments, or for which they should at least provide a working hypothesis are as follows:

1. What ecosystem functions support the provision of specific benefits and what are their key parameters, or, how can they be measured or approximated? How does land use in the watershed affect these functions?
2. What is the direction and magnitude of changes in parameters of interest?
3. At what spatial and temporal scales can these changes be detected?

Investigation of changes in the water balance and the impacts of these changes on the flow regime provide a framework for quantifying changes in watershed conditions relative to management objectives. These objectives, or points of interest, may include the following:

- Total flow yield
- Attenuation of peak or flood flows
- Maintenance of minimum low or dry season flows
- Protection of water quality
- Recharge of groundwater
- Protection of biodiversity.

(Tognetti *et al.*, 2004).

The most significant changes in the water balance are linked to extreme and randomly timed events. For example, most sediment and pollutants are transported during storms, which also produce the periodic high flows necessary for maintenance of channels, riparian areas, wetlands, and coastal mangroves. Such events are the dominant process in upstream hill-slope areas, which make up 70 to 80% of catchment areas, have tightly coupled land and water interactions, and have greater variability in discharge. This is in contrast with downstream fluvial processes that are more continuous and are dominated by regular flood pulses and movement of bedload within the channel as well as cumulative impacts of hill-slope processes (Gomi *et al.*, 2002). Therefore, it is more important to identify known ranges and patterns of variability and uncertainty than to identify average values. These ranges can then be used to put lower bounds on unknown thresholds of resilience – which refers to the range of variability within which changes can be adjusted to (Tognetti *et al.*, 2004).

Human uses also play a significant role in the hydrological cycle, and should be accounted for so that their cumulative impacts can be distinguished from natural variation, and so as to be able to distinguish physical from economic causes of scarcity – which has implications for the kinds of measures that will be effective. Economic causes of scarcity imply the need for changes in allocation among human uses. Physical causes of scarcity imply the need for changes in the flow regime, which refers to allocation between ecosystems and human uses, and changes in land use practices that affect the timing and routing of flows. This should be accounted for on a seasonal basis – to the extent water is limiting during dry periods, there will generally be a greater willingness to pay for it (Tognetti *et al.*, 2004).

Basin-wide seasonal Actual Evapotranspiration (AET) is a principal component of the water balance. It is also a key source of uncertainty because it is a function of numerous variables that include climatic factors, vegetation, and land use. Given the heterogeneity of landscapes, this is difficult to estimate. However, it is important to consider land use practices and landscape characteristics such as riparian zones, which have disproportionate impacts on levels of runoff and sedimentation and which may account for significant differences in AET (van Noordwijk *et al.*, 2004).

Because of such heterogeneity, land use impacts on flows of water and sediment are generally best addressed at small scales, at level of hillslopes and patches, at which they can be detected. With some exceptions (e.g. suspended sediment and microbial contamination), water quality impacts, diversions, and impacts of large infrastructure are more appropriately addressed at basin-wide scales, which allows for consideration of a broader range of trade-offs.

The measurement of benefits should ultimately provide a basis for estimating relationships between the extent of changes in land use and the amount of benefits provided, so as to provide justification for payment amounts. Given inherent uncertainties, it may be sufficient to rank the relative values of land uses and practices for achieving desired outcomes, and to identify opportunity costs and conflicts associated with changes in land use practices. As a general rule, greater precision and more data will be needed when it is unclear whether or not benefits exceed costs. However, this also depends on what costs and benefits are considered – which is largely a political and institutional question.

Identifying and Evaluating Trade-offs

Identifying the economic significance of changes in watershed processes provides a basis for identifying actual or potential trade-offs between meeting various objectives. This will require consideration of downstream land uses and stakeholder vulnerability, which depends on what options they have, and on their opportunity costs. Just as with biophysical processes in watersheds – vulnerability, options available to stakeholders, and conflicts become more transparent under extreme conditions. Impacts may be both positive and negative, depending on what is measured and valued. For example, whether floods increase or decrease welfare will depend on the presence of development in flood plains, and valued habitats that rely on periodic floods.

An example of an extensive assessment that was done regarding relationships between land use and hydrology is a study of the Arenal basin of Costa Rica, which examined the marginal values of changes in flows of water and sedimentation for a downstream hydroelectric plant. In this particular case, it was found that, while sediment from pasture compared with forested areas did have a cost in terms of lost hydroelectric production, ranging from $35 to $75/ha, this was exceeded by the benefits to the facility of increased water yield from pasture areas, which ranged from $250 to $1100, depending on the type of forest area cleared – the greatest yield of water appeared to be associated with fragmented cloud forest areas that have the highest rates of interception of precipitation (Aylward and Echeverria, 2001). This (counterintuitive) result occurs in part because the Arenal reservoir is an interannual regulation reservoir, in which hydroelectric production depends on total flows, and is therefore largely independent of dry season flows. Given that the reservoir also contains a large amount of dead storage space, sedimentation also provides a benefit when it fills this space and displaces water upward, which makes more water available for production.

Given the high economic values associated with forest clearing in the Arenal study, ranching was also found to produce higher net present values than was offered by the government for reforestation and thus to be more economically efficient. On the other hand, these costs and benefits were not uniformly distributed. A subsequent companion study that examined costs and benefits from the perspective of major stakeholders, and which made distinctions among various kinds of landholders, found that the higher return per hectare depended in part on location in the catchment, that they accrue primarily to large landholders, and that incentives that were being offered for conservation may still appear attractive to small landholders who, not coincidentally, also tend to disproportionately occupy the steepest slopes (Aylward and Fernández González, 1998). The scale of the study did not permit it to answer questions regarding the more localized impacts of forest clearing on landowners residing within the upstream area.

In contrast with the results at Arenal are those of another Costa Rican reservoir that is part of the La Esperanza hydroelectric facility, which is smaller, depends on dry season flows, and has higher costs associated with sedimentation. In that case, payments from the hydroelectric company to the Monteverde Conservation League, the sole owner of the upper watershed area, are simply based on the value to the company of reducing uncertainty that would accompany any change in upstream land use (Rojas and Aylward, 2002).

Because of natural variability, landscape heterogeneity, and human activities, it will be difficult or impossible to unequivocally establish links between land use and water yield at the watershed scale, even with a full analysis of land and water relationships. For example, in the case of Arenal, there are a number of land uses and vegetation types that include pasture, forest with different canopy heights, cloud forest with different degrees of fragmentation, all of which are changing over time, are a key parameter in estimating water balances, and are therefore a major

source of uncertainty. A field study in the Arenal basin found the highest capture of precipitation in fragmented primary cloud forest, of 12% compared to a negative gain of 11%, in intact high primary forest. However, during the dry season, yields were positive for all types of forest, when water availability is most limiting and therefore has higher economic value, with gains ranging from 15 to 53% (Fallas, 1996). Other potentially significant sources of variability in the interception of precipitation in cloud forests, often not accounted for, are the position of the slope in relation to moist winds and storm intensity, which affects the amount of water held in the forest canopy (Bruijnzeel, 2001). Although water quantity impacts associated with forest clearance are often ambiguous, water quality impacts can generally be expected to be negative (Aylward, 2004).

Recent reviews of the scientific knowledge base that has supported many initiatives in Costa Rica suggests that management is generally limited by the lack of reliable and precise information on forest water linkages (Pagiola, 2002; Rojas and Aylward, 2003). Instead, most are based on conventional wisdom, secondary sources of information, and also on selective references to more balanced literature reviews on forest hydrology. In other words, regardless of the source material, information used in decision-making tends to invariably support statements that protection of forests will increase water yields (Rojas and Aylward, 2003). In some cases, such as in the Arenal basin (Castro and Barrantes, 1998) and in Heredia (Castro and Salazar, 2000), the values of watershed protection are calculated on the basis of the opportunity cost of returning cleared land to forest cover, with no attempt to model and assess links between land use and hydrology, and to estimate the marginal values of water in specific consumption and production activities. In other words, estimates of opportunity costs of land under alternative uses is used to infer the benefits of forest hydrological services. In the latter case, payments are also justified on the basis of the statement that "Costa Rican society positively correlates the presence of forest with the supply of hydrological services".

Faced with these and other kinds of uncertainties, such as data that is rarely if ever complete, reliance of models on average values, the random timing and disproportionate significance of extreme events – decisions to protect watershed services are often based on the costs of alternative courses of action rather than on the value of changes in land use practices. For example, in the New York City case, the decision to invest in upstream conservation and upgrading of infrastructure was based on the avoided cost of building a filtration plant that would have otherwise been required to meet a new regulatory standard designed to insure safe drinking water. However, the relationship between changes in land use practices and resulting water quality remains the subject of ongoing research.

Other factors that have been used to inform the analysis of trade-offs and to justify decisions and influence WTP have included

- costs of implementing management plans;
- regulatory costs avoided;
- reduction of uncertainty associated with proposed changes in land use;
- individual WTP in the form of user fees and purchase of certified products;
- political WTP as indicated in national budget allocations of tax revenue;
- landowner WTA compensation or cost of supplying the service; and
- consistency with comprehensive management plans.

Given the period of time that may be required to detect the results of changes in management practices, and the impossibility of obtaining complete information, it will usually be necessary to begin with rules of thumb. These can provide a basis for constructing plausible scenarios, or serve as working hypotheses, to be tested in an adaptive approach to management, in which they are continuously questioned and revised as new information becomes available and in response to unanticipated consequences. Initiatives are likely to be more effective in the long term when uncertainty is made explicit and initiatives are also informed by a process of monitoring and assessment, which are essential as a feedback component in the design of any initiative.

Ultimately, the extent of information needed for decision-making will depend on what is required to justify an expenditure in a particular case, or, in other words, to convince the buyers. To the extent that uncertainty regarding links between actions and outcomes can be reduced – or at least made transparent so that it can be factored into decision-making, stakeholders will have greater economic incentive to participate in these initiatives and in helping to insure that objectives are actually achieved. A key challenge then is to develop greater capacity for conducting site-specific assessment of functions that support services, of threats they will be degraded or disrupted, and to use these to develop feasible and effective response options.

Development of Appropriate Institutional Arrangements

As discussed in the introduction, willingness to pay is inextricably linked to confidence in the effectiveness of management actions as well as of the institutional arrangements needed to insure access to benefits by those who pay the costs of management actions. In the absence of such arrangements, economic value is no more than hypothetical, as there would be no incentive to take actions needed to insure provision of the service. Institutional arrangements are essentially the "rules-of-the-game" that are needed to

resolve conflicts among competing demands on any limited resource so as to avoid its depletion or degradation. They may take several different forms, addressed in this section, chief among which are property rights, which define the rights and responsibilities of all players, and have implications on the distribution of costs and benefits. The second is the decision-making process, which may or may not allow for effective participation of all concerned, and the process of assessment – which includes both the gathering and dissemination to users, of information needed to support decision-making. The feasibility of these arrangements will depend largely on their transaction costs, and on the broader social and economic context in which they are embedded.

Institutional arrangements also serve the purpose of reducing transaction costs by facilitating transactions among numerous buyers and sellers, and, where necessary, collective action. For example, given that areas of high erosion tend to be marginal areas such as steep slopes, or common areas such as roads and paths, individual landowners will have little incentive to invest in improvements, which makes these areas *de facto*, open access (Swallow *et al.*, 2001). In this kind of situation, provision of services may require incentives for collective action by communities. When there are numerous stakeholders dispersed over large upper watershed areas, the establishment of intermediary organizations, who can negotiate on their behalf, serve as advocates for the rights of marginalized stakeholders, and provide technical assistance, which is an important way of reducing transaction costs and making an initiative feasible.

Rights to Watershed Services and Responsibilities for Their Provision

Property rights play an important role in creating appropriate economic incentives because they determine who has access to benefits and also define responsibilities for costs or actions needed to insure the provision of benefits. For example, in the absence of a clear land title, upper watershed land users will lack the authority to enter into contractual agreements and therefore be unable to benefit from payments. They may also risk eviction as values are placed on services to which they lack recognized rights (Landell-Mills and Porras, 2002). Property rights may take different forms, ranging from informal rights or norms recognized by users, to various forms of formally recognized public and private ownership by individuals, groups, or government entities. Failure to control access is often mistakenly referred to as a "common property" situation, but is actually an "open access" situation in which no property rights are in effect (Ostrom *et al.*, 1994).

Appropriateness of property regimes depends on whether the incentives they create are consistent with social objectives. For example, rights to water based on historic use or "prior appropriation", which usually also require that the water be used in ways that are considered socially beneficial, was consistent with social objectives in the 1800s of promoting development in the western United States. However, it creates a disincentive for reducing consumption as this would lead to a reduction of the amount of water a user may claim in the future, and is inconsistent with uses associated with emerging social objectives of conservation, such as in-stream flow, that are not legally defined as "beneficial" (Wilkinson, 1992). Rights to water based on possession of adjacent land or "riparian rights" allow reasonable use that does not interfere with the reasonable use by others, and may allow communities to control access and exercise customary rights. The latter, however, may limit the ability to transfer the water and to develop water markets, which can provide incentives for more efficient allocation among various uses (Meinzen-Dick and Bruns, 2000). In an open access situation, the incentive is simply to consume resources before someone else does.

Appropriate or not, property rights do not change easily or quickly in the absence of political momentum generated by events such as the end of the cold war, as their purpose is to provide some security without which there is little incentive for investment. Thus, they cannot be arbitrarily changed. However, they do tend to change over time to reflect changes in social values, as new problems emerge, and as technological improvements bring down the transaction costs of controlling access to particular resources – and are not always compensated. For example, development of hydropower at the beginning of the industrial era led to a change in rights to the natural flow of water because it was considered to be of greater value to society, and continues to lead to widespread displacement of communities. Similarly, as a consequence of the growth of urban areas, rivers became more highly valued for sewage disposal than for fisheries and recreational values. Just as changes in rights have been implicit in the development of physical infrastructure (hydropower, dams, irrigation, and navigation), the rise of values placed on freshwater services implies the negotiation and definition of new rights and responsibilities in which uses of land and water are limited to those that do not impair ecosystem functions that support valued services (Sax, 1993).

Typically, different claims and sources of authority will tend to overlap and conflict in a process referred to as "legal pluralism" (Meinzen-Dick and Pradhan, 2002). Therefore, changes in property rights tend to come about through a contested process that can lead to the development of new and more appropriate institutional arrangements. Any initiative to protect downstream water supplies or biodiversity either by providing compensation to upstream landowners for altering land use practices, or by attempting to hold them responsible for damages, in effect involves negotiating new and appropriate forms of property rights that resolve conflicts between these objectives and existing practices.

Allocation of Costs and Benefits

Equitable distribution of costs and benefits is an important aspect of feasibility in that, if significant stakeholders are excluded or disadvantaged, and regard existing rights as inequitable, they will have little incentive to cooperate in their enforcement. On the buyer side, some studies have found differences in willingness to pay that depended on the protection mechanism suggested and on the distribution of property rights. In some cases, stakeholders are unwilling to pay, not because they are unaware of ecosystem values, but simply because they do not feel that it should be their responsibility to do so (O'Connor, 2000).

Direct payments for environmental services raise fundamental questions as to who *should* pay and how much, and the extent to which providing these services should simply be regarded as an obligation inherent in the responsibility not to harm others. In some cases, transfer payments to upstream areas could be seen as violating the principle of "polluter pays", unless accompanied by sanctions on pollution (UN FAO, 2002). However, given the low prices paid for agricultural commodities, direct payments for providing services of maintaining the landscape and water quality may also be seen simply as recognition of the values of environmental services in addition to those of agricultural commodities.

Equity issues may also present an obstacle to nutrient trading between emitters of nutrients from point and nonpoint sources, as it has been suggested that these may not be regarded as fair by point source emitters who have already invested in point source reductions (King, 2003). Agreement on TMDLs that equitably allocate load restrictions between point and nonpoint sources, as a basis for the initial allocation of permits, may help overcome this.

In a number of cases that have been evaluated, it was found that payments for watershed have disproportionately benefited those who own larger tracts of forests or forest plantations, excluding smaller and marginalized landholders, who tend to occupy the steepest slopes, who do not have large forest areas that they can be compensated for protecting, and may not have the property rights needed to gain access to benefits. They also tend to exclude activities such as agroforestry and organic farming. This suggests the need for broader criteria for allocation of payments, so as to include smaller landholders and better support livelihood strategies (Rosa *et al.*, 2003).

Participation in Decision-making

Acceptance and cooperation of both buyers and sellers may ultimately depend on whether all of the relevant stakeholders cooperate, how funds will be spent, and whether stakeholders are able to effectively participate in allocation decisions, all of which are issues of governance. For example, in Brazil, which adopted a nationwide river basin management policy, domestic water users were found to be willing to pay more for water when the revenue from water fees is invested in the basin where the funds are generated, and when users are able to participate in decisions as to how the revenue is spent (Porto *et al.*, 1999). Other studies have found differences in WTP that depended on the protection mechanism suggested, and whether it was regarded as fair and effective (O'Connor, 2000). A study of water resources management in Cyprus found a higher WTP, even for less tangible values such as protection of wetlands along an international bird migration route, under scenarios in which all of the relevant stakeholders participate; in this case, all countries along the bird migration route (Koundouri *et al.*, 2003).

A key obstacle to effective participation of stakeholders in decision-making has been the association of large water resource infrastructure with the need for highly centralized management authority. In the case of large infrastructure projects, decision-making takes place at national levels, and is largely driven by geopolitical considerations in which local stakeholders have little in any voice. Because of environmental and institutional heterogeneity, highly centralized authorities tend to have a limited capacity to respond to livelihood concerns. The site-specific characteristics and variability of freshwater ecosystems and other natural resources imply the need for detailed local knowledge, discretionary powers, and also greater representation and accountability, which can increase the capacity to respond to factors such as variations in rainfall and crises associated with extreme events, as well as to mediate conflicts. Transfer of rights and sharing of benefits can also provide a stream of revenue to local governments that can be used to build and sustain capacity for resource management. Provision of watershed and other ecosystem services may therefore be inextricably linked with efforts to achieve democratic forms of decentralization, or to "pry open... local democratic space" (Kaimowitz and Ribot, 2002).

A second obstacle to effective participation is the gathering and dissemination of information needed to support decision-making. Given the site-specific nature of watershed services, this presents the challenge of developing an integrated and place-based approach to assessment. Given that adequate information seldom exists in advance of an initiative, and that complete information is unobtainable, this is particularly important in the implementation phase, so as to identify gaps between policies and practices. This provides a basis for course correction, as new information becomes available and as lessons are learned, and for engaging stakeholders in identifying feasible options.

Socioeconomic and Political Context

Ultimately, the development of market-based arrangements for watershed ecosystem services also needs to be

considered in the context of a broader trend of institutional changes in water resource management. Among the key elements of this trend are (Saleth and Dinar, 1999; Bauer, 2004)

1. a shift from the development of new water supplies through infrastructure development, to the reallocation of existing ones, and
2. efforts to improve cost recovery both for
   (a) operations and maintenance of infrastructure, and
   (b) to cover the costs of conservation management and research activities.

In theory, recovery of these costs could increase the capacity of governments to deliver basic water supplies and sanitation, and the capacity of ecosystems to provide freshwater supplies. However, cost recovery faces a major obstacle in that major water users, particularly in agriculture, which accounts for approximately 70% of water withdrawals worldwide (United Nations, 2003), are also accustomed to high subsidies and pay only a fraction of the costs of operations and maintenance alone. In urban areas, inability to recover costs from those who are served reduces the capacity of the government to extend services to the poor, who must then pay more to obtain water from trucks. Reallocation of existing supplies therefore faces significant political constraints, and may need to be linked to broader macroeconomic reforms that tend to be associated with crises or sweeping political changes, such as the end of apartheid in South Africa which, among other things, made it possible to make significant reforms in the country's water law (see box 1).

Conversely, given the role of water in most, if not all, sectors of the economy, the development of payment arrangements can have implications for broader policy reforms. For example, potential spin-off benefits associated with the development of markets for watershed services include clarification of property rights, stakeholder cooperation in other areas important to livelihoods as a result of strengthened institutions, technological transfer and skill development, development of market infrastructure, contributions toward the protection of other ecosystem services not traded in markets, improved scientific understanding, and environmental education (Landell-Mills and Porras, 2002). Payment arrangements for freshwater and other ecosystem services is therefore a long-term process of institutional development that needs to be considered in the context of broader issues of democratic governance. For markets to work, democratic institutions and equity are essential because there needs to be trust that people will obey rules and abide by agreements made, which may not occur unless arrangements are regarded as fair (Lipton, 1985). This is a continuing challenge in developed and developing countries alike.

Although development of appropriate supporting institutional arrangements can have high transaction costs, it should be kept in mind that this is no different from costs that have been and continue to be incurred in the development and maintenance of institutions that support existing markets and that are generally not paid for in the prices of private goods and services.

Box 1 National Water Act of South Africa

The South Africa National Water Act is among the more innovative in that it explicitly seeks to recover costs both for operation and maintenance and for conservation, management and research, as well as for meeting basic human subsistence needs. Therefore, water charges do not apply to minimal levels of water for ecosystem and human subsistence needs (DWAF, 1997). Beyond these basic needs, it requires the registration of water uses. Licensing and payment of fees are required for water service authorities, industrial uses, irrigation, and for activities that reduce streamflow, such as tree plantations. Licensing applications are evaluated for consistency with a number of criteria including individual catchment management strategies that are prepared in accordance with a national water strategy (DWAF, 1999b). Implementation has not been without problems. Among these are tensions with existing riparian rights holders, hardships associated with the withdrawal of subsidies from irrigators, and the inability of many of the poor to pay even minimal amounts for water delivery. Whether these problems can be resolved, and whether licensing can truly serve as a reallocation mechanism, may depend less on formal changes in the law than on the strength of public participation, and the bargaining power of the poor (Schreiner and van Koppen, 2000).

CONCLUSION

The specific services provided by watersheds will depend on how they are managed, and whether impacts have economic significance. This, in turn, depends on downstream uses of land and water, on the scale at which impacts can be detected, and on what options are available to stakeholders for maintaining their livelihoods. Therefore, market-based instruments will not solve all problems of watershed degradation, but are important tools that should be used as components of broader management strategy.

In the past, efforts to manage freshwater ecosystems to meet multiple objectives has been driven by the more dominant and tangible economic interests, typically navigation and hydropower (Barrow, 1998). More recently, in a somewhat similar fashion, efforts to protect watersheds using market-based instruments have been driven by the interests of those most able to pay such as municipal water suppliers and hydroelectric facilities, and have placed emphasis on protection of forests and protected areas. This approach tends to overlook management practices that may have greater impacts than forest clearing, and to exclude the most

vulnerable populations from access to benefits. A significant obstacle to cost recovery is that the most significant users, for example, agriculture, are accustomed to subsidized prices.

The use of market-based instruments to recover the costs of watershed management activities needs to be considered in the context of basin-wide management objectives, and should be part of a package of approaches constructed to identify the relative values of multiple ecosystem services of watersheds as a basis for setting conservation priorities, and to resolve conflict among multiple uses. This can provide a basis for engaging stakeholders in identifying a broader range of management options that are consistent with meeting the broader objectives of ecosystem management to support human livelihoods and general well-being. It may also increase their confidence and willingness to pay and to cooperate in management activities.

Experience to date with the use of market-based instruments to cover the cost of actions needed to insure continued provision of watershed services suggests that little is known about their effectiveness for actually delivering ecosystem services. This is, in part, because of the time lag between management activities and their outcomes in a watershed context, and, in part, because less attention has been given to development of an independent and transparent process of assessment.

Given the heterogeneity and constant change in ecosystems and in human institutions, the site-specific nature of watershed processes – which are dominated by randomly timed and extreme events, and the difficulty of linking multiple causes and effects, or predicting outcomes, an adaptive approach to management is required. Ongoing assessment to support decision-making is a critical component of such initiatives. However, assessments based on generalizations can only provide some rules of thumb and working hypotheses from which to begin. Perhaps the most significant challenge therefore is to develop the capacity for a place-based approach to assessment, which is necessary to identify ecosystem functions that support provision of valued ecosystem services in a specific context, and to select payment and institutional arrangements that are feasible and appropriate to that context. To be effective, market-based initiatives also need to be viewed as part of a long-term process of building appropriate institutions, and in the context of broader issues of structural reform.

Acknowledgment

This paper is in part based on a "Knowledge and Assessment Guide to Support the Development of Payment Arrangements for Watershed Ecosystem Services" prepared for the World Bank Environment Department, with support from the Bank-Netherlands Watershed Partnership Program, by Sylvia Tognetti, Guillermo Mendoza, Bruce Aylward, Douglas Southgate, and Luis Garcia. It also benefited from comments and suggestions provided by Benjamin Kiersch.

194: Inter-Institutional Links in Land and Water Management

JAIME M AMEZAGA

Centre for Land Use and Water Resources Research, Institute for Research on the Environment and Sustainability, University of Newcastle, Newcastle upon Tyne, UK

This article reviews the institutional aspects of Integrated Land and Water Resources Management. It explores the definition of what constitutes an institution in the land and water sector and presents several approaches to institutional analysis applicable in this context. It examines land and water interinstitutional linkages at several levels: international, national, river basin, and upstream/downstream. For each of these levels, theoretical approaches and examples are discussed. While institutional constraints such as cross-sectoral coordination and the conflict between different land-based administrative structures are still common, there are an increasing number of instruments applicable to this problem at all levels. Ensuring basic human needs and rights associated with water and land and establishing institutional systems to benefit disadvantaged people and improve livelihoods remain the greatest challenges to integrated management.

FROM WATER TO LAND AND WATER MANAGEMENT

The twentieth century saw the evolution of increasingly sophisticated approaches to integrated water management (White, 1998). At the beginning of the century, the prevailing approach was single purpose, with water harnessed independently for power, irrigation, or storage for drinking water purposes. By the third decade of the century, engineering developments made possible the multipurpose development of water resources, with the emergence of dams able to generate electricity and store water for other aims, as well as the exploitation of deep wells and systems for the treatment of wastewater. By the sixth decade, questions about the full social and environmental implications of these increasingly complex water systems started to arise. The global institutions created after the Second World War began to pay explicit attention to integrated water management in a number of conferences and reports. A critical landmark was the UN Water Conference in Mar del Plata in 1977, which sought to formulate general principles for national and international agencies. Those principles were updated in an International Conference in Dublin in 1992, which shaped the water policies and programs adopted at the UN Conference on Environment and Development in Rio de Janeiro that same year, known as the *Agenda 21* (Sitarz, 1993). The Agenda 21 was an additive document with limited efforts devoted to integration. While there was considerable attention paid to water, this was sectorized, and the stress on integration was not accompanied by indications on how to achieve it. The land-use chapters were almost completely "dry" (Falkenmark, 2001). There was neither indication of the vertical presence of water in the saturated and root zones, nor of the implications of land use for water management beyond irrigation. After Rio, it became increasingly clear that there was a need to develop the ability to integrate land/water/ecosystems management and properly incorporate land use; "a *land use decision is also a water decision*" (Falkenmark *et al.*, 1999; Newson, 1997; Calder, 1999; Calder, 2005). This integrated approach had to be translated into policy and strong institutions able to handle the potential conflicts between incompatible land and water uses.

The awareness of the land and water link is explicit in the definition of integrated water resources management (IWRM) popularized by the Global Water Partnership after the second World Water Forum in The Hague (2000):

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

"IWRM is a process which promotes the coordinated development and management of water, land and related resources, in order to maximize the resultant economic and social welfare in an equitable manner without compromising the sustainability of vital ecosystems" (GWP TAC, 2000).

This definition emphasizes that IWRM is about coordination (Jønch-Clausen and Fugl, 2001); it is the integrative handle that can lead from fragmented subsectoral to cross-sectoral water management. A key concept to be grasped is that IWRM is not a spontaneous phenomenon, but rather an institutionalized process facilitated or constrained by a particular constellation of policies and actors working in a certain time and space. It requires an enabling environment of polices and legislation from the international to the local level. There must be an institutional framework with clear demarcation of responsibilities between actors, adequate coordination mechanisms, the filling of jurisdictional gaps, and capacity to action.

The different uses of water for people, food, nature, and industry are intrinsically linked to land use. The importance of this link has seen the emergence of the concept of Integrated Land and Water Resources Management (ILWRM) as the ideal for coordination (*see* **Chapter 185, Integrated Land and Water Resources Management, Volume 5**). This article reviews how the current institutional frameworks for water management relate to this ideal.

INSTITUTIONAL FRAMEWORKS FOR WATER MANAGEMENT

Defining Institutions

Understanding institutional frameworks requires definition of what is meant by the term institutions. Ostrom (1999), one of the originators of the Institutional Analysis and Development (IAD) framework, points out that this is one of the main difficulties involved in studying institutions. The term refers to many different types of entities, including both organizations and the rules used to structure patterns of interaction within and across organizations.

The International Water Management Institute (IWMI) and the Rural Development Department of the World Bank have developed concepts and methods for institutional analysis specifically devoted for the water sector. In an IWMI study on a framework for institutional analysis for water resources management in a river-basin context, Bandaroga (2000) reviews the concepts of institution and organization. Institutional economics has defined institutions as the rules of the game in a society, or more formally, the humanly devised constraints that shape human action (North, 1990). Similarly, the IAD framework sees institutions as the shared concepts used by humans in repetitive situations organized by rules, norms, and strategies (Ostrom, 1999). Meanwhile, organizations are groups of individuals with defined roles and bound by some common purpose and some rules and procedures to achieve objectives (Bandaroga, 2000). Both concepts are linked in at least two ways. Firstly, how organizations come into existence and evolve is influenced by the surrounding institutional framework. So, for example, irrigation departments are created following the enunciation of water-related policy, and organizations such as the World Bank are the product of international agreements. The second route is that established organizations represent a set of norms and behaviors that persist because they are valued and accepted as useful. In this case, organizations can also be conceptualized as institutions or as "institutionalized" organizations. This second definition applies to river-basin organizations, water companies, or ministerial departments.

In summary, water institutions are a combination of:

- policies and objectives,
- laws, rules, and regulations,
- organizations, their bylaws and core values,
- operational plans and procedures,
- incentive mechanisms,
- accountability mechanisms, and
- norms, traditions, practices and customs.

Considering both the core meaning of the term "institutions", and the emphasis in the popular usage of the term associated with "organizations", Bandaroga (2000) proposes a broad interpretation of the term in the context of river-basin management, which sees the institutional framework for water resources as consisting of established rules, norms, practices, and organizations that provide a structure to human actions related to water management. Notably, the established organizations are to be considered here as a subset of institutions. For practical purposes, the overall institutional framework is considered in three broad categories: policies, laws, and administration, all of which are related in some way to water resources management in a river-basin context.

Institutional Analysis

Bandaroga's interpretation covers the three important elements in the institutional framework, namely, policies, laws, and organizations, identified by Saleth and Dinar in their comprehensive evaluation of water institutions and water sector performance (Saleth and Dinar, 1999; Saleth and Dinar, 2000). These authors have proposed a research paradigm for the strategic analysis of water institutions based on two complementary analytical and theoretical components, the "Institutional Decomposition and Analysis" (IDA) framework, and the "Institutional Transaction Cost" theory (Saleth and Dinar, 2004; Saleth, 2004). The theoretical basis for this paradigm is institutional economics and has analytical similarities to the IAD framework. It

sees institutions as entities defined by a configuration of legal, policy and organizational rules, conventions and practices that are structurally linked, and operationally embedded with a well-specific environment. IAD distinguishes the *institutional structure* (or governance structure) from its *institutional environment* (or governance framework). While the institutional environment is characterized by the overall physical, cultural, historic, socioeconomic and political milieu of a country or region, the institutional structure is defined by the interactive effects of the legal, policy, and organizational or administrative components and their constituent aspects. The institutional structure is embedded within the institutional environment and both elements influence each other.

The water institutional environment is characterized, amongst others, by the water resources condition and critically by other related sectors linked to land use such as agriculture, environment, forestry, and urban development. The water institutional structure can be broadly decomposed in three interrelated components: water law, water policy, and water administration. These *institutional components* cover not only the formal and macrolevel arrangements but also the informal and microlevel arrangements. Examples of the latter are those reflected in local customs, conventions, and informal contracts. The formal and informal institutional components can also be decomposed further to highlight some *institutional aspects*. Water law, for example, can be separated into intergovernmental issues, water rights, and accountability provisions. Water policy can distinguish between policy principles, project-selection criteria, pricing and cost recovery, and user and private sector participations. In water administration, one can highlight organizational structures, roles of the different layers of government, financing and management, regulatory mechanisms, and conflict resolution arrangements.

In general, the IDA framework falls within the rational choice paradigm based on methodological individualism and the concept of self-interested behavior. Mollinga (2001) has reported critical analyses of the preponderance of this type of approach in the land and water sector. The main critiques reported focus on the deficiencies of the concept of human agency employed in rational choice. There are other approaches that start from a broader concept of human agency, contextualize and emphasize the importance of history, and examine the social construction of rationality, interests, and identity. Cultural Theory (Douglas and Wildavsky, 1982) provides one counterpoint to rational choice theory that has been applied in land and water resources studies (*see* **Chapter 187, Land Use Impacts on Water Resources – Science, Social and Political Factors, Volume 5**). Cultural theory is concerned with the socioinstitutional styles, such as hierarchy, egalitarianism, individualism and fatalism, which define people's, groups' and organizations' behavior and strategic choices. Mollinga (2001) quotes a study by Gyawali in 1998, showing how, in the debates around embankment works in the Ganges plain, the government department concerned worked from hierarchical premises, the social and environmental activist from egalitarian principles, while there are fatalist masses in the background and individualistic contractors involved.

LAND AND WATER INSTITUTIONAL LINKAGES

Interinstitutional Linkages

One fundamental feature of institutional analysis is that the decomposed institutional components and aspects should be treated independently only for analytical convenience. In reality, all these elements are functionally nested and interlinked both within and across institutional components. So, water policy can be seen as the political translation of water law, and water law as the legal representation of policies, while water administration is influenced by the implementation of both law and policy. Within one component such as water law, water rights, conflict resolution, and accountability are intrinsically related. Institutions are also path-dependent. History matters, and the present status and future direction of equilibrium cannot be divorced for its earlier course (Saleth, 2004). In particular, there is a history of multisectoral relationships and the different ways in which they have been shaped by the institutional environment. These are very important concepts for understanding the institutional links in land and water management.

Interinstitutional linkages are also affected by three clusters of factors: problems of fit, problems of interplay, and problems of scale (Young, 1999). *Problems of fit* are related to the fact that the effectiveness of social institutions is a function of the match between the characteristics of institutions themselves and the characteristics of the biogeophysical systems with which they interact. This problem arises, for instance, when land and water institutions do not cover the entire geographical range of land and water units. The *problem of interplay* refers to the fact that the effectiveness of institutions often depends not only on their own features but also on their interactions with other institutions. Young (1999) recommends that in order to achieve integrated land and water management, land and water institutions must interact with other institutions dealing with activities that impact on these resources. Finally, *problems of scale* refer to the transferability of both empirical generalizations and causal inferences from one level to another in the dimensions of space and time. What works on institutional arrangements at the microlevel may not work at the macrolevel and vice versa. This is a common problem in the generalization of participatory approaches from small communities to whole river basins.

The strength of integration within land and water institutions can be formalized in terms of the strength of

institutional linkages (Saleth and Dinar, 2003), and the way in which the problems of fit, interplay, and scale are overcome by interinstitutional coordination. For instance, the way water sources as well as their relationships with land and environmental resources are treated within water law can influence water policy aspects such as priority settings for water uses and project-selection criteria. Thus, if the water law recognizes the ecological linkages between water and other resources, it is more likely to give higher priority to environmental imperatives when allocating water (see the example of the concept of the reserve in South Africa in **Chapter 186, Water and Forests, Volume 5**). The allocation of water has to happen at the catchment level and take into account all uses and integrate the logics of different scales from national economic interests to local livelihood priorities.

International Level

At an international level, the land and water institutional framework is characterized by a number of global organizations, mainly UN- and World Bank related, including, on the research side, the international and regional organizations known as the *Consultative Group of International Agricultural Research* (CGIAR) to which IWMI belongs. There are also an increasing number of binding and nonbinding instruments such as treaties, protocols, and agreements (Hannam, 2003). The international conventions form a fragmented framework, with four single-purpose international conventions directly related to crises affecting land and water resources: the United Nations Convention on Biological Diversity, the United Nations Framework Convention of Climate Change, the United Nations Convention to Combat Desertification, and the United Nations Convention on the Law of the Sea. On balance, the attention is favored more toward land-related issues than water-related issues. No freshwater related convention has entered into force that outlines the behavior of parties for balancing uses of water within their sovereign jurisdiction or for linking land management with water management (Duda, 2003).

One particularly important international institution is the Global Environmental Facility (GEF). The GEF was established in 1991 as a pilot multilateral financial mechanism to test new approaches and innovative ways to respond to global environmental challenges in the four focal areas of climate change, biodiversity conservation, ozone depletion, and international waters (Duda, 2003). The GEF builds in partnership among the United Nations Development Program (UNDP), the United Nations Environment Program (UNEP), and the World Bank. The Operational Strategy of the international waters' focal area recommends several tools that take an integrated approach to land and water resources. These are the Transboundary Diagnostic Analysis (TDA), Strategic Action Programs (SAP), national interministerial committees, and local demonstration activities. The strategic approach is to start with the entire multicountry basin, move into single country tributary basins for demonstration activities, and then assist the nations in undertaking institutional reforms to integrate land and water resources management, often in concert with investment lending from multilateral finance institutions or donor organizations. An important lesson from the GEF experience is that science-based and joint fact-finding among participant nations can serve as an important catalytic tool for developing political buy-in. This may be enhanced if official interministerial committees of national and subnational governments are involved in the joint institutions, instead of developing a supranational international organization to do the work for the countries. The GEF has stressed the development of institutional structures for land and water-related policy reforms including water rights, water allocation systems, land tenure reforms, pricing policy reforms, and creation of basin management organizations (Duda, 2003).

The development of institutional frameworks for the management of transboundary water resources has received considerable attention in the international literature. For instance, Kliot *et al.* (2001) present a comparative analysis of institutions in nine international river basins divided according to their level of cooperation and commitment in three categories: the highly committed (Colorado, Niger, Rio Grande and Senegal); the least cooperative (Ganges-Brahmaputra and Indus); and the intermediate level of cooperation (Danube, Elbe, and Mekong). Very few of the examined institutions corresponded to the theoretically ideal model of institutions for management of water resources, namely, a basin-wide multipurpose institution that treats the whole basin as one unit and integrates all riparians in an equitable manner (see section "River Basin Level"). The institutions that worked better in the examples above were those able to contend with overt conflict over the use of resources.

National Level

Looking at the national level, Hannam (2003) has developed a methodology to identify and evaluate the features of the legal and other elements of the institutional framework for the management of water and land, and applied it to four countries in the Asian region (Bangladesh, Laos, Philippines, and China). In this methodology, the capacity of a legal/institutional framework is determined by the number and type of essential legal and institutional elements present in a legal instrument in a format that enables the key issues of the sustainable use of water and land to be identified, and with the legal, administrative, and technical capability in the particular instrument to take some form of effective action. Most primary water and land management issues are multifactorial. They include a sociological, a legal, and a technical component. Therefore, generally, more than one piece of environmental legislation will be

needed for a particular nation to manage effectively individual issues.

Essential elements integrating land and water that should be present are shown in Table 1.

The general framework includes international treaties and other agreements, and national legislation. In summary, the following areas of national environmental law are applicable (see Table 2).

The methodology proposed by Hannam identifies the primary water and land management issues in a region, the operational environment, and the policy instruments at several levels. These elements are then analyzed to see if they had the standard essential elements integrating land and water in order to determine their capacity to achieve sustainable land and water management.

A critical issue at the level of national integration is the problem of interplay between policy instruments in different sectors. For instance, Wilchens (2003) points out that most of the contributions of water resources professionals to policy discussions regarding agricultural productivity are focused on increasing the output generated with limited water supplies, either at the field level or throughout a river basin. However, policy discussions can be enhanced by placing greater emphasis on the roles of nonwater inputs and resource constraints in farm-level production and marketing decisions. These could include policies that modify farm-level input and output prices directly; international trade policies; and policies that modify key institutions, such as land tenure and the sources of investment funds. Most importantly, agricultural polices have traditionally driven the need for large dams and water transfers. The construction of these expensive water systems has not always taken into account the hydrological limitations, or the impacts on environment and society (WCD, 2000; Getches, 2003). Sometimes cross-sectoral linkages are prevented by the set of beliefs prevalent in the institutional environment. One sector where policies have traditionally ignored hydrological evidence of negative impacts is forestry. Deeply engrained beliefs on the positive links of forest and water are still evident in most of the forestry policies in the world (e.g. Calder, 1999; Calder *et al.*, 2004). Saberwall (1997) has studied the historical origin of these myths and their influence on current Indian forestry policy. Another sector that has been particularly reluctant to regulate its impact on the water environment is mining. In spite of the well-documented links between mining and water (Younger *et al.*, 2002), the economic and strategic importance of the mining industry has made governments very reluctant to intervene in this sector. The global mining industry is now fully aware of the need to implement water strategies, but their application in developing countries is still deficient (MMSD, 2002). One limitation is the lack of awareness of policy-makers of the links between this particular industrial sector and water. Even in an advanced environmental regulatory system like the European Union (EU), it has taken a succession of mining disasters with high public impact (Aznalcóllar in 1998 and Baia Mare in 2000) to enact specific environmental regulation for the extractive industry. However, the chosen policy instrument has been waste legislation, with a limited coverage of mine water issues (Amezaga and Kroll, 2004). In conservation policy, the management of wetlands is particularly dependent on land and water integration. Most of the conservation approaches are limited to specific protected areas with a high local level of protection; but wetlands are connected physically and socially with processes occurring in a much wider territory. Changes on water quantity and quality generated by urban, agricultural, and industrial development can be critical for the survival of protected areas (Amezaga and Santamaría, 2000). Particularly relevant in the problem of interplay is the policy gap between water management and land use and development planning (Newson, 1997). Urban development, use of agricultural land and forestry, location of industry, and demarcation of protected areas are all determined by the planning system. Frequently, planning

Table 1 Essential elements integrating land and water according to Hannam (2003)

General intent	Education
Jurisdiction	Research and investigation
Responsibility	Community participation
Goals and objectives	Water and land planning
Definitions	Water and land management
Duty of care	Financing
Hierarchy of responsibility	Enforcement
Institutional (administration)	Dispute resolution
Policy	

Table 2 Areas of national law for the management of land and water (Hannam, 2003)

Constitutional law	Mining law
Environmental planning law	Indigenous people's and customary law
Pollution control law	Agricultural land-use law
Forestry law	Agricultural reform
Plantation and reafforestation law	Protected area law
Soil conservation law	Protection of the marine environment
Water conservation law	Land administration and tenure law
Water use law	Law for women's rights, poverty alleviation, and financial management
Environmental protection law	Criminal law and law courts

is completely independent of water management and does not take into account the impact of land-use decisions on the water environment.

In general, and most importantly in developing countries, there are two important issues that need to be developed to improve the integration of land and water management frameworks (Hannam, 2003):

- Basic human needs and rights associated with water and land.
- Legislative/institutional systems to benefit disadvantaged people (the minorities, and poverty-stricken) and improve livelihoods.

River-basin Level

The most important planning and management unit for the integration of land and water is the river basin (also referred to with similar meanings as watershed or catchment) (Newson, 1997; Falkenmark *et al.*, 1999). The river basin represents a hydrological unit that integrates land and water relationships. The challenge is to achieve a similar level of integration in the social, economic, legal, and political relationships affecting land and water. These relationships are of two types: intrabasin, including upstream-downstream relations and conflicts between water users; and the interbasin relations which represent local, regional, and national administrative levels. Ideally, planning and decision making in a river basin or management unit should be placed in an institutional system in which all components are related. However, the mismatch between river basin and land-use administrative units presents a difficult challenge.

Jaspers (2003) has reviewed the institutional arrangements necessary for integrated river basin management with a comparative assessment of the situation in Zimbabwe, South Africa, Tanzania, Turkey, Indonesia, France, and The Netherlands. The key basic institutional elements required are:

- the functioning of a platform for stakeholders involved in decision making,
- water resources management on hydrological boundaries,
- an organizational setup in river basin and subbasin authorities with their respective bylaws to incorporate decision making at the lowest appropriate level,
- a planning system oriented at the production of integrated river-basin plans,
- the introduction of a system of water pricing and cost recovery.

Tasks and competencies of river-basin organizations may differ substantially from country to country; and the distribution of tasks between basin and subbasin organizations will represent a variety of strategic and operational functions. A key function of river-basin organizations is the development of plans setting out a common vision for the river to influence private and public sector initiatives. These river-basin plans should include specific evaluations of land-use options within the river basin.

The Murray–Darling Basin in Australia is frequently presented as a paradigmatic example of a river-basin management institution (Falkenmark *et al.*, 1999) with strong coordination of governments and communities. The basin is an area of 1 000 000 km^2 with 3700 km of major rivers traversing four independent states. Each state is responsible for the management of its environmental resources. The basin is also Australia's main agricultural area, with 75% of the country's irrigated land. From the mid-1960s, governments and communities in the downstream segment were concerned about deteriorating water quality because of salinity. Meanwhile, upstream communities were calling for action to control shallow water tables that were causing waterlogging and salination. Changes in the institutional setup with the establishment of the Murray–Darling Basin Ministerial Council to promote effective planning and management for the equitable, efficient and sustainable use of the water, land, and environmental resources allowed the development of integrated solutions to these problems. Several institutional lessons have been drawn from this experience:

- the need for government leadership involving policymakers at the higher level and trade-offs of sovereignty rights;
- the need for community leadership committed to developing and implementing action plans;
- the need for technical knowledge to provide a strong knowledge base of the causes, effects, and impacts of the various land and water management options;
- the use of market instruments to ensure that the cost of resource exploitation is included in day-to-day decision making.

The Water Framework Directive (WFD) of the EU is a remarkable attempt to introduce integrated river-basin planning and management at a continental level (EC, 2000). All countries of the EU had to adopt this Directive in their national legislation by 2003 and create river-basin administrations, which will produce river-basin plans. The river-basin plans will have to take into account all the impacts and pressures from human activities on the water environment and develop a program of measures to improve its condition. The objective is to achieve good surface and groundwater status in all European river basins by 2015. But the WFD is also an excellent example of the difficulties to integrate land and water management. A good deal of the necessary measures in a river-basin plan, and in particular, those related to flooding and diffusion control, are intrinsically linked to land use. However, the Directive does not give direct powers to intervene on land uses. The

Treaty of the EU, on which all European law is based, distinguishes clearly between legislation dealing with water quality and legislation dealing with water quantity and land use (Krämmer, 1998). Water quantity and land use are considered Member State issues and can only be legislated at the EU level by unanimous decisions, which is why the EU has only adopted guidance documents on land use planning and not binding legislation. So although the WFD assumes the need for integrated land and water management, it is only the Member States that can make it legally binding in their own legislation.

Institutional inertia, partly explained by the high transactional cost of institutional reform and partly by a reluctance to tie development planning to compulsory environmental objectives, has meant that most of the EU countries have not yet introduced this legally binding link in their national legislations (2005). An interesting example is the United Kingdom, where England and Scotland have different legal systems. While England has transposed the WFD with minimal legislation and only compulsory consultation between water and land use planners, Scotland has approved primary legislation making the WFD plans legally binding for planners. Germany (Moss, 2003) has also followed the path of minimizing institutional reforms. Here the challenge is even greater because water management in Germany has traditionally followed political boundaries and not catchment boundaries. So river-basin administration is a relatively weak institution compared with local and State governments within the German federal system. By contrast, The Netherlands provides a good example of integration between environmental planning and water resources planning (Jaspers, 2003). The Netherlands is a very developed, small country with a high density of population. In order to deal with the intensive pressures on land use, the country has developed a sophisticated planning system where separate plans allocate guidelines or tasks to one another, and every plan indicates how issues earmarked by the other plan are dealt with. Every four years plans are revised in alternating sequence.

The usefulness of the river-basin administration in developing countries has been questioned because of the high transaction cost of institutional building in those conditions (Shah, 2005). However, more and more countries are trying to implement it. This is partly due to donor's pressure, who see it as best practice. Thus, South Africa has introduced via their progressive National Water Act (1998), the creation of Catchment Management Agencies for the management of water resources (Thompson *et al.*, 2001). India has also seen the emergence of some weak river-basin organizations. The Indian National Water Policy (1987) states that water resource planning should be done with reference to a hydrological unit such as a basin or a subbasin. However, the effective implementation of this policy is hampered by the fragmentation of the water sector due to constitutional constraints and the lack of administrative capacity. Iyer (2003) argues that the idea of basin planning and management, which seems eminently sound, contains within itself the seeds of centralization and gigantism. Subject to that caution, it is still necessary, and indeed logical, to take a comprehensive view of a river system as a whole.

Upstream-downstream Linkages

An integral subset of linkages within a river basin is the upstream-downstream relationship. In the year 2000, the Food and Agriculture Organization (FAO) of the United Nations Land and Water Development Division involved a number of international experts in the definition of land and water linkages in rural watersheds through an electronic conference. In a discussion paper prepared for the 2000 FAO conference, Kiersch (FAO, 2002) reviewed the instruments and mechanisms available for upstream-downstream linkages:

- regulatory instruments (command and control measures) widely used in developed countries to protect water resources from agricultural land-use practices;
- economic instruments to distribute benefits and costs resulting from land use impacts on water resources, including direct or indirect subsidies, taxes, and transferable property or use rights for land, water, and emissions;
- education and awareness building to encourage farmers to switch to less polluting practices, usually coupled with an incentive program to reduce pollution risks, and to improve the economic performance of the farm;
- market support, improving access of upstream farmers to downstream markets within the framework of a watershed agreement;
- organizational development for a successful implementation of instruments establishing linkages between upstream land users and downstream water users. Organizations can provide a forum of exchange between upstream and downstream stakeholders and a forum to consolidate the interests and opinions of scattered groups of users such as upstream farmers;
- participatory approaches. Usually participatory watershed planning and management projects focus on the community level and encompass only very small land units.

Constraints for the implementation of benefit-sharing mechanisms range from the need to find a compromise among conflicting interests over the distribution of cost and benefits to institutional challenges and up-front costs of engaging stakeholders in initial planning stages. Constraints include weak or nonexistent property rights that can provide some assurance to the people that they can reap the benefits, poverty, and a lack of perception that there is a

problem to begin with. At the most general level, there is often a conflict between objectives of sustaining livelihoods in the short term, and protection of resources. For benefit-sharing arrangements to be successful, stakeholders must at least have a common understanding and agreement about the nature of the expected impact, the approximate magnitude of cost and benefits, and the areas of uncertainty (*see* **Chapter 193, Markets for Watershed Services, Volume 5**).

A remarkable example of successful upstream/downstream collaboration is the 1997 Memorandum of Agreement (MOA), which protects the water supply of New York in the United States (Pires, 2004). This document outlining a watershed management plan was signed by the City and State of NewYork, the EPA, 73 local municipalities and eight counties in the watersheds, and five environmental organizations. The MOA contains both structural and nonstructural strategies for water quality protection. Some of the nonstructural mechanisms are directly related to land use policy. The most important ones are land acquisition, conservation easements, setbacks and buffer zones, and land trusts. Perhaps this is a best practice example of the way forward for ILWRM.

CONCLUSIONS

The institutional dimension is critical for the implementation of ILWRM approaches. Institutional development to support these approaches must take into account both institutional environments and institutional structures. While institutional constraints such as cross-sectoral coordination and the conflict between different land-based administrative structures are still common, there are an increasing number of instruments applicable to this problem at the global, regional, national, and river-basin level. Challenges remain; primary to these are ensuring basic human needs and rights associated with water and land, and establishing institutional systems to benefit disadvantaged people and improve livelihoods.

PART 17

Climate Change

195: Acceleration of the Global Hydrologic Cycle

JOHN ROADS[1], ROBERT OGLESBY[2], FORREST HOFFMAN[3] AND FRANKLIN ROBERTSON[2]

[1]*Scripps Institution of Oceanography, UCSD La Jolla, CA, US*
[2]*NASA/Marshall Space Flight Center, Huntsville, AL, US*
[3]*Oak Ridge National Laboratory, Oak Ridge, TN, US*

The global hydrologic cycle, which can be conceptually described as evaporation of water vapor from the ocean, transport of water vapor by atmospheric winds to land regions, condensation, and precipitation of atmospheric water back to the surface, and subsequent transport, by streams, of this water back to the ocean, may intensify or accelerate in the future, as the planet warms owing to an increasing greenhouse resulting from increasing emissions of anthropogenic gases. As in many previous studies, increased hydrologic fluxes are found in a 100-year integration of the NCAR Coupled Climate System Model when forced with increasing CO_2 levels. That is, as the earth warms, the evaporation increases, which not only increases the precipitation rate, but also the subsequent moisture convergence to land regions. However, if this increase in the cycling rate by various processes is measured with respect to the changing atmospheric and surface water reservoirs, then the atmospheric hydrologic cycle may appear to be actually deaccelerating since the atmospheric reservoir in this model is influenced more by the temperature changes than the actual transformation processes are. By contrast the land surface water reservoirs are less affected and thus there does appear to be an accelerated land surface hydrologic cycle, especially at high latitudes, and a coupled land-atmosphere acceleration, at least over land regions. There are also important regional differences.

INTRODUCTION

From various modeling studies as well as increasing observational evidence, we know that globally rising CO_2 and other trace gas amounts, resulting from globally increasing population and economic growth, are expected to increase the atmospheric "greenhouse" effect and thus cause an increase in the global surface temperature. The atmospheric "greenhouse" effect, which is necessary for sustaining life on the earth, results from these anthropogenic gases (and water vapor) being relatively transparent to solar radiation but relatively opaque to outgoing planetary thermal radiation; in order to maintain a radiative balance between outgoing planetary radiation and incoming radiation, the surface temperature is therefore much higher than the effective outgoing planetary emission temperature. As the anthropogenic greenhouse gases increase, the atmospheric opacity to outgoing radiation increases still further, thus requiring an increased lower atmosphere temperature as part of the planetary radiative equilibrium. Along with this lower atmosphere temperature increase, modeling studies have also suggested that global evaporation and precipitation will increase.

The water vapor capacity of the atmosphere increases exponentially with increasing temperature, according to the well-known Clausius–Clapeyron relationship. Since evaporation depends on the difference of water vapor at the surface from the relatively drier air aloft, then, other things being equal, higher temperatures tend to result in increased water vapor differences between the atmosphere and surface, which then results in increased evaporation. Indeed, it is generally true that global evaporation reaches a maximum over the ocean where the sea-surface temperature is highest. It is also generally true that evaporation is much greater during the summer than the winter and much greater during the daytime than the nighttime.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Evaporated water vapor is transported by atmospheric winds to other regions, leading to increased convergence of this water vapor mass flux in various precipitating regions. Since the atmosphere can only hold so much water vapor, depending upon the local temperature and pressure, excess water vapor condenses into cloud particles, which grow into raindrops through nucleation, condensation, coalescence, and finally by accretion into large particles, which fall as precipitation back to the surface. When the precipitation falls over land, it wets the soil (immediately or later depending on whether it first falls as rain or snow) and ultimately this surface water flows into streams, which discharge back to the ocean. In a climatological steady state, there is as much atmospheric water converged over land regions as is discharged back to the ocean.

An evaporation increase in a world with increased greenhouse gases will, of course, not happen everywhere. For example, current snowmelt-dominated regions tend to release water in great abundance as the seasons transition from winter to summer. If snow is no longer present owing to higher wintertime temperatures, or the summertime surface has desiccated, then evaporation (as well as streamflow and perhaps precipitation) may decrease in these regions as the global temperature increases. The surface water availability for a specific region is the complicating factor. Over the subtropical deserts the surface water availability is minimal and little evaporation occurs in these regions despite them being some of the hottest areas of the planet. In fact, just as one of the main heating mechanisms for the atmosphere comes from the latent heat released when vapor changes into cloud water, so too is evaporation one of the principle mechanisms for cooling the surface, through the latent heat needed to change liquid and solid water to its gaseous vapor phase.

Part of the postulated hydrologic cycle change thus depends upon how the local surface water reservoir is changed with increased temperature. In fact, global change modeling studies indicate there will be regions and times of increased drought as well as regions and times of increased precipitation, moisture convergence, and evaporation (see e.g. Han and Roads, 2004). Part of the regional hydroclimatological change is also related to how the regional atmospheric moisture, surface vegetation, surface wind, atmospheric planetary boundary-layer stability, and so on change.

The time distribution of hydrologic processes may also change. For example, increased tropical sea-surface temperatures are usually associated with more intense and deep convection. Actually, there are many places where precipitation is not only greater during the summer, but is more likely to form from convective activity. However, periods of intense convection are usually followed by even longer times of clear weather and quiescent conditions and the overall rate of the entire cycle may actually be lower. Thus besides amount, the rate at which hydrologic processes occur could also change as the global temperature increases.

Understanding and predicting future characteristics about these hydrologic processes and reservoirs are a primary motivation for the launch of earth observing satellites, development of extensive surface hydrometeorological networks, and establishment of large programs like the World Climate Research Programme's Global Water and Energy-cycle Experiment, which are designed to encourage and coordinate the multiple activities needed to observe, simulate, and predict variations in the global hydrologic cycle. Remote sensing from space has been an important reason for expanding areal coverage of conventional point measurements to cover historically data poor regions such as the global ocean and unpopulated areas.

The global hydrologic cycle is certainly not adequately observed (see e.g. Roads *et al.*, 2003). For example, evaporation is really only measured in a few land regions at specialized instrument sites, using, for example, eddy correlation techniques. Moisture convergence can just barely be determined from measurement of wind and humidity and even then there is some question as to how accurate these calculations are from the scattered measurements. Soil moisture is also only measured at a few land sites. Even over the ocean, freshwater amounts are unknown since we do not really have a good analysis of large-scale ocean salinity. Runoff is known at gauged basins but there are many ungauged sites within even these basins and besides, it is not altogether clear what the contribution of anthropogenic diversions and subsurface flows are to the cycle in many heavily managed regions. Precipitation is probably the most well known and observed hydrologic variable but there are also well-known problems involved with under catch, lack of gauge measurements over the ocean, and so on. Improving observations of the hydrologic cycle are the key to developing better models, which will ultimately be used to simulate and predict the global hydrologic cycle. Despite the lack of long-term observations, it may at least be possible to estimate precipitation variations as a guide for evaluating corresponding model simulations.

One of the most comprehensive models used to simulate and predict the global hydrologic cycle is a coupled general circulation model. General circulations models are based upon the fundamental laws governing conservation of energy and mass as approximated by large-scale finite differences or, equivalently, severely truncated spherical harmonics. These large-scale models also include parameterizations of physical processes, which are large-scale approximations to nature's small-scale physical processes. Although the models are still imperfect, they are being continually improved by comparing available simulations to observations. Many of the early atmosphere only

simulations used observed sea-surface temperatures as a driving mechanism and many studies have focused in on understanding the response of the atmosphere to changed SSTs. In that regard, it should be mentioned that the Hadley Centre has now produced monthly SSTs for the period 1900–2000, which may be useful for developing preliminary estimates of "observed" hydrologic variables. Many of the early ocean only simulations used atmospheric fluxes as the driving mechanism and many studies have focused in on understanding the response of the ocean to different fluxes. Coupled atmosphere-ocean studies are now beginning to be used as the major tool to predict future variations. For these coupled experiments, the only external forcing is radiative, which depends upon predictions of what this composition might be like given projected population and economic growth.

The hydrologic cycle from such a coupled simulation forced by projected increases in greenhouse gases is described here. In particular, starting from initial conditions relevant to the present day, a scenario that assumes a linear rate of increase of CO_2 to an almost doubled amount in 99 years (371–710 ppm) was used here. We examined mean characteristics of the hydrologic cycle during this "doubling", including how much water is in the atmosphere and subsurface, how much water is evaporated and precipitated, and how much water is converged into an area and then subsequently runs off to the ocean and how these processed changed under this scenario. In addition, we were interested in the cycling rate at which this occurred on average and how these rates might change in the future. Section PCM describes the model used for these calculations. Section "PCM hydrologic cycle" describes hydrologic characteristics and Section "Cycling Rate" describes the estimated rates at which these processes occur. Conclusions are provided in Section "Summary". Basically, the globally averaged precipitation and evaporation did increase in the model's increased greenhouse world. However, cycling rates, measured by the rate at which atmospheric processes occurred in comparison to the available atmospheric reservoir actually slowed down in the atmosphere, because of the relative increase in the atmospheric water vapor reservoir. Nonetheless, because of the dominance of surface water changes over land regions, the overall cycling rate did accelerate over land regions.

PCM

The coupled model used here – the Parallel Climate Model (PCM) – makes use of the National Center for Atmospheric Research (NCAR) Community Climate Model (CCM3), the NCAR Land Surface Model (LSM; which is a modern model incorporating vegetation effects like wilting and transpiration), the Department of Energy (DOE) Los Alamos National Laboratory Parallel Ocean Program (POP), the Naval Postgraduate School sea-ice model, and a distributed flux coupler. The CCM3 is a spectral dynamics model, which uses a T42 resolution (approximately 2.8°) with 18 hybrid levels in the vertical. The LSM simulates the biogeophysics of prescribed vegetation types and hydraulic and thermal properties of 12 soil types. The POP uses a grid with a displaced North Pole at an average of 2.3° latitude and longitude in the midlatitudes, with increased latitudinal resolution near the equator of approximately 1.2°. The sea-ice component predicts the evolution of ice thickness, ice concentration, velocity, snow thickness, and surface temperature; and it uses an elastic-viscous-plastic (EVP) ice rheology dynamics. The distributed flux coupler, originally developed for the NCAR Climate System Model (CSM) connects the PCM components and facilities exchange of flux and state variables among the component models (Washington *et al.*, 2000).

A series of climate change experiments were made with PCM; basic descriptions are given in Dai *et al.* (2001a; 2001b). Briefly, a set of historical runs was made starting in 1870 and running to the present. The model components were each spun up separately, and then run in fully coupled mode for 40 years without any anthropogenic forcing, before the first model year of analysis (1870). As described in Dai *et al.* (2001a), the model overall performed quite well in simulating the observed climate over the past 130 years, with the major deficiency being an inability to properly simulate the warming that occurred between the 1920s and the 1940s. This is likely due to the absence of changes in external solar forcing in the model simulation. On the other hand, the model captured remarkably well the rapid warming since the 1970s, which is thought to be due to the rise in anthropogenic greenhouse gases, which are included in the base model run.

A series of runs were then made projecting into the future through the end of the twenty-first century using various postulated greenhouse gas scenarios. Of particular interest for this project, an ensemble of 99-year Business-As-Usual (BAU) scenario runs beginning in the year 2000 were run on the IBM RS/6000 SP parallel computers at Oak Ridge National Laboratory (Hoffman *et al.*, 2004). These simulations used projected atmospheric increases in CO_2 and other trace gases (Dai, 2001a) comparable to the mean of all the Intergovernmental Panel on Climate Change (IPCC) Special Report on Emissions Scenarios (SRES) scenarios (Nakicenovic and Swart, 2000). CO_2 levels increased linearly from ~371 ppm in 2000 to 710 ppm in 2100. Owing to various reasons, only one of these PCM runs had a reasonably complete set of saved hydrometeorological fields and this run was analyzed here. Given the long period of the individual runs, additional ensemble members would have been nice but were not critical for this analysis of gross average properties. It should be noted, however, that moisture convergence was not available and

output runoff appeared to be erroneous. These fields were therefore deduced from the diagnostic P-E. This assumption is certainly more dubious for runoff, because surface water variations can be important, at least on seasonal timescales but for annual and longer time series the approximation is at least more reasonable.

Figure 1 shows the average surface temperature and the temperature differences (last 30 years minus the first 30 years) caused by the increase in greenhouse gases in this model. The temperature increase is greatest at high latitudes, due in part to the snowmelt and reduction in surface albedo, which also makes a major contribution. That is, the reduction in albedo causes increased solar radiation to be absorbed by the earth, which must therefore balance this increased incoming radiation with increased outgoing radiation via increased surface temperature. On the average the ocean temperatures do increase although the relative increase in the land temperatures with respect to the ocean temperatures is much greater. Of disquieting interest is the slight decrease in the North Atlantic, which is a region of deep-water formation. Presumably the ocean dynamics is acting to reduce the temperature in this region. However, as shown in Table 1, on the average, the ocean was still relatively warmer than the colder land. It should be noted here that for this paper, the land mean excluded the permanent ice covered Greenland and Antarctica continents. It should be noted however, that the global mean did include these areas. The time series of land, ocean, and global shows the temperature increase is fairly linear with respect to the linearly increasing greenhouse gases.

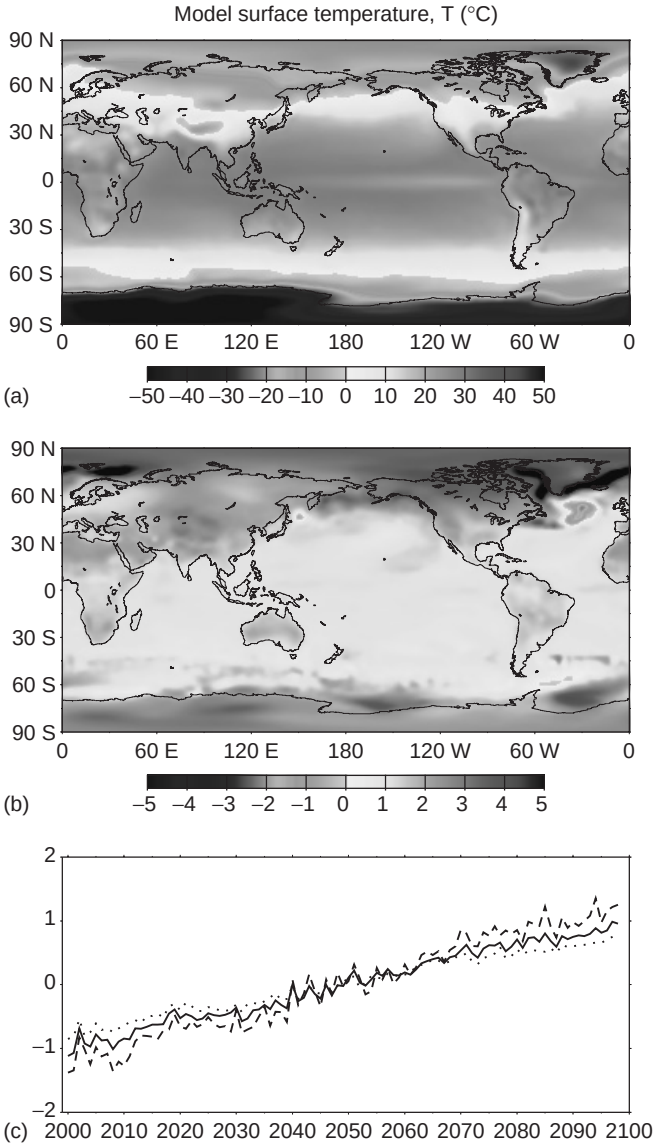

Figure 1 Model surface temperature, T, (C): (a) Mean surface temperature, T, C for the 99-year simulation: (b) difference in the surface temperature, ΔT, C (average of years 69–98 minus average over years 0–29); (c) annual differences from the overall means of the global (solid line), land (dashed line), ocean (dotted line) temperatures for each year of the 99-year simulation. PCM HYDROLOGIC CYCLE

Consider the following atmospheric and surface hydrologic cycle mass conservation equations:

$$\frac{\partial Q}{\partial t} = E + MC - P$$
$$\frac{\partial W}{\partial t} = -E - N + P$$
$$\frac{\partial (Q + W)}{\partial t} = MC - N \qquad (1)$$

Q is the total atmospheric water (usually referred to as total precipitable water and includes water vapor as well as cloud and precipitation water), W is the total surface water (over land this is the soil moisture above the saturated zone plus snow water equivalent), E is the evaporation, MC is the atmospheric moisture convergence, N is the surface runoff, and P the precipitation. Over the ocean, the surface water runoff is actually freshwater transport, which is more similar to the atmospheric moisture convergence, since it is dependent upon ocean currents instead of gravitational drainage. It should also be mentioned that the surface water is not well defined over the ocean; instead a more appropriate variable is salinity, which measures how fresh or saline a particular body of water is. It should be noted that the tendency terms are important on diurnal to daily timescales but at longer timescales (interannual to decadal) become relatively small and the magnitude of the reservoirs (Q and W) are determined by complex

Table 1 Global, land (except Antarctica and Greenland), and ocean means and differences (average of years 69–98 minus average over years 0–29) for T, Q, W, P, E, MC, N, P/Q, P/W, E/Q, E/W, MC/Q, N/W, $MC/(Q+W)$, $N/(Q+W)$. NA means this entry is not available

interactions between the other processes. That is not to say, however, that the tendency terms are negligible; seasonal and interannual variations, which measure the seasonal and interannual imbalances in the other processes, can be quite important, especially for surface water. Finally, please note that the last equation is an expression of mass conservation, which shows that atmospheric moisture convergence must equal the surface divergence or runoff (or ocean freshwater divergence) if the freshwater mass is not to increase or decrease locally, at least on the average.

The global distribution of these hydrometeorological processes in the CSM 99 year average is shown in Figure 2, along with the reservoirs. Note the concentration of the atmospheric hydrologic processes near the tropics, where precipitation, evaporation, moisture convergence, and runoff are large. Again, this geographical distribution is a consequence, but only in part, of the nonlinear Clausius–Clapeyron relation. Note that just adjacent to the tropical regions are the subtropical regions, which exhibit some of the largest evaporation regions (ocean) and some of the smallest evaporation regions (land), again despite having some of the highest global surface temperatures. Water availability at the surface as well as in the atmosphere adjacent to the surface, are just as important as temperature changes. For example, the distribution of individual hydrologic processes and reservoirs is certainly different than the temperature distribution. Precipitation is greatest in the intertropical convergence zones, where convergence is greatest, and least in the subtropical regions, where the divergence is greatest. On the average, water is diverged from the ocean to the land. This land convergence of atmospheric moisture is balanced by the surface runoff, which transports the surface water back to the ocean. The surface water is greatest in the regions of permanent ice cover (Greenland and Antarctica).

Although the qualitative distributions of these processes and reservoirs are reasonably realistic (see e.g. Roads *et al.*, 2002) and illustrate the overall complexity in the hydrologic cycle that goes way beyond simple relations to temperature, there are certainly problems with the simulation. For example, note the double intertropical convergence zone, which is a common model defect.

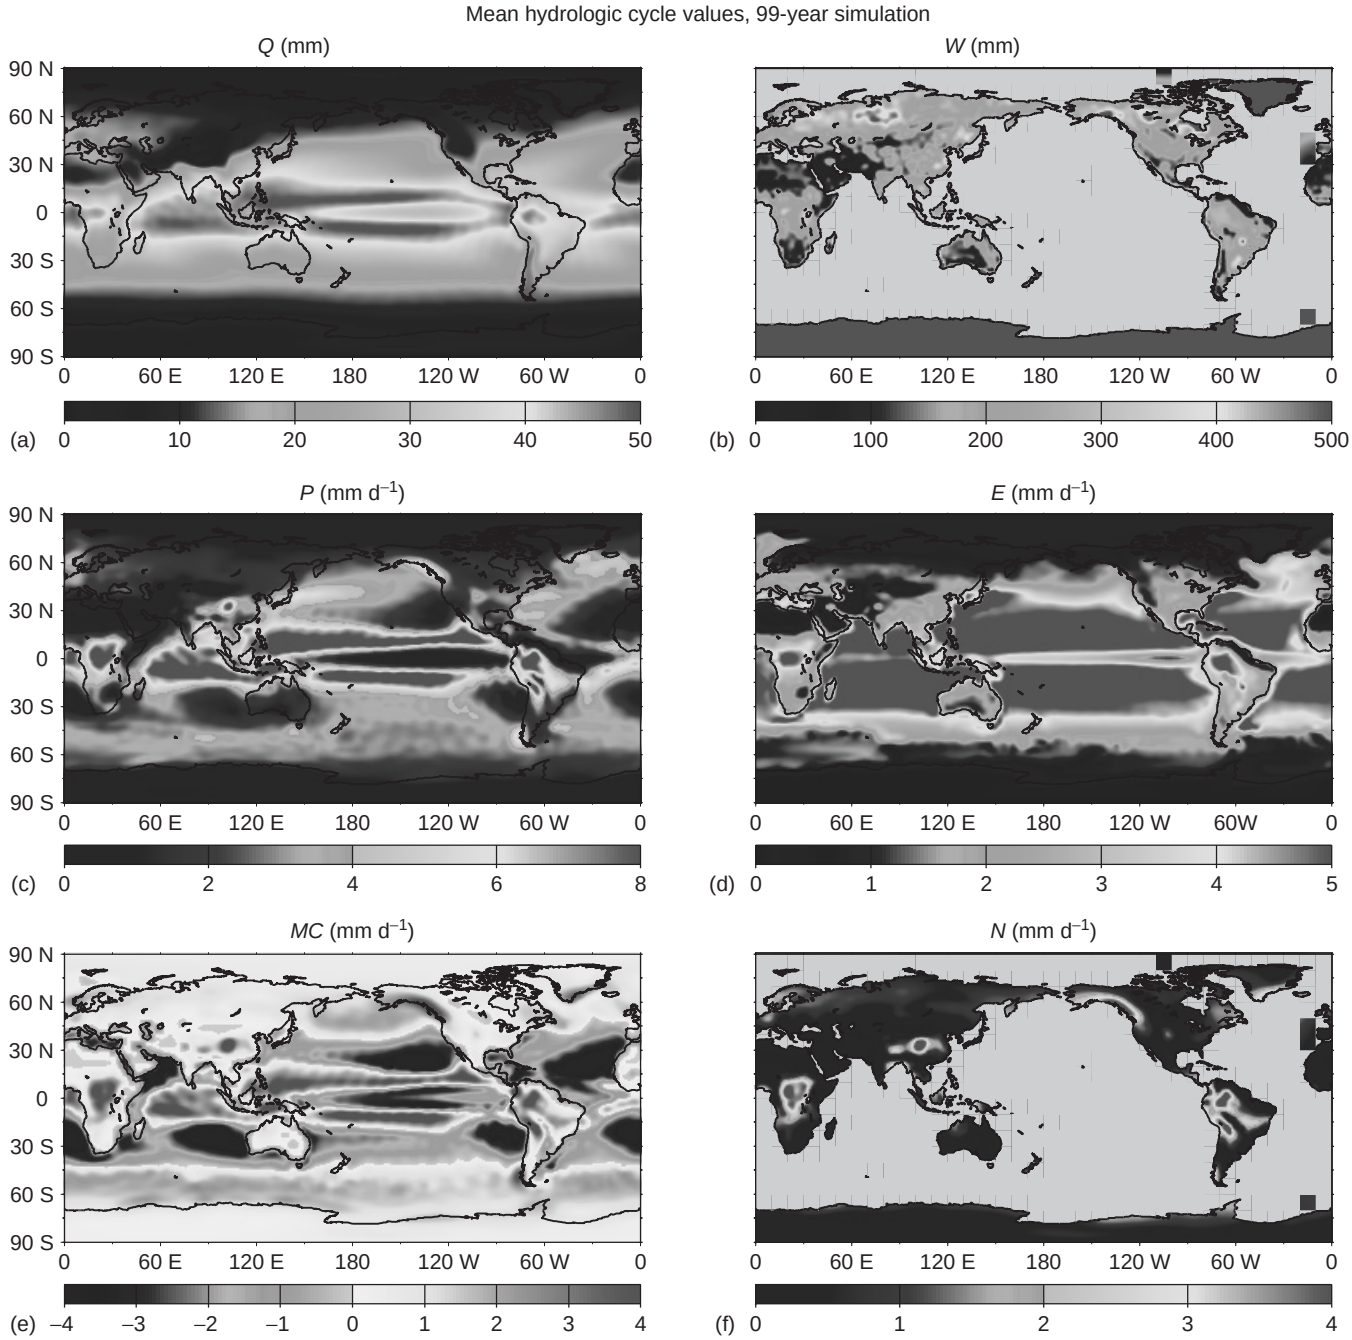

Figure 2 Mean hydrologic cycle values for the 99-year simulation: (a) *Q*, precipitable water, mm; (b) *W*, surface water, mm; (c) *P*, precipitation, mm/day; (d) *E*, evaporation, mm/day; (e) *MC*, moisture convergence, mm/day; (f) *N*, runoff, mm/day. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

There are other subtle defects that reduce our overall confidence in the overall projection, and again, efforts must continue to substantially reduce the uncertainty in the ability of these models to simulate future climate change.

Whether the hydrologic cycle will accelerate in a world with increased greenhouse gases could be defined as a simple difference in these processes. Do evaporation and precipitation increase, and where do these increases occur? How do changes in moisture convergence and runoff contribute to these increases as well as any decreases? How do the atmospheric and surface water reservoirs change? What are the regional differences? Are these regional differences significant? As a measure of the significance of

the changes, the difference of the last 30 year from the first 30-year mean is divided by the estimated standard deviation of 30-year means, which is obtained by finding the standard deviation of annual means and then dividing this value by the square root of 30, which assumes the interannual variations are independent.

As shown in Figure 3, there are certainly many significant differences between these processes at the end of the 99-year run from the beginning of the 99-year run as measured by normalized differences between the last 30 years and the first 30 years. The most significant differences occur in the precipitable water, which increases everywhere, and

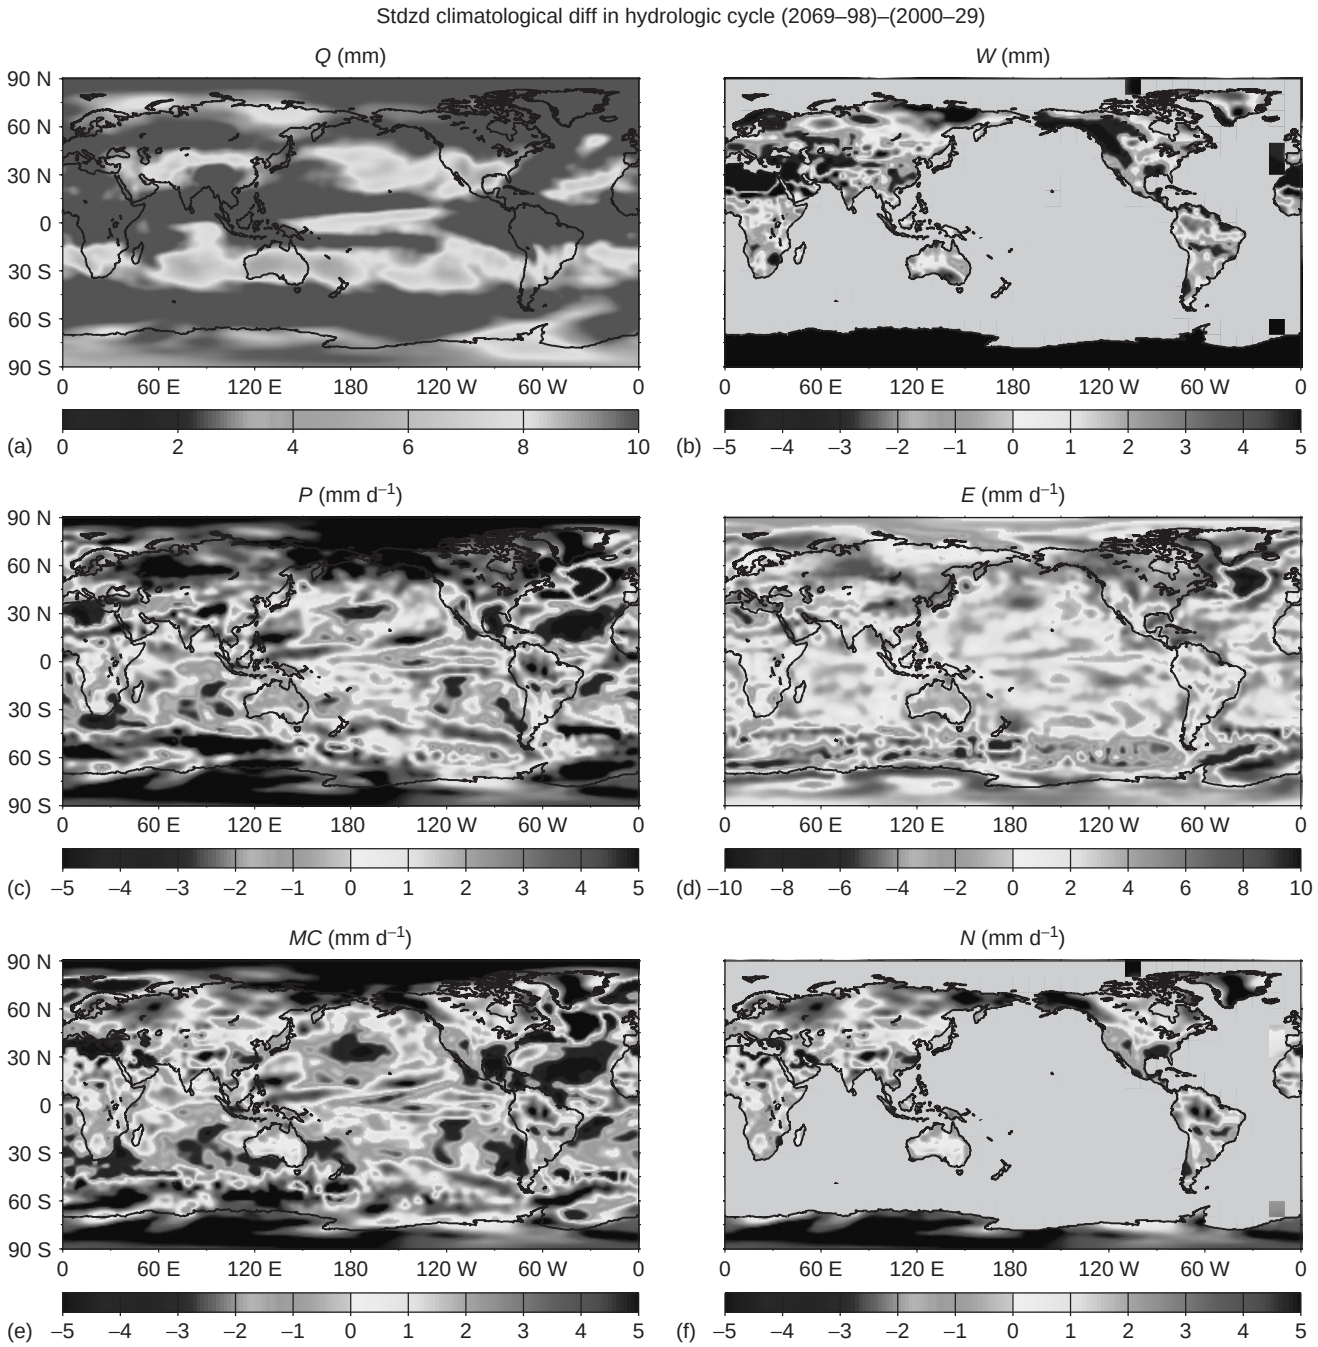

Figure 3 Climatological differences in the hydrologic cycle (average of years 69–98 minus average over years 0–29) divided by estimates of the 30-year mean standard deviation: (a) ΔQ, precipitable water; (b) ΔW, surface water; (c) ΔP, precipitation; (d) ΔE, evaporation; (e) ΔMC, moisture convergence; (f) ΔN, runoff. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

in the evaporation, which increases almost everywhere, except for the North Atlantic and high latitude southern oceans. There are also slight decreases in other regions. Precipitation shows relative increases in high latitudes, excepting the North Atlantic region again, where the evaporation was reduced. The precipitation, however, shows relative decreases in tropical to subtropical latitudes, which is consistent with model simulations covering the twentieth century Kumar *et al.* (2004). Most of the precipitation changes appear to be correlated with the changes in moisture convergence, which on the average show increased convergence in the high latitudes and increased divergence in lower latitudes. Again, there are certainly notable exceptions, including the North Atlantic, where it appears the evaporation changes are more important than the moisture convergence changes. The runoff, which must balance the convergence (and here it does by design), has the same features and perhaps, surprisingly, so does the surface water. Note, for example, the increase in surface water over Antarctica. However, over most tropical and midlatitude land regions the surface water decreases, as was previously shown by Wetherald and Manabe (1999).

Figure 4 shows a time series of the globally averaged, the land averaged, and the ocean averaged differences for these processes. Precipitable water increases linearly by about 2 mm whereas surface water has much stronger variability and overall a slight decrease. Note the gradual increase in global precipitation and evaporation from averages of 3.1 mm day^{-1} to 3.2 mm day^{-1}, which is somewhat smaller than the global value from an ensemble of models forced with +2K and −2K uniform sea-surface temperature changes (Randall *et al.*, 1992). This increase is accompanied by a slight increase in MC over land, along with an increase in runoff, and increased divergence over the ocean. The precipitation variations over land are especially high and have amplified values every 20 years or so, accompanied by shorter period high amplitude variations that may be related to the changes in surface water. These interannual variations deserve further scrutiny, but this is beyond the scope of the present study.

CYCLING RATE

Another measure of the hydrologic cycle acceleration is the cycling rate described previously by Chahine *et al.* (1997; see also Trenberth, 1997, 1998; Roads *et al.*, 1998; Douville *et al.*, 2002; Bosilovich *et al.*, 2004). The cycling rate is a measure of the timescale of the processes, which is obtained here by dividing the first equation by Q, the second by W, and the third by $(Q + W)$:

$$\frac{\partial \ln Q}{\partial t} = \frac{E}{Q} + \frac{MC}{Q} - \frac{P}{Q}$$

$$\frac{\partial \ln W}{\partial t} = -\frac{E}{W} - \frac{N}{W} + \frac{P}{W}$$

$$\frac{\partial \ln(Q + W)}{\partial t} = \frac{MC}{(Q + W)} - \frac{N}{(Q + W)} \qquad (2)$$

Note that the only unit in these equations is an inverse time or rate for the various hydrometeorological processes. These rates are hereafter referred to here as cycling rates (we prefer cycling to the previous recycling designation, which has also been previously used to describe the relative contributions of local evaporation versus transport), since these rates are a measure of how fast the various hydrologic processes occur. So, another measure of whether the hydrologic cycle is accelerating could be related to changes in these cycling rates, which, again, are related to both the change in the individual processes and the changes in the individual reservoirs. Exactly how these rates are calculated may have some influence on their perceived value. For example, instantaneous ratios could be calculated and then averaged, but here only annual means were available and as will be shown, the ratios $[P]/[Q] \approx [P/Q]$. Whether or not significant differences occur when shorter timescales (weather) are considered would be of great interest, but this is also beyond the scope of the present study (and available data).

Figure 5 shows geographical characteristics of the cycling ratio. As shown in Table 1, precipitation and evaporation have overall atmospheric cycling rates (P/Q, E/Q) of. 157 days^{-1} or residence times of 6.6 days, although in snow covered regions, where the precipitable water is small, the residence time can be on the order of 2 days. This is a bit higher than previous estimates (e.g. Roads *et al.*, 1998) in part, because of the excessive precipitation and reduced precipitable water in this model, compared to observations. Evaporation cycling rates are a bit more uniform, although certainly smaller, over subtropical regions, where moisture convergence becomes more important. The cycling rates in the land surface are much smaller, of order 100 days in colder snow covered regions although some regions, such as the tropical land regions, have cycling rates in the surface comparable to atmospheric cycling rates. The overall cycling rates for the total atmospheric and surface mass over the land regions are smaller still, since they are dependent upon atmospheric and surface transport times rather than surface flux and precipitation times.

Figure 6 shows the standardized climatological differences in these cycling rates. For the most part, atmospheric cycling rates calculated from precipitation and evaporation are negative almost everywhere. As shown in Table 1, the average precipitation and evaporation differences are on the order of −0.01 days^{-1}, which is a change in the precipitation cycling times about 6.4 to

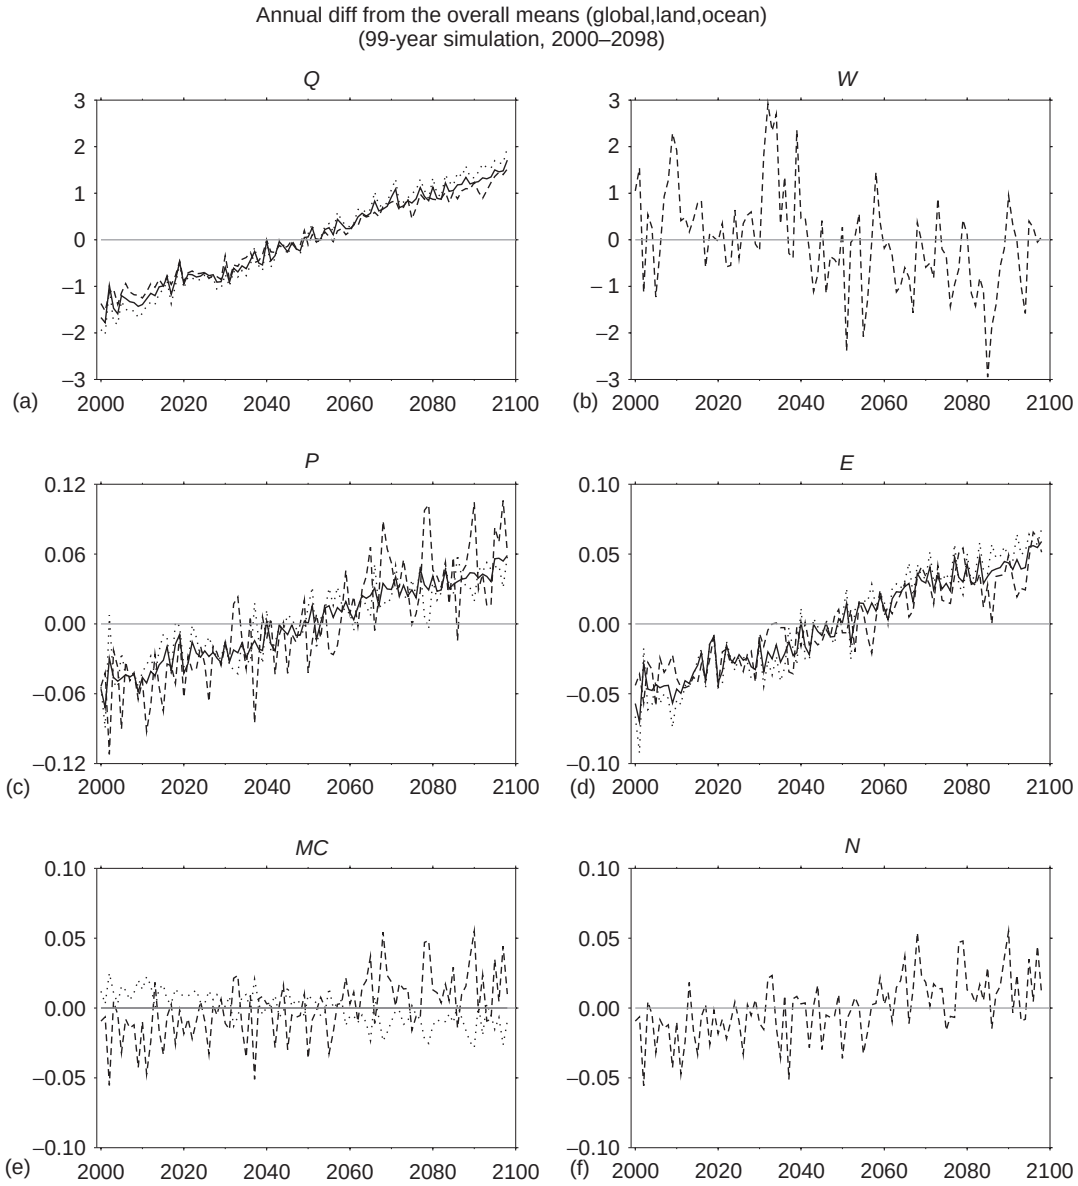

Figure 4 Annual differences from the overall means of the global (solid line), land (dashed line), ocean (dotted line) hydrologic cycle values for each year of the 99-year simulation: (1) ΔQ, precipitable water, mm; (b) ΔW, surface water, mm; (c) ΔP, precipitation, mm/day; (d) ΔE, evaporation, mm/day; (e) ΔMC, moisture convergence, mm/day; (f) ΔN, runoff, mm/day

6.8 days. The cycling rate differences due to moisture convergence are complex, and differences depend not only on changes in moisture convergence but also the precipitable water. Somewhat opposite features occur in the land surface cycling, which as noted previously showed less of an increase in the reservoir (in fact an overall decrease) as the precipitation and evaporation increase. The runoff cycling is related more to the relative increases in runoff in high latitudes and relative decrease in runoff in low latitudes. The overall cycling rate, measured by $MC/(Q + W)$ or $N/(Q + W)$, also shows this high latitude increase and low latitude decrease. A notable exception is the decrease over Antarctica, which as noted previously had a surprisingly substantial increase in the surface water.

Figure 7 shows a time series of the globally averaged cycling rates. Again note that on the average, the atmospheric cycling rate tends to decrease, despite the increasing amount of precipitation, evaporation, while the land cycling rate tends to increase. These changes are related to

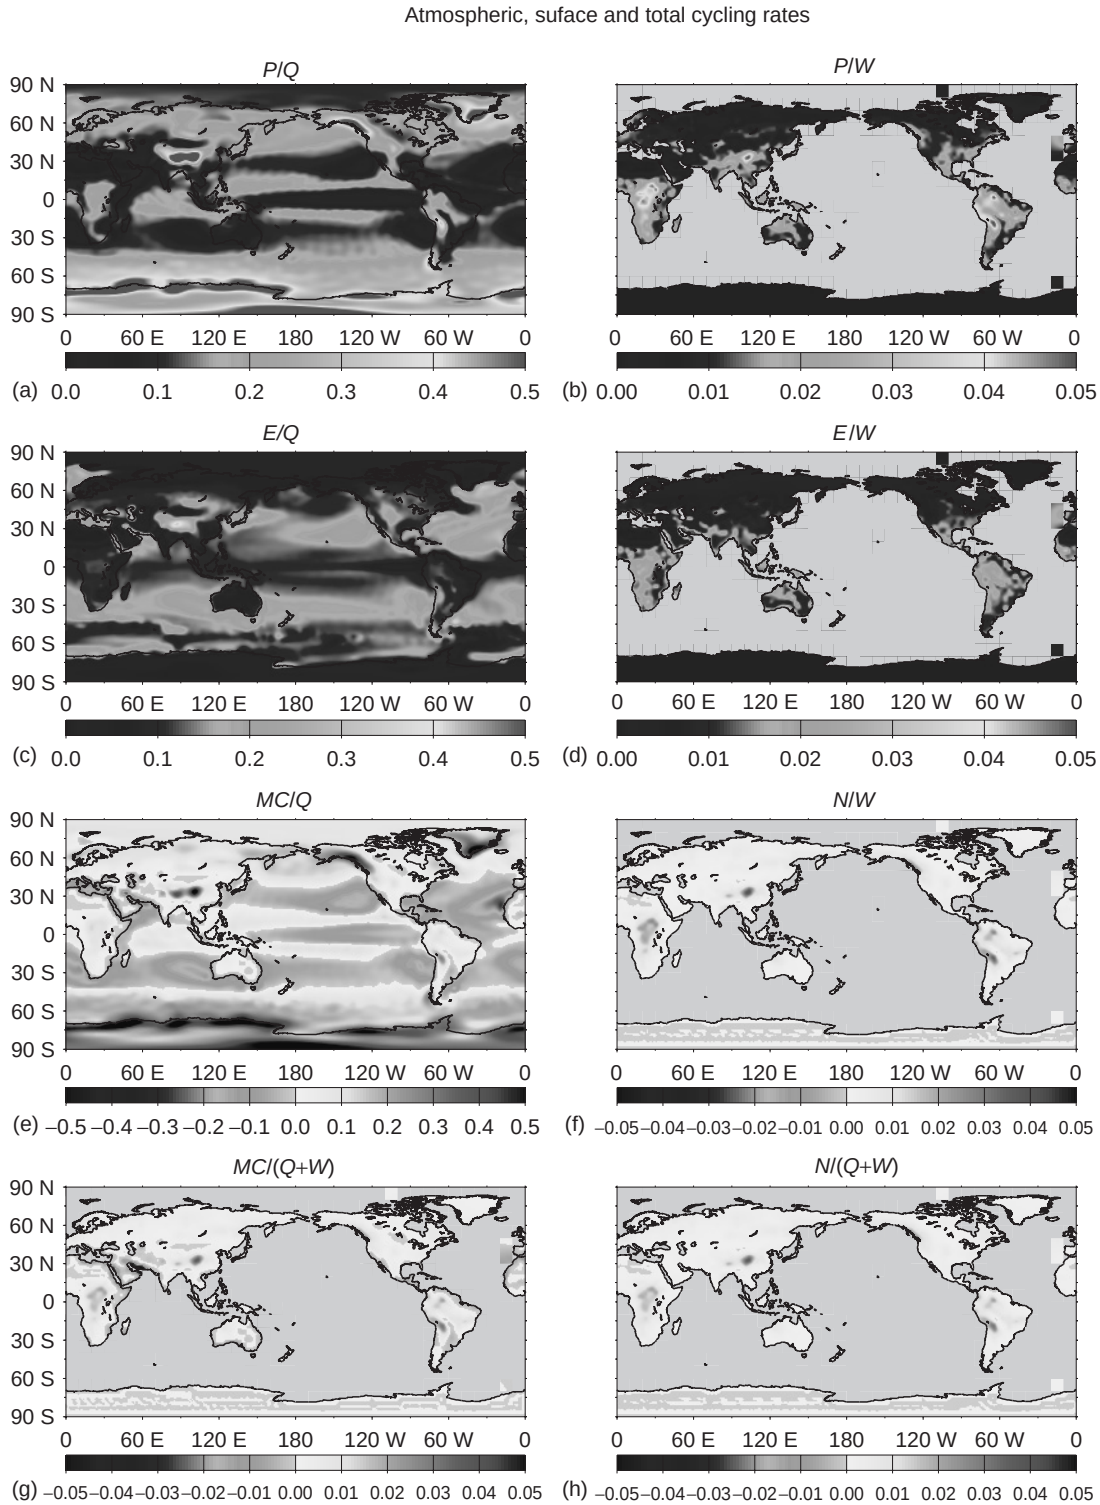

Figure 5 Atmospheric, surface, and total cycling rates, d^{-1}: (a) P/Q; (b) P/W; (c) E/Q; (d) E/W; (e) MC/Q; (f) N/W; (g) $MC/(Q+W)$; (h) $N/(Q+W)$. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

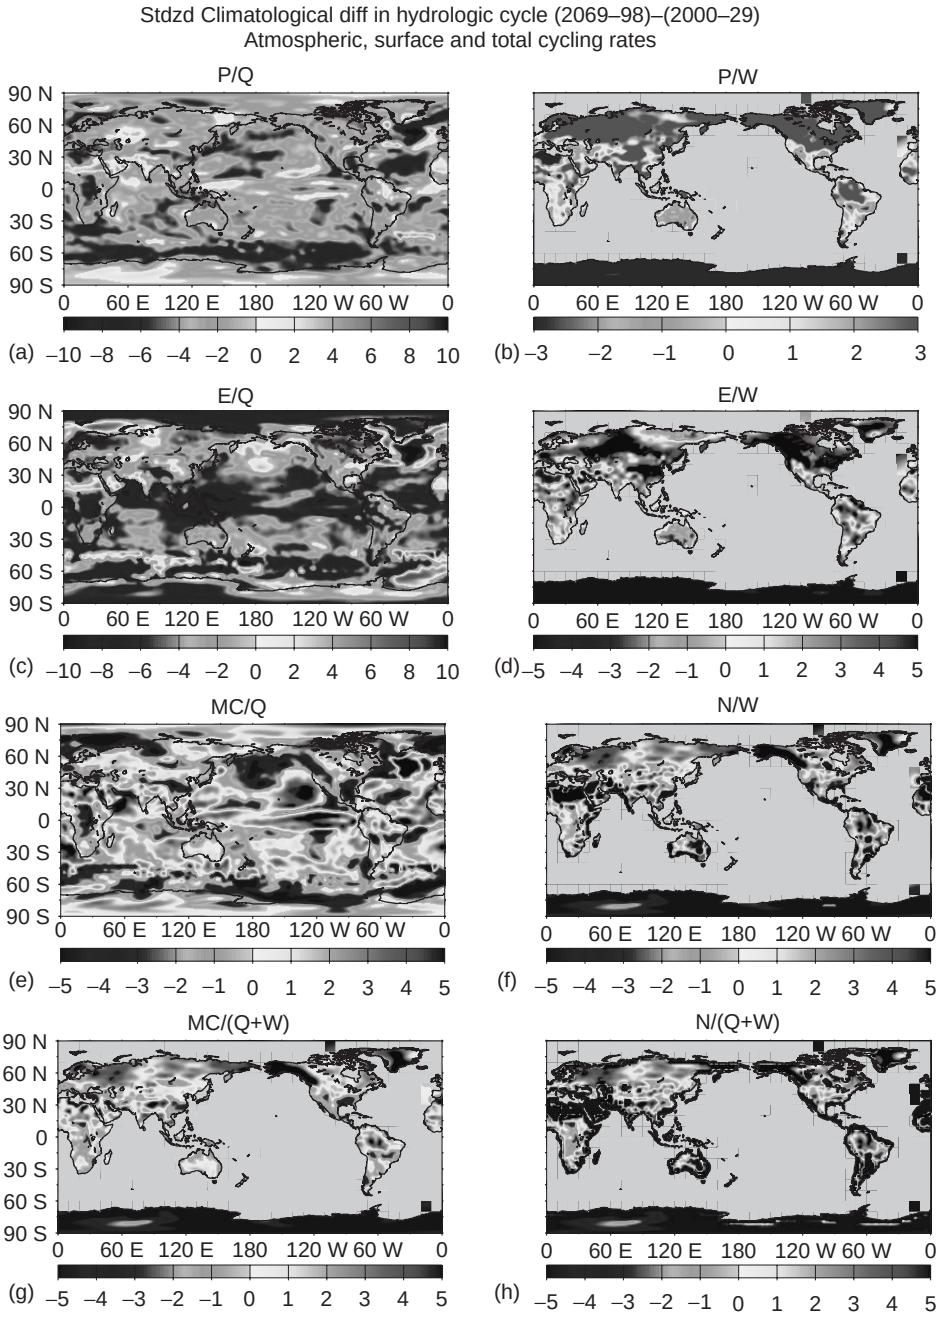

Figure 6 Climatological differences in the hydrologic cycle (average of years 69–98 minus average over years 0–29) atmospheric, surface, and total cycling rates, divided by estimates of the 30-year standard deviation: (a) $\Delta(P/Q)$; (b) $\Delta(P/W)$; (c) $\Delta(E/Q)$; (d) $\Delta(E/W)$; (e) $\Delta(MC/Q)$; (f) $\Delta(N/W)$; (g) $\Delta(MC/(Q+W))$; (h) $\Delta(N/(Q+W))$. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

the changes in the atmospheric reservoir, which increases substantially, and the surface reservoir, which slightly decreases. When the total water mass is considered over land regions, which shows a moderate increase, then the total (atmosphere and land) cycling rate does show a moderate increase or "acceleration", in a world with increased greenhouse gases.

SUMMARY

So, does the hydrologic cycle accelerate? If by acceleration we mean that there should be an increase in a particular process then on the average the evaporation and precipitation increase with increasing temperature and this results in increased transport from ocean to land. However, there are

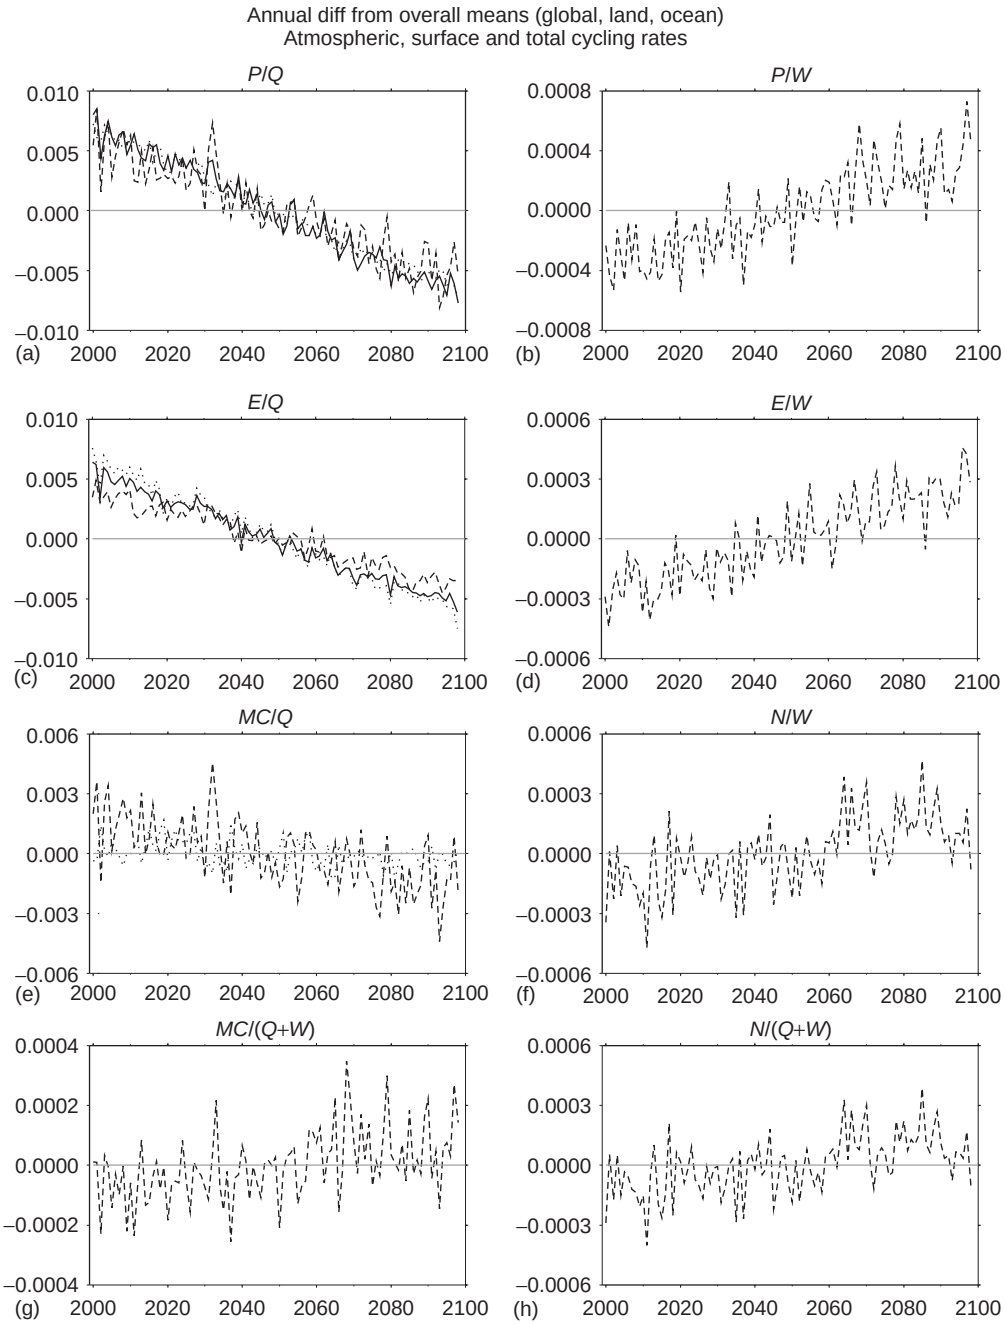

Figure 7 Annual differences from the overall means of the global (solid line), land (dashed line), ocean (dotted line) atmospheric, surface, and total cycling rates, d^{-1}: (a) $\Delta(P/Q)$; (b) $\Delta(P/W)$; (c) $\Delta(E/Q)$; (d) $\Delta(E/W)$; (e) $\Delta(MC/Q)$; (f) $\Delta(N/W)$; (g) $\Delta(MC/(Q+W))$; (h) $\Delta(N/(Q+W))$

certainly many regional differences, which are dependent upon changes in the moisture convergence, land evaporation, surface runoff, and surface water.

If we take into account the relative change in the atmospheric and surface reservoirs then on the average the atmospheric cycling is reduced, owing to the greater water holding capacity of the atmosphere and the surface cycling is enhanced, owing to the small decrease in water holding capacity of the surface water. Again, there are important regional differences. Over high latitude land (except Antarctica), the total cycling rate is increased, owing in part to the more dominant change in the processes relative to the changing surface water, whereas low latitude land does show decreased cycling rates owing more to

decreases in the processes than changes in the atmosphere, surface, or total water reservoirs.

Again, there is also a need to consider averages of instantaneous cycling rates to better understand how robust these measures using annual means are. There are also other measures of hydrologic cycle acceleration that should be considered. For example, what are the changes in the frequency of more extreme weather and short-term climate events? Does precipitation change its distribution from slowly acting processes to one of short duration but more intense processes? Rainfall rates from tropical convection are distinctly different from midlatitude nimbostratus, which has hydrologic implications for soil moisture and runoff. In other words, what are the weather and short-term climate events like in an increased greenhouse world? Understanding whether or not these weather and short-term climate events are reasonable in current large-scale coupled models, however, will require better understanding and improved capability to simulate them. We would also like to note that changes in the hydrologic cycle cannot be readily understood without also understanding associated radiative and sensible heat fluxes, their modes of variability, and their response in increased greenhouse gas climates.

196: The Role of Water Vapor and Clouds in the Climate System

GRAHAME STEPHENS

Atmospheric Sciences, Colorado State University, Fort Collins, CO, US

The exchanges of water between the different water reservoirs on Earth establishes the so-called hydrological cycle. The influence of this cycle on the energy budget of Earth is central to understanding and predicting climate change. In fact, those processes that characterize the smallest of the water reservoirs - namely the atmospheric branch of the hydrological cycle - play an especially critical role in regulating climate change through feedbacks processes. Two key feedback processes are described. The first deals with the feedback associated with the relation between water vapor, radiation and temperature and the second concerns feedbacks associated with clouds and radiation.

Understanding the climate of Earth and predicting the way it varies in time requires a quantitative understanding of the way water cycles back and forth between its main reservoirs both in the atmosphere and at the Earth's surface. The exchanges of water between these reservoirs establishes the so-called hydrological cycle and it is the influence of this cycle on the energy budget of Earth that is central to understanding and predicting climate change. Those processes that relate to the smallest of the reservoirs of water – namely the atmospheric branch of the hydrological cycle – play an especially critical role in regulating climate change through feedbacks (refer to Figure 1) that occur as a result of the influence of these forms of water on the Earth's energy balance. Changes to the amount and distribution of water vapor and clouds, in particular, such as might occur in response to the radiation imbalances induced by increases in greenhouse gases (referred to as a climate forcing), establish these key feedbacks.

THE PLANET'S ENERGY BALANCE

A global-annual-mean depiction of the Earth's energy balance is presented in Figure 2. The mean radiant energy leaving the planet is balanced by the incoming radiation from the sun ($\sim$342 W m^{-2}). The processes responsible for this balance are the emission of infrared or thermal radiation from the Earth-atmosphere system to space ($\sim$235 W m^{-2}) and the reflection of solar radiation from that atmosphere and surface also back to space ($\sim$107 W m^{-2}). The long-wave radiant energy leaving the planet is referred to as the outgoing long wave radiation (OLR) and is carried by radiation of wavelengths longer than 4 μm. The energy in reflected sunlight lies in those wavelengths shorter than 4 μm and is typically expressed in terms of the ratio between the outgoing solar radiation and the incoming solar radiation referred to as the *planetary albedo* ($= 107/342 = 0.31$).

By summing the energy fluxes that flow to and from the atmosphere in Figure 2, we learn that the atmosphere constantly loses energy by the net exchanges of radiation between the atmosphere and space. According to Figure 2, we estimate this loss to be of approximately 102 W m^{-2}. A more common way of expressing this radiative loss is in terms of the rate of cooling of the atmosphere (e.g. Stephens *et al.*, 1994) and to first order, this loss occurs primarily from the emission of infrared radiation from the atmosphere. This emission in turn is grossly influenced by the absorption and thus emission of infrared radiation (IR) by water vapor and, to a lesser extent, clouds.

The radiant energy loss from the atmosphere is balanced by energy transfer from the surface via convective and turbulent transfer (thermals, 24 W m^{-2}; evapotranspiration, 78 W m^{-2}). The dominant contribution by

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

evapo-transpiration represents the excess latent heat release because of the formation of precipitation in the atmosphere in excess of the energy taken from the surface for evaporation of water at the surface and the energy taken from air to evaporate clouds and precipitation. This net heating of approximately $78\,W\,m^{-2}$ is proportional to the precipitation falling from the atmosphere to the surface as this precipitation, as the global average is in balance with the evaporation from the surface.

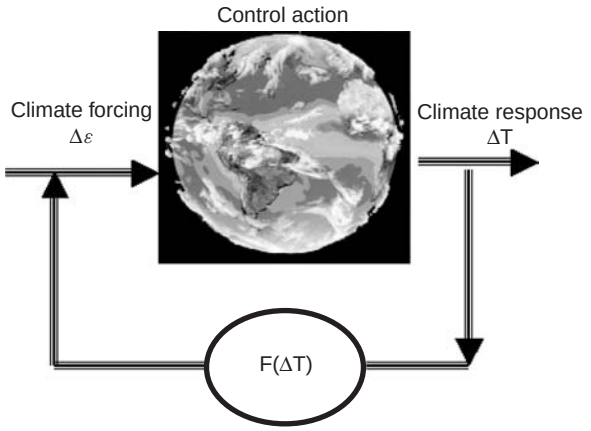

Figure 1 The notion of a climate feedback system. The system is defined by the external forcing $\Delta\varepsilon$ such as associated with the increased buildup of greenhouse gases, the system output or response such as global mean surface temperature change (ΔT), the control action that represents the physical climate system defining the connection between input and output, and processes $F(\Delta T)$ that establish the feedback through the dependence of the process on the response ΔT. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

A simple demonstration of the importance of the link between the radiative processes that govern the energy budget of the planet and the hydrological-related processes that dictate the distribution of water around the planet is provided when considering the approximate balance between the global mean radiation budget of the atmosphere and the latent heating associated with precipitation. The implication of this gross balance is that global-scale changes in the atmospheric cooling, induced for example by the buildup of greenhouse gases, most likely require compensating changes in latent heating and thus fundamental changes in the Earth's hydrological cycle. It is thus appropriate to consider this radiative cooling, controlled by water vapor and clouds, not only as a rudimentary measure of the activity of the Earth's greenhouse effect but also as an indirect measure of the gross activity of the hydrological cycle in heating the atmosphere.

WATER VAPOR, CLOUDS, AND THE PLANET'S ENERGY BALANCE

Water vapor absorbs solar radiation and both absorb and emit infrared radiation. Through absorption of solar radiation, water vapor acts to reduce the planetary albedo and through the absorption and emission of infrared radiation water vapor acts as the principal greenhouse gas, and the infrared emission from the atmosphere (both to the surface and to space) especially in clear sky regions is defined largely by the total water vapor content of the atmosphere (e.g. Chahine, 1992).

Water vapor also represents an essential stage in the hydrological cycle connecting water at the Earth's surface

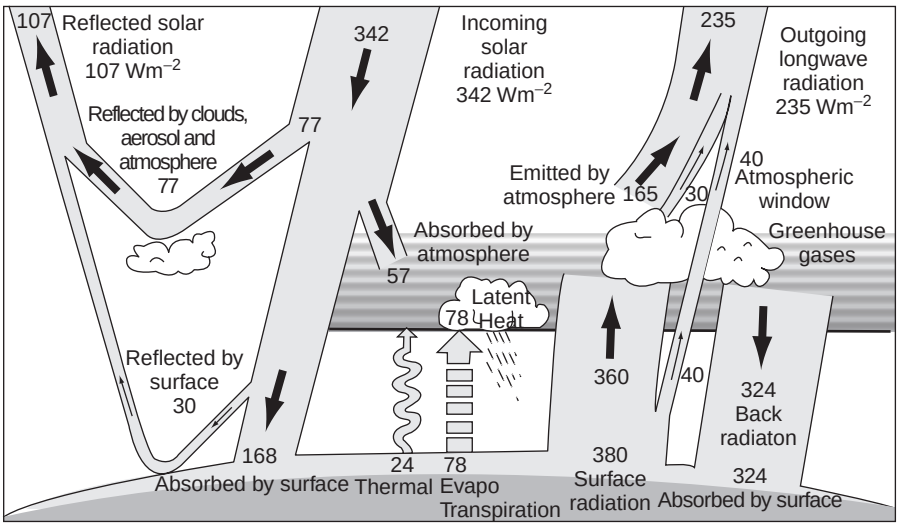

Figure 2 The annual-global mean energy balance of earth. The values given are best estimates of fluxes of energy quoted in $W\,m^{-2}$ (Reproduced from Kiehl and Trenberth, 1997 by permission of American Meteorological Society)

to clouds and the precipitation that returns water back to the surface. As such, the movement of water vapor in the atmosphere by the large-scale windfields of the planet's weather systems grossly influences where clouds form and how much precipitation falls from these systems.

Clouds also affect the planet's energy balance in a manner that is profoundly relevant to climate:

- Clouds reflect more solar radiation to space than the surrounding clear sky thus depleting the amounts of solar energy reaching the surface in these regions. This is sometimes referred to as the *albedo effect*. When viewed from the top of atmosphere (TOA), clouds increase the overall amount of (solar) radiation leaving the planet relative to clear skies.
- Clouds are generally more opaque at infrared wavelengths. As a result, more IR radiation is absorbed in the atmosphere in the presence of clouds than in clear skies. The actual amount of energy emitted to space, however, is decreased (relative to clear skies) because clouds effectively raise the altitude of the level of emission to space to heights characterized by colder temperatures.
- Clouds partition their influence on radiation differently between the atmosphere and surface. Clouds, and high clouds in particular, largely decrease the total atmospheric cooling by increasing the amount of IR energy absorbed from the Earth's surface while producing a compensating cooling at the surface by decreasing the amount of solar radiation that penetrates to the atmosphere.

Analyses of data collected from the Earth-orbiting satellites provide estimates of global distributions of TOA radiative fluxes. Differences between clear and cloudy-sky TOA fluxes (e.g. Harrison *et al.*, 1990) provides a way of estimating the extent that the solar effects of clouds and the long-wave effects of clouds cancel in the sense of the net radiative fluxes formed as the sum of IR and solar fluxes. These satellite observations demonstrate how the short-wave effect generally dominates over the long-wave effect globally. The strongest albedo effect is associated with the persistent maritime stratus off the west coast of continents and storm-track clouds in the summer hemisphere over the mid- and high-latitude Atlantic and Pacific oceans. Although these satellite observations are of immense value in testing global climate models, we are not yet able to determine the separate influences of clouds on the atmosphere and surface without major assumptions.

WATER VAPOR FEEDBACK

In his 1905 correspondence to C.G. Abbott, T.C. Chamberlain notes

> "water vapor, confessedly the greatest thermal absorbent in the atmosphere, is dependent on temperature for its amount, and if another agent, as CO_2, not so dependent, raises the temperature of the surface, it calls into function a certain amount of water vapor which further absorbs heat, raises the temperature and calls forth for more vapor. . .."

Chamberlain's comments provide a clear and concise account of the essential ingredients of the nature of water vapor feedback on the Earth's climate – this feedback requires that the strength of the "thermal absorbent effects" depends in some way on temperature. Although water vapor also absorbs solar radiation, the dominant influence on the energy budget lies in its effects on IR radiation. To first order, this influence is determined by the amount of water vapor integrated through the atmospheric column. Empirical evidence suggests that the mean relative humidity of the atmosphere remains approximately constant and it is through this empirical observation that the water vapor feedback is established (Held and Soden, 2000) since it implies a single, direct relation between column water vapor and temperature.

This constant relative humidity argument is the simple basis of water vapor feedback and more details of the feedback and our current state of its understanding are presented in Held and Soden (2000). According to climate models, this feedback contributes to the major portion of the global warming associated with increasing concentrations of atmospheric CO_2. In reality, however, the water vapor feedback is interfered with by the transport of vapor and by its condensation into clouds – both effects complicate the actual relation between water vapor and temperature. For example, changes to the small amounts of water vapor in the upper atmosphere above 5 km (i.e. in the region of the upper troposphere) produces a disproportionate influence on the radiation emitted to space. Specifically, a 10% change in upper tropospheric absolute humidity has an approximately threefold larger effect on the OLR than does an equivalent percentage change (but significantly larger absolute change) in lower tropospheric water vapor. Unfortunately many factors, over and above temperature, contribute to the observed changes in upper tropospheric water vapor thus greatly complicating our simple ideas of the water vapor feedback. Our ability to understand the specific role of water vapor in these upper layers of the atmosphere continue to be thwarted by our crude ability to observe water vapor at these levels on the global scale.

The effect of water vapor on the formation and evolution of clouds, in turn, adds to the complexity of the water vapor feedback. The actual way clouds interfere with the water vapor feedback process and the specific connection between water vapor, cloudiness, surface temperature, and the greenhouse effect of Earth are still poorly observed and inadequately understood.

CLOUD FEEDBACK

As in Figure 1, feedbacks are generally thought of in terms of a control system and its output (response) given some forcing. Therefore, feedbacks are only meaningful when defined in terms of the output. Although several meaningful measures of output could be considered, it is customary to articulate global climate change and related output in terms of surface temperature. In this context, cloud feedback refers to those cloud processes that in some way depend on temperature and induce a discernible effect on the energy balance that in turn feedback on temperature. Although this simple view of feedback has problems (e.g. Stephens, 2004), it nevertheless serves as a useful framework. We find that generally cloud feedbacks are complex and the processes that establish them are poorly understood. Consequently, cloud feedback now stands as one of the principal obstacles in the way of a meaningful prediction of climate change.

Projecting the salient points noted in Chamberlain's comment onto the topic of cloud feedback exposes a number of important issues that highlight both the essential differences between cloud feedbacks and water vapor feedbacks and offers some explanation for why progress in understanding cloud feedback has been elusive:

1. The "thermal absorbent" character of water is greatly enhanced when water is in its condensed phase. On a molecule-by-molecule basis, water in either the solid or liquid form in the atmosphere absorbs approximately 1000 times more strongly than in the gaseous form. The amount of energy actually absorbed and scattered by clouds also depends on other complicating factors, such as the amounts and vertical organization of clouds and the water contents of clouds and particle sizes, to mention a few.
2. It is reasonably clear what is meant by water vapor in the context of water vapor feedback but the meaning of clouds is much less obvious. As mentioned, a number of cloud properties affect the radiation budget of Earth and all are potentially relevant to the cloud feedback problem. A more extensive list of cloud properties that contribute to the feedback, compared to water vapor, merely reflects the greater complexity of the cloud feedback problem.
3. The dependence of clouds on temperature, and surface temperature specifically, is much less obvious than for water vapor (although complications arise even for water vapor). To first order, this dependence is governed more so by the large-scale motions of the atmosphere and thus on the complex dependence of these motions on temperature. This complexity is arguably the single most important factor to cloud feedback, yet it is generally overlooked or grossly simplified in most cloud feedback studies rendering these inconclusive.
4. Unlike water vapor, clouds also impart an effect on the disposition of solar radiation primarily through their albedo effect. This introduces further complexity to the problem since, when viewed from the TOA, the "thermal absorbent" effects are primarily, although not exactly, offset by the albedo effect in tropical regions. The tendency for long and short-wave processes to approximately balance one another in these regions has confounded our attempts to understand the cloud feedback problem.

These issues and the cloud feedback problem in general can be more succinctly posed in the form of the following questions:

1. Given a fixed distribution of clouds and relevant properties, what is the associated distribution of radiative heating? Our understanding of the radiative transfer processes is sufficiently advanced that the answer to this broad question is straightforward, given the required cloud information. Detailed issues as to how these radiative processes are most efficiently incorporated into large-scale weather and climate models, however, continue to be a focus of research.
2. Given a fixed distribution of heating, what then happens to the distribution of clouds and relevant properties? Our ability to answer this question is far less developed. What is required is a clearer understanding of how the heating and moistening effects of clouds influence the dynamical and thermodynamical properties of the atmosphere, and how these in turn affect the large-scale motions of air and the formation and evolution of clouds. Prediction of the formation and evolution of clouds is poorly handled in models, and our ability to test these predictions with global cloud observations is also limited. A satellite-based program for characterizing global cloudiness that is widely used for this purpose is the International Satellite Cloud Climatology Project (Rossow and Schiffer, 1999).

AEROSOL, CLOUD, AND PRECIPITATION

The atmosphere also contains suspensions of small aerosol particles that not only scatter solar radiation and thus directly affect the radiation balance of the planet (the so-called direct aerosol forcing) but also indirectly influence this energy balance through the effects of aerosol as sources of nucleation of cloud particles. Aerosol particles that nucleate cloud (liquid) droplets or ice crystals are referred to as cloud condensation nuclei (CCN) and ice nuclei (IN) respectively. Not all aerosol particles serve as the nucleus for cloud particle growth, and the ability to activate cloud

particle growth depends on the amount of water vapor in the environment and the chemistry of the nuclei, their size and number concentrations, and other factors.

The concentrations of CCN and IN in air profoundly influence cloud microphysical properties, notably the size and concentrations of cloud particles. Conditions of higher concentrations of aerosol and thus CCN result in clouds composed of smaller but more numerous droplets. The consequences of these changes to cloud microphysics are important to climate for the following reasons:

1. Clouds composed of higher concentrations of smaller droplets reflect more solar radiation than clouds of equivalent water content but composed of a few, larger droplets. This is referred to as the *Twomey effect* (Twomey, 1977). It is observed that mostly shallow clouds, when formed in locally polluted air masses, reflect more radiation than surrounding clouds formed in cleaner air (Figure 3). On the global scale, this effect on the albedo of clouds, although highly uncertain, is thought to be at least as large as the direct effect of aerosol on solar radiation.
2. The Twomey effect described above assumes that the water content does not differ between polluted and unpolluted clouds. This is a dubious assumption since shifting the cloud droplet populations to smaller sizes also inhibits the coalescence rain forming process leading to less precipitation from clouds formed in polluted air masses (Rosenfield, 1999). Thus for the same total mass of water, less precipitation is produced implying a reduction of the precipitation efficiency of clouds and further implying different life-cycle characteristics.

Figure 3 Clouds composed of higher concentrations of small droplets are referred to as *colloidally stable*. For the same total water content, more colloidally stable clouds reflect more solar radiation than do clouds composed of larger droplets. This enhanced reflectivity is observed in this satellite image of clouds off the west coast of California. Shown is an extreme example of the effects of aerosol emitted from the chimney stacks of ships. This higher aerosol air enters the cloud creating local areas of higher CCN, smaller droplets, and higher albedo

The effects of changing aerosol concentrations on clouds causes a chain reaction in a number of processes that affect the microphysics of both clouds and precipitation. The net result of these processes and how they effect different cloud types (such as shallow and deep clouds), and ice (cold) processes versus water (warm) processes are not well understood at this time.

197: Observed Trends in Hydrologic Cycle Components

HARRY F LINS

United States Geological Survey, Office of Ground Water, Reston, VA, US

Documentation of change in the Earth's climate is accomplished by assessing the rates, magnitude, and distribution of changes in various elements of the climate system, such as the components of the hydrologic cycle. The present section reviews the general character of changes in precipitation, streamflow, and evaporation as determined using systematically collected data through the end of the twentieth century. Precipitation over global land areas increased about 2% during the century, and streamflow also exhibited widespread increases. There was good agreement regionally between the observed precipitation and streamflow increases. The precipitation increases appear to have occurred most commonly in higher intensity categories (>50 mm per day), while the streamflow increases were overwhelmingly observed in the low to moderate range of flows. No systematic increases were observed in peak streamflows. These findings indicate that a general intensification of the hydrologic cycle occurred during the twentieth century, but that this intensification did not result in increased hydrologic extremes.

INTRODUCTION

Climate change is documented by assessing the rates, magnitude, and distribution of changes in climate system components. Although simple in concept, such documentation has proven to be problematic in practice. Existing climate observing systems are capable of only partially answering critical questions associated with climate change, particularly for such hydrologic cycle variables as precipitation, runoff, and evaporation (NRC, 1999). Changes in station location, time of observation, and monitoring equipment, as well as difficulties in operating monitoring stations over multidecadal periods and at many locations worldwide, are all factors that contribute to this problem. Significantly, however, the Third Assessment Report of the Intergovernmental Panel on Climate Change (IPCC, 2001) notes that the "certainty of conclusions that can be drawn about climate from observations depends critically on the availability of accurate, complete and consistent series of observations".

In addition, human alteration of the landscape and riverine systems can significantly affect hydrologic cycle changes, from small watershed to large river basin scales (Shiklomanov and Penkova, 2003). The data needed to account for such confounding effects, such as consumptive water use, reservoir storage, and land use change, are often less well measured or more difficult to obtain than those for precipitation, streamflow, and evaporation. Remotely sensed data are finding increasing use in hydrologic cycle investigations, most particularly in regions of the world where systematic *in situ* data collection networks are sparse or nonexistent. However, such systems are not without their own problems. In many instances, remotely sensed data are less than 20 years in length, limiting their utility for trend assessment, and they generally do not measure quantities that are directly comparable to ground-based observations.

Trend analysis results are also very sensitive to the conditions that existed at the endpoints of the time series. Differences of one or two years in the start or end points in a data time series, even when the time series are otherwise identical, can substantially alter results. Similarly, differences in analytical methods among published studies can compromise the significance of results and complicate summary assessments of change. Douglas *et al.* (2000) noted, for example, that spatial correlation among streamflow observing stations markedly affects the results of

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

trend testing. They found that regional cross correlation of flow records dramatically reduced the effective number of samples available for trend assessment, and that by not taking this influence into account, erroneous conclusions would be drawn with respect to the absence or presence of regional trends.

Despite the many problems associated with the collection and analysis of the hydrologic cycle and related data, studies aimed at identifying trends in hydrologic cycle components at regional to continental scales are increasing. The most extensive work has addressed precipitation trends. Precipitation data have been collected longer and at more sites worldwide than have streamflow and evaporation data. It should be noted, however, that despite its breath of monitoring, measurement problems and bias continue to adversely affect the quality of precipitation data. Even so, the density of land precipitation monitoring networks is sufficient to facilitate global assessments of trend, such as those reported in recent climate change assessments by the IPCC (1996, 2001).

In contrast, investigations of runoff or streamflow trends have been more geographically restricted, with the most comprehensive analyses covering Canada, Europe, the United States, and to a lesser extent, Australia and South America. Comparatively, little streamflow data are available for Africa and Asia and record lengths in these regions tend to be relatively short. Another confounding issue in assessing streamflow trends relates to the influence of human activities on rivers and streams. Flows on most gauged watercourses are modified to some extent by human activities. Humans appropriate more than 50% of accessible renewable water resources globally (Postel *et al.*, 1996). By the late 1980s, there were more than 36 000 large dams worldwide, representing a 700% increase in the standing stock of natural river water (Vörösmarty *et al.*, 1997). In the contiguous United States alone, of the 5.2 million km of rivers, there are only 42 reaches with lengths greater than 200 km that are free flowing (Benke, 1990).

Avoiding potential problems in understanding how the streamflow component of the hydrologic cycle is changing through time is most easily achieved by using streamflow records that reflect natural or near-natural conditions. To this end, some hydrologists and hydrological services have identified climate-sensitive stations within their monitoring networks that reflect unimpaired basin conditions. Unimpaired generally means that there is no overt adjustment of natural streamflow by diversion or augmentation, regulation of the watercourse by a containment structure, or reduction of base flow by groundwater pumping. In practical terms, unimpaired records are generally considered to be those where the degree of human activity in the watershed is small enough so as not to affect significantly the value of monthly mean discharge as computed on the basis of daily mean discharge. The Reference Hydrometric Basin Network (RHBN), assembled by Environment Canada (Harvey *et al.*, 1999), and the Hydro-climatic Data Network (HCDN) of the US Geological Survey (Slack and Landwehr, 1992) are examples of streamgauging networks that have been identified as meeting specific climate sensitivity criteria.

Studies of trends in evaporation, as with streamflow, are limited geographically. Nearly all are based on pan evaporation measurements because pans have been systematically used longer and in more locations than other types of equipment. Historically, pan evaporation measurements have been viewed as an index of potential evaporation or the evaporation that occurs where there is an unlimited supply of water. Recently, however, Golubev *et al.* (2001) developed a method for estimating actual evaporation from the land surface using pan evaporation measurements, a more meaningful quantity when comparing with precipitation and streamflow. Despite this development, it should be noted that pan evaporation estimates are problematic at best. Pan evaporation must be adjusted by seasonally varying coefficients in order to provide estimates of lake evaporation, and these coefficient adjustments are only approximations (Mather, 1974).

A review of the primary recent literature documenting changes in hydrologic cycle components follows. This review does not purport to establish invariant and regionally detailed trends worldwide. Rather, its purpose is to provide a *snapshot* or generalized characterization of changes in precipitation, streamflow, and evaporation as determined using systematically collected data that end around the year 2000. The dynamic nature of hydrologic cycle variables, coupled with the analytical and interpretive limitations associated with monotonic trend tests, constrain the certainty and enduring relevance of specific results.

CHANGES IN PRECIPITATION

The IPCC third assessment (IPCC, 2001) reported that global land precipitation increased about 2% during the twentieth century, but that the increase was not uniform spatially or temporally. This is evident in the seasonal precipitation change maps in Figure 1. In the middle and high latitudes of the Northern Hemisphere, for example, there have been widespread precipitation increases, particularly during the autumn months. However, precipitation decreases have been observed in Europe, Western Russia, and around the Mediterranean. In Canada, precipitation increased by an average of more than 10% during the twentieth century (Mekis and Hogg, 1999), including increases in snowfall (Zhang *et al.*, 2000). Farther south, in the United States, precipitation increased between 5 and 10% over the century. Karl and Knight (1998) reported an increase in the United States of about 10% nationwide,

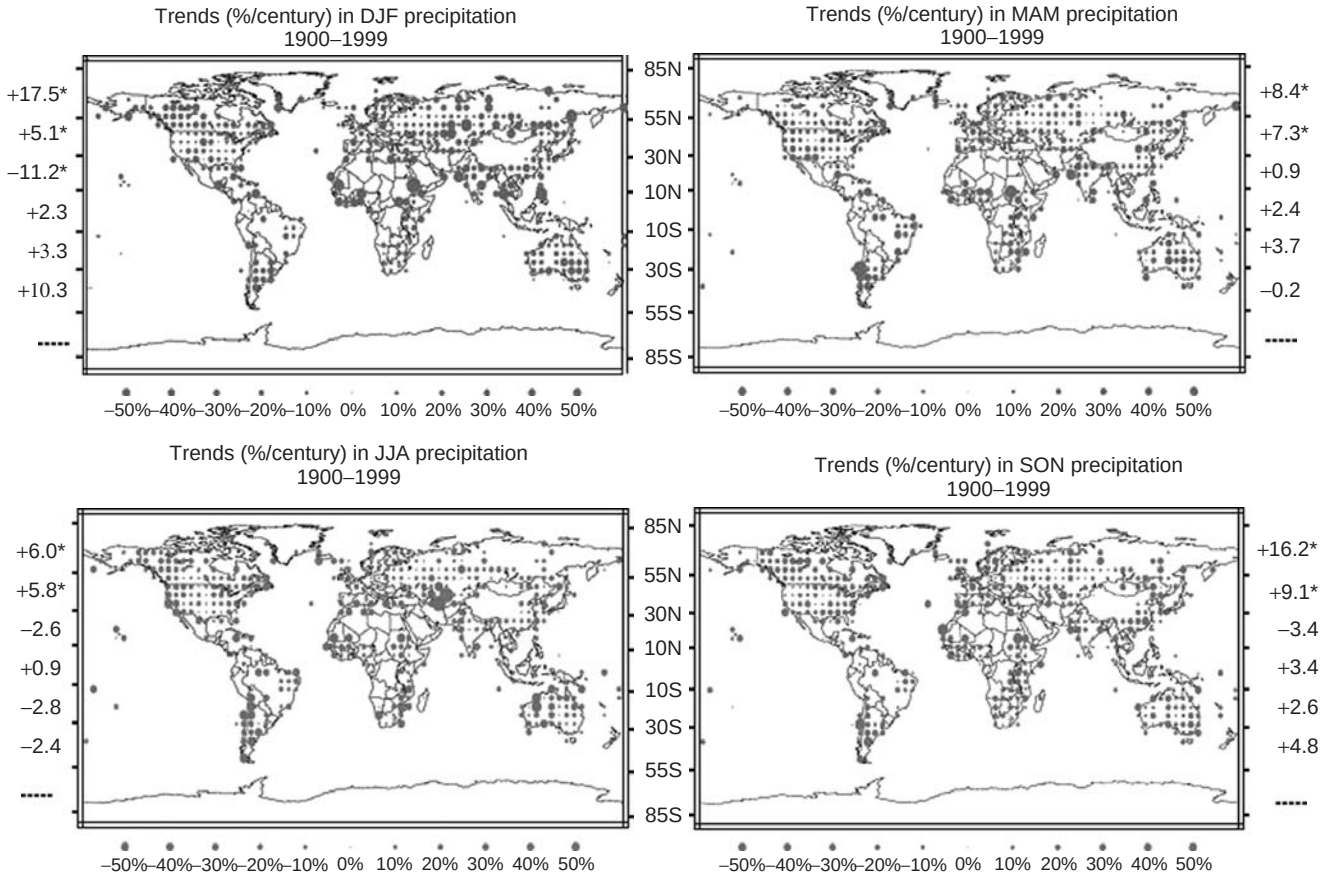

Figure 1 Trends in seasonal precipitation, 1900–1999. Trend magnitude is signified by the size of the circle (*Source:* Intergovernmental Panel on Climate Change (IPCC), 2001). Trend direction is represented by the color of the circle which can be seen in the color version of this image that is available at http://www.mrw.interscience.wiley.com/ehs

and that more than half of this increase was in heavier precipitation categories, that is, the upper 10 percentiles of the precipitation distribution. They also noted significant variability in the pattern of trends regionally and seasonally, with the increases being confined to the spring, summer, and autumn months. Groisman *et al.* (2004) confirmed this finding, adding that the largest trends were observed in the eastern two-thirds of the United States, and primarily in the warm season when intense rainfall events are most frequent. However, Kunkel *et al.* (2003) pointed out that during the late nineteenth century, intense precipitation events were nearly as high as during the late twentieth century. This suggests that the reporting of trends in precipitation since about 1900 may not encompass the full range of natural variability that has characterized the climate system in recent centuries.

During the second half of the twentieth century, annual precipitation decreased slightly in China, although increases were observed over the middle and lower Yangtze River basin (Zhai *et al.*, 1999a,b). Northern Europe and Scandinavia saw increased precipitation, while southern Europe, down to the Mediterranean, experienced a general decrease over these same decades. Coupling these results with those for North America and averaging zonally, annual precipitation increased between 7 and 12% for the zones from 30 °N to 85 °N (IPCC, 2001).

In the Northern Hemisphere subtropical and tropical zones, precipitation tended to decrease during all seasons in the twentieth century. This was particularly true in North Africa and the Asian subcontinent. Kumar *et al.* (1999a,b) found no evidence of a long-term trend in Indian monsoonal rainfall, although they did note significant multidecadal variations.

In the Southern Hemisphere, precipitation trends have also been mixed. Annual rainfall over most of Australia has increased, as have the number of rain days, but precipitation decreases during winter (June, July, and August) have been notable in the eastern and western thirds of the continent. Seasonal differences in trends have also characterized the changes in southern Africa, where warm season precipitation (December–May) has decreased and cool season precipitation (June–November) has increased. Precipitation increases have occurred in most of South America in all seasons with two notable exceptions, Chile and eastern

Brazil, where decreases were dominant during the twentieth century.

It is important to note that most of these reported changes in precipitation are within the measurement error that has been documented for precipitation. UNESCO (1978) and Legates (1987) estimate the bias in precipitation measurements, averaged globally, to be about 11%. Legates (1995) further argued that local increases in air temperature and decreases in wind speed, resulting from climatic variability or from local urbanization, can introduce spurious trends into the precipitation record. This is because the bias in measuring liquid precipitation is lower than for solid precipitation, as it is for lower wind speeds. Moreover, spurious trends can be introduced through monitoring station relocations and instrument changes (Groisman, 1991). It is likely that these factors have contributed to the variable and occasionally contradictory precipitation trend results that have been published.

CHANGES IN STREAMFLOW

Global assessments of trends in streamflow have proven to be more elusive, primarily because network limitations, data access, and data quality issues have hindered attempts at producing a unified global synthesis. However, several studies have provided noncomprehensive, low spatial density looks at worldwide trends in streamflow. Chiew and McMahon (1996) tested for trends in annual streamflow volumes and peak discharges at 142 stations on 6 continents. They found no consistent pattern of widespread trends in either variable, although most of their data ended before 1980. More recently, Kundzewicz *et al.* (2004) and Svensson *et al.* (2004) analyzed trends in annual maximum flow, and in peaks over threshold and annual low flows, respectively. The Kundzewicz *et al.* (2004) results utilized records from 195 stations on 6 continents, and are summarized in Table 1. The overwhelming majority of stations (92%) were located in North America, Europe, and Australia. Among all stations, 70% had no trend in the annual maximum flow, 14% had an increasing trend, and 16% a decreasing trend. Although the actual percentages varied from continent to continent, each exhibited a pattern of trends generally consistent with the aggregate totals. Using a much smaller sample of stations (21), Svensson *et al.* (2004) found a mixed pattern of trends in peaks over threshold, with approximately 30% of the stations exhibiting a trend, and with more downward trends than upward. A very different pattern was apparent in low flows, however (Figure 2).

Table 1 Trends ($p \leq 0.10$) in annual maximum streamflow, by continent, for 195 streamgauging stations worldwide

Region	Number of stations	Number with increasing trend	Number with no trend	Number with decreasing trend
Africa	4	1	1	2
Asia	8	0	5	3
South America	3	0	3	0
North America	70	14	44	12
Australia–Pacific	40	1	34	5
Europe	70	11	50	9
Totals	195	27(14%)	137(70%)	31(16%)

Source: Kundzewicz *et al.*, 2004.

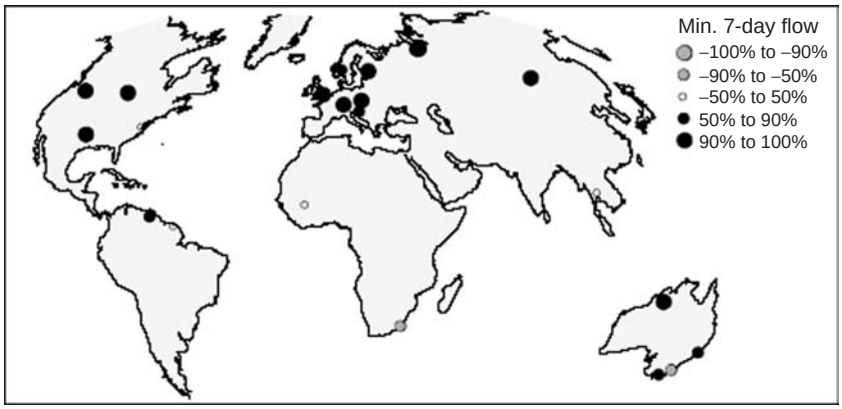

Figure 2 Trends in the annual minimum 7-day mean flow series at 21 stations worldwide. Negative trends are shown as gray circles and positive trends as black circles. The largest circles identify trends significant at $p \leq 0.10$ (*Source:* Svensson *et al.*, 2004)

Approximately 52% of the stations had statistically significant trends in seven-day low flows, and all of these were increasing trends. This implies a reduction in the incidence of hydrologic drought. Importantly, these broad-scale study results are very consistent with those from regionally specific investigations.

The most comprehensive documentation of streamflow change comes from regional studies and, of these, the most complete assessment exists for North America, where several national-scale studies have been published for Canada and the United States. Zhang *et al.* (2001) found that annual mean streamflow generally decreased in Canada between 1947 and 1996, with significant decreases occurring in the southern part of the country, particularly southern British Columbia and Alberta. They also found decreases in monthly mean streamflow for most months of the year except March and April when significant increases were observed. Changes in the frequency distribution of daily streamflow, from low to high, were also evaluated. In southern Canada, as with the annual mean, significant decreases were observed in all percentiles of daily flow. Over northern British Columbia and the Yukon Territory, however, significant increases were identified in the lower flow percentiles. Zhang and his collaborators also noted that the breakup of river ice and the ensuing spring freshet were occurring earlier, especially in British Columbia, and that river freeze-up appeared to be occurring earlier in the autumn in eastern Canada.

In the United States, numerous investigations have found a consistent pattern of streamflow increases across much of the country during the twentieth century. Lettenmaier *et al.* (1994) identified strong increases in monthly mean streamflow in the months from November to April for the years 1948–1988. The largest trend magnitudes were observed in the north-central states. This study also found streamflow decreases in the Pacific Northwest that were consistent with the streamflow decreases in the adjacent provinces of southwestern Canada noted by Zhang *et al.* (2001).

Lins and Michaels (1994) assessed trends in streamflow in the United States by region and by month. The regions were defined by principal components analysis of monthly mean streamflow. A separate analysis was performed for each calendar month. The resulting time series of component scores for each component and month were then tested for trend. Nearly all regions of the country experienced increasing streamflows between 1941 and 1988, but the significant trends were only observed during the autumn to early winter months. No regional trends were observed in the Pacific Northwest and, as Lettenmaier *et al.* found, the north-central region had the strongest trend.

During the 1990s, a series of major flooding events in the United States received significant attention and led to speculation that extreme hydrologic events (including both floods and droughts) were increasing, possibly in response to greenhouse warming. Lins and Slack (1999) evaluated this possibility by testing for trends in the percentiles of annual (on the basis of daily mean) streamflow for periods ranging from 30 to 80 years. They found that trends were most prevalent in the lower half of the frequency distribution, from the annual minimum to median flow, and that the trend was upward at 40–50% of the stations tested. In contrast, they reported a decline in the number of stations having trends in the upper half of the distribution, with the annual maximum flow reporting the least increasing trends (at 10% of the stations). The streamflow increases were observed across much of the United States, but particularly the northeastern quarter of the country, while decreases were detected in most percentiles in the Pacific Northwest and in the Southeast.

Douglas *et al.* (2000) also looked at trends in high and low flows using a regional trend test. They found no evidence for a coherent trend in high flows regionally, but did report upward trends in low flows in much of the northeastern quarter of the United States, supporting the Lins and Slack findings. A subsequent study by Groisman *et al.* (2001), however, appeared to arrive at a different conclusion with respect to trends in high flow. Working with a subset of the same data used in previous streamflow trend analyses, Groisman and his colleagues reported that the largest streamflow increase in the United States occurred in the highest streamflow percentiles, seemingly contradicting all previous work. Upon closer examination, however, what Groisman found was not that there were more stations having trends in the highest streamflow percentiles, or that the magnitude of the trend in percentage terms was greater. Their analysis actually yielded the following result: if one calculated the total volume of water that increased (or decreased) from 1939 to 1999, and then determined what proportion of that increase was produced by increases in the 0–5th percentile bin, 6–10th percentile bin, and so forth up to the 96–100th percentile bin, the bin that contributed most of the increase is the 96–100th percentile bin.

Importantly, this result is not inconsistent with, or contradictory to, the findings of previous studies that found relatively few stations with trends in the annual maximum streamflow. The reason for this is the quantity of water contained in each percentile bin of the annual streamflow distribution. Because streamflow is a lognormally distributed variable, where the annual maximum value is typically two or more orders of magnitude greater than the annual minimum value, the uppermost percentiles correspond to very large quantities of water relative to other parts of the distribution. So, even though the percentage increase in the annual maximum streamflow is relatively small (as noted by Lins and Slack and Douglas *et al.*), the corresponding volume increase can be very large. In other words, a small percentage change in a very large volume of water is a

large value in comparison to a large percentage change in a relatively small volume. Thus, the differences between the Groisman *et al.* findings and those of the others are apparent and interpretive rather than substantive. This situation does, however, underscore the problems that can attend trend assessments on the basis of different analytical approaches.

Finally, McCabe and Wolock (2002) found a significant increase in annual minimum and median daily streamflow around 1970, and a less significant mixed pattern of increases and decreases in annual maximum daily streamflow. These changes were primarily observed in the eastern United States and are consistent with previous studies. Notably, though, McCabe and Wolock observed that the streamflow increases appeared as a step change rather than as a gradual trend, which has important implications (Figure 3). The inference drawn from a gradual trend is that

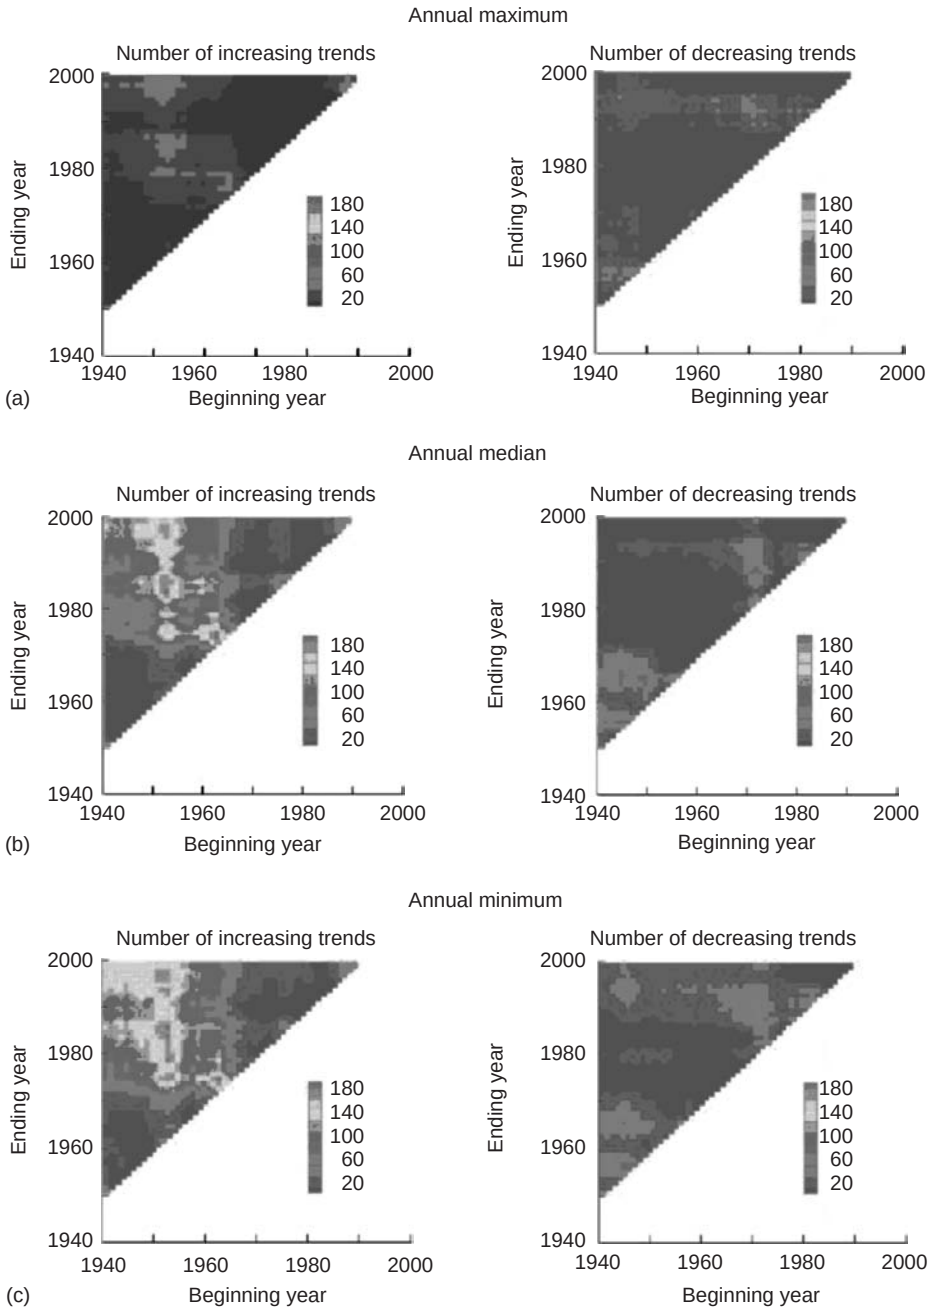

Figure 3 Number of sites with significant ($p \leq 0.05$) increasing and decreasing trends in (a) annual maximum, (b) median, and (c) minimum daily streamflow for various periods at least 10 years in length, and for 400 stations in the United States during 1941–1999 (Reproduced fromMcCabe and Wolock, (2002) by permission of American Geophysical Union (AGU)). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

it is likely to continue into the future, while the implication of a step change is that the climate system has shifted to a new regime that will likely remain stable until a new shift occurs.

Fewer studies of streamflow trends have been published for other continental areas. In South America, discharge data for several major rivers in the southeastern part of the continent covering the period 1901–1995 indicate that streamflow increased after the mid-1960s (Garcia and Vargas, 1998; Genta *et al.*, 1998). This increase was also accompanied by a decrease in the amplitude of the seasonal cycle in most rivers.

In Europe, much of the published work on streamflow trends has focused specifically on flooding. Robson *et al.* (1998) and Robson (2002) evaluated local and national flood series in the United Kingdom, and the effect of climatic variability on trend detection. Their results indicated that more protracted episodes of high flow have occurred during the second half of the twentieth century. However, they found no statistical evidence of a long-term (80–120 years) trend in flooding. An analysis of systematic flood records for winter and summer seasons in central Europe since the middle of the nineteenth century, and longer-term historical records of major floods since the sixteenth century, was performed by Mudelsee *et al.* (2003). They found a decrease in the occurrence of winter floods on the Elbe and Oder rivers over an 80- to 150-year period with no trend in summer flooding. They attribute the winter season decrease in part to a decline in strong freezing events that reduce late winter ice jamming events and consequent higher flood peaks. This study also detected significant long-term changes in flood occurrence between the sixteenth and nineteenth centuries, but concluded that reductions in river length, construction of reservoirs, and deforestation had minor effects on flood frequency. One study, by Kahya and Kalayci (2004), focused on trends in average flow conditions. Using monthly mean streamflow records for 26 basins in Turkey from 1964 to 1994, they found that streamflow had generally decreased in western and southern Turkey, while not changing significantly in eastern Turkey. Finally, Hisdal *et al.* (2001) tested for trends in hydrologic drought using a pan-European data set of more than 600 daily streamflow records encompassing four time periods: 1962–1990, 1962–1995, 1930–1995, and 1911–1995. For most stations tested, no significant changes were detected, and the authors concluded that there was no evidence to indicate that drought conditions, in general, had become more severe or frequent.

CHANGES IN EVAPORATION

Most work on trends in evaporation has been done using pan measurements from the former Soviet Union and the United States. The IPCC Second Assessment Report (1996) described widespread decreases in pan evaporation during the twentieth century using these data. Subsequent to the Second Assessment, several authors noted an inconsistency between the reported decreases in pan evaporation, which was interpreted as a decrease in actual land surface evaporation, and observed increases in both temperature and precipitation in Russia and the United States. Brutsaert and Parlange (1998), for example, noted that the contradiction in the trends of evaporation, temperature, and precipitation was difficult to reconcile in the context of a general intensification of the hydrological cycle over northern extratropical land areas. Lawrimore and Peterson (2000) and Golubev *et al.* (2001) conducted additional studies and arrived at conclusions similar to Brutsaert and Parlange.

Golubev *et al.* (2001) developed a procedure for estimating actual land surface evaporation from pan evaporation measurements using coupled observations of both actual and pan evaporation at multiple field sites in Russia. In applying this procedure to pan data from Russia and the United States, they concluded that the actual evaporation increased over most arid regions of both countries, as well as over humid maritime regions of the eastern United States during the warm season. They also found that the actual evaporation decreased over heavily forested areas of Russia and the northern United States.

SUMMARY AND CONCLUSION

Analyses of trends in the hydrologic cycle indicate that precipitation over global land areas increased about 2% during the twentieth century, and that the streamflow also exhibited widespread increases. There was generally good agreement regionally between the observed trends in precipitation and streamflow. Moreover, some investigations that reported precipitation increases also found that these increases occurred more frequently in higher intensity categories (e.g. >50 mm per day). Notably, in regions where such precipitation increases were observed, there appeared to be increases in low to moderate streamflows. There is no evidence of widespread or systematic increases in peak streamflows, although there is widespread evidence of increases occurring in annual low flows. This pattern of trends indicates that a general intensification of the hydrologic cycle occurred during the twentieth century, but contrary to the hypothesis that such an intensification would result in increased hydrologic extremes (i.e. floods and droughts), it did so in a more benign and beneficial manner.

The cryosphere, which includes seasonal snow, frozen ground, sea ice, glaciers, ice caps, and ice sheets, is one of Earth's five main regimes together with the atmosphere, biosphere, hydrosphere, and pedosphere. It is estimated that the cryosphere contains about 1.8% of all water on Earth but nearly 70% of the freshwater. Interactions between snow and ice cover and the radiation budget make the cryosphere especially important to climate at local to global scales, while strong positive feedback mechanisms mean that the cryosphere is particularly sensitive to climate change. Impurities trapped in glaciers and ice sheets archive detailed, high-time resolution records of the Earth's changing climate and hydrologic cycle over the past million years. These and other records document repeated variations in the size of the cryosphere including very large, long-duration changes such as the glacial and interglacial periods as well as much smaller, though still important changes such as the Medieval Warm Period and Little Ice Age during the last two millennia. The cryosphere is shrinking rapidly in response to the current warming, particularly in the Northern Hemisphere.

INTRODUCTION

The Earth's environment can be divided into five main regimes: atmosphere, biosphere, cryosphere, hydrosphere, and pedosphere. The cryosphere is the frozen portion and it includes snow, frozen ground, sea ice, glaciers, ice caps, and ice sheets. The cryosphere is an integral part of the hydrologic cycle. It is estimated that the cryosphere contains about 1.8% of all water on Earth but nearly 70% of the freshwater. Annual to millennial scale storage of water in glaciers and ice sheets impacts sea level, while seasonal to annual storage of water in mountain snow packs regulates runoff and river flows.

Snow and ice cover at high latitudes dramatically increase albedo there and so enhance poleward temperature gradients. These temperature gradients play an important role in the movement of heat and energy around the globe through atmospheric and oceanic circulation, with net heat transport from the low to high latitudes. Without such transport, the equatorial regions would be 14 °C warmer and the North Pole 25 °C colder (Barry and Chorley, 1992). Because exchanges between the cryosphere and the rest of the hydrologic cycle depend on the change of water to and from the solid phase (ice and snow) and because much of the cryosphere exists near the melting point, the size and behavior of the cryosphere is highly sensitive to climate change. Decreased snow and sea ice cover decrease albedo and so increase radiative heating, resulting in a positive feedback and amplification of global climate change in the polar regions and at higher elevations.

Impurities trapped in glaciers and ice sheets, together with the thickness of snow and ice in annual layers, comprise arguably the most detailed and direct archive of paleoclimatic and paleoenvironmental information available. These archives document changes in the size of the cryosphere over the past million years, including large increases such as the glacial periods during the Pleistocene. The sensitivity of the cryosphere is demonstrated by recent smaller but significant increases in the size of the cryosphere such as the Little Ice Age from A.D. 1400 to 1650 when temperatures were only about 1 °C cooler than it is presently (Graedel and Crutzen, 1995).

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

RESERVOIRS IN THE CRYOSPHERE

The cryosphere consists of a number or reservoirs that, in sum, contain about 1.8% of all the water on earth and about 70% of all freshwater resources. The reservoirs include seasonal snow, frozen ground, floating ice such as sea, lake and river ice, glaciers, ice caps, and ice sheets.

In terms of area, seasonal snow cover is the largest component of the cryosphere, covering up to 33% of the Earth's total land surface with about 98% of the total seasonal snow cover located in the Northern Hemisphere. Seasonal snow packs accumulate winter precipitation that is subsequently released through melt, thereby generating surface runoff during the spring and summer when it is needed for agriculture. In many semiarid and arid regions, as much as 90% of the annual surface runoff results from melting of the seasonal snow pack in nearby mountains.

Much of the soil that underlies the high latitude and high elevation regions of the Earth is permanently or seasonally frozen. Although the amount of water stored as ice in seasonally or permanently frozen ground (or permafrost) varies from nearly zero to more than 30%, the total amount of freshwater stored in permafrost is estimated to be 0.3 million km^3 or about 1% of that stored in the Antarctic Ice Sheet (Intergovernmental Panel on Climate Change, 2001). 22.8 million km^2 or nearly 24% of the exposed land of the Northern Hemisphere contains permafrost including over half of Canada and much of the Russian Arctic. Permafrost thickness varies from tens of meters to over a thousand meters and temperatures range from just below freezing to less than $-10\,^{\circ}C$. Permanently frozen ground is usually overlain by an "active layer" that freezes and thaws annually. Freezing and thawing processes impact ecosystem diversity and productivity, and understanding such processes is important for civil engineering and architectural projects in cold regions.

Floating ice includes river, lake, and sea ice. During their respective winter seasons, sea ice covers 14 to 16 million km^2 of the Arctic Ocean and 17 to 20 million km^2 of the Southern Ocean around Antarctica. Conversely, the Arctic minimum in summer sea ice cover is approximately 7 to 9 million km^2, far greater than the 3 to 4 million km^2 minimum found in the Antarctic. Traditional human cultures and biological systems are adapted to the seasonal cycle of sea ice extent. Penguins, polar bears, seals, and other mammals depend entirely on sea ice for habitat.

The large ice sheets in Antarctica and Greenland contain the bulk of the water stored in the cryosphere. With an area of 12.37 million km^2 and mean thickness of 2.5 km, the Antarctic Ice Sheet covers an area half the size of North America and contains 25.71 million km^3 of ice or about 23.3 million km^3 of freshwater. Covering 1.71 km^2, the Greenland ice sheet is about 14% the size of the Antarctic Ice Sheet and has a mean thickness of 1.6 km. The Greenland ice sheet contains some 2.85 million km^3 of ice or about 2.6 million km^3 of freshwater. Glaciers and small ice caps outside the Antarctica have a combined area of about 0.54 million km^2 and a mean thickness of approximately 0.2 km. The total volume of these glaciers and small ice caps is 0.18 million km^3 of ice or 0.16 million km^3 of freshwater (Intergovernmental Panel on Climate Change, 2001).

OBSERVING THE CRYOSPHERE

Seasonal snow packs accumulate winter precipitation that is subsequently released through melt, thereby generating surface runoff during the spring and summer when it is needed for agriculture. In many semiarid and arid regions, as much as 90% of the annual surface runoff results from melting of the seasonal snow pack in nearby mountains. Measurements of the water stored in seasonal snow packs are used to predict spring runoff and also to manage reservoir and water conveyance systems. Systematic measurements of snow depth and snow density on specific dates throughout the snow accumulation season called *snow surveys*, together with empirical relationships between such snow pack measurements and observed stream flows in previous years, have been used for much of the twentieth century to predict spring runoff. More recently, networks of autonomous systems to measure snow depth and snow water equivalence (SWE) have been developed. The SNOWTEL network is operated by the National Resource Conservation Service and provides 15 min measurements of snow depth, SWE, temperature, wind, and soil moisture at more than 750 locations throughout the western United States. SNOTEL data are available in real-time over the World Wide Web (**`http://www.wcc.nrcs.usda.gov/snow/`**). Systematic manual measurements of seasonal snow depth and water content are made routinely at many locations throughout the world (e.g. Central Asia, Andes). Though less extensive than the SNOTEL network in the United States, autonomous snow measurement systems have been deployed in other parts of the world.

While empirically based runoff prediction is often adequate for spring runoff prediction, understanding of the physical processes underlying snow melt, infiltration, runoff generation, and plant physiology in snow-covered regions is required to assess the impact of climate change on hydrologic systems where snowfall occurs. Studies intended to develop such understanding require detailed information on the distribution of snow-covered area (SCA) and SWE. Because of the strong differences in albedo between snow-covered and exposed soils and vegetation, satellite and airborne remote sensing provide an efficient means to measure SCA. Measurements from satellites have been used routinely since the late 1960s to monitor seasonal snow cover. However, while progress has been made in measuring SWE via remote sensing, campaign style measurements

of snow depth and snow density are still required (e.g. NASA's Cold-land Processes Field Experiment).

Because permafrost is defined solely by soil temperature and not by soil moisture content, overlying snow cover, or air temperature, determining the location and extent of permafrost is difficult particularly at regional to hemispheric scales. Systemic monitoring through borehole and probe temperature measurements of the seasonally melting and freezing or active layer that overlies most permafrost is particularly important to assess changes in frozen ground. The Circumpolar Active Layer Monitoring Program (CALM) was established in 1991 under the auspices of the International Permafrost Association to acquire long-term active layer measurements. The network includes more than 80 sites distributed throughout the permafrost regions of the Northern Hemisphere and efforts are under way to establish a similar network of sites for long-term active layer measurements in the Southern Hemisphere (Brown *et al.*, 2000).

Because of the importance of sea ice extent to the shipping industry, surface and airborne sea ice surveys have been conducted routinely for decades. Prior to the satellite era, sea ice extent was derived from observations from ships, aircraft, and land installations. Since the 1970s, satellite measurements such as those from NASA's Nimbus 7 Scanning Multichannel Microwave Radiometer (SMMR), the Defense Meteorological Satellite Program Special Sensor Microwave Imagers (SSMIs), and the National Space Development Agency of Japan's recently launched Advanced Microwave Scanning Radiometer for the Earth Observing System (AMSR-E) have been used to monitor sea ice extent. Satellite data from the Southern Ocean show general increases in sea ice extent since the late 1970s.

Measurements from radar and laser altimetry surveys such as those from NASA's recently launched Ice, Cloud and land Elevation Satellite (ICESat) will be used to measure changes in surface elevation. The ICESat mission's primary focus is the cryosphere and it will provide detailed measurements of surface elevation of sea ice. Such data will be used to measure and monitor changes in sea ice thickness. Indeed, ice thickness measurements from submarines, together with surface and other observations, show that sea ice has thinned dramatically in the Arctic over recent decades.

Because glaciers and ice sheets hold nearly 70% of the Earth's freshwater resources and because changes in these cryosphere reservoirs directly impact the sea level, monitoring changes in glaciers and ice sheets is especially important to understanding the cryosphere. Measurements fall into two primary categories: ground-based measurements through snow pits and ice cores, and remotely sensed observations from aircraft and satellites.

Glaciers and ice sheets can be divided into accumulation and ablation regions where surface mass balance is positive and negative respectively, with ice flow within the glacier or ice sheet from the accumulation to the ablation zones. Much like tree rings or lake varves, layers of snow accumulate in the higher elevation regions. Ice cores and snow pits collected in the accumulation zones provide a means to sample these snow layers. Chemical and physical parameter measurements are used to identify annual layers and to document historical changes in atmospheric chemistry (e.g. important greenhouse gas concentrations such as carbon dioxide and methane) and atmospheric fallout from volcanism (e.g. sulfur, lead), industrial pollution (e.g. lead, vanadium, sulfur), biomass burning (e.g. black carbon, ammonia), and dust (e.g. aluminum, calcium, iron) and sea salt (e.g. sodium, magnesium, strontium) transport. Such measurements provide insights not only into natural and perturbed biogeochemical cycles and atmospheric and oceanic circulation but also into historical changes in meteorology (e.g. snow accumulation rate, windiness), climate (e.g. temperature, circulation), and the state of ice sheet or glacier (frequency of summer melt, surface mass balance, ice sheet elevation). Ice cores have been collected from glaciers and ice sheets at least since the 1950s including those collected from lower latitude, high altitude glaciers throughout the world as well as from smaller glaciers and ice caps around the Arctic Basin.

Five ice cores reaching bedrock have been collected in Greenland, including two nearly adjacent cores completed in the early 1990s at the highest point of the ice sheet (72 °N, 38 °W, 3200 m): the US Greenland Ice Sheet Project 2 (GISP2) and the European Greenland Ice Core Program (GRIP) cores. Each over 3000 m in length and analyzed for a broad range of physical and chemical parameters, these cores provided for the first time nearly replicate high-resolution environmental records spanning more than 250 000 years with annual layering identified over the past 110 000 years. In 2003, the European North Greenland Ice Core Project (NGRIP) (75 °N, 42 °W, 2900 m) reached bedrock, providing a 3010-m record spanning ~200 000 years from the northern part of the ice sheet. Hundreds of snow pits and shallow and intermediate (~150 m) cores, including more than 85 cores since 1995 as part of the ongoing US Program for Arctic Regional Climate Assessment (PARCA), have also been collected from most regions of the Greenland ice sheet (Thomas *et al.*, 2001).

A number of cores reaching bedrock have also been collected in Antarctica, including the Siple Dome core (78.5 °S, 106.8 °W, 623 m) in West Antarctica and the Vostock (78.5 °S, 106.8 °E, 3500 m) and the recently completed Dome Concordia (81.7 °S, 148.8 °W, 3200 m) cores in East Antarctica. A coordinated international research program

called the International Trans Antarctic Scientific Expedition (ITASE) is underway. ITASE includes the collection and analysis of a large number of shallow ice cores from all regions of Antarctica spanning the last 200 years. Interpretations of glaciochemical records are complicated by air-to-snow transfer processes and modifications of the chemical or physical record after snow deposition. While far more important for some parameters than others, such transfer processes may modulate the relationship between concentrations in the air and those in the snow and thence preserved in the ice core record. Recent research efforts have been directed toward better understanding and modeling of these transfer processes.

Developments in remote sensing have and will advance our ability to observe the cryosphere in the coming years. For glaciers and ice sheets, aircraft and satellite-mounted laser altimeters such as those aboard NASA's recently launched ICESat will be used to measure changes in surface elevation, with thickening indicating regions of positive mass balance. Similar measurements using radar altimetry will be made from the European Space Agency's CryoSat platform. CryoSat is scheduled for launch in 2004.

Precise gravity measurements from the Gravity Recovery and Climate Experiment (GRACE) satellites will be used to track how water is transported and stored within the Earth's environment, including measuring changes in mass of cryospheric reservoirs such as the ice sheets and permafrost. The GRACE satellites were launched in 2002. GRACE is a joint mission between NASA and German Center for Air and Space Flight.

General background information on the cryosphere, as well as regularly updated satellite and other global cryosphere measurements, are available from the US National Snow and Ice Data Center (**`http://nsidc.org/`**) and the CRYosphere SYStem in Canada (CRYSYS) program (**`http://www.msc.ec.gc.ca/crysys/`**).

GLACIERS AND ICE SHEETS AS PALEOCLIMATE ARCHIVES

Studies of chemical and physical parameters in ice cores form a cornerstone of global climate change research because glaciers and ice sheets contain arguably the most complete archives of paleoclimate information available. Unlike other long-term proxies such as tree ring records and lake sediment and peat bog cores, ice cores collected from glaciers and ice sheets contain direct, very high-resolution records of precipitation and atmospheric chemistry through soluble and insoluble impurities contained within the ice and gases within trapped bubbles. Among other issues, these data are used to study long-term climate variability and recent warming as well as changes in hemispheric-scale atmospheric and oceanic circulation, sea ice extent, anthropogenic pollution, and volcanism (Legrand and Mayewski, 1997; McConnell *et al.*, 2002).

Deep ice core measurements have documented rapid climate changes such as the 7 °C increase in North Atlantic temperature that occurred over a 50-year period at the end of the last glacial period. Measurements of important greenhouse gases like methane, carbon dioxide, and chlorofluorocarbons in bubbles within the snow and ice extend direct atmospheric chemistry measurements from recent decades and so provide historical records of changing atmospheric chemistry and related greenhouse forcing (Raynaud *et al.*, 1993).

Ocean productivity is in a large part modulated by fertilization from atmospheric dust containing iron and other nutrients and is a major component of the global carbon cycle. Recent advances in ice core analytical techniques allow for a sub-annually resolved determination of past atmospheric dust and iron fluxes to the Arctic and Antarctic. Such proxies are important for understanding how both naturally occurring and human-caused changes in dust fluxes in remote regions have altered carbon sequestration in the oceans over recent decades to centuries to millennia. Similar measurements from ice cores may one day provide better understanding of large-scale rapid climate changes such as those that occurred during the last glacial to interglacial transition (National Research Council, 2002).

Annually resolved records of net water accumulation from the accumulation zones of glaciers provide a direct measurement of the past changes in the hydrologic cycle and are important for detecting recent changes in the global hydrologic cycle and for determining the current mass balance of glaciers and ice sheets. Because much of the Earth's water is stored in glaciers and ice sheets, understanding ice sheet mass balance is critical to predicting future sea levels. While it is generally believed that climate warming will accelerate the global hydrologic cycle and result in increased precipitation over many of the colder regions of the Earth, extensive recent measurements of precipitation from ice cores in Greenland do not show any significant increases in recent precipitation. However, determination of significant long-term precipitation trends is difficult because precipitation over much of Greenland is cyclical and highly variable from one location to another.

VULNERABILITY OF CRYOSPHERE TO CLIMATE CHANGE

Interaction between the cryosphere and other components of the hydrologic cycle depends on the change of water to and from the solid phase (ice and snow) and much of the cryosphere exists near the melting point so the size and behavior of the cryosphere is highly sensitive to climate change. There is a strong positive feedback

between the cryosphere and climate through changes to the albedo or surface reflectivity. The albedo of freshly fallen snow, aged snow, and sea ice are approximately 0.9, 0.5, and 0.8 respectively, although sea ice albedo is highly variable since it depends on the presence or absence of snow cover. Conversely, the albedo of bare and vegetated land and open seawater is approximately 0.2, 0.1, and 0.1 respectively. Enhanced snow cover and sea ice increase albedo, decreasing absorption of solar radiation and leading to enhanced cooling. In a positive feedback loop, the enhanced cooling results in reduced melting and so persistence of the snow cover and sea ice. Conversely, lower snow cover and sea ice result in lower albedo and enhanced heating, leading to increased melting and less persistence of snow and sea ice. Impurities, in particular black carbon from combustion, significantly reduce the albedo of snow and ice. Recent evidence suggests that even small increases in black carbon emissions to the atmosphere from human industrial activities deposited with snow may be significantly altering the global climate (Hansen and Nazarenko, 2004).

Seasonal snow packs accumulate winter precipitation that is subsequently released through melt, thereby generating surface runoff during the spring and summer when it is needed for agriculture. In many semiarid and arid regions, as much as 90% of the annual surface runoff results from melting of the seasonal snow pack in nearby mountains. The likely results of climate warming would be increased rainfall in winter and earlier onset of the melt season, both of which result in an earlier release of water from the snow pack reservoir, resulting in higher river flows in winter and early spring before the growing season and lower late spring and summer flows.

Reconstructions using historical surface observations coupled with more recent satellite measurements indicate that the overall snow cover increased over North America from the early 1900s to the mid-1970s, in particular fall snow cover, followed by a pronounced decrease in SCA during the 1980s and 1990s due to more rapid melting in early spring. While the historical data for Eurasia are more sporadic, they indicate little long-term change in fall snow cover, but a rapid reduction in spring snow cover. Note that 98% of the Earth's seasonally SCA is in the Northern Hemisphere. It is likely that the increasing early winter snowfall observed over North America dominated through the mid-1970s, resulting in longer duration snow cover. Since then, however, early springtime warming has dominated (Brown, 2001).

As with other parts of the cryosphere, permafrost is sensitive to the changing climate. Changes in the depth of the active layer and permafrost temperatures are closely related changes in overlying air temperatures, although variations in the depth and persistence of snow cover also play a role since the snow cover insulates the ground from air temperature extremes. Differences in rock and soil type between monitoring sites also modify the responsiveness of the subsurface to changes in air temperature. While consistent, long-term records are relatively few, indications are that active layer depths and borehole temperatures have increased in some parts of the Arctic and at lower latitudes in parallel with increasing air temperatures and decreasing seasonal snow cover, especially in the late 1990s.

By the middle of the twenty-first century, modeling studies indicate that near-surface permafrost area will decline by 12% to 15% and an active layer thickness will increase by 15% to 30% in response to climate warming. Release of methane and other gases by melting permafrost further increases greenhouse gas concentration, resulting in an indirect positive feedback that will accelerate decreases in permanently frozen ground (Intergovernmental Panel on Climate Change, 2001).

By insulating the relatively warm ocean water from the cold polar atmosphere, sea ice regulates the exchange of heat, moisture, and salinity in the polar oceans. The large differences in albedo between ice covered and open ocean lead to a strong positive feedback between warming and decreases in sea ice extent. While seasonal changes in sea ice extent are large in both the Northern and Southern Hemispheres, they are much larger in the Antarctic. Long-term trends in sea ice extent from satellite measurements over the past 25 years show that in most of the Arctic, sea ice season has decreased ($\sim$2.7% per decade) while in much of the Antarctic, sea ice season has increased ($\sim$1.1% per decade) (Cavalieri *et al.*, 1997; Parkinson, 2002). In the latter, trends in sea ice season duration were found to correlate to observed spatial patterns in air temperature trends, with decreases found around the Antarctic Peninsula where strong warming has been observed and increases in sea ice season duration in the Ross Sea region.

Another consequence of decreased sea ice cover, particularly in the Arctic, may be a change in deep water formation. Rejection of brine as sea ice forms has important influences on sea surface salinity, deep water formation rates, and large-scale ocean circulation. Sea ice has also been found to play an important role in the redistribution of freshwater in the North Atlantic (Intergovernmental Panel on Climate Change, 2001).

Sea level and the size of the cryosphere are directly linked because $\sim$1.8% of Earth's water is stored in glaciers and ice sheets. Neglecting thermal expansion of the oceans, isostatic rebound, and other changes that would result from large increases in global temperature but allowing for calculated isostatic rebound and sea water replacing grounded ice, sea level would rise by 7.2 m if the entire Greenland ice sheet melted, 61.1 m if the Antarctic ice sheet melted, and 0.51 m if all glaciers and smaller ice caps melted, respectively (Intergovernmental Panel on Climate Change, 2001).

Also important to global climate is the timing and rate of melt water delivery to the oceans, particularly in the North Atlantic. Numerous studies suggest that melt water production from the Greenland ice sheet and deepwater formation in the North Atlantic played a major role in the well-documented Younger Dryas rapid climate shift to glacial conditions about 10 500 years ago (Intergovernmental Panel on Climate Change, 2001; National Research Council, 2002).

While an understanding of the current mass balance of ice sheets is not complete, models suggest a decrease in the size of the Greenland ice sheet under likely warming scenarios because much of Greenland is relatively close to the melting point, contributing to an increase in sea level (Intergovernmental Panel on Climate Change, 2001). Indeed, repeat altimetry surveys over recent decades suggest that while the upper elevations of the Greenland ice sheet are in overall mass balance (i.e. there is no change in the thickness of the ice sheet in these regions), the margins of the ice sheet are shrinking rapidly (Krabill *et al.*, 2000). Much of this behavior is a result of natural cycles in atmospheric and oceanic circulation that determines the meteorology over Greenland is uncertain and so the current mass balance of the ice sheet is unclear, however. Warmer atmospheric temperatures will likely accelerate the hydrologic cycle and lead to increased precipitation. Because temperatures over most of Antarctica are well below the melting point, it is likely that the Antarctic ice sheet will increase in size under possible global warming scenarios, contributing to a decrease in sea level (Intergovernmental Panel on Climate Change, 2001).

Mountain glaciers are particularly vulnerable to climate change with twentieth century consequences observed throughout the world. As much as 20% of the sea level rise observed during the twentieth century has been attributed to the retreat of mountain glaciers (Intergovernmental Panel on Climate Change, 2001). Increased melting of mountain glaciers has resulted in increased flooding along major river systems such as the Rhine, while melting of glaciers and retreat of permafrost has resulted in increased erosion, debris flows, and avalanches. The complete loss of mountain glaciers, projected to occur as early as the middle of the twenty-first century in some high mountain regions such as the Andes and Himalayas, will have disastrous impacts on subsistence agriculture and hydropower generation that depend on flows from mountain glaciers.

199: Role and Importance of Paleohydrology in the Study of Climate Change and Variability

BRENDA EKWURZEL

Global Environment Program, Union of Concerned Scientists, Washington, DC, US

Paleohydrology has advanced our understanding of climate by uncovering the variability of the prehistoric water cycle. Various proxy records provide insight into aspects of the hydrologic cycle that occurred before the instrumental record and allow for paleoclimate reconstructions locally or over large regions. For example, geomorphologic methods can quantify megafloods; coral or sediment core methods create paleodischarge records; rodent middens archive changes in precipitation volume and temperature; closed-basin lake level fluctuations offer quantitative evidence of changes in water balance, and tree-rings provide a high-resolution archive of precipitation or drought. This article reviews representative examples from the field of paleohydrology and demonstrates the role each has played in enhancing our understanding of climate variability.

INTRODUCTION

Time-series measurements span a range of timescales from rapidly repeating satellite measurements to time series that begin with the earliest historical records that continue to the present day. Long historical records, such as the typhoon records in local gazettes kept since 975 A.D. in the Guangdong Province of southern China (Liu *et al.*, 2001; Perkins, 2002b), are rare. The longest surface air temperature record (daily back to 1772 and monthly since 1659) is located in the English Midlands, commonly referred to as the *Central England Temperature Record* (Brabson and Palutikof, 2002). Historical freeze and thaw dates for rivers and lakes exist for the past 150 years; a rare 550-year record persists for Lake Suwa in Japan (Magnuson *et al.*, 2000). Historical records of grape-harvest dates extend back to 1370 in Burgundy France (Chuine *et al.*, 2004). Unfortunately, the time frame of human observation may not be long enough or the records accurate enough for many climate-variability studies. Paleohydrology can be a vital approach for extending our reference time over longer periods where climate cycles, trends, or dramatic shifts may give full expression. Furthermore, paleohydrology can reconstruct extreme hydrologic events that humans have never observed such as the Missoula Flood and the Altay Flood, both with peak discharges of around 20 million $m^3\ s^{-1}$ (O'Connor and Baker, 1992; Baker, *et al.*, 1993). This is roughly equivalent to over 7000 times the average flow rate over the Niagara Falls (i.e. the combined flow of American Falls, Bridal Veil Falls, and Canadian Horseshoe Falls).

Unlike the modern hydrologist who can probe the current hydrologic cycle to record a specific property of interest, the paleohydrologist is often at the mercy of preserved physical, chemical, and biological data that serve as a proxy for hydrologic processes. This article is organized into two broad sections. The first section addresses examples of climate archives that exist in preserved elements of the ancient hydrologic cycle that can be directly sampled today. Reservoirs of old H_2O molecules in the form of glacial ice and old groundwater serve as important archives of climate information. Calcite deposits in caves provide another groundwater archive because they record groundwater geochemistry and surface recharge conditions at the time of formation. The second broad section reviews elements of the hydrologic cycle that are too transient to be preserved as water that can be directly sampled today. Instead, other records serve as proxy evidence for past precipitation, surface water discharge, or the lack of water such as during droughts. This article presents some of the more successful paleohydrology methods that have added new insights to climate

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

variability or that may play a more prominent role in future studies.

LONG RESIDENCE TIME ELEMENTS OF HYDROLOGIC CYCLE: CLIMATE ARCHIVES

Frozen Precipitation As a Climate Archive: Continental Ice Sheets

Precipitation that falls at high altitude or latitude may encounter cold enough temperatures to fall as snow. In regions where a winter's snow survives a summer season, glaciers can form as additional snow accumulates each year and eventually turns into ice. Mountain glaciers and large continental ice sheets archive local precipitation, atmospheric gases, dust, and other constituents through their annual snow accumulation. A proper understanding of the hydrologic conditions that impact the precipitation (e.g. humidity, moisture sources or prevailing storm track patterns, temperature, elevation, global sea level, etc.) is critical for proper paleoclimatic interpretation of the ice-core records. The most famous locations for the longest ice records are in Antarctica and Greenland (Figure 1).

These ice-core records with exquisite resolution have had a profound impact on our interpretation of climate variability during the late Quaternary period. The Greenland Ice core data reach as far back as 150 000 years while the third core drilled at Vostok, Antarctica, extends over the past 420 000 years and the ice core from Dome C Antarctica offers a view of climate variability over the past 740 000 years (Figure 1; Stauffer, 1999; Petit *et al.*, 1999; EPICA, 2004). Extensive research on ice cores has produced significant results such as correlations and lead/lag relationships between the Greenland and Antarctic ice cores (e.g. Blunier *et al.*, 2001). In this article, we focus on the analysis of the Vostok ice-core record as representative of the techniques used and major findings of the ice-core climate archive in general.

The major techniques used to extract climate information from the ice are to measure the stable isotopes of the precipitation, the dissolved constituents in the precipitation, dry deposition on the snow surface (e.g. dust), and to measure the atmospheric trace gases eventually trapped within the ice. The stable isotopes of the water molecule hydrogen (δD (in ‰) $= [(({}^{2}H/{}^{1}H)_{sample}/({}^{2}H/{}^{1}H)_{standard}) - 1] \times 1000$) and oxygen ($\delta^{18}$O (in ‰) $= [(({}^{18}O/{}^{16}O)_{sample}/({}^{18}O/{}^{16}O)_{standard}) - 1] \times 1000$) are measured relative to the Vienna Standard Mean Ocean Water and in general are most depleted in Antarctic precipitation. Details regarding how ice-core researchers reconstruct temperature of the atmosphere from the stable isotopes measured in the ice can be found in Petit *et al.* (1999). The trace gases trapped in air bubbles about 100 m below the snow surface preserve the variability of atmospheric trends (Stauffer, 1999; Petit *et al.*, 1999) which causes an age offset between the ice and the trapped gas in a given layer. This age offset creates some difficulty determining the exact chronology

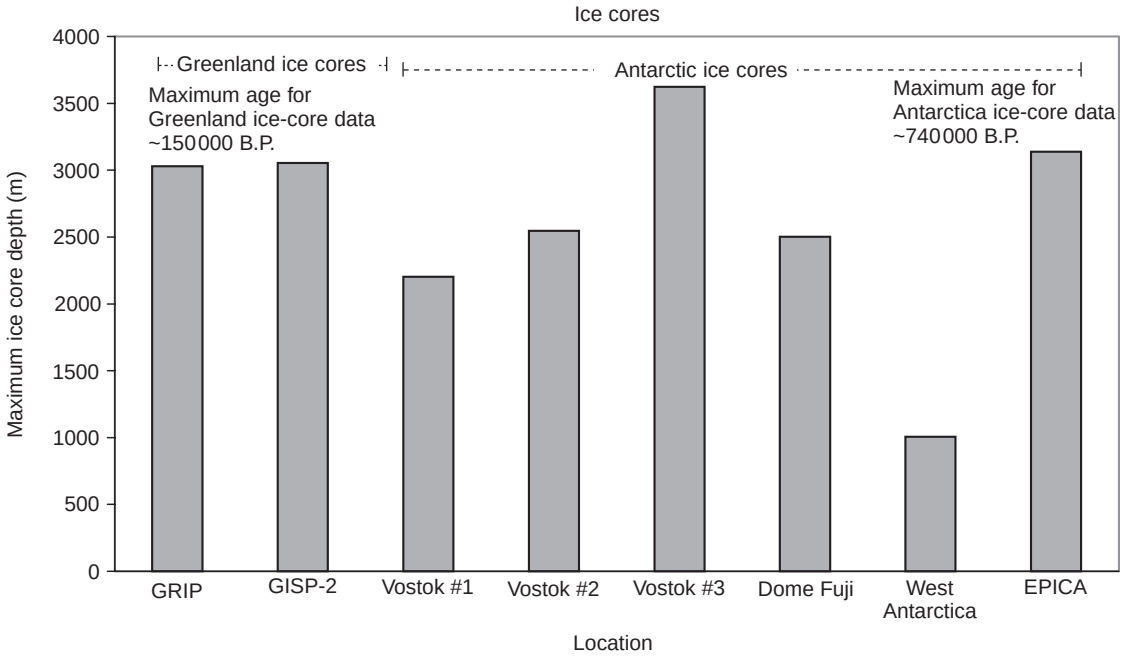

Figure 1 Long ice cores with their associated project names. Their general location (i.e. Greenland or Antarctica), their maximum drilling depth, and regional maximum age limit are depicted. (Adapted from Stauffer (1999), Petit *et al.* (1999) and EPICA (2004)) A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

for forcing mechanisms and climate response. However, Petit *et al.* (1999) argue that the new glaciological timescale known as *GT4* for the Vostok core yield age accuracy of ±15 kyr for most of the record and better than ±5 kyr for the last 110 kyr. This age resolution will be accurate enough to see general climate response and most lead-or-lag trends between trace gas measurements and ice measurements.

The ice-core results confirm what has been found in other climate records such as ocean sediment cores and lake sediment cores regarding glacial cycles over the past million years (Figure 2). Ice core glacial-to-interglacial cycles exhibit periodicity similar to Milankovitch orbital forcing periods of 100 000 and 41 000 years (Imbrie *et al.*, 1992; Petit *et al.*, 1999). Dust decreased while temperature, methane, and CO_2 all increased during the glacial-to-interglacial transition (Petit *et al.*, 1999). Methane, in particular, increased significantly during the last half of deglaciation. This sequence, Petit *et al.* (1999) argue, implies that the Milankovitch orbital cycles trigger the climate response which is amplified by the trace gases and then the strong ice-albedo feedback leading to rapid deglaciation.

Groundwater As a Climate Archive

In contrast to the short residence times of water in the atmosphere and in rivers, water that travels through porous media in the subsurface can have much longer residence times. Indeed aquifers such as the Milk River aquifer in Alberta, Canada, and the Great Artesian Basin in Australia are amongst the oldest groundwater (ca. one to four million years old) dated thus far (Phillips *et al.*, 1986; Torgersen *et al.*, 1991; Collon *et al.*, 1998). In the geologic record, periods of erosion erase prior deposition history, leaving only an erosional surface to document the period as compared to the preserved periods of sedimentation. Likewise, confined aquifers can archive periods of active recharge yet leave gaps during periods when recharge does not occur (e.g. during a drought or when covered by ice during a glacial period). Ideal settings for groundwater archives of climate are confined aquifers with a single recharge region where minimal mixing occurs with other formation water during the subsurface transit. Perhaps the most successful groundwater paleohydrology contribution to the evolution of the global climate-variability theory is the mean annual temperature reconstructions of the

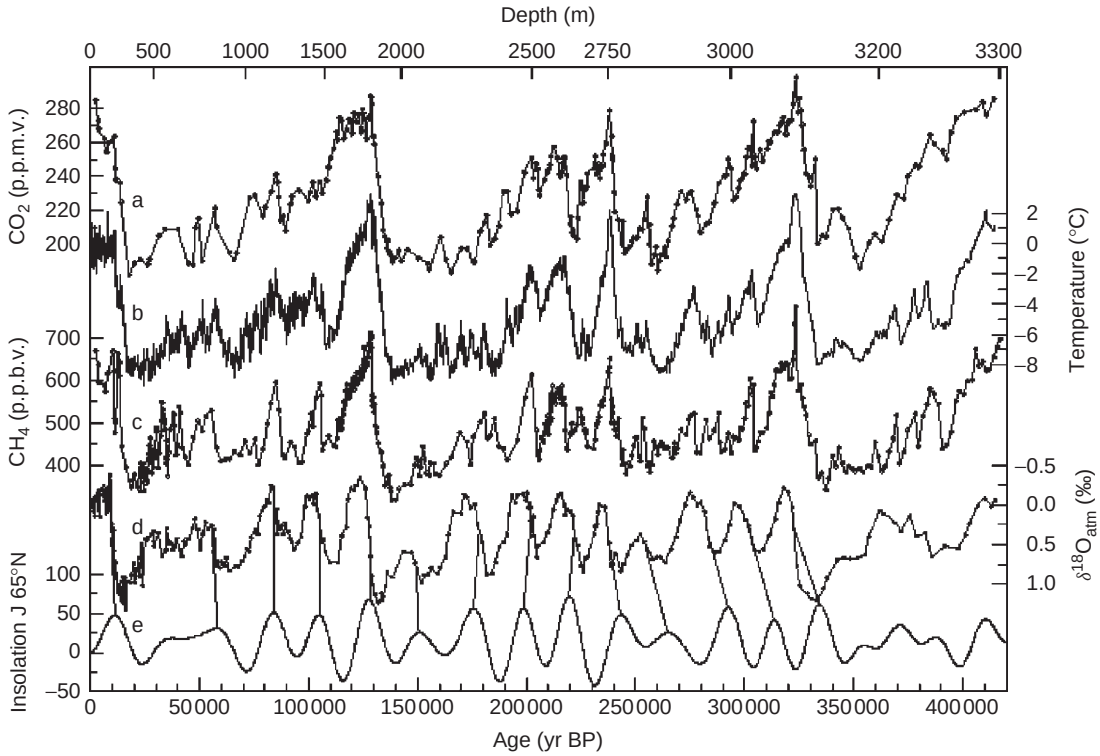

Figure 2 Vostok time series and insolation. Series with respect to time (gt4 timescale for ice on the lower axis, with indications of corresponding depths on the top axis) of (a) CO_2; (b) isotopic temperature of the atmosphere; (c) CH_4; (d) $\delta^{18}O_{atm}$; and (e) mid-June insolation at 65 °N (in Wm^{-2}). The mean resolution of the CO_2 (CH_4) profile is about 1500 (950) years. It goes up to about 6000 years for CO_2 in the fractured zones and in the bottom part of the record, whereas the CH_4 time resolution ranges between a few tens of years to 4500 years. The overall accuracy for CH_4 and CO_2 measurements are ±20 p.p.b.v. and 2–3 p.p.m.v. respectively. $\delta^{18}O_{atm}$ standard is modern air composition. No gravitational correction has been applied. (Reproduced from Petit *et al.* (1999) by permission of Nature)

Last Glacial Maximum (LGM) period on continents. In particular, theories regarding high latitude versus tropical latitude climate response during the LGM came under intense scrutiny and revisions and refinements were made, as we shall see after a brief discussion of the noble gas approach.

Groundwater: Reconstructing Paleotemperature from Dissolved Gases

Noble gases have properties that make them appropriate for archives of the temperature and elevation of the recharge conditions for an aquifer (Stute and Schlosser, 2000). The solubility of noble gases is a direct function of temperature, atmospheric pressure, and salinity of the water. Noble gas solubility increases with decreasing temperature and the sensitivity to this trend is different for each noble gas (i.e. higher mass noble gases are more sensitive.) If the water table is between 5 and 30 m from the surface and the recharge rate is active but not exceeding several hundred mm year^{-1}, the noble gas recharge temperature is about 1 °C different from the ground surface temperature. For further discussion regarding methods to account for other sources of various noble gases, see Stute and Schlosser (2000).

The noble gas hydrologist interested in reconstructing LGM paleotemperatures chooses a confined aquifer in which the recharge zone elevation is well known. Thus, if one knows the confined aquifer recharge elevation, and one assumes the precipitation is not saline, one can unravel the ground temperature at the water table by measuring the noble gas concentrations from wells pulling water up from the appropriate age water for the LGM. The typical approach has been to measure noble gases, stable isotopes, and radiocarbon throughout the confined aquifer (Andrews and Lee, 1979; Heaton *et al.*, 1986; Stute and Deák, 1989; Stute *et al.*, 1992, 1995a, 1995b; Dennis *et al.*, 1997; Ballantine and Hall, 1999; Beyerle *et al.*, 1998; Clark *et al.*, 1998; Stute and Talma, 1998; Edmunds *et al.*, 1998). The radiocarbon data combined with stable carbon isotope measurements and a refined geochemical evolution model is critical for placing the noble gas paleotemperatures into a chronologic reference frame. The water stable isotopes serve as a check on the radiocarbon ages because the glacial ocean $\delta^{18}O$ and $\delta^{2}H$ shifted to more enriched values worldwide (1.3%) as much of the depleted water was locked up in the ice during the LGM (Fairbanks and Matthews, 1978). Note that the water stable-isotope signal may be complicated by other factors such as temperature, storm track patterns, and evaporation, which must be accounted for.

A key distinction between groundwater as a climate archive and annual tree-rings, annual lake varves, ice core, or other high-resolution records is that the climate-variability signal will be smoothed in a confined aquifer archive. The water and dissolved constituents will be dispersed over thousands of years as the water flows through a heterogeneous aquifer (see, for example, Stute and Schlosser, 2000; Figure 6). Groundwater dispersion is the reason researchers usually are only able to distinguish the relative shift in paleotemperature between the LGM and today. Statistically, this is achieved by averaging many measurements for aquifer waters in the most recent few thousand radiocarbon years and compare those with the average of many measurements of water collected from several thousands radiocarbon years around the LGM time period. This is also necessary when one considers the average age error for older radiocarbon dated waters is around 2000 years (Phillips *et al.*, 1989).

Groundwater: LGM Paleotemperature Provokes Further Scrutiny of Tropical SST

One of the central issues that evolved in the paleoclimate debate was whether the tropical sea surface temperatures (SST) were similar to modern values while the polar ocean regions experienced more extreme swings in temperature through time as indicated by foraminiferal tropical sea surface temperature reconstructions. Central to this debate was the difference between tropical SST and the tropical-mountain glacier snowline elevation also known as *equilibrium line altitude.* Geomorphic reconstructions of equilibrium line altitude during the LGM coupled with foraminifera reconstructions of tropical SST implied a LGM lapse rate that would not match known physical principles of the modern lapse rate (Greene *et al.*, 2002). During this debate, several Global Circulation Models had a difficult time holding tropical SST relatively constant while the higher latitude SST cooled during their LGM simulations (Hansen *et al.*, 1984; Manabe and Broccoli, 1985).

As with most paleoclimate discussions, debate evolved as the proxy evidence accumulated. Early paleoclimate work indicated relatively stable tropical SST. After extensive work in the oceans, the Climate: Long-Range Investigation, Mapping, and Prediction (CLIMAP) Project Members (1981) endeavored to reconstruct SST history based on the planktonic foraminifera assemblages (CLIMAP, 1981). CLIMAP predicted little change in tropical SST for the LGM with a global statistical cooling of 1.4 °C and 1.7 °C for February and August respectively (CLIMAP, 1981). Matthews and Poore (1980) argued that tropical SST remained constant throughout the Cenozoic, despite swings in high-latitude SST.

Despite the more sporadic nature of the terrestrial paleoclimate records compared to the synoptic scale oceanographic records, continental reconstructions indicated that the tropics were probably cooler during the LGM. The most notable records were the tropical snowline elevation reconstructions that indicated a significant lowering of the snowline in tropical mountains during the LGM representing a 4 °C to 6 °C cooler temperature (e.g. Broecker and

Denton, 1989). Tropical vegetation records also indicated a greater LGM cooling compared with CLIMAP and the Global Circulation Model research questioned the inconsistency (Rind and Peteet, 1985). This controversy drove researchers to look for other continental proxy records for temperature in the tropics and the search began in earnest for aquifers with archived LGM waters in order to apply the noble gas paleotemperature method.

The paleohydrology work in groundwater archives is still ongoing, but the results thus far confirm that the recharge locations of tropical aquifers record cooler LGM temperatures. Table 1 summarizes the results: (i) tropical aquifers ($<33°$ latitude) were on average $5.8 \pm 1.5\,°C$ cooler during the LGM, and (ii) midlatitude aquifers (33° to 51° latitude) were on average $7.0 \pm 1.8\,°C$ cooler during the LGM (some locations were near the ice sheet). Higher latitudes were usually ice-covered regions during the LGM, which eliminated or restricted recharge to high-latitude aquifers; thus, most of this research has been conducted in tropical to midlatitude aquifers.

The straightforward physics of the noble gas paleotemperature results compelled paleoclimate researchers to reevaluate the CLIMAP results and to search for other proxy records for tropical ocean SST. Guilderson *et al.* (1994) developed an important independent ocean proxy for tropical sea surface temperature based on $\delta^{18}O$ and Sr/Ca data from Barbados corals and found a tropical cooling of around 5 °C at the LGM. More recent faunal reconstructions yield a wider range of tropical SST during the LGM, which reflect the spatial variability of the tropical ocean. The faunal reconstructions suggest as much as 5.5 °C SST depression in the eastern equatorial Pacific and equatorial Atlantic ocean while only a 2 °C cooling was found near Hawaii during LGM (Lee and Slowey, 1999; Mix *et al.*, 1999). Entirely different proxy records for tropical ocean SST yield minimal depression at LGM of about 2 °C based on alkenones (Bard, 1999). In summary, the more recent ocean proxy records for tropical SST suggest a larger cooling (i.e. 2–5 °C) than the original CLIMAP reconstruction (i.e. 1–1.7 °C) of tropical SST during the LGM, based on a wider range of ocean proxy SST interpretations.

Greene *et al.* (2002) worked with a comprehensive set of tropical snowline (i.e. glacier equilibrium line altitude) data to reconstruct the LGM freezing level which was a combination of the lowered sea level, reduction in snowline elevation, and a host of other factors tested with their analysis. Using a single-cell tropical climate model, Greene *et al.* (2002) found that LGM precipitation did not have to be changed significantly but rather that the snowline depression combined with lapse-rate physics implies that the tropical SST had to be around 3 °C cooler during the LGM. This is less than the most extreme ocean proxy SST records, but is consistent with the average of these ocean proxy records and their associated errors, with vegetation or tropical pollen reconstructions for the tropics, with the recharge temperature locations from noble gas groundwater records, and with many Global Circulation Model results (Farrera *et al.*, 1999). The groundwater archive provides a mean annual paleotemperature at a terrestrial elevation that can be directly compared with lapse-rate gradients. The paleohydrologic evidence from the groundwater archives filled an important gap between the sea surface elevation and mountain snowline elevation to confirm that LGM lapse rates adhered to physical principles that create modern lapse rates. Now researchers have a more refined understanding of how precipitation along with temperature influence local equilibrium line altitude (Hostetler and Clark, 1997) while recognizing significant regional variability in tropical ocean SST during the glacial period (Farrera *et al.*, 1999).

Water Supersaturated with Respect to Calcite: Caves As Climate Archives

Settings where water supersaturated with respect to calcite causes precipitation of mineral layers that reflect the water geochemistry create the potential for long paleoclimate records. These records are preserved in calcite veins, stalactites, stalagmites, dripstones, or speleothems (a general term for a mineral deposit formed in a cave by the action of water). Cave-record time spans are on par with continental ice sheets and ocean sediment cores. For example, a core from a calcite vein in a Nevada extensional fault, Devils Hole, has uranium series dates that span from 566 to 60 ka (Ludwig *et al.*, 1992; Winograd *et al.*, 1992). As we shall see in the following examples, the speleothem records found in caves will play a more critical role in climate-variability studies if the paleohydrology of each study location is properly reconstructed. The following paleohydrology aspects must be understood (i) recharge locations; (ii) recharge water geochemistry; (iii) recharge vegetation; (iv) transit time in the groundwater between recharge location and mineral deposition location; (v) groundwater geochemical evolution between recharge and mineral deposition location; and (vi) conditions that impact the isotopic fractionation during the phase change between dissolved phase and solid mineral precipitation (e.g. temperature). The net result is that the ages given by the methods used to reconstruct the dates for mineral precipitation need to be corrected for the transit time between recharge and mineral deposition. Such offsets are critical if we are to understand potential lead-or-lag relationships between individual site responses and global forcing mechanisms.

The Devils Hole calcite-vein data provoked a spirited debate in the paleoclimate community (e.g. Broecker, 1992; Shackleton, 1993; Imbrie *et al.*, 1993; Herbert *et al.*, 2001; Herbert *et al.*, 2002), because if the published chronology was accurate, the $\delta^{18}O$ measured in the calcite mimicked the broad patterns seen in the ice and ocean records

Table 1 Dissolved noble gas reconstructions of the difference between the Last Glacial Maximum (LGM) and Holocene mean annual recharge temperature. Recharge elevations and recharge location are indicated for each study region. Table is arranged in order of increasing latitude

Study location	Holocene noble gas mean temperature	LGM noble gas mean annual temperature (parentheses indicate when dates are not from LGM)	Holocene/LGM noble gas temperature difference (parentheses indicate when dates are not from LGM)	Recharge elevation	Recharge latitude	Recharge longitude	Reference
Maranhão Basin, Brazil	29.6 ± 0.3 °C	24.2 ± 0.3 °C	5.4 ± 0.6 °C	450 ± 50 m	7 °S	41.5 °W	Stute *et al.* (1995a)
Chad Basin, Nigeria	30.5 ± 0.5 °C (present-day groundwater temperature)	22 ± 1.5 °C	8.5 ± 2.0 °C	330 ± 60 m	11 °N	13 °E	Edmunds *et al.* (1998)

Bunter Sandstone Aquifer, United Kingdom	9.6 ± 1.4 °C	(Diminished or no recharge at LGM due to permafrost cover. Nearest well in age (22 kyr) is 3.4 ± 1.0 °C)	(At least 6.2 ± 1.7 °C)	(Not specified)	53.4 °N	0.5 °E	Andrews and Lee (1979)

with a subtle twist. Winograd *et al.* (1992) pointed out the subtle difference between the records, remarking that the Devils Hole $\delta^{18}O$ curve suggests variability in glacial period duration. At Devils Hole, the glacial-interglacial periods became aperiodic and increased in length until the present (i.e. 80 000 and 130 000 years long) while interglacial periods lasted on the order of 20 000 years (Winograd *et al.*, 1992; Winograd, 2002). The aperiodic nature of the record along with a prominent deglaciation and glacial cycle occurring near 450 to 350 ka plus the difference in timing between this record and the Marine Isotope Stage 6 created much controversy and debate.

Reducing the uncertainties with the Devil's Hole chronology may lie in increasing our understanding of the hydrologic conditions of the past. Potential recharge locations for Devils Hole include several nearby ranges that have different flow path distances (80 to 160 km) from the calcite-core location (Winograd *et al.*, 1992). The interpretation of the groundwater geochemistry profoundly impacts the age assignment. Assumptions regarding paleorecharge conditions for temperature, vegetation, partial pressure of soil CO_2 and pH combined with measurements for the stable carbon isotope and radiocarbon evolution in the groundwater are required for accurate radiocarbon residence time calculations. Winograd *et al.* (1992) report uncertainty in radiocarbon residence time estimates for Devils Hole that range between 10 000 and 30 000 years. Winograd *et al.* (1992); Winograd (2002) point out that the U-series dating suggests the Devils Hole deglaciation cycles, as indicated by the calcite $\delta^{18}O$ curve, precede deglaciation dates for both the Vostok ice core and the orbitally tuned global ice volume record (known as SPECMAP) that is based on ocean cores. Winograd *et al.* (1992) emphasize that adding on the groundwater residence time will only increase the lead time for the onset of deglaciation at Devils Hole.

A further intriguing aspect of the Devils Hole record is that the concurrent calcite $\delta^{13}C$ measurements match the broad pattern of the $\delta^{18}O$ curve variations with the important observation that all the changes in $\delta^{13}C$ lead the $\delta^{18}O$ shifts. Coplen *et al.* (1994) were unsure whether the $\delta^{13}C$ variability reflected isotopic shifts in global atmospheric CO_2 or vegetation changes in Nevada at the recharge locations for Devils Hole. Refinement of global and regional lead/lag relationships is the focus of climate-variability research. Recent high-resolution ice-core data depict millennial-scale warming in Antarctica that precede by 1500 to 3000 years warming at Greenland over the past 90 ka B.P. (Blunier and Brook, 2001). The Devils Hole $\delta^{13}C$ variability may reflect either atmospheric CO_2 or vegetation shifts, but both would have important implications for climate variability.

Herbert *et al.* (2001) posit that the Devils Hole record represents a regional response and does not contradict the Milankovitch theory for the ice ages. They cite their own research into sea surface temperature reconstructions for the California Current, which warmed 10 to 15 ka in advance of deglaciation. Herbert *et al.* (2001) show no such sea surface temperature warming south of the modern California Current location. Their interpretation is that the Devils Hole and California Current region have responded to reorganized wind systems over the North Pacific when the continental ice sheets were large and represent a regional response (Figure 3). Imbrie *et al.* (1993) found through spectral analysis that the Devils Hole chronology has peaks in the spectrum that occur at 91 kyr and 42 kyr, with adjacent peaks at 27 kyr and 23 kyr. They suggest that coherent concentrations of variance at or near orbital periods support orbital influence.

The lead-and-lag relationships are critical for climate research, which makes the Devils Hole chronology very important. Refinement of chronology may be critical for placing the seminal record of Devils Hole into a regional and global context. Certainly, changes in recharge conditions in a semiarid setting would have a profound impact on groundwater travel times. Furthermore, the two nearby mountain ranges have varying flow path distances to the discharge location and the relative mixture of these waters could impact the Devils Hole chronology. The major filter between the climate signal at the surface that paleoclimatologists seek and the calcite-vein record is a complex groundwater regime that beckons for improved understanding. Refinement of the paleohydrology for the Devils Hole story is a rich area for future research that may be important for unraveling the regional, global, as well as orbital teleconnections of the land–ocean–atmosphere system.

To eliminate dating uncertainties, such as those associated with the 80 to 160 km distance between recharge locations and the Devils Hole calcite vein (Winograd *et al.*, 1992), the ideal study location may be one with the shortest possible residence time (e.g. less than a year) between recharge and mineral precipitation. Some locations where speleothems that have been studied have a short residence time between recharge and speleothem formation. One recent study fills the gap between where the Devils Hole record terminates and modern time. The Devils Hole calcite-vein surface has a U-series date of about 60 000 years before present (Ludwig *et al.*, 1992). Speleothem deposits in the Cave of Bells in southern Arizona yielded U-series dates extending from 9000 to 55 000 years before present (Wagner *et al.*, 2002). Common to many speleothem studies, the $\delta^{13}C$ record may be difficult to interpret due to lack of constraint on the degassing of carbon dioxide when the water enters the cave atmosphere and possible disequilibrium with soil CO_2 in the recharge zone (Baker *et al.*, 1997). Fortunately, the stable isotopes of hydrogen and oxygen in water often exhibit more conservative behavior in speleothems. The Cave of

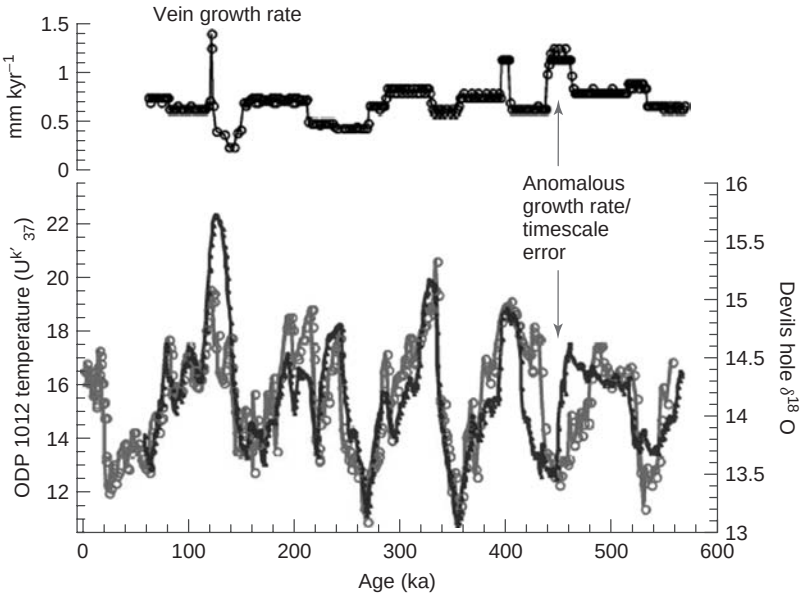

Figure 3 Comparison of a representative alkenone record (ODP 1012) with the Devils Hole δ^{18}O record, on independent timescales. The alkenone record represents sea surface temperature along the California Margin. The good match, in particular the rise in temperature and δ^{18}O of both records before deglaciation, suggests that regional, not global, temperature changes dominate the isotopic composition of the terrestrial record. The growth rate of the Devils Hole vain inferred from the Devils Hole timescale contains an anomalous interval beginning at 438 ka, suggestive of a dating anomaly. (Reproduced from Herbert *et al.* (2001) with permission of American Association for the Advancement of Science) A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Bells speleothems δ^{18}O record reveal rapid changes during the last deglaciation that appear synchronous, within dating error, with the deglacial sequence of the GISP-2 δ^{18}O Greenland ice-core record (Wagner *et al.*, 2002). The rapid transit between recharge and speleothem deposition at Cave of Bells increases our confidence that the δ^{18}O record more directly reflects δ^{18}O of recharge water conditions at the surface (Wagner *et al.*, 2002). Speleothem research promises to play an important role in climate-variability studies in the future, particularly if the paleohydrology for each speleothem setting is well understood.

TRANSIENT RESIDENCE TIME ELEMENTS OF HYDROLOGIC CYCLE: PROXY RECORDS FOR PALEOHYDROLOGY

Precipitation History

Rodent Middens: Proxy for Precipitation

Locations where climate is extreme can serve as ideal places for archives because climate shifts create a dramatic and unmistakable local response. Semiarid and arid regions often have sharp climate gradients where shifts toward more pluvial (i.e. wetter) periods result in the sudden appearance of vegetation or a shift in vegetation species. Rodent middens have become an important source of information in arid and semiarid regions where lakes, glaciers, and other rich paleoclimate archives are often not available. Fossil rodent middens, as defined by Latorre *et al.* (2002), are "amalgamations of rodent feces and plant, insect, and vertebrate remains encased in hardened urine (amberat) and commonly preserved in rock shelters, caves, and crevices". The plant record preserved in a midden reflects the vegetation within about 100 meters of the midden site, the typical foraging range for most rodent species (Betancourt *et al.*, 2000). Packrat middens in the southwest United States, stick-nest rat middens in Australia, hyrax and dassie rat middens in Africa, and a variety of rodents (genera *Abrocoma, Lagidium, Octodontomys*, and *Phyllotis*) in South America have proven to be valuable archives for paleoclimate research (Pearson and Betancourt, 2002).

A successful reconstruction of the history of precipitation requires a number of steps. After sorting through plant remains in middens, the vegetation zones for the region must first be carefully mapped out and understood in terms of temperature, precipitation volume, elevation, and latitude or longitude factors. For example, Figure 4 depicts the major vegetation zones used to study rodent middens from Calama-Salar de Atacama basins in northern Chile. Second, specimens from the largest size middens are identified to the highest taxonomic resolution possible and a portion of the midden is extracted for pollen identification (Lyford *et al.*, 2002). Third, fecal pellets or plant remains from middens are dated by conventional or Accelerator

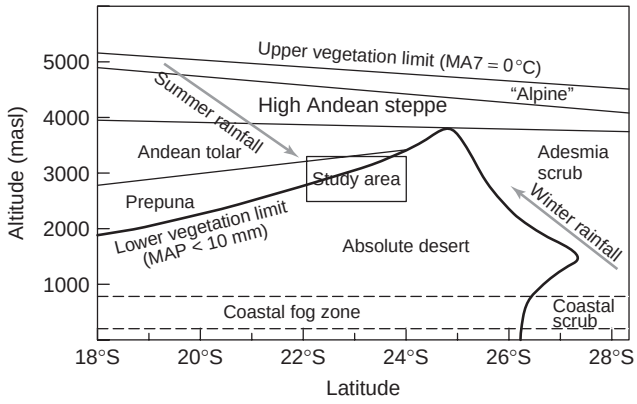

Figure 4 Example of a diagram used for the major vegetation zones found in northern Chile for a rodent midden study. (Reproduced from Latorre *et al.* (2002) by permission of Geological Society of America)

Mass Spectrometry (AMS) radiocarbon dating methods (Betancourt *et al.*, 2000; Lyford, *et al.*, 2002; Latorre, *et al.*, 2002). The final step is to correlate modern vegetation-assemblage patterns that reflect precipitation, temperature, and elevation aspects with midden vegetation changes. At a given midden location, presumably over the radiocarbon time period, the major orography, latitude, and longitude of the site have remained relatively constant. Thus, any changes in vegetation detected in the midden represent local shifts in precipitation and temperature.

The limitations of this method are that the middens are hard to find leaving large gaps in the stratigraphic record, and that pollen from middens often suffers from poor spatial and taxonomic resolution (Pearson and Betancourt, 2002). The strengths of the method are that middens are available in semiarid regions, the macrofossils have high spatial resolution and excellent taxonomic resolution while the available pollen provides quantitative vegetation reconstruction (Pearson and Betancourt, 2002).

Rodent Middens: Evidence for Climate Variability and Regional Teleconnections

The above methods have been successfully applied to reconstruct precipitation history for many arid regions of the world. Presented below is a case study in Chile that illustrates how the paleohydrologic evidence refined prevailing theories of the major climate-forcing processes for the region. The midden record in the Atacama Desert of northern Chile spans over the past 40 000 years, but is strongest with regard to stratigraphic continuity and reliable radiocarbon dates over the past 22 000 years. The present extreme climate conditions make the Atacama Desert part of the distinct group of driest regions on earth. The South Pacific Anticyclone restricts Pacific moisture transport, while the high elevation of the Andes blocks most of the moisture from the Amazon Basin to help create the extreme desert (Placzek *et al.*, 2001). Heating in summer of the warm-cored, closed, anticyclone develops the Bolivian High over the Altiplano which intensifies the trade winds and creates the South American Summer Monsoon precipitation (Zhou and Lau, 1998; Placzek *et al.*, 2001).

The Atacama paleohydrology record differs from the central Andes paleoclimate reconstructions regarding the timing and maximum wetness and aridity since the LGM (Betancourt *et al.*, 2000). The rodent midden record for the Atacama indicates that between 16.2 and 10.5 kyr B.P. precipitation was 70 to 100 mm per year at 2600 m elevation and 100 to 150 mm per year at 3000 to 3200 m elevation (Betancourt *et al.*, 2000; Latorre *et al.*, 2002). These elevations today experience mean annual precipitation of 20 mm per year at the lower elevation and 50 to 70 mm per year at the higher elevation. Another advantage of rodent midden vegetation records is that the seasonality of precipitation can be inferred which is often not possible with lake level, or paleogroundwater reconstructions. This is possible because a plant classification system exists (i.e. C3, C4, or Crassulacean acid metabolism (CAM)) that is based on photosynthetic pathway processes that result in different carbon isotope signatures. The dominance of summer-flowering herbs, C4 plants, and southward displacement of northern species in the rodent midden record during the wettest period over the past 22 000 years (16.2–10.5 kyr B.P.) is strong evidence for increased summer precipitation events (Betancourt *et al.*, 2000; Latorre *et al.*, 2002).

Prior to the discovery of the rodent midden record, researchers linked fluctuations in the South American Summer Monsoon precipitation to fluctuations in summer insolation in the Southern Hemisphere (Rech *et al.*, 2002). Yet, the period for wettest conditions at the Atacama Desert coincides with a minimum in austral-summer insolation (Figure 5). Local records around Atacama all indicate a pluvial period between 10.2 and 9 kyr B.P. (Betancourt *et al.*, 2000; Latorre, *et al.*, 2002; Rech *et al.*, 2002; Rech *et al.*, 2003). This has led researchers to look for larger teleconnections to explain the Atacama pluvial period. During El Niño events, westerly wind anomalies inhibit moisture advection from the east to the western part of the Bolivian Altiplano and central Atacama. Whereas La Niña conditions favor strong easterly winds that create convection and precipitation in the region. Combined paleohydrologic evidence led Betancourt *et al.* (2000) to conclude that strengthened Pacific trade winds (easterlies) during persistent La Niña conditions of the late glacial-early Holocene period created the pluvial period of the Atacama region.

The rodent midden record has contributed significant paleoprecipitation evidence regarding temporal resolution, a quantitative precipitation volume reconstruction, and links to the dominant season for increased precipitation (summer). The debate over why sustained millennial pluvial

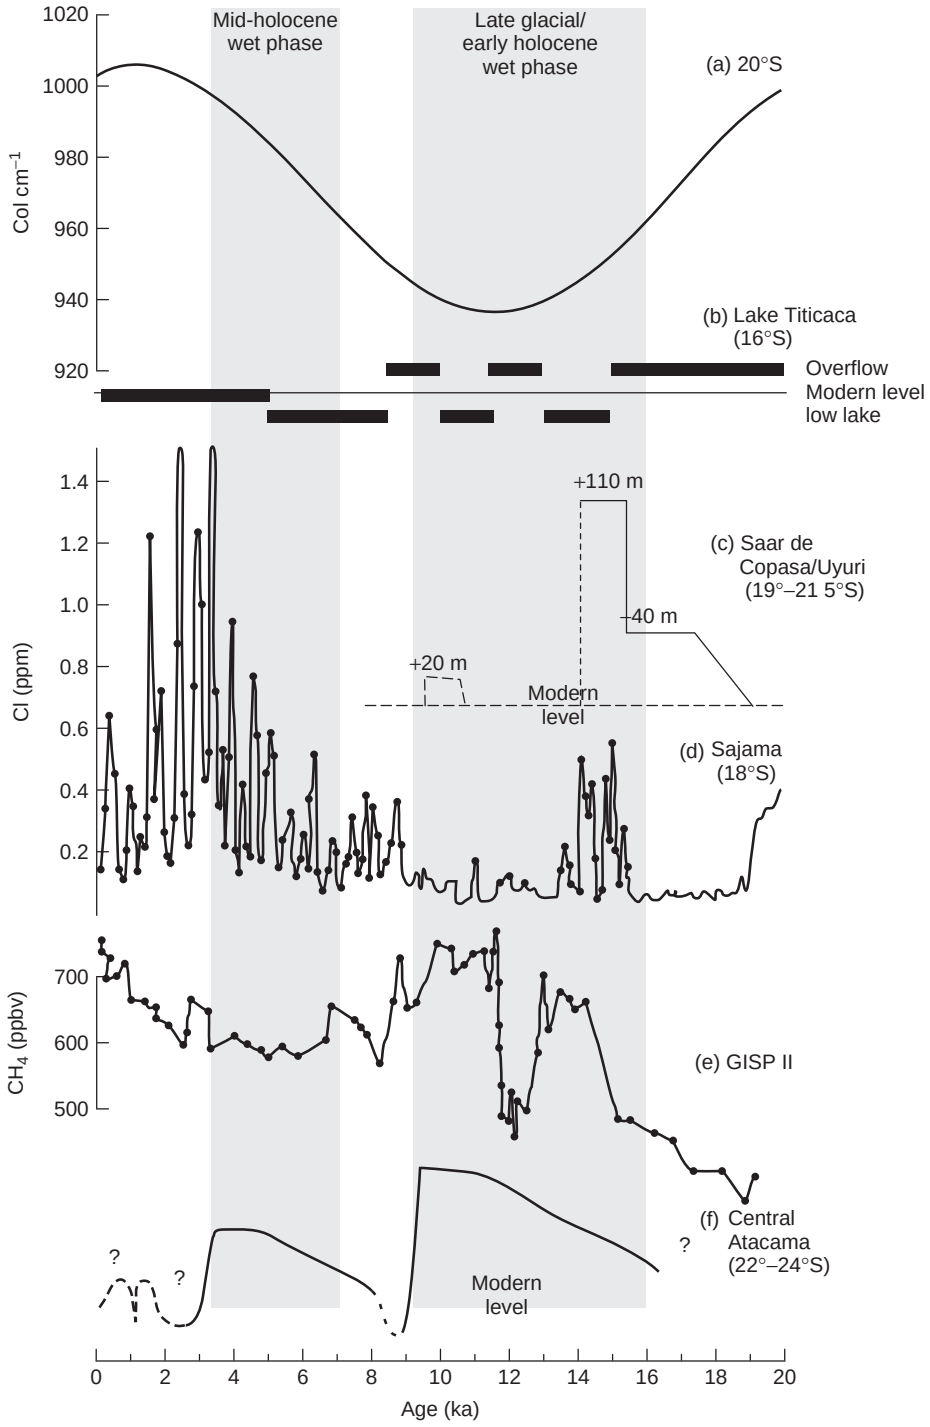

Figure 5 South American summer insolation at 20 °S and paleoclimatic records from the central Andes (a–d) and the global methane record (e) and wetland records for groundwater discharge reconstructions (f) figures. (Reproduced from Rech *et al.* (2002) by permission of Geological Society of America)

periods occurred in the Atacama region will continue, but certainly this evidence points to global teleconnections as potential mechanisms such as the Walker circulation combined with orbital scale forcing such as insolation anomalies.

Tree-rings: High-resolution Proxy Record for Precipitation

Tree-rings perhaps come closest as the ideal tool for terrestrial paleoclimate research. They satisfy many of the characteristics needed: high temporal resolution (annual and

even seasonal in some cases), wide spatial distribution, and clear climate-forcing parameters. Tree-ring width strongly correlates with precipitation and temperature trends. In order to create precipitation reconstructions, cores taken from several trees at each site are detrended to remove tree aging effects and the detrended core widths are averaged to reduce nonclimatic noise specific to individuals (Meko *et al.*, 1993). To further illustrate the tree-ring method, several studies in western North America serve as representative examples.

To establish the validity of tree-ring precipitation reconstruction, Dettinger *et al.* (1998) compared the tree-ring record with the gridded monthly precipitation anomalies from the instrument record (1880–1965) for the western United States region. Zonally averaged empirical orthogonal functions of the instrumental precipitation data reveal an interannual (3–7 years) and decadal "north–south seesaw of precipitation pivoting near 40 °N" that are strongly linked with sea level pressure variations (Cayan *et al.*, 1998; Dettinger *et al.*, 1998). The tree-rings matched the same pattern: (i) Southwestern US precipitation increased during El Niño events while Pacific Northwest precipitation increased during La Niña events (Dettinger *et al.*, 1998). Similar patterns persist over the entire 260-year tree-ring chronology. In contrast to the instrument record, the tree-ring chronology is long enough to also suggest a very low frequency variation with greater than 30-year periods (Dettinger *et al.*, 1998). As more tree-ring records are produced around the world, perhaps a new understanding of climate teleconnections over the very low frequency time periods will emerge.

Surface Water Discharge Reconstructions

Paleodischarge: Sediment and Coral Records of Paleodischarge

Sediment records are strongest for recording flood events and weakest at preserving drought occurrences. It is difficult to generate a quantitative discharge volume from sediment records. However, flood frequency is available through various geomorphic and geochemical dating techniques and provides another important method for climate-variability research. A few representative examples follow from three depositional environments: floodplain, estuary, and ocean.

Floodplain sediment cores combined with ^{210}Pb dating can provide annual resolution of large discharge events that deposited sediments in floodplains over the last century. Aalto *et al.* (2003) employed X-ray analysis and clay-normalized ^{210}Pb activity of floodplain sediment cores to correlate 20–80 cm thick packages of low-energy silt-rich sediment packages. The cores were collected from the Beni and Mamore river basins in the Andean–Amazonian foreland that comprises 720 000 km^2 of the Amazon Basin. The authors interpreted the sediment record as a series of crevasse splays formed during levee failure. Aside from a minimum flood threshold of 6000 m^3 s^{-1}, the method does not yield further refinement of flood discharge volumes. Instead, the power of the annual-resolution ^{210}Pb dating yielded a tight correlation for the timing of crevasse-splay occurrences with the cold-phase El Niño/Southern Oscillation (ENSO) or La Niña events. Aalto *et al.* (2003) found that rapidly rising floods were the preconditions for forming the crevasse-splay deposits and found no flooding after 1974 signaling a shift in response to ENSO forcing over the latter decades of the last century. Similar paleohydrologic records of discharge will be important for gathering many different watershed responses to climate-forcing mechanisms such as ENSO. Theoretically, the future may yield classification of various watershed characteristics that respond in predictable ways to variable climate-forcing processes such as ENSO.

Stratigraphic and radiocarbon dating techniques were used to form the chronostratigraphy of marsh sediments in the San Francisco Bay Estuary study by Goman and Wells (2000). The Sacramento and San Joaquin river drainages comprise over 40% of California's surface area and together provide 90% of the freshwater flow into the San Francisco Bay. Goman and Wells (2000) chose core locations to be at the confluence of the two rivers (Browns Island) and the modern mixing zone (Peyton Hill marsh) between freshwater and saline ocean water. Through a combination of techniques to characterize each depositional facies (i.e. grain-size analysis, organic content, iron concentration, vegetation identification of macrofossils, and Accelerator Mass Spectrometry (AMS) radiocarbon dates on seeds) the authors were able to identify periods of sedimentation from freshwater floods that outpaced sea-level rise versus other periods of more saline conditions with decreased freshwater outflow from the rivers. The vegetation analysis allowed for salinity reconstruction of the estuary. Goman and Wells (2000) identified a 2000-year period beginning in 3800 calendar year B.P. where the Sacramento and San Joaquin rivers had higher flows than modern discharge. These dates correlate with other studies that record evidence of increased precipitation as recorded by lake levels (e.g. Mono Lake and a shallow lake that existed in the Mojave Desert). The two largest flood events, preserved in the sediment, occurred at 3600 and 530 calendar year B.P. In addition to extreme floods, the record preserved the sustained 2000-year period of increased river discharge. As a climate-forcing mechanism, Goman and Wells (2000) proposed deep penetration of cyclonic winter storms further south than today due to a significant low pressure system formed along the west coast from a weakened subtropical high in the eastern North Pacific. The longer records provided by paleohydrologic research enable researchers to evaluate different climate

patterns that have not been recorded by the relatively short-term instrumental record.

Researchers have measured the Ba/Ca in Australia's Great Barrier Reef corals to reconstruct sediment discharge from the Burdekin River (McCulloch *et al.*, 2003). Barium sorbed to river suspended particles will desorb once the freshwater encounters the higher salinity ocean water. McCulloch *et al.* (2003) exploited the fact that corals incorporate the local seawater Ba/Ca ratio into their skeletons to track the times in the past when the terrestrial river source of barium swamped the typical seawater Ba/Ca ratio. The researchers analyzed a core from a 250-year-old coral to create a proxy record for local flood discharge events. They checked the proxy method and found that the spikes in coral Ba/Ca record correlated with historical Burdekin river discharge recorded since 1921. The longer coral record suggests that natural climate variability was overwhelmed by the impact of European settlement since 1862. Changes in grazing and agricultural land-use practices created an increase in coral Ba/Ca ratios by 5–10 orders of magnitude over pre-settlement ratios (McCulloch *et al.*, 2003). The exciting prospect of this novel technique is that the widespread distribution of corals in tropical latitudes may permit the extensive reconstruction of high-resolution paleodischarge records. These reconstructions may prove critical for future climate-variability studies.

Extreme Floods: Paleohydrology Reconstruction of the Earth's Largest Floods

At various points in the Earth's history, ice sheets captured and retained significant amounts of freshwater for many thousands of years. The growth, prolonged existence, and decay of these ice sheets created significant feedbacks into the global climate system. Ice sheets increase the global albedo thereby altering the world's energy balance, and ice sheets over a kilometer thick can alter major atmospheric circulation (e.g. Herbert *et al.*, 2001). Ice sheets also tend to form dams that capture meltwater into glacial lakes, some of which have been enormous. Breaches of dams retaining these immense glacial lakes created megafloods that delivered freshwater to sensitive ocean basins which decreased deep-water formation and ultimately impacted global climate (Leverington *et al.*, 2000; Fisher *et al.*, 2002; Perkins, 2002a; Fisher, 2003).

The paleohydrologist who studies extreme floods confronts a common problem in geology: are modern processes the key to understanding the past or are some events so extreme that notions of uniformitarianism do not apply (Baker, 2002a)? Most of the largest floods on earth have occurred when dams retaining major bodies of water have been breached, as has been the case with natural dams storing large volumes of meltwater from ice-covered regions.

Megafloods have altered the landscape through major erosion and have left depositional features for the geomorphologist to decipher. A combination of geomorphology (e.g. scour marks, streamlined depositional features, boulders, giant current dunes, washload, slope-area features) and principles of fluid hydraulics (e.g. Chezy and Manning equations and Froude number) provide tools for paleohydraulic peak flow reconstructions (Baker, 2002b). Large boulders transported and ultimately deposited with associated downstream scour marks help quantify flow velocity and bed shear stress values (Baker and Ritter, 1975). Equally important are the relationships between the range of sediment sizes carried as washload, suspended load, and bedload for reconstructing sustained bed shear stresses. Geomorphic evidence for washload sizes can be found in deposits located high above the paleochannel floor (O'Connor, 1993). Paleoflood water-surface levels for peak discharge have been determined in settings where the geometry of the valley and scoured divide crossings were mapped in detail for paleohydraulic calculations (Baker, *et al.*, 1993). The reconstructed hydraulic properties of the two largest floods on Earth are breathtaking. The Pleistocene Missoula floods of the Channeled Scabland region of Washington State and the Altay Mountain floods of Siberia had peak flow velocities of around $25\,m\,s^{-1}$, peak discharges of around $2 \times 10^7\ m^3\ s^{-1}$, maximum bed shear stresses of 10 000 to 40 000 $N\,m^{-2}$, and peak stream power per unit area values of 2×10^5 to $1 \times 10^6\ W\,m^{-2}$ respectively (Baker, 2002b). When one considers that the Sverdrup unit used by oceanographers for ocean currents flow volume ($1\,Sv = 10^6\ m^3\ s^{-1}$) is an order of magnitude smaller, one could imagine that flood flow volumes on the order of $10^7\ m^3\ s^{-1}$ could impact global climate.

Extreme Floods: Paleohydrologic Links to Younger Dryas Cold Period

In contrast to the more subtle, yet significant climate impact of water as it continuously travels through the hydrologic cycle, the extreme floods around 13 000 and 11 350 years ago perhaps represent the most direct and spectacular links between hydrology and global climate. Paleoclimatologists have gathered strong evidence for glacial and interglacial cycles, improved dating for these transitions, and established links to Milankovitch solar insolation forcing along with a host of other indicators for the synchronous, filtered, or lagged responses in ice, ocean, land, flora, and fauna. The most intensely studied glaciation-and-deglaciation cycle is the last one, since so many of the paleo-indicators have not yet been erased from the record. Even if the first-order forcing is understood for major climate trends such as glacial cycles, there are features recorded in the paleoclimate record that reveal specific paleotectonic, paleolatitude, paleohydrologic, and other conditions that make each glacial cycle unique. For example, a prominent cold

period around 13 000 to 11 000 years ago stood out in contrast to the overall interglacial climate rebound from the LGM around 18 000 years ago. This period is known as the *Younger Dryas*.

Mounting paleoclimate evidence has emerged for the Younger Dryas. Where sediment cores show dramatic increases in ice rafted debris indicative of large "iceberg armadas" that traversed the North Atlantic, both ocean surface salinity and SST in the region decreased (Broecker *et al.*, 1988, 1990). North Atlantic Deep Water formation significantly decreased, effectively diminishing the northeastward movement of warm, tropical ocean waters that normally kept Europe relatively warm (Broecker and Denton, 1989). Dramatic shifts in lake sediment core pollen records indicated a systematic change toward colder vegetation species and surges in mountain glaciers.

Ironically, it was probably the release of water that had been stored in the frozen state for so many years over North America that created the cold excursion during the earth's overall warming trend. Recent paleohydrology evidence, summarized in Table 2, suggests the sequence of hydrologic processes that eventually led to the Younger Dryas cold period. On the North American continent during the glacial maximum 20 000 to 18 000 years ago, the Laurentide Ice Sheet extended over most of Canada east of the Rockies and southward into present-day Iowa and Illinois, and was thickest (~5 km) over present Hudson Bay (Leverington *et al.*, 2000; Fisher *et al.*, 2002; Perkins, 2002a; Fisher, 2003). Figure 6 depicts the Laurentide Ice sheet and glacial lake Agassiz with arrows delineating the three major drainage outlets used at different times as the ice sheet

Table 2 Example of a direct link between hydrology and global climate change. Events surrounding the Younger Dryas and Preboreal Oscillation cold periods (after Leverington *et al.*, 2000; Fisher *et al.*, 2002; Perkins, 2002a; Fisher, 2003)

Time period (years B.P.)	Paleohydrologic conditions
20 000–18 000	Laurentide Ice Sheet at maximum extent
Prior to 13 000	Laurentide Ice Sheet retreats past the divide that separates Mississippi watershed from northward drainage. Meltwater pools against ice sheet to form glacial Lake Agassiz (~134 000 km^2). Overflow spilled down the Mississippi River drainage valley.
13 000	New spillway to the east was breached creating a sudden Lake Agassiz level drop (~100 m) and 9500 km^3 of freshwater flooded through the Great Lakes and exited the St. Lawrence River into the North Atlantic. Over the next several decades, freshwater discharge remained twice as large as the discharge prior to the breach down the St. Lawrence River.
13 000–11 400	Younger Dryas 1600 year cold period.
11 400–11 350	Laurentide Ice Sheet grew, extended southward and blocked St. Lawrence drainage to the North Atlantic. Meltwater again flowed down the Mississippi River valley.
	North Atlantic Deep Water formation increased and a return to warmer conditions prevailed.
11 350–11 100	Preboreal Oscillation occurred due to a 50-m drop in Lake Agassiz level over several years. Water drained out the Mackenzie River valley into the Arctic Ocean. This freshwater froze into sea-ice and circulated out through Fram Strait and again into the North Atlantic Ocean where it melted and shut down deep water formation.
8500–8100	Laurentide Ice Sheet collapsed over Hudson Bay and released 163 000 km^3 of water through Hudson Bay and into the North Atlantic, raising global sea level by 0.5 m. The next 400 years was a cold period (Figure 7).

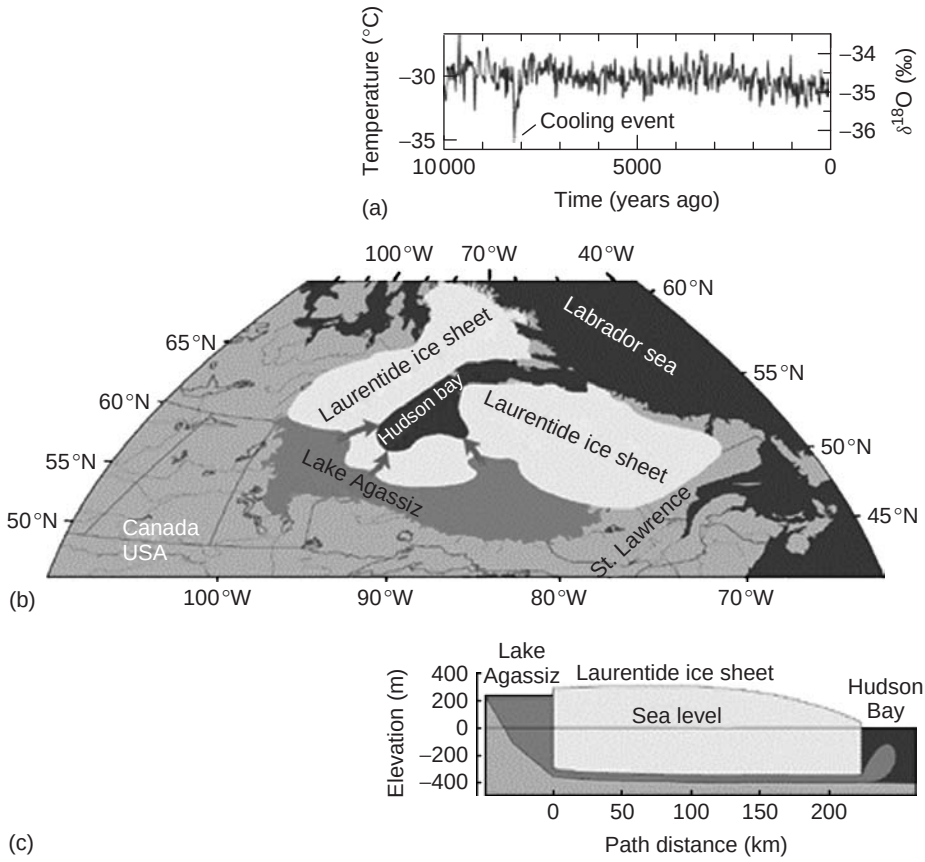

Figure 7 The climate, the lake, and the dam (a) The climate record from ice cores in central Greenland reveals an abrupt cooling event about 8200 years ago. Data from Dansgaard *et al.* (1993) (b) Lake Agassiz formed at the southern margin of the disintegrating Laurentide Ice Sheet and released its stored water to Hudson Bay. Possible flood routes are indicated by arrows. Many more routes are possible (c) At the time of the flood, the ice dam was probably several hundred kilometers wide. Subglacial drainage from the lake to Hudson Bay would have started when the pressure of lake water approached that for flotation of the dam. (Reproduced from Clarke *et al.* (2003) by permission of American Association for the Advancement of Science) A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

covered or retreated from major continental drainage divides.

Over the last decade, researchers have debated whether a large volume of freshwater released into sensitive regions could impact the world's climate enough to reverse a global warming trend for over a millennium. North Atlantic Deep Water, formed in the subpolar seas of the North Atlantic (Greenland Sea, Iceland Sea, Norwegian Sea, and Labrador Sea), drives the global circulation system that distributes heat around the world's oceans. Deep water is created in the North Atlantic rather than in the similarly cold latitudes of the North Pacific because of the higher salinity of the North Atlantic (~35 psu vs. ~32 psu). North Atlantic Deep Water forms as saline, cold surface water cools, which increases the density and causes it to sink (Broecker *et al.*, 1988, 1989, 1990). A sufficiently large influx of cold, fresh, and more buoyant water to this region would decrease the surface density, thereby capping the North Atlantic and preventing deep-water formation during the winter months. These deep-water formation sites were directly affected as Lake Agassiz emptied into the St. Lawrence River valley and into the Mackenzie River to exit the Arctic Ocean through Fram Strait. When Lake Agassiz drained instead into the Mississippi River to the Gulf of Mexico, there would likely have been less impact on global climate. The recent paleohydrology work on Lake Agassiz provided convincing evidence for the timing and volume of flood events and provided concurrent terrestrial evidence for triggering events recorded in North Atlantic Ocean sediment cores during the Younger Dryas.

Droughts

The extreme events of hydrology, floods and droughts, both can wreak havoc on flora, fauna, and human interests such as water resources, agriculture, livestock, or property. A

better understanding of the climate-forcing parameters and regional responses may improve forecasting, and hopefully lead to improved seasonal preparation and damage mitigation from such extreme events. Drought cycles that extend further back in time than the instrumental records have the potential to confirm patterns that have emerged in the instrument record or uncover some extreme forcing conditions not yet experienced. As stated by Cook *et al.* (1999) "There are often too few realizations of proposed forcing mechanisms of drought in the short instrumental records to test any of them in a statistically rigorous way." Thus far, we have discussed the many proxy records for the presence of water. Drought, or the lack of water, changes the available climate proxy records. The fluctuations of closed-basin lakes are a sensitive and long-term indicator of drought, and vegetation response has also proven to be a successful proxy record of a lack of water. Ultimately, tree-ring records provide not only a sensitive indicator of drought but also provide a high annual resolution record over a millennial timescale.

Droughts: Closed-basin Lake Levels

Reconstruction of the fluctuations of closed-basin lakes is a sensitive indicator of drought. Closed-basin lake levels provide quantitative evidence for the changes in the entire basin water balance, which is otherwise difficult to obtain. All the various methods have several common elements: identify the paleoshoreline elevation, date the prehistoric lake level, and check for the possible tectonic shifts that may have influenced the shoreline elevation.

Most hydrographically closed lakes studies measured the multicentury to millennial-scale lake level changes (Komatsu *et al.*, 2001; Licciardi, 2001; Oviatt, 1997; Ridge and Larsen, 1990). The more recent lake level reconstruction of the past 3800 years at Mono Lake, located east of the Sierra Nevada Mountains in east-central California, illustrates this method (Stine, 1990 and Stine, 1994). Several rivers flow into Mono Lake and drop their sediment load to form deltas. The transgressive and regressive sequences in the deltaic sediments preserve the former fluctuations of the lake level. A progressive upward fining sediment sequence reflects the transition from a high-energy stream to the silts of deep lake water. As the lake recedes, in contrast, the same location would have an upwardly coarsening sediment sequence. Past Mono Lake high stands are preserved as berms, bars, clifflines, or pronounced breaks in vegetation. The engineer's level and rod was used to survey the prior lake levels.

Chronology at Mono Lake was provided by volcanic ash deposits, charcoal, or other organic debris that can be radiocarbon dated, and relict tree stumps. If the death of the tree stump is associated with shoreline transgression, then the radiocarbon age of the outer growth-ring provides the age of transgression. The annual tree-rings give the number of years the lake level was below the basal root elevation of the relict stump. Two severe and long-term drought periods were identified this way for Mono Lake; an over 200 year drought that ended around 1112 A.D. and a 140 year drought that ended around 1350 A.D. Stine (1994) linked these extreme droughts to a reorientation of midlatitude storm tracks that may have been associated with the warmer temperatures of the medieval period. Such findings could have profound implications for the future of California water resources if further warming occurs over the next century.

Droughts: Tree-ring Reconstructions

Lack of water during the growing season will restrict the width of a tree-ring for that year. Regional drought reconstructions rely on statistical techniques to find patterns of drought in a region. The measured ring widths of cores are handled the same way as described above for the paleoprecipitation research (Meko *et al.*, 1993). Similar methods have led to successful regional drought chronologies in the northeast United States (Cook and Jacoby, 1977), southeast United States (Cook *et al.*, 1988; Stahle *et al.*, 1985, 1988), western United States (Gray *et al.*, 2003; Graumlich, 1993; Stahle and Cleaveland, 1988; Stockton and Meko, 1975) and other parts of the world.

Recent efforts to create continental-scale drought records by combining the tree-ring chronologies to produce statistical data that correlate favorably with the Palmer Drought Severity Index (PDSI) based on the instrument record back to 1895 (Meko *et al.*, 1993; Cook *et al.*, 1996, 1999). These methods give confidence for reconstructions beyond the instrumental record. The primary elements of continental-scale drought reconstruction are as follows and are based upon the United States continental-scale reconstructions of Meko *et al.* (1993) and Cook *et al.* (1996, 1999). First, both the PDSI data and tree-ring data are converted to the same coarse grid scale for a more direct comparison of the derived results. For example, in the Cook *et al.* (1999) case, this resulted in a reduced PDSI network to 15% of the original size while the same grid for the tree-ring data had some data gaps or spatial holes in the Great Plain States due to lack of local tree-ring sites. Second, despite the known northward shifts in the timing of the growing season which can be directly compared on a regional scale between monthly PDSI and tree-ring grid data, they used the summer PDSI as the most comprehensive drought index in order to compare with the tree-ring grid across the entire continental scale. Third, the investigators employed various regression and statistical techniques to compare the tree-ring data for the same time period as the instrument-based PDSI results. Finally, the tree-ring grid data were put through various rotated principal component analysis techniques to search for factors that may be linked to patterns for drought variability. The extremely high correlation

between these two drought indicators for the period of historical record strongly supported the validity of the tree-ring chronologies further back in time. Perhaps more than any other paleohydrology method, the high-resolution tree-ring record with its extensive spatial and temporal distribution of measurements yields continental-scale reconstructions that are useful to global climate modelers.

Droughts: Climate Significance of Frequency and Spatial Patterns

Severe multiyear droughts have occurred in the United States about twice per century over the past 400 years and the causes have remained elusive (Woodhouse and Overpeck, 1998). The major findings of the United States continental-scale tree-ring drought reconstructions are (i) the 1930s drought (predominantly the northern Great Plains) was the most severe since 1700; (ii) the next most severe droughts occurred around 1820, 1860, 1950 (predominantly the southwest), and 1977; and (iii) the wettest periods clustered around 1820–1840 and 1900–1920 periods (Cook *et al.*, 1999; Gray *et al.*, 2003). The success of the tree-ring paleohydrology reconstruction of PDSI has led to a new analysis on the causes of persistent drought.

Earlier research suggested a strong link between La Niña conditions and drought in the southwest United States, but not consistently for each drought period (Cole and Cook, 1998). Hence the search for concurrent extratropical forcing conditions or lag responses continued. Cole *et al.* (2002) compared the updated record of ENSO, the tree-ring PDSI reconstruction, and the extended Pacific Decadal Oscillation (PDO) and found clear links between the oscillation phases and persistent drought conditions in the United States. The PDO is an index based on trends in SST in the North Pacific. The paleoclimate reconstructions showed that long-period La Niña events existed in earlier centuries in contrast to the typical short-period La Niña events prevalent in the twentieth-century record. Also, Cole *et al.* (2002) found a spatial shift in the drought centers from the Arizona/California region for the earlier periods to Texas/New Mexico region in the twentieth-century (Figure 8). La Niña conditions when the PDO remains in a negative state correlate with a persistent multiyear drought (Cole *et al.*, 2002). Such paleoclimate revelations may help climate forecasters to predict when economically devastating multiyear drought conditions are a high probability by tracking current ENSO and PDO conditions.

CONCLUSIONS

Water plays a critical role in climate, and paleohydrology has helped elucidate climate variability prior to human recording of climate data. Over the past several decades, paleohydrology has made important contributions to climate knowledge such as refining the tropical terrestrial temperature shift between today and the LGM that helped resolve some of the conflicting tropical ocean proxy records. Often it is the extremes of the hydrological cycle, such as floods or drought that capture the public's attention when loss of crops, livestock, property or life occurs. Understanding the conditions in the past that created multidecadal megadroughts or extreme flooding may increase our chances for earlier detection and possible mitigation if similar ocean–atmosphere forcing conditions arise in the future. We expect that as more proxy records for the hydrologic cycle are discovered, paleohydrology will continue to advance our understanding of climate variability.

Acknowledgment

I wish to thank Soroosh Sorooshian who started me on this path of paleohydrology review. This chapter benefited from discussions with V. R. Baker, J. E. Cole, and J. D. M. Wagner. Review comments by F. Phillips and V. A. Childers significantly improved the manuscript.

200: Changes in Regional Hydroclimatology and Water Resources on Seasonal to Interannual and Decade-to-Century Timescales

DAVID MEKO

Laboratory of Tree-Ring Research, University of Arizona, Tucson, AZ, US

Precipitation, runoff, snowpack, and other elements of the hydrologic cycle respond to climate change on many different timescales. Responses are typically regional rather than local and are linked to large-scale features of the general circulation of the atmosphere. Changes in regional hydroclimatology are important to water resources in most parts of the world, but especially in arid and semiarid regions that are often plagued by chronic shortfalls of water. Instrumental records of precipitation and streamflow indicate that changes on decadal-and-longer timescales have been large enough to be of practical importance, and paleoclimatic records suggest that even larger changes have occurred over the past few centuries. Tree-ring records are perhaps the most useful of the paleoclimatic resources for extracting hydroclimatic estimates with annual resolution. Paleolimnological data has also figured prominently in pointing out possible large changes in regional hydroclimatology prior to the start of the tree-ring record. In North America, multiple types of proxy records suggest low-frequency variance in runoff may have been amplified about 500 years ago, with associated multidecadal periods of drought and wetness.

INTRODUCTION

Change is inherent to the hydroclimatology of a water basin or region. From the standpoint of water resources, the record of past changes in regional hydroclimatology is important in providing information on the natural range of variability of water supply. This information can be useful in probabilistic estimates of likely future stresses on water resources, as well as in understanding the dynamics of climate change and interactions of climate variation and hydrology. Changes in regional hydroclimatology can be tracked with instrumental data back to the late 1800s in some places. Paleoclimatic data can extend this record to several more centuries with annual resolution and thousands of years with reduced resolution and spatial coverage.

Changes in regional hydroclimatology are ultimately of interest because of their potential impact on man and his environment. Paleoclimatic studies point to the decline of entire civilizations at least partly in response to droughts of prehistoric times. In recent decades, large fluctuations in precipitation and river runoff have been associated with stresses on water resources systems. As the gap between water demand and available supply narrows in many parts of the world, it is becoming increasingly important to understand the full range of regional hydroclimatic variability and to identify its causes.

Variables

Hydroclimatic change can be quite inclusive in encompassing change in virtually any element of the hydrologic cycle (*see* **Chapter 2, The Hydrologic Cycles and Global Circulation, Volume 1**). Examples are precipitation, temperature, runoff, evapotranspiration, and recharge. A change might affect amounts (e.g. total annual runoff), as well as rates of processes (e.g. intensity of precipitation). Frequencies and return intervals of events, such as floods and droughts are also of interest.

Definitions of Change

Change in the most general sense is any form of deviation from constancy. Year-to-year variations in runoff, for

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

example, would be classified as "change" by this definition regardless of the size of the variations. In contrast are the more stringent statistical definitions of change used in climatology. For example, climate change has been defined as "a statistically significant variation in either the mean state of the climate or in its variability, persisting for an extended period (typically decades or longer)" (IPCC, 2001). By the strict definition, a variation in runoff would need to be evaluated in the context of the statistical distribution properties of runoff before being classified as a change. But a change may well be practically significant as far as its effect on the water resources of the region without being statistically significant (*see* **Chapter 3, Hydrologic Concepts of Variability and Scale, Volume 1** and **Chapter 7, Methods of Analyzing Variability, Volume 1**).

Timescales

The timescale of a hydroclimatic change refers to the interval of time over which the change occurs. Changes on interannual to century timescales are most relevant to water resources planning and operations. It is well known, however, that the Earth's climate has also varied significantly on timescales of thousands to millions of years (*see* **Chapter 34, Climate Change – Past, Present and Future, Volume 1**). The most recent past is generally considered most relevant to water resources planning. Certainly the period since the end of the last ice age, some 10 000 to 15 000 years ago, is more relevant than earlier epochs, when boundary conditions of regional hydroclimatology in many places were much different than today. The highest-quality paleoclimatic data are restricted to about the last 1000 to 2000 years, and spatial coverage and time resolution increase greatly over even that short interval.

In general, the time series for studying hydroclimatic change must be much longer than the timescale of interest. It follows that many years of data are needed to study interannual changes, many decades of data to study decadal changes, and so forth. Regionally extensive instrumental records of precipitation, streamflow, and other variables are generally on the order of a few decades to a century in length, and so are unsuitable for addressing the longer timescales of hydroclimatic change. Tree-ring records can extend the record of moisture variations back to a few centuries, and other paleoclimatic data (e.g. trace elements and stable isotopes in dated lake sediments) can extend the record to a few millennia in scattered locations (*see* **Chapter 199, Role and Importance of Paleohydrology in the Study of Climate Change and Variability, Volume 5**).

Spatial Scale

The spatial scale of changes in regional hydroclimatology is governed by features of the general circulation of the atmosphere. Because these features are dynamically interrelated over great distances, hydroclimatic changes tend to be spatially coherent over hundreds to thousands of kilometers, and changes in widely separate areas tend to be statistically correlated. Anomalous positioning of ridges and troughs in the atmospheric circulation is generally associated with widespread drought or wetness. For example, an amplified upper level ridge over the west coast of the United States in January 2003 was associated with exceptionally dry conditions across the southern states and a contrast of warmth in the west with cool conditions in the east (Figure 1).

The overriding importance of atmospheric circulation patterns to spatial features of runoff variation must be considered in any attempt to define hydroclimatic "regions". Boundaries of regions of similar hydroclimate generally do not correspond to watershed boundaries (Lins, 1997). There may be an overlap, however, when watershed divides also happen to be major impediments to atmospheric flow or to affect the anchoring of troughs and ridges in the general circulation of the atmosphere.

Spatial scale of hydroclimatic changes is important to water resources (*see* **Chapter 3, Hydrologic Concepts of Variability and Scale, Volume 1**). For large basins, size can act as a buffer against the effects of drought, as a drought in one part of the basin might coincide with a wet period in another part. Paleoclimatic data emphasize the importance of sample period in the evaluation of spatial scales of hydroclimatic change. For example, tree rings identify a North American "megadrought" in the 1500s to much greater extent than any drought in the period covered by precipitation and streamflow records (Stahle *et al.*, 2000).

DATA

Instrumental

Precipitation and Temperature

The most regionally extensive direct evidence for hydroclimatic change comes from continuous records of precipitation and temperature. These two variables are particularly useful because of the existence of long instrumental records. Precipitation is more directly relevant to hydroclimatology, but temperature records are also useful as temperature is correlated with potential evapotranspiration and plays a role in processes that affect the timing of runoff (*see* **Chapter 41, Evaporation Modeling: Potential, Volume 1** and **Chapter 160, Energy Balance and Thermophysical Processes in Snowpacks, Volume 4**).

Instruments that could reliably measure precipitation and temperature were developed by the late seventeenth and the early eighteenth centuries (*see* **Chapter 35, Rainfall Measurement: Gauges, Volume 1**). But few continuous instrumental records exist from the late seventeenth and eighteenth centuries, and in many regions

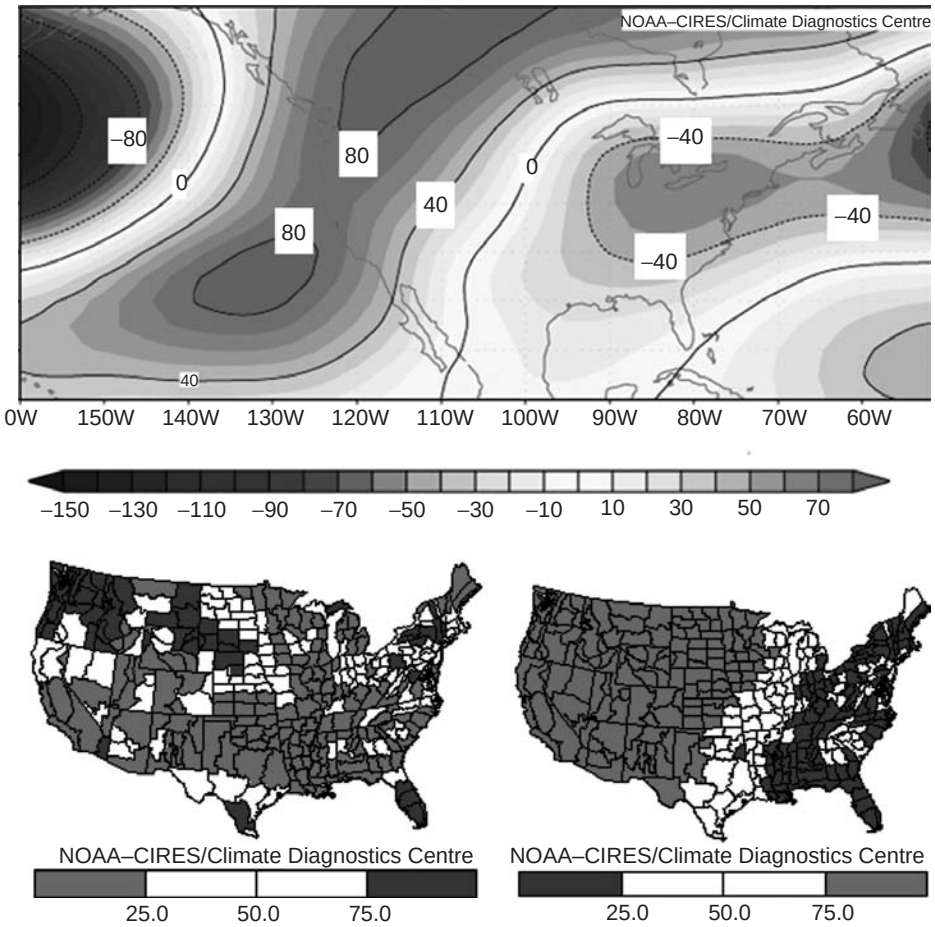

Figure 1 Anomalous climatic patterns in January 2003, an extreme drought month in the southwestern United States. (a): 500 mb geopotential height anomaly (m); (b) left: precipitation percentile by climate division, bottom right: temperature percentile by climatic division. Percentiles computed on the period 1895 to 1999. Images provided by the NOAA-CIRES Climate Diagnostics Center, Boulder Colorado from their web site at **`http://www.cdc.noaa.gov/`**. Data from Climate Division Dataset (NCDC, 1994). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

records exist for only part of the twentieth century. Multiple stations are needed for regional assessment, especially in mountainous regions and other places where climatic gradients are sharp. Various networks of station data have been developed for use in climatology (see Section "Sources of data"). One example is the Global Historical Climatology Network (GHCN), with more than 6000 long-term monthly precipitation and temperature stations specifically screened and processed for the monitoring and detection of climatic change (Vose *et al.*, 1992). The earliest series in the GHCN starts in 1697, but coverage does not become sufficiently dense for regional hydroclimatic studies until the late 1800s or early 1900s. To facilitate analyses at regional and larger scales, quality-controlled gridded precipitation networks have also been developed.

In addition to precipitation and temperature, hydroclimatic studies have made wide use of drought indices. A drought index is a mathematical index that distills the information from more basic measurements (e.g. precipitation and temperature) to summarize the severity of drought. Two commonly used drought indices are the standardized precipitation index, or SPI that is based entirely on precipitation (Guttman, 1999), and the Palmer Drought Severity Index, or PDSI that combines the effects of precipitation and temperature through a simple water-balance accounting model (Palmer, 1965).

Streamflow

Streamflow records are measurements of the discharge, or flow, of rivers and streams and are usually derived from a stage-discharge curve that relates the water level in the river to the volume rate of flow past the gage. Streamflow records worldwide are considerably less numerous than precipitation records, but have the advantage for regional hydroclimatology of integrating moisture conditions over space on

a watershed-scale, and of directly providing an approximation to the residual of precipitation and evapotranspiration. Gaged records of stream discharge are sometimes flawed as indicators of hydroclimatic change because of various factors, including watershed changes, irrigation losses, instability in the stage–discharge relationship, and changes in evaporative losses and timing of flows due to reservoir storage (*see* **Chapter 191, Environmental Flows: Managing Hydrological Environments, Volume 5**). A network of minimally distorted streamflow records with coverage to the late 1800s has been assembled for hydroclimatic studies in the United States (Slack *et al.*, 1988).

Where high-quality stream gage data is unavailable, an alternative is gaged streamflow that has been adjusted for removal of known effects of man by adding back in recorded or estimated diversions of water, and so on. These so-called "natural-flow", "unimpaired-flow", or "virgin-flow" records are sometimes available from water management agencies and can be quite useful in hydroclimatic analysis (e.g. Hidalgo and Dracup, 2003).

Lake Levels

The water level of lakes has long been recognized to respond to changes in climate. Factors affecting the sensitivity of lake-level to climatic fluctuations include the size of the drainage area, the presence or absence of an outlet, the water-balance type, the basin relief, and the extent of human disturbance. The most sensitive lakes for recording hydroclimatic changes are generally those lacking an outlet. Many instrumental records of lake-level change extend back to the nineteenth or early twentieth centuries. For example, the record for the Dead Sea starts in 1800; the Caspian Sea in 1851; and the Great Salt Lake, US, in 1880. Globally, many closed lakes relatively free from human disturbance show broadly parallel patterns of behavior, with high levels in the latter part of the nineteenth century, low levels in the 1920s to 1940s, followed by higher levels to at least the early 1980s (Street-Perrott and Harrison, 1985).

Paleoclimatic Data

Tree Rings

Indices of the ring widths of moisture-sensitive trees are the most widely used type of paleoclimatic data for studying changes in hydroclimatology on interannual-to-decadal timescales. The period of analysis from living trees is limited only by the maximum tree age that typically exceeds 300 years for useful species. The period can be extended much further – to thousands of years – using deadwood material from snags, buried logs, and other sources. Tree rings can be dated exactly to the year, enabling an accurate resolution of interannual hydroclimatic variations. The strength of hydrologic signal depends on the sensitivity of growth of the particular tree species or specimen to the parameter of interest. Tree rings generally provide opportunistic sampling of important runoff-producing areas in semiarid regions because of the tendency for undisturbed forests to be in the mountains. Moreover, the wide distribution of suitable tree species over the temperate latitudes facilitates regional analysis.

The biological basis of the relationship between tree rings and climate is covered thoroughly by Fritts (1976); aspects relevant to dendrohydrology are covered by Meko *et al.* (1995). Dendrohydrologic reconstructions are statistical estimates of hydrologic variables from networks of tree-ring chronologies. The most commonly reconstructed variables are precipitation, streamflow, and lake levels. The development of statistical reconstruction methods has been an active area of research in dendrohydrology. Multivariate methods, including principal components analysis and canonical correlation analysis were first applied in the reconstruction of lake levels (Stockton and Fritts, 1973) and soon after to streamflow records (Stockton and Jacoby, 1976). The statistical methodology of dendrohydrologic reconstruction as of the early 1990s has been thoroughly reviewed by Loaiciga *et al.* (1993). Some recent extensions are neural networks as an alternative reconstruction model (Woodhouse, 1999), cross validation in model selection (Hidalgo *et al.*, 2000), and "noise-added" reconstructions to facilitate probabilistic interpretation of reconstructed flow series (Meko *et al.*, 2001).

Several statistical issues remain key concerns in the evaluation of tree-ring reconstructions of hydrologic or climatic variables. Measured widths of tree rings generally have a size-related or age-related trend that must be statistically removed, and the approach to removal of this growth trend determines the lowest frequency of climatic signal that can be identified. A tree-ring chronology is an average over many trees at a site, and the sample-depth, or number of trees, generally decreases back in time in accordance with the age distribution of available trees. This sample-size heterogeneity necessitates safeguards against loss of signal and possible inflation of variance due to the changing sample size. The problem becomes more complicated when chronologies are formed by merging living-tree samples from sites with known hydrologic settings with archaeological samples whose original setting is unknown. Statistical issues in application of tree-ring data in hydrologic reconstruction are discussed further by Cook and Kairiukstis (1990).

Although the tree-ring variable of choice for most dendrohydrologic reconstructions has been the annual index of precisely dated, measured ring widths, other tree-ring indicators have occasionally been used. Stable isotopes of hydrogen and carbon in dated tree rings, for example, have shown some promise in hydroclimatology (Leavitt and Wright, 2002). In a radically different type of application, tree-ring counts alone, without precise dating and width

measurement, can yield useful hydrologic information. For example, ring counts of radiocarbon-dated submerged stumps in Mono Lake, California, delineated two epic droughts – periods in which trees were able to take root and grow for more than a century in what is now a submerged lake (Stine, 1994).

Lake Cores

Just as the measured stages of closed basin lakes are a record of modern-day changes in aridity, the past stages of such lakes inferred from cores of lake sediments are a record of long-term changes in aridity (*see* **Chapter 110, Paleolimnology and Paleohydrology, Volume 3**). The climatic record obtainable from lake cores is potentially much longer than that provided by tree rings, and can cover the entire time period the lake existed within a closed basin. Many lake-core records extend well before the start of the Holocene, although dating can be problematic beyond about 20 000 to 30 000 years (Street-Perrott and Harrison, 1985). Biological and chemical properties imprinted by animals and plants that lived in the lakewater are one source of information in lake cores. Ostracodes are very small animals, rarely large enough to be seen by the naked eye, that have been present on Earth since the Ordovician Period. They occur today in great numbers in lakes, rivers, and seas, and their shells are preserved in sediments. Diatoms are unicellular algae whose cell walls are made of silica, and whose fossils are often well preserved in lake and marine sediments. Particular species of ostracodes and diatoms have restricted ranges tolerance to salinity and water depth. Changes in species composition can be interpreted as a signal for changes in salinity and water depth that in turn are related to changes in lake volume and aridity. The Mg/Ca ratio in ostracode shells has been found to be an especially robust indicator for changes in lake salinity (Yu *et al.*, 2002).

Interpretation of the Mg/Ca ratio and other measured quantities from the core as time series requires dating of the cores, and there is often considerable uncertainty in dates. Radiocarbon dating and magnetostratigrapy have been used with considerable success in lake-level studies (Street-Perrott and Harrison, 1985). The resolution of the hydroclimatic signal is limited by the sedimentation rate and the accuracy of the dating technique. Even for lakes with high accumulation rates, however, dating by ^{14}C is accurate to only about ± 50 years.

If sediments are laminated (varved), much higher resolution is possible. If varves are unequivocally annual, dating is reduced to counting the annual layers, and the potential exists for millennia-long records of hydroclimatology on interannual to century timescales (Overpeck, 1996). Varved lake sediments are the exception rather than the rule in semiarid environments, however, so that the potential for regional information in some of the more critical water-limited environments is limited.

Other

Other paleoclimatic indicators have met with some success in inferring past hydroclimatic conditions (*see* **Chapter 199, Role and Importance of Paleohydrology in the Study of Climate Change and Variability, Volume 5**). Past lake levels have also been inferred from geomorphic interpretation on the basis of surveying and description of landforms along lake shores (Street-Perrott and Harrison, 1985). Flora composition inferred from pollen and plant parts in radiocarbon-dated packrat middens has been used to infer wet or dry conditions relative to the present (Betancourt *et al.*, 1990). Periods of reactivation of sand dunes – and drought – can be identified by ^{14}C dating of organic matter or bone fragments from buried soils, and accuracy to perhaps ± 30 years is now possible with optically stimulated luminescence and single aliquot regeneration (OSL-SAR) dating of quartz grains (Forman and Pierson, 2003; Wolfe *et al.*, 2001). Geomorphic interpretation of backwater deposits and other features have been used for paleoflood estimation. Coring studies for hydroclimatic information have not been restricted to lake sediments. Relative abundance of different taxa of fossilized testate amoeba in cores of peat bogs, for example, has been used to infer changes in water-table depth near Lake Michigan (Booth and Jackson, 2003). It should be noted that while cores provide a continuous history of hydrologic variation, other methods often provide just a snapshot of conditions at a particular time.

SOURCES OF DATA

Instrumental and paleoclimatic data for studying hydroclimatic change are readily available online. Precipitation data, including the Global Historical Climatology Network (GHCN) baseline global data set for monitoring climate change, are available from National Oceanic and Atmospheric Administration (NOAA's) National Climatic Data Center (URL: **`http://www.ncdc.noaa.gov/oa/ncdc.html`**).

Online mapping of climatic parameters, including precipitation, temperature, and geopotential height fields, is possible through the NOAA-CIRES Climate Diagnostics Center (URL: **`http://www.cdc.noaa.gov/`**). Indices of sea surface temperature (SST) and atmospheric circulation can be obtained from the National Center for Atmospheric Research (URL: **`http://www.cgd.ucar.edu/cas/catalog/climind/`**) and the University of Washington's Joint Institute for the Study the Atmosphere and Ocean (JISAO) (URL: **`http://tao.atmos.washington.edu/data_sets/`**). The JISAO site is also an excellent source of gridded precipitation datasets. Gaged streamflow time series for the United States can be found at a web site of the US Geological Survey (USGS) (URL: **`http://water.usgs.gov/data.html`**). Included on the USGS site is a hyperlink to the Hydro-climatic Data Network (HCDN) of Slack

et al. (1988). The HCD consists of streamflow records unaffected by artificial diversions, storage, or other works of man; the records span the period 1874 to 1988 and the dataset includes some 1659 sites throughout the United States and its territories. No single online source exists for the so-called "natural-flow" streamflow records, as these are usually created and managed by various agencies. For example, natural-flow data for the Sacramento and San Joaquin River systems, California, can be obtained from the California Department of Water Resources (URL: `http://cdec.water.ca.gov/cgi-progs/iodir/WSIHIST`).

A clearinghouse for paleoclimatic data and reconstructions is NOAA's World Data Center for Paleoclimalogy (URL: `http://www.ngdc.noaa.gov/paleo/`). The "Paleoclimatic Data" link from that site leads to a vast assortment of data sets relevant to hydroclimatology. Among these are tree-ring reconstructions of streamflow and precipitation, lake-level records, and a unique dataset of gridded drought index reconstructed from tree rings for North America (Cook *et al.*, 1999).

PRECIPITATION

Studies too numerous to list here have addressed regional changes in precipitation around the world. Significant correlation is often found between time series of regional precipitation and various indices of atmospheric circulation and SST. Gridded precipitation for western North America indicates that, regionally, a significant part (20–50%) of the variance of annual precipitation is at decadal timescales, and that spatial modes of variability are on the order of 1000 km in size (Cayan *et al.*, 1998). Wet and dry decades are associated with changes in the frequency of atmospheric circulation modes, such as the Pacific-North-America (PNA) pattern, and some low-frequency components appear to be linked to global-scale climate processes. Significant correlations have been reported between regional precipitation in the United States and the El Nino/Southern Oscillation (ENSO) phenomenon, which reflects SST and surface pressure differences across the equatorial Pacific on timescales of a few years (3–7 years). Although significant correlations can be found between regional precipitation and individual circulation or SST indices, stronger relationships emerge with combinations of indices. Apparently, the ENSO signal in precipitation in North America is complicated by the influence from SST anomalies in the North Pacific – as reflected in the Pacific Decadal Oscillation (PDO), which acts on multidecadal timescales (McCabe and Dettinger, 2000). It is not clear that ENSO and the PDO represent independent modes of SST behavior, and indeed some evidence suggests that the PDO is a low-frequency manifestation of ENSO (e.g. Newman *et al.*, 2003). Influence on North America precipitation may also be exerted from North Atlantic SST through the Atlantic Multidecadal Oscillation (AMO), on timescales of 65 to 80 years (Enfield *et al.*, 2001). In Europe and Africa, a north–south atmospheric pressure oscillation known as the *North Atlantic Oscillation* (NAO) has been linked with multidecadal variations in precipitation.

Tree rings have been used for quantitative reconstruction of regional precipitation in the United States since the mid-twentieth century. Early tree-ring studies focused on the semiarid western United States, where most of the developed tree-ring chronologies were located. Recent decades have seen the expansion of regional tree-ring studies to other parts of the globe where water is in short supply, such as Jordan and Turkey. A fairly complete inventory of recent regional precipitation reconstructions, with data and references, is available at the NOAA World Data Center for Paleoclimatology (see Section "Sources of Data"). Earlier reconstructions are described in Stockton *et al.* (1985) and other sources (see Section "Further Reading"). A recent example serves to illustrate typical methodology and interpretation.

Example from Tree Rings: Southern Manitoba, Canada

Hydroclimatic changes in southern Manitoba, Canada, since 1409 A.D. have been reconstructed from the widths of tree rings by St. George and Nielsen (2002). The region for this study is a 100-km long corridor along the Red River (Figure 2). Tree-ring samples were taken from a variety of sources: living trees (*Quercus macrocarpa*), timbers from historical buildings and Euro-Canadian archaeological sites, and subfossil logs from alluvial sections along river. The assorted tree-ring material gave a time coverage to 1720 A.D. from living trees and to 1286 A.D. from subfossil samples.

Data Treatment and Reconstruction Modeling

To preserve as much low-frequency climate information as possible, an age-related trend was removed using regional curve standardization (RCS) in converting ring width to a dimensionless index of the growth of each tree (Briffa *et al.*, 1992). Indices for different samples at a site were averaged together to form a single tree-ring chronology, and sample replication was judged adequate to allow the chronology to be reliably used for hydroclimatic reconstruction back to 1409 a.d.

Exploratory correlation analysis with monthly precipitation series identified the 12-month sum of precipitation ending with July of the growth year as a reasonable hydrologic variable for reconstruction. A regression model ($R^2 = 0.43$) relating the annual precipitation to the tree-ring chronology was calibrated over the period 1896 to 1996 and validated using cross validation (Michaelsen, 1987).

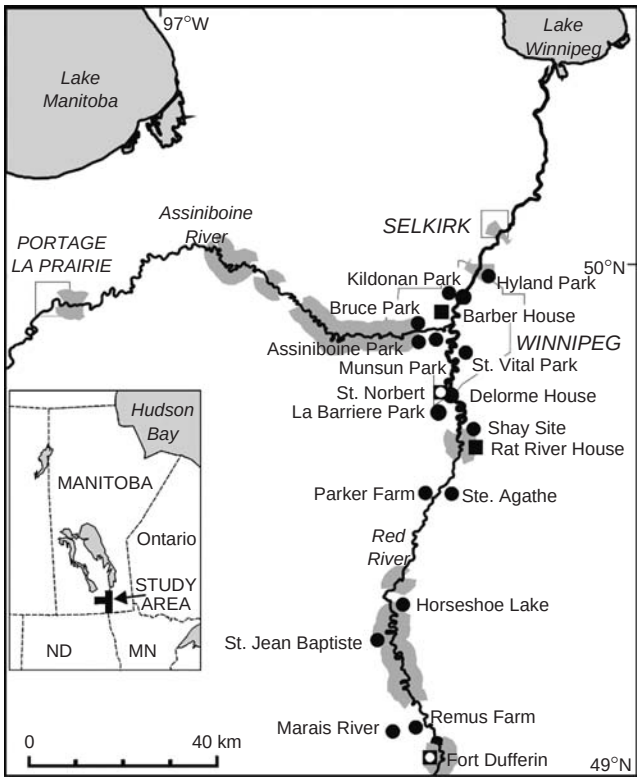

Figure 2 The Assiniboine and Red River in southern Manitoba and the tree-ring sampling network for reconstruction of annual precipitation at Winnipeg, Canada. Tree-ring samples from living-tree sites (circles), historical buildings and archaeological sites (squares), and subfossil logs from alluvium along rivers (shading) (Reprinted from St George & Nielsen 2002. ©2002, with permission from Elsevier)

Hydroclimatic Changes

The reconstructed annual precipitation, 1409 to 1998 A.D., plotted in Figure 3, suggests that hydroclimatic conditions after the establishment of the first Euro-Canadian settlement in Manitoba (1811 A.D.) are not representative of the conditions since 1409 A.D. Precipitation anomalies are more persistent and precipitation is more variable in the first half of the reconstruction than the second half. Moreover, the most extreme precipitation values fall within the first half of the reconstruction, and all years with reconstructed precipitation greater than two standard deviations above the instrumental mean occur before 1800 A.D.

The extended wet period near 1600 A.D. is synchronous with wet epochs elsewhere in the northern Plains (North Dakota, Minnesota) as inferred from limnological studies, and suggests that hydroclimatic shifts in this region can last for several decades and cover several thousand square kilometers. Interestingly, the early part of the wet period overlaps with a well-documented megadrought that apparently affected watersheds across much of northern Mexico and the southwestern United States (Stahle *et al.*, 2000). The results imply that climatic case studies in regional drought and flood planning based exclusively on experience during the twentieth century may dramatically underestimate true worst-case scenarios for southern Manitoba.

RUNOFF

Like precipitation, runoff has been shown to have a large spatial structure and to be significantly correlated with indices of atmospheric circulation and SST. Strong linkages between regional streamflow variations and indices of atmospheric circulation and SST have been demonstrated on global, regional, and basin scales (e.g. Dettinger and Diaz, 2000; Jury, 2003; Eltahir, 1996; Hidalgo and Dracup, 2003).

Much research has addressed circulation and SST linkages to runoff variation in western North America. The ENSO phenomenon is associated with opposite-sign streamflow anomalies in the southwestern and northwestern United States (Cayan and Peterson, 1989), and streamflow in widely separated parts of the United States is significantly related to the extreme modes of southern Oscillation variability (Dracup and Kahya, 1994).

The large spatial scale of runoff variations can be illustrated with natural-flow records for the Colorado River and Sacramento River, two rivers of vital importance to water resources in western United States (Figures 4 and 5). Despite being separated by some 1000 km, these basins are simultaneously in drought more often than expected by chance alone. Perhaps the best example of joint drought is the water-year 1977, when flow reduced to less than 34% of normal on both rivers. Regionally, low streamflow events such as these are typically associated with departures from normal atmospheric circulation over wide parts of the Northern Hemisphere. The winters of 1976 and 1977 were so unusual as to be the focus of a case study of anomalous atmospheric circulation (Namias, 1978). The winter was characterized by amplification of the normal seasonal 500-mb ridge over the western United States, with teleconnections to anomalously strong troughs over the Aleutians and the eastern United States.

Tree rings are frequently used to extend runoff records before the start of the instrumental period. The usual approach is to calibrate tree records with either a gaged-flow or natural-flow record, and substitute earlier tree-ring data into the equation to generate a long-term reconstruction. Western North America has been the geographic focus of many such reconstructions. Findings on contrasts of twentieth century and earlier hydroclimatology from seven of these reconstructions are summarized in Table 1. Note that basins studied are highly variable in size, with mean annual flows varying by a factor of almost 500. A common theme is the relative wetness of the twentieth century, especially the early decades. Identification of a common period of "worst" drought in these records is somewhat problematical because of the uneven time coverage.

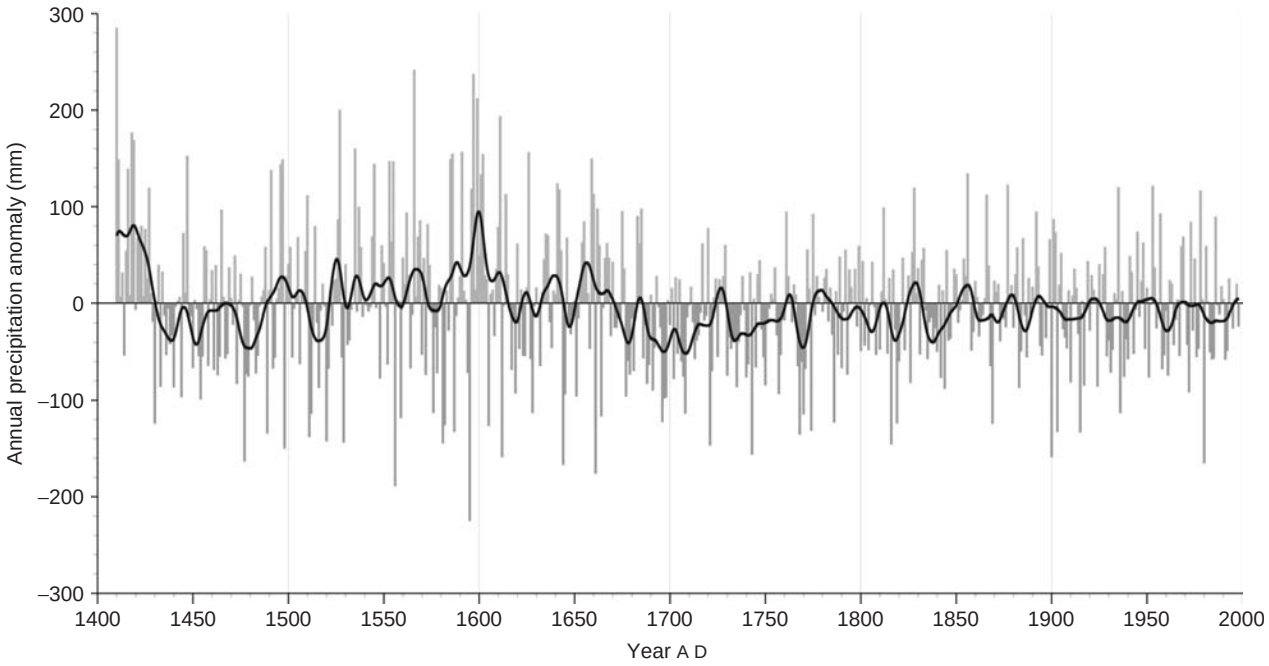

Figure 3 Tree-ring reconstruction of annual (August–July) precipitation, 1409 to 1998 A.D., at Winnipeg, Canada. Precipitation as departures from 1961 to 1990 mean. Smooth curve is 15-year running mean (Reprinted from St George & Nielsen 2002. ©2002, with permission from Elsevier)

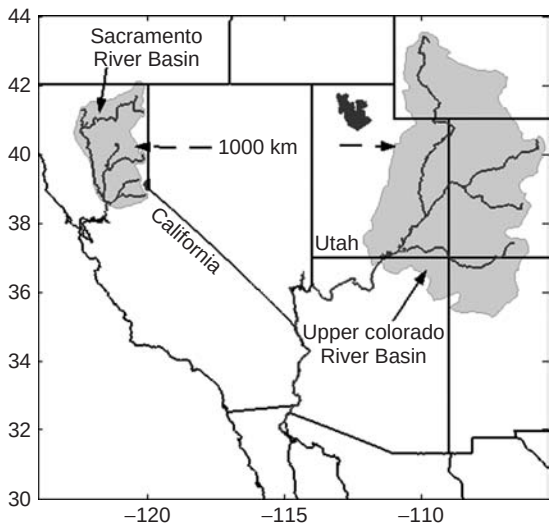

Figure 4 Drainage basins of Upper Colorado and Sacramento Rivers. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Example from Tree Rings: Colorado River Basin, US

Tree-ring records have been especially useful for pointing out important components of long-term variability of runoff in the Upper Colorado River basin. The annual flow for the Colorado River at Lees Ferry, Arizona, has been reconstructed back by Stockton and Jacoby (1976) from a network of some 17 tree-ring sites strategically located relative to major runoff-producing areas. The reconstruction, generated with a regression model ($R^2 = 0.87$) that used principal components of tree-ring chronologies as predictors, covers the years 1520 to 1961 and shows great variability of runoff on decadal timescales (Figure 6). The 20-year running mean reaches an all-time high in the early 1900s, which happens to coincide with the period used as a baseline to allocate the waters of the river. The smoothed series illustrates the importance of considering the long-term record in assessing range of severity of extended droughts: flows in the late 1500s average just 80% of the long-term mean reconstructed flows. The tree-ring record also suggests a bias in the observed long-term mean flow, with the mean from the tree-ring record 1520 to 1961 just 90% of the observed mean for 1906 to 2001.

It is important to keep in mind that tree-ring reconstructions are estimates rather than measurements of streamflow, and that the accuracy of the estimates depends on many factors, including the basic quality of the tree-ring data, the method of processing that data, and the statistical reconstruction model. An alternative reconstruction for the Colorado River at Lees Ferry, Arizona, using a slightly different method of data reduction than Stockton and Jacoby (1976) shows even more severe drought conditions in the late 1500s than indicated in Figure 6 (Hidalgo *et al.*, 2000). An assessment of tree-ring records by Stahle *et al.* (2000) suggests that the low flows of the 1500s on the

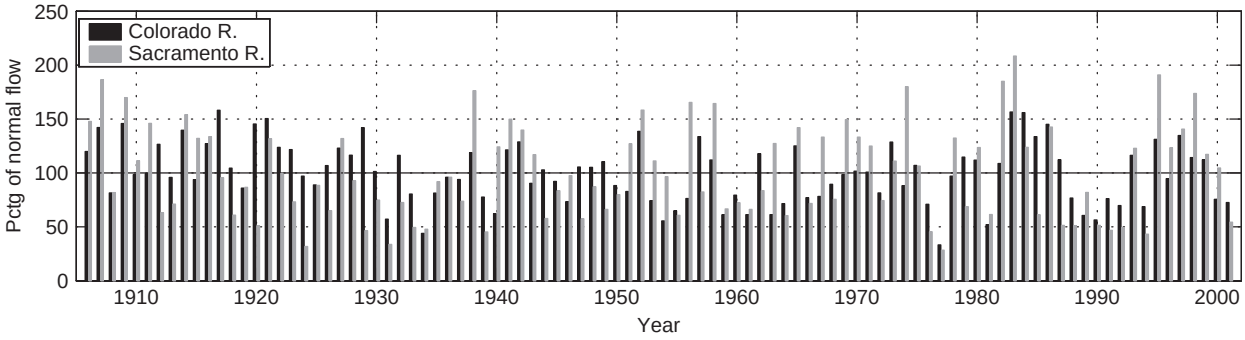

Figure 5 Annual (water-year) totals of natural flow of the Sacramento River, California, and the Colorado River at Lees Ferry, Arizona. Means are for period 1906 to 2001. Colorado River data from US Bureau of Reclamation; Sacramento River data from California Department of Water Resources (see Data Sources)

Table 1 Hydroclimatic changes inferred from tree-ring reconstructions of streamflow in western North America

River /reference[a]	Mean flow[b] ($m^3\,sec^{-1}$)	Reconstruction Period[c]	Hydroclimatic change[d]
Colorado R, AZ	590.22	1520 to 1961	Longest period of high-flow years 1907 to 1930
Stockton and Jacoby (1976)			Drought in late 1500s longer and more severe than any in the twentieth century
Salt R, AZ	24.50	1580 to 1979	Frequency of high-flow relatively high in the twentieth century
Smith and Stockton (1981)			Most severe sustained periods of low flow before the twentieth century
Gila R, AZ	13.08	1663 to 1985	Clustering of high-flow years in the early twentieth century
Meko and Graybill (1995)			Drought in 1950s most severe on record
Middle Boulder Ck, CO	1.55	1703 to 1987	Low flows less persistent in the twentieth century than in the nineteenth century
Woodhouse (2001)			Multiyear drought in the 1840s more severe than any in the twentieth century
Sacramento R, CA	707.49	869 to 1977	Lowest average (10–50 yr) means near 1300 A.D.
Meko *et al.* (2001)			Extreme single-year low flows in late 1500s
Yellowstone R, WY	85.58	1706 to 1977	Relatively high mean flows in the twentieth century (except 1930s)
Graumlich *et al.* (2003)			Drought of 1930s more severe than any reconstructed drought
South Saskatchewan R, Canada;	302.81	1470 to 1992	Relatively high mean flows in the twentieth century
Case and MacDonald (2003)			Droughts more severe in the 1840s than in the twentieth century

[a]river for which flow reconstructed, followed by reference to study.
[b]mean daily observed flow for period used to calibrate reconstruction (all greater than 50 years).
[c]time period of reconstruction (A.D.).
[d]selected outstanding findings, with emphasis on comparison with the twentieth century.

Colorado River are just one component of a much larger-scale phenomenon.

Example from Tree Rings: White River Basin, Arkansas, Southeastern United States

In this second example, summer (JJA) runoff of the White River, Arkansas, was reconstructed from tree rings of bald cypress (*Taxodium distichum*) by Cleaveland (2000). In contrast to the Colorado River basin, the White River basin is less arid, has less extreme climate gradients, and a seasonal flow regime not dominated by mountain snowmelt. The White River, a major tributary of the Mississippi River, drains some 66 000 km^2 in Arkansas and Missouri (Figure 7).

Bald cypress is an extremely long-lived species, and the three tree-ring chronologies for the study extend to earlier than 1200 A.D. The gaged-flow record for the White River at Clarendon begins in 1900, and has a cool-season dominant regime with lowest monthly mean flows

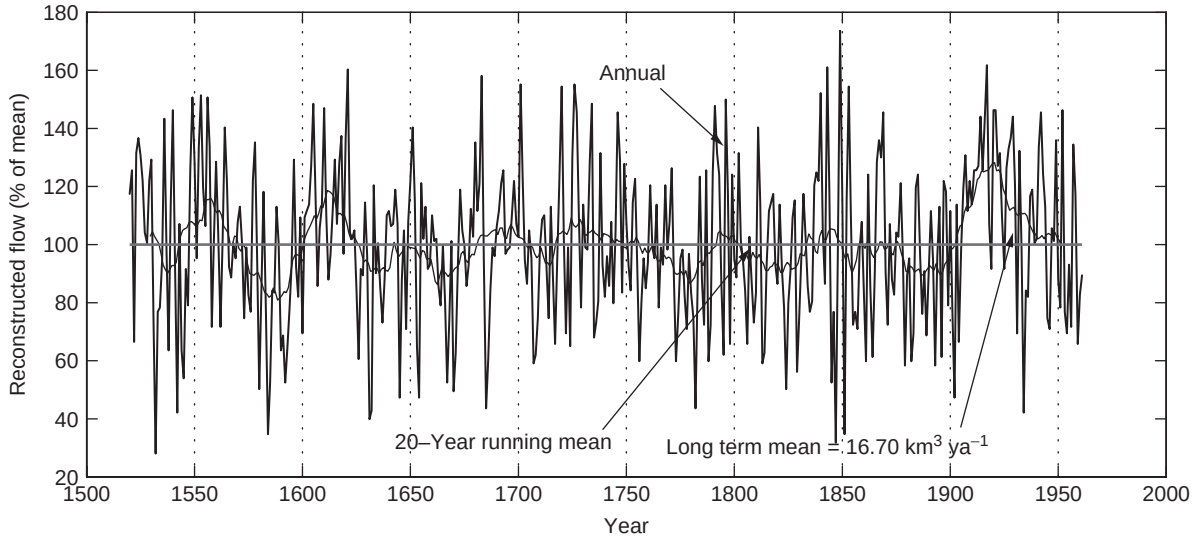

Figure 6 Tree-ring extension of annual flow of Colorado River at Lees Ferry (data from Stockton and Jacoby, 1976). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

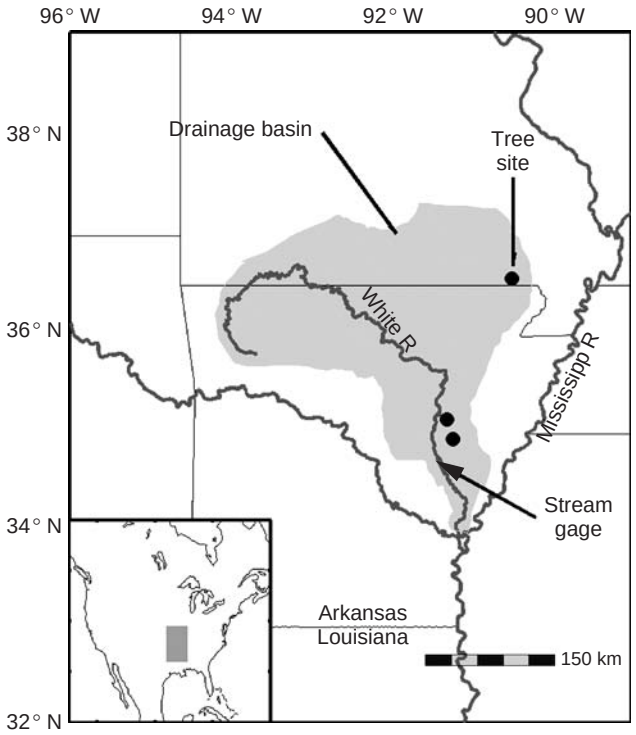

Figure 7 Map showing location of drainage basin, stream gage, and tree-ring sites for reconstruction of White River, Arkansas, summer flow (Reproduced from Cleaveland (2000) by permission of Hodder Arnold). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

in the summer months. Bald cypress from this region are responsive mainly to growing-season rainfall, however, and it is this summer component of flow that was reconstructed. The reconstruction was generated with a linear regression model ($R^2 = 0.67$) calibrated during 1931 to 1985 and validated during 1900 to 1930.

Hydroclimatic Changes

The reconstruction of summer (JJA) mean daily flow, 1023 to 1985 A.D., contains extended dry periods and wet periods that exceed anything in the modern record (Figure 8). One focus of the interpretation was on the tendency for persistence of flows above and below thresholds of wetness and drought defined by percentiles of the long-term reconstruction. A difference in persistence regimes was identified: low flows were persistent from year-to-year and high flows were random. An example of the persistence of low flows is the sequence of 10 consecutive years below the median from 1449 to 1458 A.D. In contrast, the modern gaged record contains no examples of such recurrently low summer flows.

Mean and variance are basic properties tied to the concept of stationarity of hydrologic time series (Salas *et al.*, 1980). A *t*-test of the reconstructed flows plotted in Figure 8 revealed no significant changes in mean from one century to the next. A nonparametric test (Conover, 1980) did, however, indicate significant changes in variance. The twentieth century had anomalously high variance, with a significant increase from the nineteenth century.

In discussing the differences between flow characteristics in the twentieth century and earlier centuries, Cleaveland (2000) leaves open the possibility that human modification of the watershed may have had some impact on the results of the study. For example, the loss of wetland forests would tend to reduce infiltration and speed up

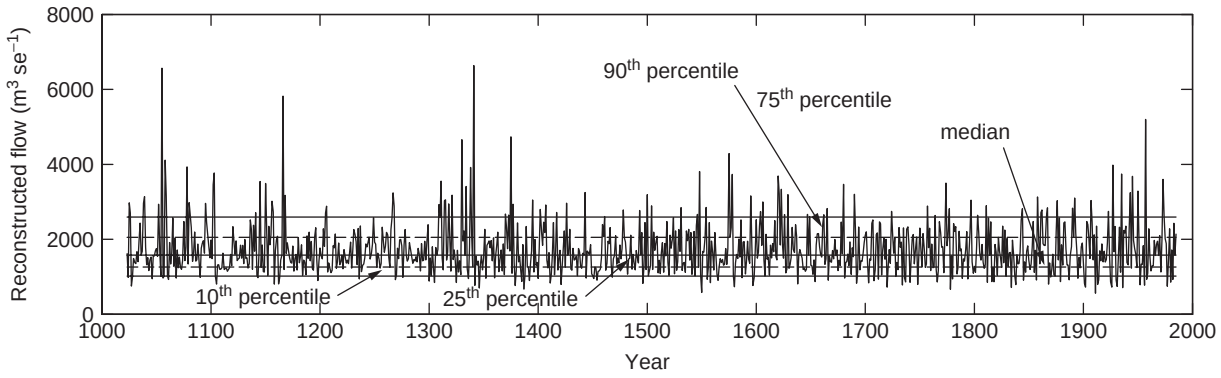

Figure 8 Total summer (JJA) mean daily streamflow of White River at Clarendon, Arkansas, reconstructed from tree rings (Reproduced from Cleaveland (2000) by permission of Hodder Arnold)

overland flow of runoff, possibly making low flows more intense by reducing base flow (*see* **Chapter 111, Rainfall Excess Overland Flow, Volume 3**; **Chapter 187, Land Use Impacts on Water Resources – Science, Social and Political Factors, Volume 5**).

ARIDITY

Annual resolved, calibrated, and validated reconstructions, as generated from tree rings, are useful for evaluating long-term statistical properties of hydrologic variables, but more qualitative information on relative wetness and dryness can also be useful for placing the instrumental record in context. Aridity information derived from lake cores is particularly relevant in assessing multidecadal change (*see* **Chapter 110, Paleolimnology and Paleohydrology, Volume 3**). Lake-core data is also somewhat complementary to tree rings in that, longer-term and possibly lower-frequency hydrologic information can be extracted from the lake cores. Lake-core time series of various quantities, some related to aridity, are available from the World Data Center for Paleoclimatology (see Section "Sources of data").

Example from Paleolimnology: Northern Great Plains, US

Multi-proxy paleolimnological data were used to infer long-term changes in aridity in the northern Great Plains, US (Yu *et al.*, 2002). The paleoclimatic samples were salinity/drought proxies in sediment cores from four lakes in North Dakota and Minnesota (Figure 9). The chronology for the core was established by Accelerator Mass Spectrometer (AMS) ^{14}C dating at a series of depths in the core, and then interpolating between those depths with a straight line fit to age against depth.

Data Treatment

The core from Rice Lake (Figure 9) was the central focus of the study. The top 5.5 m of that core, covering the last 2100 years, was sampled at decadal time intervals for ostracodes. Carbonate shell fragments were subjected to isotope analysis for the computation of $^{18}O/^{16}O$ and $^{13}C/^{12}C$ ratios, and the acid residual from the isotope analysis was analyzed for various trace elements, including Mg and Ca. The hydroclimatic interpretation was centered on time variations in the ostracode-shell Mg/Ca ratio, which indirectly is a proxy for aridity (see Section "Data").

Smoothed series of the Mg/Ca ratio from the four lakes were averaged together after a resampling of the original

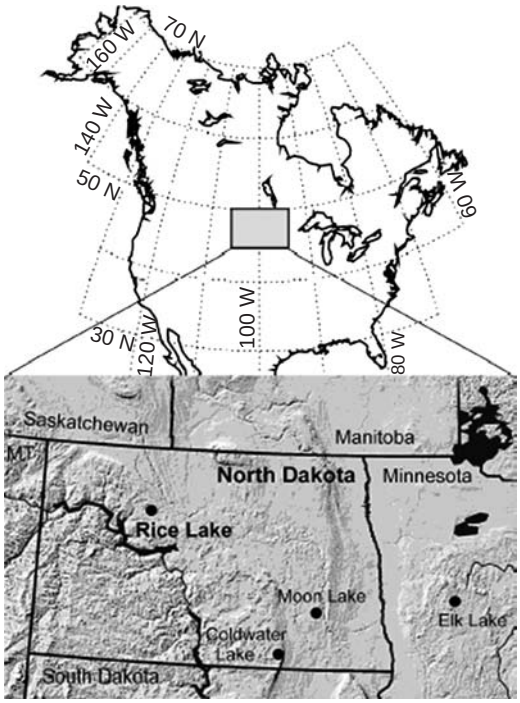

Figure 9 Lakes yielding a 2100-year proxy record of wet and dry conditions in the northern Great Plains from sediment cores (Reproduced from Yu *et al.*, (2002) by permission of Hodder Arnold)

time series at even 10-year intervals to arrive at the regional aridity index. The resolution in the resulting time series is too crude to track interannual fluctuations in aridity, but is suitable for identifying multidecadal fluctuations. The inferred drought signal is qualitative rather than quantitative, as the Mg/Ca ratio is not calibrated statistically with any particular instrumental time series of aridity.

Hydroclimatic Changes

The composite time series of lake aridity index has several upward excursions interpreted as hydrologic droughts (Figure 10). Key features are dry periods lasting some 400 years each, separated much shorter wet intervals. The earliest dry period, the "medieval climate anomaly" (MCA) has two aridity peaks that happen to correspond to multidecadal droughts in the southern Sierra Nevada of California (Stine, 1994, 1998). Another notable feature is the peak in dryness about 300 years ago, in a period that is generally considered the Little Ice Age (LIA). The results imply that much of the LIA was relatively arid in the northern Great Plains and that rhythms of aridity may have occurred in this region on a longer timescale than typically amenable to study with tree rings.

SNOWPACK

Snow accumulation is an interesting climatic index as it responds to both precipitation and temperature variations (*see* **Chapter 159, Snow Cover, Volume 4**; **Chapter 160, Energy Balance and Thermophysical Processes in Snowpacks, Volume 4**). Regional hydroclimatic variability as reflected by changes in snow accumulation in the mountainous western United States has been studied by Cayan (1996), who used the snow water equivalent (SWE) on April 1 as a summary variable. Snow course data extending back to the 1920s indicated considerable year-to-year variability in SWE, with some years having anomalously high or low accumulation across multiple basins. A notable shift in the time series occurred in 1977, which coincides with a widely reported regime change in the climate of the North Pacific sector (Ebbesmeyer *et al.*, 1991). One characteristic of the shift is decreased snow accumulation in the northern watersheds of the western United States and increased accumulation in the southern watersheds. Cayan (1996) links the observed snowpack changes to stronger North Pacific lows in the winters and increased occurrences of the warm phase of ENSO.

Another aspect of snowpack important to regional water resources is the timing of snowmelt (*see* **Chapter 114, Snowmelt Runoff Generation, Volume 3**). Changes in timing can affect the operation of reservoirs systems, which frequently must respond to competing interests of water storage and flood control. An interesting study combining phenological and hydrologic data suggests that a change toward earlier snowmelt has occurred in the western United States since the late 1970s, and that the change resulted from a 1–3 °C increase in spring temperatures over western North America (Cayan *et al.*, 2001).

Snowpack data are being increasingly used in dendrohydrology as longer, quality-controlled SWE datasets are becoming available. Snowpack for the Gunnison Basin in western Colorado has been reconstructed from tree rings back to 1569 A.D. (Woodhouse, 2003). years of persistent low April-1 SWE are not distributed evenly through the record, and the twentieth century is notable for reduced frequency of persistently low SWE events compared with the long-term record.

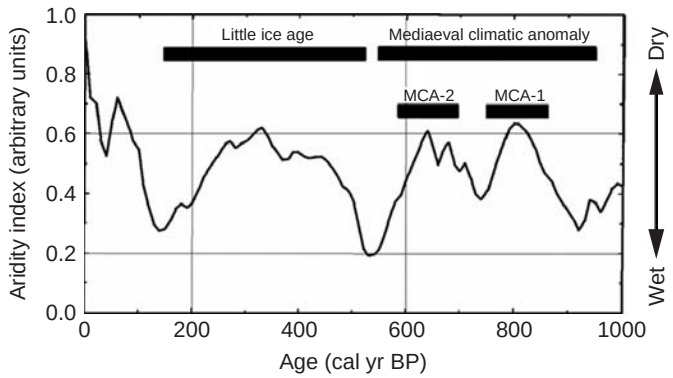

Figure 10 Aridity index for the Northern Great Plains of North America from salinity/drought profiles Rice, Moon, Coldwater, and Elk Lakes. The index shows a double-peak pattern during the Mediaeval Climate Anomaly (MCA; Stine, 1998). Note that time increases toward left on the time axis, with years before present (BP) representing years before 1950 A.D. (Reproduced from Yu *et al.*, (2002) by permission of Hodder Arnold)

FLOOD FREQUENCY

Changes in the amount and timing of runoff also affect the frequency of floods (*see* **Chapter 125, Rainfall-runoff Modeling for Flood Frequency Estimation, Volume 3**). For many years the subject of climatic change was not considered relevant to flood-frequency analysis, but that viewpoint has changed. Subtle shifts in the locations of the low and high pressure anomalies in the North Pacific have been shown to affect the occurrence of large winter floods in the southwestern United States (Ely *et al.*, 1994). The probability distribution of partial duration flood series, moreover, can differ from one climatic regime to another (Hirschboeck, 1987). Paleoclimatology has been useful in extending information on flood history beyond the instrumental record (e.g. Tardif and Bergeron, 1997; Enzel *et al.*, 1993). Other paleoclimatic flood evidence, as well as the general topic of climate variability and frequency of floods at decadal to millennial timescales has been reviewed Redmond *et al.* (2002).

CAUSES

The root causes of changes in regional hydroclimatology on various timescales are still largely unknown. The search for "causes" proceeds to a deeper level than mere associations (e.g. correlations between precipitation and SST indices), and often centers on possible "forcing factors" of change. One view is that no forcing factors need be invoked, and that variations on interannual-to-century timescales naturally evolve from the inherent random variability of the atmosphere or from inherent variability in the ocean dynamical system. Hypotheses for outside forcing include solar variability and variability in volcanic aerosol loading of the stratosphere. Paleoclimatic data from North America hint at a solar-variability link on large spatial scales (Cook *et al.*, 1997; Yu *et al.*, 2002), although statistical evidence is weak and demonstrated mechanism is lacking. It is of course possible that some combination of the above factors (and possibly others) has influenced the hydroclimatic variations evident in the instrumental and paleoclimatic record (Goodess *et al.*, 1992).

The possible anthropogenic influence on recent and future hydroclimatic changes is a topic of much recent research. Coincident with the increase in atmospheric greenhouse gases and aerosol loading of the troposphere since the preindustrial period are a number of hydroclimatic changes. With varying degrees of certainty, it can be said that changes in the twentieth century include (i) an increase (5–10%) in continental precipitation for much of the Northern Hemisphere, (ii) an increase in heavy precipitation events at high latitudes, and (iii) increased summer drying and incidence of drought in some areas (IPCC, 2001) (*see* **Chapter 195, Acceleration of the Global Hydrologic Cycle, Volume 5** and **Chapter 33, Human Impacts on Weather and Climate, Volume 1**).

201: Land-Atmosphere Models for Water and Energy Cycle Studies

BART NIJSSEN[1] AND LUIS A BASTIDAS[2]

[1]Departments of Hydrology and Water Resources/Civil Engineering and Engineering Mechanics, University of Arizona, Tucson, AZ, US
[2]Department of Civil and Environmental Engineering/Utah Water Research Laboratory, Utah State University, Logan, UT, US

Land surface models simulate the temporal evolution of the energy and water balance at and near the land surface. These models can be used coupled to an atmospheric model, in which case feedbacks between the land surface and atmosphere are explicitly represented, or they can be used in a stand-alone, uncoupled mode, in which case observed or simulated atmospheric conditions act as time-varying boundary conditions. This article reviews the basic layout of land surface models, their history, and their uses, specifically in uncoupled simulations. In this context, the challenges of model performance evaluation and the role of model intercomparison projects are discussed. The article ends with a look toward the future and the next series of developments that land surface models are likely to undergo.

INTRODUCTION

About 70% of the Earth's surface is covered by oceans, seas, lakes, and other large bodies of open water. As such, much of the interaction between the Earth's surface and the atmosphere occurs as an exchange of energy, mass, and momentum across a liquid/gas interface. Immediately above this interface, the air is saturated with moisture because the supply of water is essentially unlimited and moisture can be freely exchanged. As a result, the sea surface temperature (SST) defines both the thermal energy state of the sea surface and the amount of moisture in the air immediately above it, two important lower boundary conditions for atmospheric circulation models (Betts *et al.*, 1996).

Over land, the situation is more complicated because the supply of moisture is neither unlimited nor can moisture be exchanged freely. The amount of water available for exchange with the atmosphere is a function of the amount of water stored in the soil, which varies with time, as well as the type of soil and its vegetative cover. Vegetation actively regulates the exchange of moisture with the atmosphere through stomatal control. Stomata are small openings on leaf surfaces through which a plant exchanges carbon dioxide, oxygen, and water with the atmosphere. Stomatal control allows a plant to limit the amount of transpiration at times when moisture is in limited supply. As a result, the air above the land–atmosphere interface is often unsaturated, and knowledge of the land surface temperature alone is generally insufficient to determine the moisture state of the atmosphere close to the land surface.

Because of the large specific heat of water, active mixing, and the sheer amount of water stored in the world's oceans, the ocean surface provides a much larger amount of heat storage than does the land surface. In addition, ocean currents can transport large amounts of heat over long distances, while horizontal heat transport through the land surface is negligible. Instead, the atmosphere provides a means of heat transport between different locations at the land surface.

Because of its smaller role in heat storage and transport, and because of its smaller spatial extent, the land surface is arguably of lesser importance as a lower boundary condition to the atmosphere than the ocean surface. However, for many important exchange processes, the land surface exhibits greater spatial and temporal variability in controlling characteristics than the ocean. For example,

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

soil hydraulic properties and water-holding capacities vary greatly over short distances, as does vegetation. Vegetation typically exhibits a seasonal cycle of growth and decline, and surface albedo varies as a function of time and place, with direct effects on the amount of energy reflected and absorbed at the land surface. In addition, even though in many cases the effects of the land surface on the atmosphere are mostly local, the land boundary condition is of special interest because this is where people live.

Although the exchange mechanisms of mass, energy, and momentum between the land surface and the atmosphere are reasonably well understood qualitatively, it is precisely this variability of land surface properties and states in both space and time that complicates the development of a quantitative description of land–atmosphere exchange processes. A quantitative description of the mass, energy, and momentum exchanges, as well as the spatial distribution and temporal evolution of mass and energy storage at the land surface is the domain of land surface models. These models serve both as a representation of the lower boundary in atmospheric models and as stand-alone models to study and predict land surface fluxes and states.

The land surface continually exchanges energy with the overlying atmosphere. Incident shortwave radiation, either in the form of diffuse or direct beam radiation, originates from the sun, and is partly absorbed by the land surface. Direct beam radiation is shortwave radiation that is not scattered by the atmosphere and comes from the direction of the solar disk, while diffuse radiation is scattered by the atmosphere and emanates from all directions of the sky. Globally, only 45% of the shortwave or solar radiation at the top of the atmosphere is absorbed by the land surface. 25% is reflected by the atmosphere, 35% is absorbed by the atmosphere, and 5% is reflected by the Earth's surface (Trenbert, 1992). Note that these figures reflect global average values, including both land and ocean surfaces. Absorbed shortwave radiation (R_s) at the surface is given by

$$R_s = (1 - \alpha) R_s^{\downarrow} \tag{1}$$

where α is the shortwave albedo, and $R_s^{\downarrow}$ is the incoming shortwave radiation at the land surface. Absorption of solar energy by the atmosphere and the land surface leads to an increase in heat storage and hence temperature. Any body emits radiation, so both the land surface and the atmosphere reradiate some of the energy absorbed from the sun. The land surface and atmosphere emit radiation at a much longer wavelength than the sun, because of their lower temperatures. This emitted radiation is referred to as long-wave radiation. Part of the energy emitted by the atmosphere is intercepted by the land surface and consequently the radiative energy incident on the land surface is the sum of the incident shortwave and long-wave radiation. The land surface itself emits long-wave radiation at a rate of

$$R_L^{\uparrow} = \varepsilon \sigma {T_s}^4 \tag{2}$$

where $R_L^{\uparrow}$ is the emitted long-wave radiation, ε the emissivity of the land surface, σ the Stefan-Boltzman constant, and T_s the land surface temperature.

The land surface and overlying atmosphere also exchange energy by means of turbulent transport, in which eddies of varying sizes transport heat, moisture, and momentum. The energy exchanged through the transport of warm air parcels is termed *sensible heat* (H), and is a function of the temperature gradient near the land surface

$$H = -\rho c_p K_h \frac{\partial T}{\partial z} \tag{3a}$$

where ρ is the air density, c_p is the specific heat of air at constant pressure, $\partial T/\partial z$ is the temperature gradient near the surface, and K_h is a turbulent exchange coefficient or eddy diffusivity. Equation (3a) is often written in the integral form

$$H = -\rho c_p \frac{(T_a - T_s)}{r_{ah}} \tag{3b}$$

where T_a is the air temperature, and r_{ah} is an aerodynamic resistance to sensible heat exchange between the levels where T_a and T_s are measured or calculated.

Energy exchanged through turbulent transport of water vapor is termed *latent heat exchange* (LE). The phase change that occurs when water is evaporated from open water surfaces, transpired by vegetation or sublimated from snow and ice, requires a large amount of energy. This energy is released when the water vapor condenses, which can happen large distances away from the original place of evaporation. LE between the land surface and the atmosphere can be described as

$$LE = -\lambda \rho K_v \frac{\partial q}{\partial z} = -\frac{\rho c_p}{\gamma} K_v \frac{\partial e}{\partial z} \tag{4a}$$

where λ is the latent heat of vaporization, K_v is the eddy diffusivity for vapor exchange, q is specific humidity, e is vapor pressure, and γ is the psychrometric constant ($c_p p/0.622\lambda$ with p the atmospheric pressure). Similar to equation (3b), this equation can also be written in the integral form as

$$LE = -\frac{\rho c_p}{\gamma} \frac{(e_a - e_*)}{r_v} \tag{4b}$$

where e_a is the vapor pressure of the air, e_* is the vapor pressure near the surface, and r_v is an effective resistance to vapor exchange between the levels where e_a and e_* are measured or calculated.

The land surface not only exchanges energy with the overlying atmosphere, but also exchanges heat with deeper soil layers, largely through conduction. This heat transport (G) is generally described by the heat flux equation

$$G = -k_s \frac{\partial T}{\partial z} \tag{5}$$

where k_s is the soil thermal conductivity and T is the temperature in the soil.

Because energy is conserved, any imbalance between incoming and outgoing fluxes of energy will result in a change of the energy stored at the ground surface, largely expressed as a change in land surface temperature. Thus, the change in energy stored at the land surface (S_E) is given by

$$\frac{dS_E}{dt} = R_n - H - LE - G \tag{6}$$

where R_n is the net radiation given by

$$R_n = (1 - \alpha)R_s^{\downarrow} + R_L^{\downarrow} - R_L^{\uparrow} \tag{7}$$

where $R_L^{\downarrow}$ is the long-wave radiation flux incident on the land surface. For surfaces with small thermal heat capacities, the amount of energy storage is small and the net radiation is balanced by the sensible, latent and ground heat fluxes.

Conservation of mass can be used to develop a mass balance equation for a segment of the land surface similar to equation (6). In hydrology, the mass conservation of water is of primary interest. In this case, the change in the amount of water stored in a section of the land surface or control volume equals the net flow of water into and out of this segment. Storage changes consist of changes in water stored in the soil, on the surface and in the vegetation canopy if one is present. Surface water storage can consist of liquid water in lakes, ponds, and depressions, or of water stored in solid form as snow or ice. The main moisture flux into the control volume is precipitation, while evapotranspiration, surface runoff, and percolation to deeper soil layers are the main mass fluxes out of the control volume. In its simplest form, the mass conservation equation for water or water balance equation takes the form

$$\frac{dS_W}{dt} = P - ET - Q_s - Q_g \tag{8}$$

where S_W is the amount of moisture stored at and near the surface per unit of land surface, P is the precipitation rate, ET is the evapotranspiration rate, Q_s is the surface runoff, and Q_g the percolation of water to deeper soil layers. The evapotranspiration term links the water balance and energy equation, because the latent heat-flux term in equation (6) is the energy equivalent of the evapotranspiration term in equation (8). Consequently, the energy and water balance at the land surface are tightly linked. The conservation equations (6) and (8) form the basis for all land surface models.

Land surface models typically divide the land surface in a large number of model elements, for each of which the energy and moisture balance terms are calculated. Because land surface schemes were initially developed to simulate feedbacks between the land surface and the atmosphere, they largely focus on the vertical exchange of energy and moisture and tend to neglect horizontal exchanges between the model cells. Some schemes include routing models that will transport the runoff generated at the level of individual grid cells through an idealized channel network to simulate river discharge at a number of locations in the basin.

EVOLUTION OF LAND SURFACE MODELING

Richardson (1922), in his book *Weather prediction by numerical process*, already pointed out that "the atmosphere and the upper layers of the soil or sea form together a united system". He identified three different varieties of earth surface that should be represented, namely, sea, bare soil, and soil covered by vegetation. Richardson suggested that the combination of these surface types in a single model cell (200×200 km in his case) could be represented by area-weighted, average constants, with "due regard being paid to the season and the customary times of ploughing, harrowing, sowing, and the like". Heat and water transfer in the soil could be represented by finite difference approximations of the differential equations governing their transport. The soil layers were discretized so that the layers were progressively thicker with increasing depth to allow for a detailed treatment of the steep gradients near the surface (Richardson suggested layer boundaries at depths of 0, 0.0192, 0.0639, 0.191, 0.536, and 1.475 m below the surface). Richardson based much of the empirical part of his model on observations in the British Isles. These observations indicated that during the wintertime, which tends to be wet and damp in northwestern Europe, evaporation from bare soil was similar to that from an open water surface. During the summer, soil evaporation was to be modeled explicitly as a function of moisture and vapor transport in the unsaturated soil. The equation that Richardson suggested is the same as the Richards equation in soil water transport, except for the additional vapor flux term (note that Richards published his equation for moisture transport in unsaturated media almost a decade later (Richards, 1931)). Evaporation from vegetated surfaces was represented differently. Richardson recognized that "a portion of rain, and the greater part of dew, is caught on foliage and evaporated without ever reaching the soil". Citing work by Brown and Escombe (1900) and Brown and Wilson (1905), he suggested that transpiration through leaf surfaces might be represented analogously to

electric conduction, in that "the rate of transpiration may be said to be inversely as the 'resistance' of the stomata" (Richardson, 1922). Transpiration is then a function of this resistance and the vapor gradient between the leaf cavities and the surrounding air. Scaling from a single leaf to the leaf canopy is done through an increase in the conductance. Transpiration diminishes when soil moisture falls below a certain level.

The treatise by Richardson (1922) is remarkable given that he outlined a blueprint for a numerical weather prediction (NWP) model, including a land surface model, before the advent of modern computers. Richardson discusses an example on "computing forms" for a single 6-h time step, in which "all computations were worked twice and compared and corrected" and "multiplications were mostly worked using a 25 cm slide rule". However, given these computational resources, near real-time simulation of weather and land surface conditions did not make further significant advances until the development of modern computers.

Pitman (2003) has given an extensive review of the development of modern land surface schemes designed for climate models. Following Sellers *et al.* (1997a), he considers three generations of land surface models in climate models. The first-generation model is typified by the "Manabe bucket model" (Manabe, 1969), and is much simpler than the land surface scheme envisioned by Richardson in 1922. This model ignored the heat flux into the soil, assumed a globally constant soil depth and water-holding capacity, and evaporation was limited when the soil moisture fell below a certain threshold. Vegetation, and its role in controlling evaporation from the land surface, was not represented explicitly. Runoff was generated when the moisture storage capacity was exceeded.

Second-generation models, starting with the work by Deardorff (1978), are characterized by an explicit treatment of vegetation and a more realistic representation of evaporation, including evaporation from interception storage and a separation of soil evaporation and transpiration. The soil is typically divided into a number of layers, and vertical moisture transport between the layers is modeled on the basis of a simplified version of Richards equation. These models also allow for a dynamic representation of the ground heat flux, initially based on the force-restore method (Bhumralkar, 1975; Deardorff, 1978), and later on finite difference approximations of the heat-flux equation. As such, they are much closer to the land surface schemes envisioned by Richardson (1922), than the first-generation models. Runoff is typically produced through a fast response or event response mechanism that simulates surface runoff, and a slow runoff mechanism that simulates subsurface runoff. When these land surface models are employed in climate models, all runoff is directly moved to the ocean, unless an explicit routing scheme is employed.

The production of runoff and the partitioning between fast and slow response mechanisms varies widely between the existing land surface schemes as is evident from model intercomparison projects such as the Project for the Intercomparison of Land Surface Parameterization Schemes (PILPS) (e.g. Lohmann *et al.*, 1998; Bowling *et al.*, 2003; Nijssen *et al.*, 2003). As a result of the strong interaction between the energy and moisture balance, these differences in runoff production and the resulting differences in moisture storage, have a direct impact on the partitioning of the available energy in latent and sensible heat (Pitman, 2003).

Although the second-generation land surface schemes include much more process understanding than the first-generation schemes, Pitman (2003) raises the point that in the case of coupled simulations "it is an open question as to what extent changing a first-generation scheme to a second-generation scheme has really improved the simulation of climate." However, he concludes that there is a definite majority view in the land surface modeling community that second-generation models perform better than first-generation models. This is supported by the observation that in model intercomparison studies they tend to perform better, as a group, than first-generation models.

Development of third-generation models started in the late 1980s and is currently (2005) an active area of model development and research. These models are characterized by a much more complete representation of plant physiological processes, in particular, the representation of plant photosynthesis and canopy conductance. Consequently, third-generation models incorporate a representation of the carbon cycle, and its interaction with the water and energy cycle (Pitman, 2003). Although these third-generation land surface models can respond to changes in atmospheric conditions by growing bigger trees or larger leaves, they typically do not allow for a succession of vegetation types in response to changes in atmospheric conditions. Dynamic vegetation models, which allow such a succession of vegetation types, typically operate at longer timescales than the land surface schemes, but a combination of the two modeling approaches will be important to simulate long-term climate dynamics and their interaction with land surface processes.

Land surface models used in uncoupled studies, that is, without being interactively coupled to an atmospheric model, are essentially the same as those in climate and NWP models. The main differences are that they are typically operated at higher spatial resolutions and that water is often routed through some idealized channel network to simulate river discharge at selected locations within a basin. Because of the large spatial extent of the individual grid elements in most land surface applications (spatial resolutions are typically 1/8° or larger), horizontal exchanges of moisture between grid elements over the surface or through the subsurface have generally been neglected. However, as the

size of model elements decreases as a result of increased computing resources and increased data availability from remote sensing, the assumption that land surface model elements do not interact becomes more tenuous. As a result, new approaches are being developed to allow for horizontal exchange between model elements and to better represent saturated groundwater processes.

ROLE OF LAND–ATMOSPHERE MODEL EXPERIMENTS IN REDUCING ERRORS AND UNCERTAINTIES

Land surface model validation and intercomparison projects such as PILPS (Henderson-Sellers *et al.*, 1993, 1995) and the Global Soil Wetness Project (GSWP) (Dirmeyer *et al.*, 1999) helped to assess the previous and current generations of land surface models. PILPS has made major contributions to their evaluation at the local scale by using observed atmospheric boundary conditions or forcings and high quality measured fluxes for validation of the simulated processes. In GSWP, on the other hand, the land surface models were used in a mode much closer to their application in global climate models (GCMs), that is, the models were implemented on a global grid with a resolution coarser than the typical spatial scale of surface processes. Both of these projects have proven very useful in identifying model strengths and weaknesses and need to be continued with the next generation of land surface models for the validation of added processes. However, they also need to be supplemented by new experiments.

Results of field experiments that measure surface fluxes and variables as local point values or on a regional scale are regularly used to test surface parameterization schemes. For example, ARME data over the Amazon basin (Shuttleworth *et al.*, 1984) have been used in validating SiB (Sellers *et al.*, 1989), ISBA (Noilhan *et al.*, 1993), and the ECMWF surface model (Viterbo and Beljaars, 1995). FIFE data over the Konza Prairie in Kansas, United States (Sellers *et al.*, 1988, 1992), and Cabauw data in the Netherlands (Beljaars and Bosveld, 1997) have been used to validate the ECMWF model (Betts *et al.*, 1993; Beljaars and Viterbo, 1994) and, in the case of FIFE, to validate ISBA. HAPEX/MOBILHY data in southern France (André *et al.*, 1986) have been used to test the ISBA model and the ECMWF model. SEBEX data, over the Sahelian region, have been used to validate the ECMWF model (Beljaars and Viterbo, 1998). Data from several sites in Illinois have been used to improve the parameterization of the NCEP Noah model (Mitchell *et al.*, 2000). At most of these field sites, snow is not a major component of the hydrological cycle. Field campaigns in the Canadian boreal forest (BOREAS, Sellers *et al.*, 1997b) and the Scandinavian forest (NOPEX, Halldin *et al.*, 1998) and more currently the Cold Land Processes Experiment (CLPX) in northern Colorado are filling that gap.

As applications of land surface models change from the plot scale to the regional scale and from an uncoupled to a coupled mode, new experiments must be designed, which will specifically address the representation of subgrid-scale variability of the surface and the feedbacks between surface processes and the atmosphere. The difficulties encountered in attempting to compare simulations and observations for these different applications can be illustrated, for instance, for the case of soil moisture. In some of the PILPS experiments, local soil moisture measurements could be compared with simulated soil moisture values on the basis of model simulations that were forced with locally measured meteorological variables (e.g. Shao and Henderson-Sellers, 1996). However, when each model grid cell represents a large area rather than a small plot, it is not obvious how model simulated soil moisture is related to soil moisture measured at a specific location. This is further complicated because soil moisture, though it goes by the seemingly unambiguous name, has a necessarily model-specific meaning (see the Section on "Model performance evaluation"). In GSWP-1, only the soil moisture anomalies at a spatial resolution of $1^\circ \times 1^\circ$ could be evaluated, because the models used different water-holding capacities, which were all different from the one that was deduced from observations (Entin *et al.*, 1999). When a land surface model is coupled to an atmospheric column model, the relationship between soil moisture and the atmospheric conditions can again be explored at the local scale. This setup was used by Douville *et al.* (2000) to determine how the assimilation of near-surface temperature and humidity can improve the simulated soil moisture. Finally, with coordinated GCM sensitivity experiments the impact of the different approaches to soil moisture modeling on climate change could be evaluated in a coupled environment (Crossley *et al.*, 2000).

Unfortunately, we are not presently able to say how the results obtained in PILPS can be related to the uncertainty in soil moisture changes found for a climate with increased greenhouse gas concentrations. Within this context, the Global Energy and Water Cycle Experiment (GEWEX) Global Land Atmosphere System Studies (GLASS) working group intends to foster an evaluation of the next generation of land surface models and to coordinate their evaluation in different applications. GLASS is also serving as an interface between the land surface community and other GEWEX projects. The structure of GLASS highlights the spatial scales at which the schemes are applied and the degree of interaction allowed with the atmosphere. GLASS also supports ALMA (Assistance for Land Surface Modelling Activities), which provides an infrastructure and technical support for these model intercomparison projects. To facilitate the exchange of forcing data for land surface schemes and the results produced by these schemes, ALMA has established data standards. The aim is to have a data exchange format that is stable but still general and

flexible enough to evolve with the needs of land surface schemes. This should ensure that ALMA-compatible data exchange procedures only need to be implemented once in a land surface model and that future model intercomparisons of land surface schemes can be run more efficiently. PILPS 2e (Bowling *et al.*, 2003), PILPS C1, and the current (2005) PILPS San Pedro Experiments have made use of those standards.

Another current experiment run under GLASS, the Global Land-Atmosphere Coupling Experiment (GLACE) is a multimodel intercomparison experiment that focuses on the ability of the land surface state to affect rainfall generation and other atmospheric processes. The experiment aims to quantify the strength of land–atmosphere coupling in the different global atmospheric models used for weather and climate studies. The hope is that the development of a "table" of coupling strengths would aid in the interpretation of the many land–atmosphere interaction studies now appearing in the literature.

APPLICATIONS OF UNCOUPLED LAND SURFACE MODELS

A problem in coupled land surface/atmosphere simulations is that errors in atmospheric conditions will cause errors in the energy and moisture states of the land surface. Similarly, errors in land surface conditions will cause errors in the energy and moisture states of the atmosphere. Consequently, the land surface and atmospheric states in a coupled model system will typically drift away from observed conditions and develop a climatology or long-term average state, significantly different from the observed. This is particularly problematic for real-time weather and climate prediction models, because the future state of the atmosphere is at least in part dependent on the current state of the atmosphere, ocean, and land surface. Hence, errors in the characterization of the current state diminish the reliability and accuracy of model forecasts.

For this reason, observed conditions are often used as boundary or initial conditions. For example, observed sea surface temperatures, which can be derived from satellite observations, are often used as boundary conditions in coupled land surface/atmosphere models that do not include an explicit ocean model. NWP is an initial value problem, in which the model forecasts a future state on the basis of the initial state (Kalnay, 2003). Because of the relative scarcity of atmospheric observations, particularly of the conditions in the upper levels of the atmosphere, a complete specification of the initial state is not possible based on observations alone. Hence, information, for example, based on climatology or a previous model state, is often used as an additional source of information. In NWP, the process that produces the initial state is referred to as analysis. Data assimilation is an analysis technique that integrates real-world observations and model states, to determine the best possible representation of the state of the system. For a discussion of data assimilation methods in the atmospheric sciences, see for example Daley (1991) or Kalnay (2003).

In a global context, the state of the land surface is less important than the state of the oceans for forecasting future states of the atmosphere. However, a number of studies have demonstrated the role of the current state of the land surface in determining future conditions (e.g. Garratt, 1993; Koster *et al.*, 1995, 2003; Brubaker and Entekhabi, 1996). Consequently, not only atmospheric and oceanic observations should be assimilated into NWP and earth systems models, but land surface states should be assimilated as well. Unfortunately, direct observations of land surface states, such as soil moisture, soil temperature, and snow water equivalent are made only in a few locations. Even then they are rarely available at the same scale as the computational elements in NWP and earth systems models. Hence, an alternative approach has been developed in which land surface models, forced with observed atmospheric conditions, are used to produce continuous fields, continuous in both space and time, of land surface states. These land surface states in turn can then be assimilated into NWP models. A prominent example of this methodology is the Land Data Assimilation System (LDAS) started in 1999, which had as its original goal the development of real-time, hourly, distributed, uncoupled land surface simulations for the United States domain at 0.125° resolution (Mitchell *et al.*, 1999). This has led to the subsequent development of a Global LDAS or GLDAS (Rodell *et al.*, 2004). As part of LDAS, a number of physically based land surface models are run on the basis of model-independent, observation-based atmospheric forcings. Mitchell *et al.* (1999) describe the goals of the LDAS project as "(i) improve land surface model physics by sharing algorithms, methods, and insights against a backdrop of joint intercomparison and validation, (ii) identify causes of and reduce extent of the spread in surface water fluxes and surface water storage typically seen in land surface model intercomparisons, (iii) reduce the uncertainty in land surface water budget estimates, (iv) utilize several new real-time GCIP-sponsored forcing and validation products, (v) compare uncoupled LDAS with traditional coupled 4DDA, (vi) support water resource application (water supply and agriculture), and (vii) provide land surface initial conditions (e.g. soil moisture and snowpack) for both (a) predictability studies of the role of sea versus land lower boundary conditions on seasonal forecasts and (b) real-time weather and climate model predictions on several timescales (days, weeks, seasons)".

The geographical extent of the original LDAS project covered a large part of North America, with the main focus on the contiguous United States. To provide global fields of land surface states, a GLDAS was developed

jointly by the National Aeronautics and Space Administration (NASA), Goddard Space Flight Center (GSFC), and the National Oceanic and Atmospheric Administration (NOAA) National Centers for Environmental Prediction (NCEP) (Rodell *et al.*, 2004). This latter system can be operated on variable spatial resolutions. Koster *et al.* (2004) have demonstrated the potential benefit of realistic initialization of land surface states on subseasonal forecasts in coupled simulations.

As a further step in engineering computational environments that can take advantage of multiprocessor computing clusters and large amounts of real-time or near real-time atmospheric and land surface inputs, NASA has developed a land information system (LIS), in which multiple land surface models are embedded (Tian *et al.*, 2004; Kumar *et al.*, 2004). This software environment allows simulations to be run at variable spatial and temporal resolutions and, at least to some extent, automates the necessary interpolation and averaging of model inputs.

While the above-mentioned data assimilation systems simulate most land surface moisture and energy states, the Snow Data Assimilation System (SNODAS) developed by the NOAA National Weather Service (NWS) National Operational Hydrologic Remote Sensing Center (NOHRSC), was specifically developed to "to provide a physically consistent framework for integrating the wide variety of snow data that is available at various times" (Carroll *et al.*, 2001). This system is driven with near real-time surface weather observations and the output from NWP models, while observations of snow water equivalent, snow depth, and snow areal extent are assimilated to update the model states. SNODAS products are made available on an operational basis through the National Snow and Ice Data Center (NSIDC) since October 2003 (Barrett, 2003).

Uncoupled land surface simulations can also provide a valuable tool in the study of predictability within the earth system at seasonal and interannual scales. Predictability can be defined as the extent to which the future state or flux of a system can be predicted on the basis of its current state. Not all land surface or atmospheric states and fluxes demonstrate the same level of predictability. Even for a given land surface state or flux, the level of predictability may vary as a function of place and time. For example, Maurer *et al.* (2003) used a 50-year uncoupled simulation with the Variable Infiltration Capacity (VIC) land surface model (Liang *et al.*, 1994; Cherkauer *et al.*, 2003) to study the predictability of runoff in the Mississippi Basin in the United States. The 50-year simulation was forced with a station-based forcing data set at a spatial resolution of 0.125° and a temporal resolution of 3 h (Maurer *et al.*, 2002). Using the Southern Oscillation Index (SOI) and Atlantic Oscillation (AO) as surrogates for climate predictability, they found that, in the Mississippi Basin, soil moisture is the dominant source of runoff predictability at lead 0 in all seasons. Lead 0 here refers to the season at the start of which the soil moisture is known and represents an average lead time of 1.5 months (note that the analysis in Maurer *et al.* (2003) was done at a seasonal timescale). The only exception to this was the summer season (June–August) in the western, more mountainous, part of the basin. During this season and in this region, snow water equivalent formed the dominant source of predictability. For lead times of one to three seasons, the climate indicators provided a small, but significant predictability for winter (December–February) runoff, especially in the eastern part of the basin.

Uncoupled land surface simulations have also been used in scenario evaluation studies. For example, Matheussen *et al.* (2000) used the VIC model to simulate the effects of land cover change on streamflow in the interior Columbia River Basin (United States and Canada). They compared model results on the basis of two different vegetation scenarios to determine vegetation-related changes in runoff, evaporation, and snow accumulation. The vegetation scenarios consisted of historical vegetation conditions, estimated for 1900 prior to widespread European settlement of the basin, and current vegetation conditions, estimated for 1990. An unanswered question at this point is how well the model-predicted sensitivities to changes in land cover mirror the observed changes.

Nijssen *et al.* (2001) used the same land surface model to evaluate the effects of climate change on nine, continental river basins. Changes in climate were based on the differences between control runs and climate change runs from a number of GCMs. In addition, they studied the effect of a fixed change in temperature (+2 °C) or precipitation (+10%) in any given season on the runoff and evaporation in all seasons. Although it could be argued that the effects of climate change on hydrology would be better represented in coupled land surface/atmosphere models, the output from these coupled models generally shows significant biases in the simulation of both temperature and precipitation under current climate conditions. These biases are often so large that direct application of the modeled meteorology in a land surface model is not meaningful (e.g. Doherty and Mearns, 1999). Consequently, uncoupled simulations allow for the application of a bias correction to the GCM output prior to the simulation of the land surface hydrology. Furthermore, the spatial resolution of most GCMs, particularly when operated in climate mode, is significantly coarser than the resolution supported by most uncoupled land surface models. GCM output is therefore "downscaled" to the resolution of the land surface model. In Nijssen *et al.* (2001), GCM model output was bias corrected by calculating the differences in temperature and precipitation between a control run and the climate change run, and imposing these differences on a historic, station-based forcing data set. Wood *et al.* (2002) discusses a probability mapping method for bias correcting GCM output. The

probability mapping method maps the empirical cumulative density function of a GCM predicted variable to the empirical cumulative density function of historic observations of this same variable. Although this method does not accommodate changes in the shape of the empirical density function with time (everything is mapped to the historic cumulative density function), it provides a more flexible method for bias correcting than a simple superposition of differences. Wood *et al.* (2004) evaluated the hydrological implications of six different techniques for downscaling climate model output.

MODEL PERFORMANCE EVALUATION

Advances in our understanding of the processes that control biosphere–atmosphere interactions are spurring the development of increasingly sophisticated land surface models that aim to represent the transfer of mass, energy, and momentum between a vegetated surface and the atmosphere (Dickinson *et al.*, 1986; Sellers *et al.*, 1986). The use of these land surface models is being extended beyond their original implementation in general circulation models to diverse applications in hydrology, biogeochemistry, and ecology. Model improvements include better representations of the vegetation physiology and attempts to represent surface heterogeneity at the GCM subgrid scale. However, model predictions are biased due to simplified model physics, errors in input forcing, limited knowledge of parameter values, and inadequate treatment of subgrid-scale spatial variability. Consequently, even state-of-the-art land surface model predictions are erroneous in space and time. When coupled with GCMs to predict future climate scenarios, these biases may lead to systematic or long-term errors and may render unrealistic or unreliable forecasts of land surface hydrology.

Land surface models are largely defined by: (i) parameters, which are generally time-invariant descriptions of surface characteristics (such as percent-vegetated cover, soil porosity, surface roughness, etc.); and (ii) states, which are storages of water and energy that are propagated in time by the model physics. Although some model parameters may be measured or estimated directly (albedo, percent-vegetated cover, leaf area index, etc.) at the patch or grid scale, other parameters (soil hydraulic conductivity, stomatal resistance, aerodynamic resistance, etc.) are not easily measured (even at the patch scale) and are difficult to interpolate to large GCM size scale. The majority of land surface schemes currently use look-up tables to define large-scale parameter values associated with specific soil-vegetation regimes. For these parameters, a reasonable range estimated from published values may be the best estimation of a grid average value.

Originally, model intercomparison studies assumed that parameters with the same physical interpretation should have the same value in all land surface models. However, land surface models are used on a GCM grid scale and, hence, effective model parameter values are required to model grid-scale average processes (e.g. Bastidas *et al.*, 1999; Beven, 1995; Brewer and Wheatcraft, 1994; Gupta *et al.*, 1999; Sorooshian *et al.*, 1999). These effective values are, by their very nature, dependent on the particular parameterization that varies from model to model. Consequently, even though the parameters might share the same name and conceptual representation among different land surface models, their model-specific values vary.

The increase in complexity of process representations has resulted in large numbers of model parameters. The actual number depends on the number of soil and canopy layers and the complexity of the associated process descriptions. Most of these parameters vary in space, and some also vary in time. For example, soil hydraulic properties must be specified to establish the relationship between hydraulic conductivity, soil metric potential, and soil water content. The values of these soil properties significantly affect model behavior, implying that land surface models need to be calibrated or regularly corrected, particularly if the model output has significant sensitivity to variations in the parameter. In that case, an adjustment or calibration of the initial parameter value may be needed to better match observations.

In a discussion of environmental modeling, Beck (2002a) points out that the contention once was that any model requiring calibration against past observations was thereby rendered inferior, and certainly incapable of extrapolation to conditions not previously observed. In contrast, it was assumed that a model based *truly* on the Laws of Physics would not suffer from such difficulties, because these models would employ physical constants whose values are known *a priori* and which are universally applicable. Ideally, these models would contain no parameters without immediate physical meaning. All their parameters could be determined through independent measurements in the field; none would require calibration. Beck (2002a) argues that such a happy state of affairs is not attainable in practice. To believe otherwise has been an illusion, albeit an extraordinarily useful one for the development of models.

In addition, even the most advanced data acquisition platforms in operation in 2005 do not adequately capture the spatial heterogeneity of geophysical systems and biological states of the environment (Beck, 2002b). As a result, land surface models contain a profusion of unobserved state variables. Reconciling model with observed behavior to improve understanding is quintessentially an issue of demonstrating, beyond reasonable doubt, that a match of the two approximations of the truth has not been achieved at the expense of imposing absurd values on the model parameters.

Model performance is typically evaluated by calculating the error of the simulation, which is usually defined as the difference between the observed and the computed series. This difference has two sources: observation errors and model errors. The model error is the combined result of the model structural error and the error due to improper identification of the parameter set:

$$\begin{matrix}\text{Total}\\ \text{error}\end{matrix} = \begin{matrix}\text{Data}\\ \text{error}\end{matrix} + \begin{matrix}\text{Model}\\ \text{structural}\\ \text{error}\end{matrix} + \begin{matrix}\text{Parameter}\\ \text{specification}\\ \text{error}\end{matrix} \quad (9)$$

The identification and elimination of the latter error is one of the goals of the parameter estimation procedures. The reduction of the model structural error (the total elimination of this error would not be feasible) is a task for the developers of the specific models. Some of the problems with the model structure are usually identified if a proper calibration procedure is used. The data error is related to the way the information is collected, the instrumentation used, and its precision. In general, the identification of these separate errors is a difficult task. One approach to estimate the data error is the use of artificial neural networks (ANN) because they do not have a dependence on model structure (Bastidas *et al.*, 2003).

By using parameter estimation procedures, the overall error in the predicted fluxes can be reduced by as much as 20 to 40%, on average, for the heat fluxes at different locations throughout the world (e.g. Bastidas *et al.*, 1999, 2001, 2003; Demarty *et al.*, 2004; Demarty *et al.*, 2005; Gupta *et al.*, 1999; Hogue *et al.*, 2005; Leplastrier *et al.*, 2002; Rosolem *et al.*, 2005; Sen *et al.*, 2001; Yang *et al.*, 2005; Xia *et al.*, 2002). This finding is of importance for the comparison of different models. A fair comparison is possible only if the best solutions from different models are compared. Only the elimination of the improper parameter identification-induced error allows for the comparison of the model structural error.

As discussed, observations can be used to constrain the models, that is, to bound the parameter values so that the model outputs are consistent with the field observations. To attain this consistency, different parameter sets should be obtained for different environmental conditions and environments. Remote sensing has the potential to provide information about the space-time variations on the land surface processes. This is of particular relevance because this information can be used to parameterize land surface models and to derive estimates of the latent heat flux (see e.g. Bastiaanssen *et al.*, 1994; Franks and Beven, 1999; Kustas and Humes, 1996; Lakshmi, 2000; Pelgrum and Bastiaanssen, 1996; Wood and Lakshmi, 1993).

Liu *et al.* (2003) and Liu *et al.* (2004) have shown that proper parameter estimation is of paramount importance when a land surface model is coupled to an atmospheric model. In that case, parameter sensitivities and any deficiency associated with the parameter values are amplified through the coupling. Using the NCAR-LSM coupled to a single column atmospheric model, they found that a small, intentional, but incorrect parameterization for canopy evaporation produced wild oscillations in model output when the canopy parameters were changed beyond a very limited range (Liu *et al.*, 2003). The original parameterization was introduced to speed up the convergence of the solutions in an off-line mode, where these oscillations did not appear. Using the same model and a multiple objective sensitivity analysis procedure (several fluxes analyzed simultaneously), they established that parameter sensitivity changed significantly between coupled and off-line modes (Liu *et al.*, 2004). However, coupled modeling also imposes strong land surface forcing biases predicted by the atmospheric models on the land surface model. These biases in precipitation and radiation can overwhelm the behavior of land surface model physics (Dirmeyer, 2001).

INTO THE FUTURE

Workshops organized during the past few years by GEWEX, the European Centre for Medium-Range Weather Forecasts (ECMWF), the International Geosphere-Biosphere Programme (IGBP), and others have pointed out a number of directions in which innovation in the next generation of land surface models will be necessary. A number of these have also been identified by Pitman (2003) in his review of land surface models. Specifically, innovations in land surface models must focus on the following aspects:

1. representation of the full carbon cycle;
2. use of the catchment as the basic unit of land surface hydrological processes rather than an arbitrary grid cell;
3. changes in root distribution as a result of changes in CO_2 concentrations;
4. representation of heterogeneity and subgrid-scale processes, in other words, larger importance of the horizontal complexity of the surface;
5. increased recognition of the significance of chemistry in land surface processes and consequently its representation in land surface models;
6. use of new remotely sensed variables for data assimilation;
7. improved representations of feedbacks between surface and atmosphere.

To these we would like to add the following:

8. model structures to represent spatial variability at a scale appropriate for the dominant processes and required output – a multiple resolution framework;

9. new methods for a more realistic representation of spatial variability; either deterministic or statistical; either explicit or in the form of subgrid representations
10. improved methods for comparing observations and predictions of spatial response.

At the time of this writing (2005), the land surface modeling community has successfully met the challenges outlined by Richardson in 1922. However, as listed above, many challenges and research questions remain, particularly in the development of more robust parameterizations of surface processes, in the assessment of model sensitivities, and in the development of a better understanding of the relationship between uncoupled and coupled model simulations. These questions are not merely academic. Land surface models have come to play an important role in our attempts to evaluate and predict changes in a rapidly changing world. Better land surface models, both for coupled and uncoupled simulations can play their part in anticipating change and in making us a better steward of our planet.

202: Use of Climate Information in Water Resources Management

HOLLY C HARTMANN

Department of Hydrology and Water Resources, The University of Arizona, Tucson, AZ, US

Failures in water resources management, evolving societal objectives, and advances in the scientific understanding of hydroclimatic systems have led to reassessment of techniques traditionally used in support of water resources management policies and practices. Climate information, encompassing a variety of timescales, is clearly useful for water resources management, yet remains underutilized. This article examines historical climate information provided by instrumental records and paleoclimatological indicators, and prognostications of future climate conditions provided by climate forecasts and assessments of climate change, and issues related to their use in water resources management. Two issues are of central importance: nonstationarity and uncertainty. The water resources community must accept that in many cases one of the fundamental assumptions underlying classical hydrology is simply incorrect. However, the water resources management community need not assess climate information and its use in isolation. Networks of researchers, including hydroclimatic and social scientists, are actively seeking more integrated involvement with the water resources management community, are adapting their research agenda and activities to address the needs of decision makers and stakeholders, and are committed to developing practical products and decision-support tools.

INTRODUCTION

Water resource managers have long been incorporating information about climate variability in their decisions. The tremendous, regionally ubiquitous investments in infrastructure to reduce flooding (e.g. levees, reservoirs) or assure reliable water supplies (e.g. reservoirs, groundwater development, irrigation systems, water allocation, and transfer agreements) reflect societal goals to mitigate the impacts of climate variability at multiple time and space scales. Myriad engineering and hydrology manuals (e.g. Linsley *et al.*, 1975; Water Resources Council, 1981; Maidment, 1993) are replete with techniques for estimating expected climate and hydrologic conditions (jointly referred to as hydroclimatic conditions) and their variability.

However, accumulated experience, evolving societal objectives, and advances in the scientific understanding of hydroclimatic systems have complicated the use of traditional techniques in support of water resources management. Many communities have faced multiple events earlier thought to have low probabilities of occurrence (e.g. National Research Council NRC, 1995). Extreme conditions (e.g. floods, droughts) are by definition rare events and their likelihood of recurrence is difficult to judge with data collected over only the few decades often available (Stedinger *et al.*, 1993). Also, as instrumental records grow in length, long-term shifts in streamflows can be observed (Lettenmaier *et al.*, 1994; Lins and Slack, 1999; Douglas *et al.*, 2000) leading to questions about the relative impacts of shifts in climate conditions, land use, and river hydraulics.

Further, the growing financial, political, social, and environmental costs of infrastructure options have shifted the focus of large water management institutions to optimizing operations of existing projects (Bureau of Reclamation, 1992; Beard, 1993; Stakhiv, 2003). In many cases, this includes improving project returns (both economic and noneconomic) outside the range of conditions considered in original procedures (e.g. optimizing returns under average conditions in addition to reducing damages during extreme events). Further, increasingly diverse and often conflicting demands prompt searches for additional potential trade-offs

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

among interests by considering a broader range of hydroclimatic conditions (e.g. Congressional Budget Office, 1997; Pulwarty and Melis, 2000).

Finally, the evolving understanding of earth dynamics has changed perspectives about potential climate variability. Extremely long time series of paleoclimatological indicators (e.g. *see* **Chapter 199, Role and Importance of Paleohydrology in the Study of Climate Change and Variability, Volume 5**) have made clear that climate and water supplies in many regions are more variable than indicated by instrumental records alone, with periods of extreme drought or wetness lasting from several years to several decades, albeit often interrupted by more typical conditions. Also, climate is now recognized as a chaotic process shifting among distinct regimes with statistically significant differences in average conditions and variability (Hansen *et al.*, 1997). Further, myriad studies related to global warming are becoming more confident in their conclusions that the future portends statistically significant changes in hydroclimatic averages and variability.

Until the last decade, climate was viewed largely as a collection of random processes. This paradigm informs much of the water resource management practices developed over the past 50 years, which persist today. However, climate variability and long-term change are now considered by the scientific community to result from phenomena that can be understood at a fundamental level and that, in some cases, can be predicted with long lead-times. This revolutionary paradigm shift calls into question water management practices developed under assumptions that random chance and time-invariant probability distributions are key drivers of variability.

The objective of this article is to examine several categories of climate information and issues related to their use in water resources management. Because water resources management takes place in a complex milieu in which climate is but one, and perhaps not the most important factor, this article also examines recent efforts to more effectively integrate climate research and water resources management. Finally, this article offers recommendations for the water resources management community in their attempts to improve their use of advanced climate information.

CONSIDERING CLIMATE

Traditionally, instrumental observations of temperature, precipitation, and streamflow, among other variables, measured over years to decades comprised the bulk of climate information used in support of water resource management decisions. Climate information has evolved to encompass a broad range of timescales, as illustrated in Figure 1, each having its own conceptual and analytical approaches. Historical climate and paleoclimatological information rely on direct observations or proxies to describe how conditions have varied in the past. Climate forecasts and climate-change information address a future, impossible to know with certainty before it occurs.

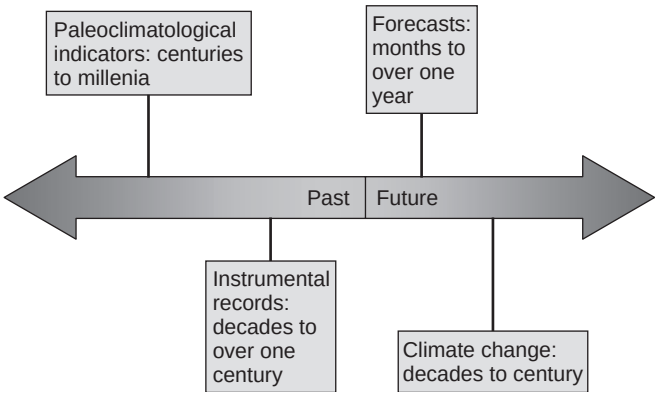

Figure 1 Climate information encompasses paleoclimatological indicators, instrumental records, climate forecasts, and climate change scenarios

Historical Climate Variability

Instrumental Records

The early design and operation of water management systems were based largely on trial and error, for example, repeated reconstructions of levees along the Illinois River (Thompson, 2002) and rebuilding of shipping harbors (Shallot, 2003). The recurring need to "fix on failure" and the increasing complexity of water management systems led to the installation of instruments for gauging streamflows and the development of analytical techniques for evaluating water supply reliability and hydrologic risk. Lettenmaier (2003) tracks the concurrent evolution of methods to analyze historical time-series and approaches for water resource management from the perspective of management capacity to incorporate climate variability. Standard practice has been to embed climate variability through analytical techniques that use observed hydrologic time series such as variants of mass curve analysis to size reservoir systems and frequency analysis to assess hydrologic risk (Hirsch *et al.*, 1993; Salas, 1993; Stedinger *et al.*, 1993). Direct use of climate information includes hydrologic and hydraulic routing of "design storms" of various magnitudes and likelihoods and the use of rainfall-runoff models in which meteorological variables drive watershed response (Lettenmaier and Wood, 1993; Urbanas and Roesner, 1993).

Notwithstanding past successes, there exist serious challenges in the use of instrumental records in water resources management. First, instrumental records have often been too short to adequately express climate variability and resulting impacts. A classic example concerns the allocation of Colorado River flows in 1922 (Rhodes *et al.*, 1984;

Hobbs, 2004). Understandably, few instrumental observations were available to reliably estimate water supply availability; climate variability was accommodated by the use of a 10-year average to monitor compliance with flow obligations. Observations over the ensuing decades have revealed flows prior to 1922 to be unusually high with unusually low variability, leading to overestimation of Colorado River flows and their reliability, over allocation of available water supplies, and costly interstate conflict. Another clear example concerns the American River in California, where 10 of the largest 13 floods since 1905 have occurred only since 1950 (NRC, 1995).

Second, as instrumental records have grown longer, they increasingly belie one of the fundamental assumptions behind most extant water resources management – stationarity. Stationary time series have time-invariant statistical characteristics (e.g. mean, variance), meaning that different parts of the historical record can be considered equally likely. Further, within the limits posed by sampling, statistics computed from stationary time series can be used to define a probability distribution that will also then faithfully represent expectations for the future (Salas, 1993). Yet, long climate and hydrology time series often show trends (e.g. Baldwin and Lall, 1999; Olsen *et al.*, 1999) or persistent regimes, that is, periods characterized by distinctly different statistics (e.g. Angel and Huff, 1995; Quinn, 1981, 2002) with consequences for the estimation of hydrologic risk (Olsen *et al.*, 1998). Observed regimes and trends can have multiple causes, including climatic changes, watershed and river transformations, and management impacts (e.g. irrigation return flows, trans-basin water diversions).

Finally, instrumental records occur at timescales directly experienced by individuals and embodied in institutional memory. Experience may provide cognitive advantages for perceiving the connections between climate variability, hydrologic impacts, and water resources management. However, the risk in water management is that direct experience associated with specific events (i.e. the conditions and success or failures of actions taken during those periods) can "anchor" perceptions during subsequent events, precluding full appreciation of variability of climate patterns, effects on hydrology, and implications for water management. For example, the extremely high flows leading to the placement of plywood extensions on the massive Glen Canyon Dam and fears for the structure's integrity (Rhodes *et al.*, 1984) are firmly fixed in the memory of hydrologists and water managers familiar with the episode and affect both water supply forecasts and management decisions (Pagano *et al.*, 2004).

Multiple techniques exist to more effectively exploit instrumental records and to more accurately represent potential hydroclimatic variability and uncertainty. Walker and Douglas (2003) review statistical techniques for detecting and accommodating different types of nonstationarity (e.g. estimating nonstationary hydrologic risk) in water management applications. For example, for streamflows showing interannual persistence, computing hydrologic risk using concepts of "time to first occurrence" rather than "time between occurrences" can reduce the risk of failure over a system's design life (Douglas *et al.*, 2002). Stochastic hydrology techniques use various forms of autoregressive models to generate multiple synthetic streamflow time series with statistical characteristics matching available observations. Early stochastic hydrology work challenged the assumption of stationarity (Mandelbrot and Wallis, 1969; Klemes, 1974; Potter, 1976), but ultimately had little impact on water management practices (Lettenmaier, 2003). Exceptions can be found, however. In estimating the risk of low flows for the Sacramento River Basin in California, the Bureau of Reclamation (Frevert *et al.*, 1989) generated twenty 1000-year streamflow time series matching selected statistics of observed flows (adjusted to compensate for water management impacts on natural flows); the nonexceedance probabilities of low flows were computed by counting the occurrences of low flows within 1- through 10-year intervals for all twenty 1000-year sequences. The U.S. Army Corps of Engineers (1992) uses a similar approach to estimate flood magnitudes with return periods exceeding 1000 years, using Monte Carlo sampling from within the 95% confidence limits of a Log Pearson III distribution developed by synthesizing multiple streamflow time series. Several practical statistical approaches were demonstrated using the long instrumental record for Lake Erie water level records (Herche and Hartmann, 1992; Kite, 1992; Kubik, 1992; Potter, 1992; Privalsky, 1992).

Conceptual rainfall-runoff models offer some advantages over statistical techniques in using instrumental climate records; these models represent, with varying levels of complexity, the transformation of rainfall and other meteorological forcing variables (e.g. air temperature, humidities) to watershed runoff and streamflow, including accounting for hydrologic storage conditions (e.g. snowpack water storage, soil moisture, groundwater storage). Recent models use spatially distributed representations of local topography, soil and land-cover characteristics, vegetation dynamics, and the surface energy balance (Wigmosta *et al.*, 1994; Ivanov *et al.*, 2004). These models can be used to assess the impacts and implications of various climate scenarios, by using historic meteorological time series as input, generating hydrologic time series, and then using those hydrologic scenarios as input to hydraulic routing and water management models. This approach enables consideration of current landscape and river channel conditions, which may be quite different from that embodied in early instrumental records, and which can dramatically alter a watershed's hydrologic behavior (Vorosmarty *et al.*, 2004). The use of multiple input time series or system parameterizations enables a probabilistic assessment of an ensemble

of scenarios. For example, Carpenter and Georgakakos (2001) and Yao and Georgakakos (2001) linked an ensemble streamflow simulation model and representations of the hydraulic system to assess the capabilities of extant and alternative reservoir operation schemes for the Folsom River, California.

Paleoclimatological Indicators

As described by Ekwurzel (**Chapter 199, Role and Importance of Paleohydrology in the Study of Climate Change and Variability, Volume 5**), many paleoclimatological techniques have shed light on climate conditions prior to instrumental observations. Glacier ice, groundwater chemistry, cave and coral formations, lakebed sediments, and tree-rings, among others, have each been used to infer climate conditions occurring hundreds and even thousands of years ago. Paleoclimatological information can put modern extreme climate events in a broader perspective; studies of paleoclimatological indicators have identified flooding events far exceeding any measured in modern times and the recurrence of severe droughts over large regions and lasting many years. Paleoclimatological studies have also helped to establish teleconnections between climatic conditions across oceans and continents and have led to the identification of oceanic and atmospheric patterns favoring persistent drought.

There are several overarching messages for water management professionals provided by paleoclimatological information. First, past climate conditions in a region may have been more extreme and persistent than indicated by historical records, suggesting that similarly severe conditions can recur; analyses based only on instrumental records underestimate hydrologic risk. For example, in reconstructions of US Southwest cool-season precipitation (the region's strongest determinant of annual streamflows), Ni *et al.* (2002) found five 5-year periods drier than the severe drought of 1999–2003 in northern Arizona, when precipitation was only 69% of the average over the years 1000–1988. The most extreme five-year period (1666–1670) experienced only 47% of the millennial average. Using slightly different methods, Salzer and Kipfmueller (in press) found the late 1500s to be the most severe drought period in that same region, on timescales from single-year drought (1584) to 10-year drought (1583–1592). However, the sixteenth-century droughts appear mild compared to multiple persistent droughts reflected in tree-ring records exceeding 2000 years (Grissino-Mayer, 1996).

Second, in some cases, the same climate processes and forcing conditions leading to paleoclimatological extremes continue to affect climate variability today, reinforcing prospects that similar extremes may recur. As presented in more detail by Ekwurzel (*see* **Chapter 199, Role and Importance of Paleohydrology in the Study of Climate Change and Variability, Volume 5**), links have been established between the El Nino/Southern Oscillation (ENSO), the Pacific Decadal Oscillation (PDO), the North Atlantic Oscillation (NAO) and tree-ring reconstructions of the Palmer Drought Severity Index (PDSI), among others (Cole *et al.*, 2002; Gray *et al.*, 2003), although the characteristics of some patterns differ (e.g. longer La Nina events in earlier centuries compared to those of the twentieth century) and issues remain regarding independent evaluation of reconstructed variables (i.e. tropical sea surface temperatures, continental precipitation and temperature).

Finally, climate nonstationarity is the rule, not the exception. The normal behavior of regional climate consists of transitioning among persistent regimes having significantly different statistical characteristics. Further, these regimes can differ in several ways, including their central tendency, variance, persistence, and intra-annual seasonality. There is no "normal" climate to which any deviations must return.

To date, the use of paleoclimatological information in water management remains more prospect than practice. While paleoclimatological indicators provide a longer perspective about past climate regimes and extremes, they have less spatiotemporal specificity, less precision, and greater estimation uncertainty than the direct observations comprising the instrumental hydroclimatic record. Additionally, from a cognitive perspective, paleoclimatological information is far removed from personal experience or institutional memory, posing difficulties for individuals to comprehend within their existing paradigms. For example, in a workshop with consulting engineers, a 300-year (1700–1999) paleoclimatologic reconstruction of the PDSI was used to explore how concepts of climate nonstationarity were or could be incorporated into civil engineering design (Hartmann *et al.*, in review). The entire group was dismissive of the relevance of paleoclimatological data for water management, due to their confidence in the stationarity assumption and, in a seeming contradiction, skepticism about the similarity between past and present hydroclimatic teleconnections. Further, water managers are typically focused on specific planning horizons (e.g. a 20-year infrastructure development plan). Even when interested in paleoclimatological information, they have difficulty linking general long-term (e.g. over 1000 years) risks with specific risks defined within their planning horizon. For example, should they use statistics derived from (i) the entire paleoclimatological record to reflect the maximal potential variability; (ii) the most recent decades to reflect that, with evidence of recent strong trends, the near term may be a better predictor than the distant past; or (iii) specific periods from the distant past to reflect that secular patterns may be more likely to dominate upcoming decades?

However, in the US West, as the region's severe drought (beginning in the mid- to late-1990s) has evolved, so has the water resources sector's interest in considering paleoclimatological information. Individuals and organizations

are actively exploring the relevance of paleoclimatological information for water resources issues, including requesting paleoclimatological information and background briefings from scientists (G. Garfin, University of Arizona, personal communication, 2004). Whether the information and its implications for water resources management will be integrated into the sector's cognitive framework (e.g. acknowledging that design of long-lived infrastructure or policies must accommodate nonstationarity) remains to be seen. Fully integrated use of paleoclimatological information will require the development of prospective scenarios, sensitivity studies of infrastructure design and operating plans (e.g. regulation rules), and water resources management policies and practices that accommodate the increased variability posited by the paleoclimatological record. These efforts require scientific research support through development of paleoclimatological time series at higher spatial and temporal resolution (e.g. Ni *et al.*, 2002), establishing that the climatic patterns and teleconnections leading to specific paleoclimatological conditions are still operative, development of methods to identify the time periods and statistical characteristics of paleoclimatological information that have relevance for specific planning horizons, and further identification of the implications for water supplies of long-term climate variability and nonstationarity reflected in paleoclimatological information.

Climate Forecasts

Virtually all water management decisions require some sort of climate forecast. Even the consideration of historical information to assess hydrologic risk or estimate typical conditions represents an expectation about possibilities for future conditions. Seasonal climate forecasts have long promised the potential to improve water management responses to the vagaries of climate variability (Changnon and Vonnhame, 1986), but have often played only a marginal role in real-world decision making (Changnon, 1990; Sonka *et al.*, 1992; Pulwarty and Redmond, 1997; Callahan *et al.*, 1999; Pulwarty and Melis, 2000; Pagano *et al.*, 2001, 2002; Hartmann *et al.*, in review). However, recent advances in modeling and predictive capabilities continue to motivate the use of climate forecasts. In the United States, the Pacific Northwest, California, and the Southwest are strong candidates for the use of long-lead forecasts because ENSO and PDO signals are particularly strong in these regions and each region's water supplies are closely tied to accumulation of winter snowfall, amplifying the impacts of climatic variability (Redmond and Koch, 1991). Climate forecasts in these regions show substantial skill, even at lead times approaching 8 months for the winter season, especially for temperature (Hartmann *et al.*, 2002a).

A variety of seasonal climate forecast products are available (Hartmann *et al.*, 2002b); they are typically generated by combining results, often subjectively but sometimes objectively, from a variety of techniques (including statistical and conceptual modeling) and sometimes making adjustments based on current observations, recent research, and expert judgment (Goddard *et al.*, 2001; Hartmann *et al.*, 2002b). The official US products are issued by the National Weather Service (NWS) Climate Prediction Center (CPC). Climate forecasts cover varying periods and are issued with different lead times. For example, each month, the CPC issues a suite of forecasts, including one 1-month outlook and a series of 13 3-month outlooks each offset by 1 month. Climate forecasts are typically issued in probabilistic terms and in reference to the observed frequency distribution of a specific historical period. For example, the CPC seasonal climate forecast maps show the likelihood of occurrence for average air temperature or total precipitation over the period to fall within tercile categories defined by the upper, middle, or lower third of conditions reflected in the historical record from 1971 to 2000. An alternative product expresses the climate outlooks using probability of exceedance curves, using different rules shifting probabilities among the tercile categories (Barnston *et al.*, 2000). The probability forecasts require additional information to place their information in context. For example, the CPC provides maps of temperature and precipitation probabilities, maps and tables of historical probability class limits, a text discussion of the rationale behind the forecast, and skill maps for some of the analytical techniques used in producing the forecast. Finally, it is important to note that seasonal climate forecasts should be considered "forecasts of opportunity", that is, possible only when specific climate patterns (e.g. ENSO) exist. Often, no techniques have shown skill for some regions, seasons, and lead times, so forecasters decline to issue an actual prediction, substituting a statement intended to convey complete uncertainty, although using confusing terminology (e.g. "climatology", "equal probability") (Hartmann *et al.*, 2002a).

Water management processes (e.g. reservoir regulation rules) typically require estimates of hydrologic conditions (e.g. monthly or seasonal streamflow volumes), rather than outlooks of seasonal precipitation or temperature. Researchers and operational hydrologic forecasters have long sought to incorporate climate forecasts into water supply forecasts (Pagano and Garen, 2003). The Columbia Basin Interagency Committee (CBIAC) initially considered the use of climate outlooks shortly after the NWS began issuing 30-day climate outlooks in 1953 (CBIAC, 1955), but concluded at that time and in later assessments (CBIAC, 1964) that forecast skill was too low for practical use, the risks of very poor forecasts were too great compared to the use of climatological average conditions for streamflow forecasting, and the uncertainties introduced by downscaling regional climate outlooks to the scale of small basins were too great. Instead, hydrologic forecasts have long been based on regression approaches (Hartmann *et al.*, 2002b)

because the relationship between snowpack and subsequent streamflow is so strong that hydrologists have often considered it to be deterministic (Pagano and Garen, 2003); in the infrequent cases where climate information has been integrated into hydrologic forecasts, climate indices (e.g. the intensity of the Southern Oscillation index [SOI]) have been used as regression predictor variables (Hartmann *et al.*, 2002b; Pagano and Garen, 2003).

Further, because the relationships between climate variables (temperatures and precipitation) and streamflow show greater variance, they are more appropriately considered in probabilistic terms. Hydrologic forecasters have been reluctant to issue probabilistic forecasts of water supplies and streamflows, considering them to be too vague to be useful, especially where reservoir operating rules require single streamflow values. However, that trend is changing, albeit slowly (Hartmann *et al.*, 2003); the NWS is committed to providing hydrologic forecasts in probabilistic terms (NWS, 1999), because they enable quantitative estimation of inevitable uncertainties associated with inherently chaotic weather and climate systems. From a decision-making perspective, probabilistic forecasts are more informative because they explicitly communicate uncertainty and are more useful because they can be directly incorporated into risk-based calculations (e.g. expected consequences).

Increasingly, hydrologic forecasters have turned to conceptual rainfall-runoff models to create hydrologic forecast ensembles using several meteorological sequences to produce several hydrologic predictions, keeping constant the hydrologic model's initial conditions (e.g. snowpack or soil moisture). Termed *ensemble streamflow prediction* (ESP), early implementations (Day, 1985) considered each ensemble member (i.e. trace) independent and equally likely; however, persistent climate patterns leading to nonstationarity mean that some meteorological sequences are more or less likely during certain periods. Hamlet and Lettenmaier (1999a) implemented an ESP system for the US Pacific Northwest using conditional sampling, reflecting the conditional hydrologic response of the Columbia River Basin to the ENSO state, which was further conditioned by epochal PDO forecasts. They used historic meteorological data, gridded at a one-degree spatial resolution, to drive the spatially distributed macroscale hydrology model (Liang *et al.*, 1994; Cherkauer and Lettenmaier, 2002) over the entire Columbia River Basin. Ensemble traces, consisting of precipitation and air temperature time series organized by water years (October–September), were associated with one of six predefined PDO/ENSO categories in a 50-year historical record. Given an anticipated PDO/ENSO climate signal for the coming water year, resampled meteorological traces were then used as "forecasts" to drive the VIC model on the basis of the initial soil and snow conditions as of the forecast date. Use of PDO/ENSO categories obviates the need for predicting ENSO intensity with great accuracy, an element of ENSO forecasts currently problematic at long-lead times.

Alternatively, meteorological sequences can be selected on the basis of consistency with weather and climate forecasts. Several researchers (Perica, 1998; Perica *et al.*, 1999; Smith *et al.*, 1992; Croley and Lee, 1993; Croley, 1996, 1997) have developed procedures for efficiently considering multiple meteorological forecasts by restructuring the set of possible future scenarios. Croley (1997) uses all possible meteorological sequences as hydrologic model input, then biases the resulting hydrologic ensemble through differential weighting of the traces to match the meteorological forecast probabilities. Croley (2000) provides software for combining meteorological forecasts that specify multiple event probabilities (e.g. with variable probabilities for several categories as in the NWS seasonal climate outlooks) and most-probable event outlooks (e.g. seasonal climate outlooks issued by the Canadian Meteorological Center). The South Florida Water Management District uses Croley's approach for weighting ESP traces, according to climate outlook probabilities, in their water supply forecasts (Cadavid *et al.*, 1999). Other methodological enhancements have been developed and implementation issues remain (Hartmann *et al.*, 2003), but ESP hydrologic forecasts provide information not available from regression approaches, even at their earliest lead times (Franz *et al.*, 2003).

Incorporation of probabilistic climate outlooks into regression-based water supply outlooks (e.g. Modini, 2000) have proved more operationally demanding yet no more accurate than simply using climate indices as predictor variables within regression equations (Pagano and Garen, 2003). However, the poor performance of statistical streamflow forecasts in unusually warm years (e.g. water year 2004 in the US West) highlights one of the critical advantages of forecasting systems based on conceptual rainfall-runoff models: their robustness to changing climate regimes, for example, the increasingly warm winters in the US West. This situation also highlights that even operational practices can be affected by nonstationarity, as forecast system performance degrades under climatic transitions.

Realistically, climate outlooks and advancements are typically initially incorporated into water management decisions informally, using subjective, *ad hoc* procedures on the initiative of individual water managers (Changnon, 2000; Rayner *et al.*, 2001; Pagano *et al.*, 2002). While improvised, those decisions are not necessarily insignificant. For example, the Salt River Project, among the largest water management agencies in the Colorado River Basin and primary supplier to the Phoenix metropolitan area, decided in August 1997 to substitute groundwater withdrawals with reservoir releases, expecting increased surface runoff during a wet winter related to El Nino. With that decision, they

risked losses exceeding $4 million in an attempt to realize benefits of $1 million (Pagano *et al.*, 2002). However, because these informal processes are based in part on confidence in the predictions, overconfidence in forecasts can be even more problematic than lack of confidence, as a single incorrect forecast that provokes costly shifts in operations can devastate user confidence in subsequent forecasts (e.g. Glantz, 1982). Single forecasts, even if not used, can reinforce misperceptions of generally poor climate forecast capabilities; in the winter of 2000/01, climate outlooks for the Pacific Northwest indicated a low chance for dry conditions, yet the region experienced the driest year on record; the water management community felt fortunate that they had not considered the climate forecasts (Pagano and Garen, 2003).

Ongoing relationships among researchers, operational forecasters, and decision makers are essential to ensure appropriate interpretation and application of evolving forecast products. Considering the diversity of water management circumstances, the continually evolving nature of predictive capabilities, the variety of forecast performance requirements and criteria, and workloads facing the research and operational forecasting communities, personalized support for individual water managers on a broad scale is impractical. However, dynamic decision-support tools implemented using Internet technology and accessing diverse data sources enable individual decision makers to perform their own data exploration and analyses, customized to reflect their specific situations and concerns with sufficient expert guidance to transform data and information into practical knowledge (e.g. **`http://fet.hwr.arizona.edu/ForecastEvaluationTool/`**). Experience demonstrates that a decision-support tool focused on forecast evaluation can help decision makers in their strategic thinking about essential forecast attributes; requisite performance thresholds; relationships among forecast quality, utility, and value; and the potential utility and value of forecast improvements (Hartmann *et al.*, 2004).

Alternatively, end-to-end decision-support tools that embody unique resource management circumstances enable formal, and more objective, linkages between climatological, hydrologic, and institutional processes. Typically, these end-to-end tools are developed for organizations making decisions with high impact (e.g. state or national agencies) or high economic value (e.g. hydropower production), and which possess the technical and managerial abilities to efficiently exploit research advances. A rapidly growing literature (Scott *et al.*, 2000; Hamlet and Lettenmaier, 2000; Hamlet *et al.*, 2002; Carpenter and Georgakakos, 2001; Yao and Georgakakos, 2001; Georgakakos, 2002a; Clark *et al.*, 2002) describes end-to-end studies that evaluate the implications of using hydroclimatic forecasts in the operation of large river systems. Used in design studies (Lee, 1999; Davis and Pangburn, 1999), they offer a way forward for decision makers reluctant to shift from statistical analysis of historical data based only on theoretical advantages.

Climate Change

Prospects for climate change due to global warming have moved from the realm of speculation to general acceptance (Intergovernmental Panel on Climate Change (IPCC), 1990; IPCC, 1995a, IPCC, 2001a). The potential impacts on water resources and their implications for management have been central topics of concern in climate-change assessments (e.g. Environmental Protection Agency, 1989; IPCC, 1995b, 2001b; National Assessment Synthesis Team, 2000; Gleick and Adams, 2000; Barnett *et al.*, 2004). The near-universal analytical approach has been one of sensitivity analysis (Lettenmaier, 2003):

1. downscaling outputs from a dynamic general circulation model of global land–atmosphere–ocean system to generate regional- or local-scale meteorological time series over many decades,
2. using the meteorological time series as input to rainfall-runoff models to generate hydrologic time series,
3. using the hydrologic scenarios as input to water management models, and
4. assessing differences among baseline and change scenarios using a variety of metrics.

Estimates of prospective impacts of climate change on precipitation have been mixed, leading in many cases to increasing uncertainty about the reliability of future water supplies. However, where snow provides a large fraction of annual water supplies, prospective temperature increases dominate hydrologic impacts, leading to stresses on water resources and increased hydrologic risk. Higher temperatures effectively shift the timing of the release of water stored in the snowpack "reservoir" to earlier in the year, reducing supplies in summer when demands are the greatest, while also increasing the risk of floods due to rain-on-snow events. Early studies on the Great Lakes system (Croley, 1990; Hartmann, 1990) demonstrated additional impacts of higher temperatures – greater lake heat storage leading to loss of ice cover, increased winter lake evaporation, lower lake levels, and potential failure to meet Lake Ontario regulation objectives under extant operating rules – and have been confirmed by more recent analyses (Lee *et al.*, 1994; Lee *et al.*, 1997; Sousounis *et al.*, 2000; Lofgren *et al.*, 2002). For other regions, extant water management systems for large river basins appear to be effective for all but the most severe scenarios (Hamlet and Lettenmaier, 1999b; Lettenmaier *et al.*, 1999), although in many regions, extensive detailed studies of the ability of existing reservoir systems and operational regulations to meet water management goals under changed climates are fairly recent

(e.g. Saunders and Lewis, 2003; Christensen *et al.*, 2004; Payne *et al.*, 2004; VanRheenen *et al.*, 2004).

Cognitively, climate-change information is difficult to integrate into water resources management. First, within the water resources engineering community, the stationarity assumption is a fundamental element of professional training; current hydrologic analysis techniques used in practice are seen as generally sufficient (e.g. Matalas, 1997; Lins and Stakhiv, 1998), especially in the context of slow policy and institutional evolution (Stakhiv, 2003). Second, the century timescales of climate change exceed typical planning and infrastructure design horizons and are remote from human experience. However, in the face of circumstances nearing or exceeding the effectiveness of existing management paradigms, individuals can become more cognizant of the need to consider climate change. In the US Southwest, over 1999–2004, Lake Powell levels declined faster than previously considered scenarios of extreme sustained drought (e.g. Harding *et al.*, 1995; Tarboton, 1995), from full to only 38% capacity in November 2004 (Bureau of Reclamation, 2004); the spatial extent, cascading ecological effects, and the rate of changes in the forested landscape on the Colorado Plateau over that same period have exceeded all prior expectations (7th Biennial Meeting on Integrating Science and Management on the Colorado Plateau, US Geological Survey, 4–7 November, 2003, Flagstaff, Arizona). Resource managers, policymakers, and the general public are now actively seeking scientific guidance in exploring how management practices can be more responsive to the uncertainties associated with a changing climate. Finally, even individuals trying to stay up-to-date can face confusion in conceptually melding the burgeoning climate change impacts literature. Assessments are often repeated as general circulation and hydrologic model formulations advance, or as new models become available throughout the research community. Further, assessments can employ a variety of techniques for downscaling; transposition techniques (e.g. Croley *et al.*, 1998) are more intuitive than the often mathematically complex statistical and dynamical downscaling techniques (e.g. Clark *et al.*, 1999; Westrick and Mass, 2001; Wood *et al.*, 2002; Benestad, 2004). The multiplicity of scenarios and vague attribution of their prospects for occurrence, which depend so strongly on feedbacks among social, economic, political, technological, and physical processes, further complicate conceptual integration of climate-change impacts assessment results in a practical water management context.

There is a rapidly growing literature on the consideration of climate change in water resources management (Frederick *et al.*, 1997; Gamble *et al.*, 2003; Lettenmaier, 2003; Loomis *et al.*, 2003; Snover *et al.*, 2003; Stakhiv, 2003; Ward *et al.*, 2003). Some (Matalas, 1997) contend that existing approaches are sufficient for water resource management planning and risk assessment because they contain safety factors. However, an inescapable message for the water resource management community is the inappropriateness of the stationarity assumption in the face of climate change. While precipitation changes may remain too uncertain for consideration in the near term, temperature increases are more certain and can have strong hydrologic consequences.

CONSIDERING WATER MANAGEMENT

Governments have made large investments to improve climate information and understanding over the past decades through satellites, *in situ* measuring networks, supercomputers, and research programs. However, there has been broad disappointment in the extent to which improvements in hydroclimatic science from large-scale research programs have affected resource management practices in general (Pielke, 1995, 2001; NRC, 1998a, 1999a), and water resource management in particular (NRC, 1998b, 1999b,c). Ensuring that improved data products, conceptual models, and predictions (forecasts and scenarios) are useful to the water resources management community has explicitly been identified as an important objective by several national and international programs (Endreny *et al.*, 2003 and also **Chapter 203, A Guide to International Hydrologic Science Programs, Volume 5**).

The water resources management milieu is complex and diverse, and climate influences are only one factor among the many affecting water management policies and practices. Many reasons exist for the slow adoption of advanced scientific information in water management including the lack of familiarity with available information, disconnects between the specific information available (e.g. variables, spatiotemporal timescales) and those relevant to decision makers, skepticism about the quality and applicability of information, and institutional impediments (Changnon, 1990; Pulwarty and Redmond, 1997; Pagano *et al.*, 2001, 2002; Jacobs, 2002; Jacobs and Pulwarty, 2003). Repeatedly, reviews of hydroclimatic science and water resources management (NRC, 1999a,b,c, 2001, 2004) recognize that more effective application of evolving hydroclimatic information requires coordinated efforts among the research, operational product generation, and water management communities.

Several ongoing efforts are leading the way forward to establish more effective ways of incorporating climate information into water resources management (Pulwarty, 2002; Office of Global Programs, 2004). While diverse in their details, all link natural variability, analytical and predictive technologies, and water management decisions within an end-to-end context extending from data through large-scale analyses and predictions (forecasts or scenarios), prediction evaluation, impacts assessment, applications, and evaluations of applications (e.g. Young, 1995; Miles *et al.*,

2000). For example, Georgakakos *et al.* have focused on linking climate forecasts with the management of complex river and reservoir systems (Georgakakos, 2002b). Key aspects of their approach include: (i) identifying the response of the hydrologic systems to climatic variability (Georgakakos *et al.*, 1998; Yao and Georgakakos, 2001); (ii) integrating meteorological forecasts into hydrologic forecasts (Carpenter and Georgakakos, 2001; Georgakakos and Krzysztofowicz, 2001); (iii) working with water managers to determine preferences when competing demands require trade-offs (Yao and Georgakakos, 2001); (iv) quantifying the impacts of alternative operational scenarios (Yao and Georgakakos, 1993); and (v) transferring end-to-end decision-support tools to water management entities (Georgakakos, 2002b).

However, water management situations often involve many different and increasingly competitive interests (e.g. energy production, reservoir recreation, downstream ecology). In these circumstances, effective integration of climate information into actual management practices and policies requires understanding what various interest groups value and how they interact and frame their problems (Pulwarty and Melis, 2000). For example, reliability of water supplies, as a key value in the US West, fosters decisions based more on "fear of failure" rather than "prospects for success" (Pagano *et al.*, 2001, 2002; Pagano and Garen, 2003). In contexts with large numbers of actors facing contentious issues, the barriers to the use of climate information can be formidable (Pulwarty and Redmond, 1997). However, the "use" of climate information, when broadly defined (Ray, 2004), may be more extensive than first perceived. Ray's typology of use of climate information includes:

1. *Consultation*. If individuals aren't receiving and looking at information, they lack the means for even this most basic type of use. If conditions aren't problematic, this use may be sufficient for most of the water management community.
2. *Consideration*. Information is confirmed or rejected by comparison with prior knowledge and experience-based personal judgment and mental models. Consideration requires prior consultation.
3. *Incorporation*. Information is generally required in specific forms that match decision processes, including the required variable (e.g. seasonal total precipitation, number of days between rain events), availability at the proper time within a decision calendar, appropriate spatial and temporal scale, and sufficient confidence in the information, among others. Incorporation requires prior consultation and consideration.
4. *Dialog about risks with stakeholders*. Risk dialog requires consultation and consideration, but can occur and be important even without explicit incorporation of climate information (e.g. because mitigation options are not available). For example, even if reservoir regulation rules cannot be used to mitigate anticipated drought impacts on water supply availability, it is useful for junior water rights holders to understand the risks they face in experiencing shortages of irrigation water.

Several projects, in the US Pacific Northwest, Southwest, and Great Lakes regions, embrace the complexities involved in integrating hydroclimate research and information in water resources management (Gamble *et al.*, 2003). The Great Lakes region has a long history of sustained relationships among hydroclimate researchers, operational water management entities, and stakeholders affected by management decisions. Efforts in the Pacific Northwest and Southwest are more recent and explicitly designed to be ongoing, dynamic processes; they are particularly useful for assessing the effectiveness of specific strategies for working with the water management community as new perceptions and practices emerge with regard to responding to climate variability and, increasingly, climate change. All three projects have developed an extensive literature (see Gamble *et al.*, 2003; Bales *et al.*, 2004; Lemos and Morehouse, 2005; Hartmann *et al.*, in review) detailing their methods for mutual knowledge development among researchers, operational information providers, decision makers, and stakeholders, which can provide guidance for others seeking to advance the use of climate information in water resource management in other contexts.

Key processes that facilitate the use of climate information include the use of highly structured workshops and collaborative prediction efforts (e.g. Garfin and Morehouse, 2001) to develop consensus forecasts or scenarios, establishment of permanent collaborative groups that meet repeatedly or network over extended periods (e.g. annual briefing workshops at the beginning of each water year; Gamble *et al.*, 2003), and exploiting environmental events that trigger interest in climate information and its application. Effective matching of water resource management professionals with the specific issue is critical as well. For example, innovative mid-level managers acting on their own initiative have proven effective at incorporating experimental climate forecasts in water resources operations and planning, and they have unique insights valuable for evaluating the appropriateness and effectiveness of particular hydroclimatic products (e.g. Changnon, 2000; Rayner *et al.*, 2001; Pagano *et al.*, 2002; Gamble *et al.*, 2003; Hartmann *et al.*, in review). However, experience in the Pacific Northwest demonstrated that the risk-averse tendencies of mid-level water managers makes them ineffective vectors for integrating climate-change information into water management policies and practices; rather, high-level decision makers have more capacity to use climate-change information (Climate Impacts Group, 2001; Gamble *et al.*, 2003). These projects and other assessments (e.g. Jacobs, 2002;

Wilson, 2002; Jacobs and Pulwarty, 2003) also confirm the importance of systematic approaches to knowledge development and better understanding of institutions from a dynamic perspective.

CONCLUSIONS AND RECOMMENDATIONS

Climate information, encompassing a variety of timescales, is clearly useful for water resource management, yet remains underutilized. Advances in climatological information and understanding are uneven; some regions have much information available, while others do not. It is incumbent on members of the water resource management community to know the state of climatic understanding for their region. For example, for their region, is there evidence of climate or hydrologic regimes or trends? Is there paleoclimatological evidence of extended drought? Are good climate forecasts available, and for what seasons and lead times? What are the anticipated climate and hydrologic impacts of global warming?

However, the water resource management community need not assess climate information and its use in isolation. Networks of researchers including hydroclimatic and social scientists are actively seeking more integrated involvement with the water resource management community, are adapting their research agenda and activities to address the needs of decision makers and stakeholders, and are committed to developing practical products and decision-support tools. Individuals in the water resource community should seek out these research groups to define the appropriate end-to-end chain connecting climate variability to hydrologic impacts and water management implications; the status of current climate information products vis-à-vis their practical use in water management practice; loci within various water management decision processes where climate uncertainty and information has potential to change outcomes; indicators to be used as triggers for management action (e.g. in drought plans); and options for increasing the flexibility of policies, planning processes, and operational practices. Members of a region's water resource management community, from high-level policy makers to operational field personnel should participate in two types of permanent collaborative groups: (i) those that provide ongoing dynamic integrated climate assessments; and (ii) those that focus on innovative water management practices, planning, and policies. However, because traditional funding mechanisms for hydroclimatic research limit technology transfer activities (Georgakakos, 2002b), the water resource management community must be willing to participate in cooperative agreements, provide incentives for conducting decision context-specific research, and commit to systematic institutional knowledge development (e.g. personnel training).

Although many issues are involved in better utilizing climate information in water resources management, two issues are of central importance: nonstationarity and uncertainty. The water resources community must accept that, in many cases, one of the fundamental assumptions underlying classical hydrology is simply incorrect. Water resource management practices and policies should begin with a presumption of nonstationarity, and justify their use of stationarity concepts in hydrologic analyses with strong evidence. Some (e.g. Matalas, 1997) contend that the stationarity assumption should not be completely disregarded, but it is clear that regimes and trends in hydroclimatic conditions are the rule, not the exception. Where applicable, the water resources management community must also recognize the important hydrologic implications of warmer temperatures both at the scale of extended climate forecasts and climate change.

The message that the water resources management community must better appreciate and accommodate uncertainty is not new (Matalas and Fiering, 1977). The computation of "best estimates" using instrumental records is clearly insufficient. Also, deterministic streamflow synthesis, simulation, and forecasting must be replaced with approaches that explicitly express uncertainty and risk, whether in terms of probabilities or using scenarios. Both scenario-based approaches and stochastic hydrology techniques, especially those that weigh more recent observations or observations from similar regimes more heavily, should be considered. While standard practices for scenario-based approaches have not yet emerged, practices to avoid are clear. For example, in using instrumental or paleoclimatological analog scenarios, assessments should search for "rhymes" rather than repeats of past situations. Further, assessments should not become fixed on the details of specific scenarios and their consequences, but focus on implications that are consistent (e.g. warming) versus implications that are more uncertain (e.g. precipitation). Finally, the water resource management community needs to better communicate uncertainty and risk generally, and in specific decision contexts, with stakeholders and the public.

Increasing the utility of hydroclimatic information is ultimately an interactive, iterative process involving researchers, forecasters, and the water resources management community over extended periods and multiple hydroclimatic events. Focusing on incremental improvements provides opportunities for sustained interactions as new analytical techniques, assessment processes, information products, and decision-support tools become available. Progress in hydroclimatic research and water resource management is neither easy nor assured. However, working together offers opportunities for progress unlikely to be realized independently.

203: A Guide to International Hydrologic Science Programs

RG LAWFORD[1] AND S EDEN[2]

[1] *International GEWEX Project Office, Silver Spring, MD, US*
[2] *US Climate Change Science Program Office, Washington, DC, US*

Building on the successes of a few mature organizations dealing with the hydrological sciences and the International Hydrologic Decade of the 1960s, the number of water research and applications programs has grown rapidly in the past two decades. This growth can be attributed to new global research priorities (e.g. climate change), new technologies (e.g. satellites and high speed computers), new environmental awareness (e.g. globalization and its environmental impacts), and a growing awareness of the limits to available safe water in many parts of the world. Although some progress was made towards better structuring of hydrologic research activities during preparations for the International Water Decade (1981–1990), the relative roles and relationships among the plethora of groups and projects can still be confusing unless the range of activities and responsibilities is viewed in a broader context. This overview provides some context for these programs.

In general, international hydrologic research activities are undertaken within a programmatic framework developed by a community of scientists and coordinated by international scientific organizations and government agencies. Because international frameworks and programs do not fund research directly, they must rely on nations for funding support and experts. Frequently, national and international programs are implemented in an iterative and symbiotic way whereby national programs provide a core set of projects, while international programs provide the intellectual frameworks and organizational structures. Effective implementation of international hydrologic science programs in this context relies on mutual trust and respect, and on the clear articulation and pursuit of a shared vision.

This article provides an overview of the international hydrological science programs and their priorities, and identifies related global hydrometeorological and applications programs that either directly or indirectly provide scientific support for water management. It also describes mechanisms that facilitate the application of hydrologic science to regional and national water resource issues and those that inform the public and decision makers of the results from these international science programs.

INTRODUCTION

International hydrological science has developed rapidly in the past two decades. This development has taken a unique path because of the nature of hydrologic issues. Until recently, many hydrologic problems focused on individual basins or catchments; consequently, the requirement for international collaboration was limited. Institutions developed independently such that authorities and responsibilities for water resources varied from nation to nation. In some countries the control of water was highly centralized, with monitoring and forecast services maintained at the national level; in other countries, responsibilities were delegated to regional or county levels or were never fully developed. These differences affect data collection and archival issues, making it more difficult to assemble consistent data sets. Data problems are compounded by policies that limit access in the name of national security or revenue generation. Collaboration on transboundary waters was largely limited to bilateral structures, such as the International Joint Commission (United States–Canada).

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

On the science side, hydrology has always been highly multidisciplinary. It has drawn on diverse groups such as civil engineering, which emphasizes models and application of hydrologic information to infrastructure design. It has also entrained geographical sciences, with their spatial and inventory perspectives. New complex system challenges are widening the range of disciplinary perspectives with useful contributions to hydrological science. International organizations, programs, and initiatives have received more attention and have accelerated development and more effective coordination to overcome this fragmentation as a result of two special programs; the International Hydrological Decade (IHD from 1965–1974) and the International Water Decade (1981–1990).

Internationally, hydrologic research is undertaken frequently within a programmatic and scientific framework developed by a community of scientists and coordinated by an international science organization. These organizations can be academic, governmental, or private. They play a major role in international science because they bring together experts from a broad range of specialities to address a full spectrum of science questions and provide a forum for science discussions and program formulation.

These international frameworks and programs do not fund research directly and must rely on individual nations to fund the activities and experts required to make the program a success. International programs continue to have an important role in hydrology where, historically, research has focused on basin scale phenomena. They give researchers access to a much broader community of experts, allow for a coordinated and comprehensive approach to problems so nations can use their funds more effectively, and advance and improve the science by making national contributions compatible with increasing implicit global standards.

Some international hydrology research programs progress by coordinating, influencing, and guiding national research activities to achieve the goals set out in their internationally approved science plans. This approach has been successful where strong leadership is present. Frequently, scientific leadership is provided through both a steering committee composed of active and knowledgeable scientists and a project office or secretariat that tracks progress and ensures that participants are contributing to the needs of the program in a timely and effective manner.

Some science efforts at the international level involve large projects that entrain a number of scientists from different regions to work on common questions. Because of their size and the opportunities they provide for international collaboration, these projects often attract some of the best and most visionary researchers. International project leaders and frequently facilitators with an ability to draw together international scientists to develop science plans, coordinate implementation, and interpret research results in a broad context.

The coordination of science within an international framework can be challenging because it relies on trust and the development and pursuit of a shared vision. Even though scientific approaches are apolitical, the issues addressed can be politically sensitive (e.g. the construction of new dams), so that trust is essential at all levels. A challenge for some programs arises from a reluctance of suitable scientific experts to work in international coordination roles for this type of research.

In hydrologic sciences, research is also coordinated through United Nations (UN) Water, and its special agencies, such as the World Meteorological Organization (WMO) and the United Nations Education, Scientific and Cultural Organization (UNESCO). Generally, the largest contributions for hydrological and related climate programs come from the United States, Europe, and Japan. There appears to be a second tier of funders, including Brazil, China, Canada, and Australia with other countries contributing as they can. All the three major funders maintain strong space programs and consider hydrological and water cycle issues as part of their observations and research related to the Earth's system. Another coordination mechanism is the International Council for Science (ICSU) and its International Association for Hydrological Sciences (IAHS), which works directly with the scientists.

This article provides an overview of the international hydrological science programs and briefly identifies related hydrological and hydrometeorological application programs that directly or indirectly provide scientific support for water management. This discussion is limited to programs that are global or at least multinational in scope. It also describes international mechanisms that facilitate the application of hydrologic science to regional and national water resource issues.

Before the individual programs and initiatives are discussed, the primary broad research frameworks and coordinating organizations will be described (Sections "Factors and principles governing the development of international hydrologic science programs" and "Umbrella programs for hydrologic research"). Program descriptions are divided into three sections: the Section on "Programs focused on observations and data management", the Section "Programs focused on process and modeling studies and basic science", and the Section "Knowledge transfer: applications, assessments, applied research, and outreach" discusses assessments, applications, and outreach. Most programs and initiatives have activities in two or more of these categories, although one is usually a priority. However, for this article, they are classified according to their primary purpose. The following review draws heavily on Lawford *et al.* (2003) and web-based sources (the web sites are listed in Appendix A).

FACTORS AND PRINCIPLES GOVERNING THE DEVELOPMENT OF INTERNATIONAL HYDROLOGIC SCIENCE PROGRAMS

In the past the international hydrologic sciences may have developed more slowly than meteorological and oceanographic sciences because water resource problems are primarily experienced at local, regional, basin, and/or national scales and, with the exception of transboundary problems, are addressed by national or state governments. Issues such as transboundary river flows are often viewed as sensitive and may involve sociopolitical and legal disputes. Even though science itself strives to be apolitical and objective, the funding and requirements for science do influence the directions in which science develops. Although international coordination of hydrological research has taken place since at least 1922, the demands and opportunities for global-scale hydrologic science have appeared only in the last few decades. IHD was a landmark event for international water science, because a network of research basins was established around the world. Since then hydrologic systems have come to be viewed as a global concern, rather than just a mosaic of disconnected local and regional problems. Nations without sufficient water resources are becoming aware that they need to be open to new strategies for overcoming shortages in supply. In addition, the advent of advanced computing systems has accelerated the development of data assimilation and prediction capabilities. Scientific research and technological developments can provide the scientific basis and infrastructure needed to advance international cooperation in hydrology. Factors that contribute to this change in perspective are discussed below.

The View from Space

Since their advent in the late 1960s, meteorological and other Earth satellites have gradually been changing our view of the hydrological cycle. The ability to look at the Earth from space has given us a more holistic appreciation of the Earth's global water cycle. Hydrologic sciences are an essential element of Earth science as it expands its boundaries to gain an integrated understanding of the functioning of the Earth system.

Global Environmental Change

A major impetus for international hydrological science programs in recent years has been the concern about the impacts of global change associated with global climate change and with growing demands for water and other resources arising from increasing populations and economic development. Large, shared resources, such as the Arctic Sea, are being polluted by multiple countries, and the anthropogenic alteration of such a global-scale ecosystem is likely to result in correspondingly global-scale consequences (IPCC, 2001). Arguably, the major issue pushing hydrologists to develop and provide a global perspective is the issue of global environmental change, of which climate change is a significant aspect. It is clear that the uncertainties arising from issues of climate variability and change cannot be understood without a complete understanding of the global water cycle. Furthermore, a broader base for hydrologic research is needed to understand the scientific basis for strategies to meet the goals of Rio 21 and the UN Millennium Development Goals (MDGs). Indeed, the globalization of hydrologic research is coming about partly because of the need to encourage more nations to share hydrologic data to improve models for global analysis and assessment and partly because many contiguous countries are facing similar environmental challenges as they share international river basins.

Sustainable Development

Through its Commission on Sustainable Development (CSD), the UN provides a major policy framework for addressing international water issues. This approach supports the principles embodied in the UN charter, namely, the promotion of peace and equality among the people of the world and the protection of societies from threats that may lead to widespread loss. The adoption of the principle of sustainable development as outlined in the "The Brundtland Report" (World Commission on Environment and Development, 1987) is widely regarded as a feasible path to achieve long-term global stability. In order to clarify its approach to water and other renewable resources, the UN has structured many of its new initiatives around the theme of sustainable development. Furthermore, the linked concerns of global environmental change and meeting the growing need for underserved communities for access to clean water are motivating applied research in support of sustainable resource management, such as "Integrated Water Resource Management (IWRM)".

International and Intersectoral Dialogue

The emergence of organizations that promote and facilitate international and intersectoral dialogue has stimulated the communication needed to advance hydrologic science and its application to real problems. The World Water Council (WWC) and Global Water Partnership (GWP) are examples of organizations attempting to draw groups together to identify issues that transcend national boundaries and to develop policy options. These organizations use cross-sectoral dialogue as well as dialogues within international fora (such as the World Water Forum) to address common water issues. Some of these issues are

short-term, such as the need for flood warning systems and data inputs to aid tactical water management decisions. Other issues require long-term approaches because they are linked with evolving factors such as depletion of groundwater reserves, increasing demands for surface water, and declining water quality. Dire, long-term consequences can result from the cumulative effects of poor short-term water management decisions, especially when these are superimposed on land use and socio-economic choices that increase vulnerability to risks like floods or water-mediated diseases, and on the uncertain, but potentially important effects of climate change. Hydrologic sciences have made substantive progress in areas where international collaboration has been strong. National and international assessments have relied on dialogue to bring together information that traditionally has been fragmented and available only locally. The hydrologic components of global change research in particular have benefited from international collaboration (e.g. Dialogue on Water and Climate (DWC) and Intergovernmental Panel on Climate Change (IPCC)).

Capacity Building

Capacity building in less developed countries involves the development of the capability to develop and operate advanced observations and prediction systems, independent data providers and programs of water and environmental management, or to improve their national services. Capacity building also includes education and research capabilities. Capacity building goals frequently include economic and related technological gaps between developing and developed countries. The contributions of science are of greatest value when the research provides techniques and information to deal with these obstacles. Increasingly, international science programs that have an element devoted to capacity building and technology transfer, in addition to improving scientific understanding, are the most effective in achieving their goals.

The following sections provide information on coordinating bodies, the umbrella hydrologic science programs, and the projects and activities that take place under each organization.

UMBRELLA PROGRAMS FOR HYDROLOGIC RESEARCH

The UN provides an institutional structure for initiation, coordination, and application of international science efforts. UN Water provides the institutional structure for hydrological research and related activities. Other international bodies, principally ICSU and its affiliated programs, provide additional nonpolitical, nongovernmental scientific perspectives. They identify critical scientific issues and develop frameworks for addressing them through coordinated programs. Additionally, a number of nongovernmental partnerships are using hydrologic sciences in their deliberations.

International Scientific Associations

ICSU, through its several member unions provides an umbrella for international scientific activities in numerous fields. A nongovernmental organization founded in 1931, ICSU has been bringing scientists from a wide spectrum of natural and human sciences together to address major international and interdisciplinary issues including hydrology and water since its founding. ICSU mobilizes the expertise and knowledge of the international scientific community, stimulates constructive debate, and acts as an authoritative independent voice for international science and scientists.

IAHS was founded in 1922 as a branch of the International Union of Geodesy and Geophysics (IUGG) to promote research in the hydrologic sciences. IAHS became part of ICSU when the organization was formed. Through its eight committees and working groups, IAHS provides hydrologic scientists with a forum for planning and reviewing scientific projects. The committees, many of which are discussed in more detail later in this section, include the International Commission on Surface Water (ICSW), the International Commission on Groundwater (ICGW), the International Commission on Continental Erosion (ICCE), the International Commission on Snow and Ice (ICSI), the International Commission on Water Quality (ICWQ), the International Commission on Water Resources Systems (ICWRS), the International Commission on Remote Sensing (ICRS), the International Commission on the Coupled Land–Atmosphere System (ICCLAS), and the International Commission on Tracers (ICT). In addition, IAHS frequently relies on Working Groups, such as the Hydrology 2020 Working Group, the IAHS/WMO Working Group for Global Energy and Water Cycle Experiment (GEWEX), and the Prediction in Ungauged Basins (PUB) Working Group to address emerging issues in hydrology. IAHS promotes scientific exchange by organizing major scientific conferences, distributing a newsletter, and publishing a series of "red books" of conference and symposium proceedings.

Under the ICSU umbrella, several programs have been initiated with a focus on understanding the changes that are occurring to the Earth System and the implications of these changes for global sustainability. These include the International Geosphere Biosphere Programme (IGBP), the International Human Dimensions Programme on Global Environmental Change (IHDP), and DIVERSITAS, a scientific program on global biodiversity. ICSU is also a sponsor, along with UNESCO and WMO, of the World Climate Research Programme (WCRP). In 2001, these global environmental programs formed a coordinated superstructure called the Earth System Sciences Partnership (ESSP), a

partnership that provides a mutually agreed mechanism for these programs to work together towards shared science objectives in areas of carbon, water, food security, and health. Hydrologic sciences are fundamental components of the ESSP programs.

The UN System

The UN system provides a framework for identifying issues that require information from scientific inquiry, establishing international goals, and initiating and coordinating implementation activities. As indicated below, many individual UN agencies are responsible for programs and projects that relate to water. Cooperation within the UN system on freshwater issues is coordinated through UN Water. Generally, UN agencies work with the appropriate national government agencies that play a critical role in determining how science can be applied to specific issues.

WMO was established in 1951 as a specialized agency of the UN. It facilitates international cooperation in planning and establishing networks for making meteorological, hydrological, and other observations and in promoting the rapid exchange of meteorological information, the standardization of meteorological observations, and the uniform publication of observations and statistics. It also furthers the application of meteorology to aviation, shipping, water problems, agriculture, and other human activities; promotes operational hydrology; and encourages research and training in meteorology. The main WMO program dealing with hydrology is the Hydrology and Water Resources Programme (HWRP) and its supervisory body is the Commission on Hydrology (CHy).

The International Hydrological Programme (IHP) of UNESCO addresses a wide range of priority water resources from physical, ecological, and socioeconomic perspectives. Its research is directed to improve the scientific and technological basis for the management of water resources, including the protection of the environment. IHP also maintains a growing number of centers of excellence, regional research and training centers, and directed research projects. Some of these are described more fully in later sections.

The Food and Agriculture Organization (FAO) of the UN was founded in 1945 with a mandate to raise levels of nutrition and standards of living, to improve agricultural productivity, and to better the condition of rural populations. In the realm of hydrologic science, the FAO cosponsors several observational, data management and research programs with other UN organizations, ICSU programs, and nongovernmental organizations.

The United Nations Environmental Programme (UNEP), which was established in 1972, relies on hydrologic and other environmental sciences to address problems of the human environment. UNEP supports the Global International Waters Assessment (GIWA), the Global Environmental Monitoring System (GEMS/Water) Freshwater Quality System, the International Environmental Technology Center (IETC), and the World Conservation Modeling Center (WCMC).

Joint and Multisponsor Programs

Since its inception in 1979, the World Climate Programme (WCP) has been cosponsored by WMO, UNEP, UNESCO Intergovernmental Oceanographic Commission (IOC), and ICSU. The WCP includes four components: the World Climate Data and Monitoring Programme, World Climate Impact Assessment and Response Strategies Programme, World Climate Applications and Services Programme, and WCRP.

WCRP was established in 1980 to develop the fundamental scientific understanding of the physical climate system and climate processes (including hydrologic processes) needed to determine the extent to which climate can be predicted and the extent of humans' influence on climate (WCRP, 1984). One of WCRP's four major projects, GEWEX, focuses on closing water and energy budgets on global and regional scales and on enhancing the value of climate information for water resource management. WCRP research also provides the scientific foundation for meeting the research challenges posed in international policy frameworks such as the United Nations Framework Convention on Climate Change (UNFCCC) and Agenda 21.

Other components of the UN system that support water science and related activities include: United Nations Development Programme (UNDP), United Nations International Children's Emergency Fund (UNICEF), United Nations University (UNU), World Health Organization (WHO), International Atomic Energy Agency (IAEA), and the World Bank. UN Regional commissions with responsibilities in water include: the Economic Commission for Europe (ECE), the Economic Commission for Africa (ECA), the Economic and Social Commission for West Asia (ESCWA), the Economic Commission for Asia and the Pacific (ESCAP), and the Economic Commission for Latin America (ECLAC). Specific issue-focused conventions with administrative bodies established by the UN include the International Strategy for Disaster Reduction (ISDR), United Nations Framework Convention on Climate Change (UNFCCC), Convention on Biological Diversity (CBD), and United Nations Convention to Combat Desertification (UNCCD). The water-related activities of many of these are described in the following sections.

Partnerships for Research

Increasingly, nongovernmental organizations are partnering with governments and intergovernmental organizations that develop or apply the results of hydrological research in

order to achieve important goals in the area of water. A very brief introduction to these partnerships appears below.

The World Bank, UNDP, and the Swedish International Development Agency (SIDA) created GWP in 1996. It provides a policy framework for coordinating financial, technical, policy, and human resources to address critical issues related to sustainable water management and it has attracted many partners globally.

The WWC was established in 1996 as a nonprofit, nongovernmental umbrella organization dedicated to strengthening international and national efforts to develop methods for improved management of the world's water resources. It organizes a triennial conference known as the *World Water Forum* (WWF) and an associated Ministerial conference to bring attention to water issues.

The DWC was initiated in the Netherlands in 2001 to improve the capacity in water resources management to cope with the impacts of increasing variability of the world's climate. It established a global platform through which policy makers and water resources managers have better access to, and make better use of, information generated by climatologists and meteorologists. In 2003, it reestablished itself as the Cooperative Programme on Water and Climate (CPWC).

Regional intergovernmental organizations facilitate international hydrologic research at the regional level. The ESSP's Asia–Pacific Network for Global Change Research (APN) is an intergovernmental network for the promotion of global change research and links between science and policy making in the Asia–Pacific Region. The Inter-American Institute for Global Change Research (IAI) is an intergovernmental organization supported by 19 countries in the Americas that carries out work related to water resources and environmental issues.

PROGRAMS FOCUSED ON OBSERVATIONS AND DATA MANAGEMENT

Historically, the understanding of physical water cycle processes has been derived from observations at the watershed or catchment scale. As previously discussed, with the advent of satellites and their ability to observe large-scale hydrologic phenomena, the water cycle is increasingly being viewed as a global system. Furthermore, water cycle processes at all scales are fundamental to the climate system; consequently, the hydrologic sciences are an important aspect of climate research. Recognition of this fact has led to new requirements for, and approaches to, global observations. In addition, global and regional hydrological models are needed to support climate studies, and development of these models requires specialized data sets. Most national data programs are maintained for reasons other than global-scale sustainability or environmental understanding. In particular, they usually are designed for national purposes that include planning, national prediction services, developing local design standards, and monitoring the implementation of policies and standards. Yet, transboundary policies and management rely on continued access to multinational data and products to provide baseline information on water supply and the factors that may influence future water availability.

In order to address data issues, many international organizations with programs focused on water-related issues must include observations, data collection, and data management among their functions. For example, UN agencies use data extensively in their research programs to contribute directly to research for developing scientific understanding of the physical systems (e.g. WCRP), while others oversee the implementation and maintenance of observing systems and promote the sharing of data and technology transfer on a global basis (e.g. the Global Observing System (GOS) components: see Section "Monitoring and observational programs").

Experiments and Field Campaigns

Some international programs develop global hydrometeorological data sets for use in water management, precipitation forecasting, and climate monitoring. The potential of this approach has increased significantly with the availability of global data sets from polar-orbiting satellites.

In 1990, the WCRP launched GEWEX with the goal of determining energy and water budgets for the globe (WCRP, 1990). Individually existing projects and newly initiated activities were drawn together to ensure that the most appropriate satellite data were used to produce global water vapor, cloud, and precipitation fields. In order to relate these data sets to regional water problems and to obtain regional data sets for evaluating the satellite products, Continental Scale Experiments (CSEs) were established in a number of large basins around the world. Over the past decade, GEWEX scientists have acquired research data sets to examine a range of land, surface hydrology, and atmospheric processes. The GEWEX CSEs include the GEWEX Americas Prediction Project (GAPP) in the United States, the Baltic Sea Experiment (BALTEX), the GEWEX Asian Monsoon Experiment (GAME) in East Asia, the Large-scale Biosphere Atmosphere Experiment in Amazonia (LBA) primarily in Brazil, the Mackenzie GEWEX Study (MAGS) in Canada, the Murray Darling Basin (MDB) in Australia, the La Plata Basin (LPB) in South America and, most recently, the African Monsoon Multidisciplinary Analysis (AMMA) in west Africa. Data from these regional studies contribute to algorithm development and testing, and provide a baseline for evaluating the reliability of global products. Research in these programs contribute to land surface and hydrological process understanding and to the GEWEX Water Resources Application Project (WRAP).

An important and relatively new component of the WCRP is the Coordinated Enhanced Observing Period (CEOP) Phase I. This is a cooperative effort carried out to compile global-scale continental data sets for the 2001–2004 time period using the new generation of satellites as well as operational satellite data products, reference site data, and model derived data. The data sets, collected in different CSE areas representing different hydrologic regimes and supplemented with model output and satellite data, enable modelers to test the transferability of parameterizations to other, unsampled but hydrologically similar locations. The goal is to improve the prediction of climate variability and its effects on water resources in various regions of the world. Details on CEOP are provided in Stewart *et al.* (2001) and Koike (2004).

Monitoring and Observational Programs

Observational programs continue to play a central role in the hydrological sciences. Data is needed for the analysis, development, and evaluation of models required to address water issues related to consumption, sanitation, irrigation, hydropower production, water transport, floods, and droughts.

Observational networks are maintained by national governments to support objectives that may be national in scope, such as maintaining national forecast services and monitoring the state of national resources. Data from these national networks are the foundation of many global observing programs. For example, the WMO supports the collection and analysis of data from national networks of hydrological and meteorological stations and promotes data sharing. Historically, the ability to measure streamflow, surface water storage, and precipitation has been the basis for the development of engineering criteria for dams, reservoirs, and other water works. In addition, the ability to analyze water samples for chemical and biological constituents has enabled environmental regulation programs.

The planning of networks for different purposes has taken place relatively independently, with many meteorological measurements taken at airports and streamflow measurements taken at accessible areas along riverbanks. During the past decade, a great deal of effort has been directed toward more integrated network planning. The following review of organizations addressing measurement needs discusses those focusing on *in situ* measurement first, followed by activities that are bringing both *in situ* and space-based measurements into a common framework.

In Situ Measurements

The GOS programs, which include the Global Climate Observing System (GCOS), Global Terrestrial Observing System (GTOS), and Global Ocean Observing System (GOOS), were established in the early 1990s. They address the data needs of resource managers, scientists, and policy makers to monitor the Earth system and to provide a capability to monitor the Earth's climate. The purpose of GCOS is to ensure that the comprehensive, long-term observations and information (atmospheric, oceanic, terrestrial, and cryospheric) needed to improve our capability to detect, predict, and assess climate variability and change are obtained and made available to all potential users. GCOS facilitates the coordination and collaboration of national and international observational programs. Through a strategy of observations, modeling, and analysis of terrestrial ecosystems, GTOS focuses on the very diverse surface observational systems needed for land areas. It was established to provide necessary data on surface freshwater hydrology (including the cryosphere and nonconfined subsurface hydrology) and other land processes to detect, quantify, and give early warning of changes in terrestrial ecosystems, with the ultimate goal of supporting sustainable development and improving human welfare.

GCOS, GTOS, and Global Terrestrial Network for Hydrology (GTN-H) receive advice on data needs from a joint scientific advisory panel known as the *Terrestrial Observation Panel for Climate* (TOPC). On the basis of a meeting of experts (reported by Cihlar *et al.*, 2000), a global hydrological observation network for climate was established to share hydrologic information that would meet policy and science requirements in the area of climate research. This network, known as the *Global Terrestrial Network for Hydrology* (GTN-H), has now been adopted as an active international project under the sponsorship of GTOS, GCOS, and WMO.

Many real-time hydrometeorological data are acquired through the WMO's World Weather Watch (WWW) Programme. This global monitoring and assessment program maintains a meteorological database and distributes data and products including basic meteorological, hydrologic, oceanographic, and other environmental data and weather analysis, warnings, and forecasts.

The World Hydrological Cycle Observing System (WHYCOS) is a developing program based, in concept, on a global network of reference stations that transmit hydrological and meteorological data in near-real time, via satellites, to national hydrologic and regional centers and regional forecast centers. These data enable the provision of constantly updated national and regionally distributed databases of consistently high quality. WHYCOS supplements existing hydrological observing networks and supports the establishment and enhancement of information systems that can supply reliable water-related data to resource planners, decision makers, scientists, and the general public. It produces consistent regional data sets for use in preparing products for water resources assessment and management. WHYCOS is developing regional components known as *regional HYCOSs* to meet the regional priorities expressed by the

participating countries. In its initial phase WHYCOS has focused on establishing components in international river basins, in the catchment areas of enclosed seas, and in regions of Africa that are poorly served with hydrological information.

The Global Network of Isotopes in Precipitation (GNIP) was initiated in 1958 by the IAEA in collaboration with WMO. The objective of the program is to collect systematic data on isotope content of precipitation on a global scale. Regular intercomparisons among the national laboratories using standards developed by the United States Geological Survey (USGS) and statistical evaluations of the data are organized by the IAEA. The IAEA also sponsors the monitoring and analysis of isotopes in surface and groundwater, thereby enabling climatological (interpretation of paleorecords), atmospheric (validation of global circulation models), and hydrological (large regional and global-scale water balances) studies. An IAEA/UNESCO Joint International Isotopes in Hydrology Program (JIIHP) was initiated in 2003 to improve implementation and coordination of the isotope hydrology programs of both agencies. Integrated isotope databases allow for the gathering, storage, and dissemination of isotope, chemical, hydrogeological, and geographical data of water studies around the world.

A project within the International Shared Aquifer Resources Management (ISARM) program, jointly sponsored by the International Association of Hydrogeologists (IAH), UNESCO, FAO, and others, is developing pilot groundwater monitoring networks for selected aquifers that extend across country borders. UNESCO IHP initiated an inventory of groundwater contamination through its National Committees and Regional Offices of Science and Technology, and it has been exploring the need for a consistent groundwater monitoring program.

Satellite Capabilities

While slow to penetrate the field of hydrology, satellites are now making major contributions to the field. This is particularly true for the last decade, when the number of Earth-observing satellites increased markedly and hydrological research began to make more use of satellite products. For example, hydrology has made extensive use of precipitation data from satellites, and water management recognizes the great potential of the development of high-resolution precipitation products. In addition, development of high-resolution global land surface data sets has provided an incentive to hydrological modelers to develop distributed hydrological models that can take full advantage of these products. Of course, calibrating these new models is one of the major challenges facing hydrology today.

Currently, space agencies have developed a range of sensing technologies that provide new ways of looking at the Earth and new opportunities for deriving hydrological variables. For example, the planned suite of research satellites includes gravimetric measurements that can provide insight on groundwater and surface water levels, microwave sensors that can provide information on soil moisture, and radars, synthetic aperture radars, and surface lidars that can provide high-resolution information on topography and vegetation cover. Space agencies that are taking the lead in dealing with these satellite issues include the US National Aeronautics and Space Administration (NASA), European Space Agency (ESA), Japan Aerospace Exploration Agency (JAXA), and the Chinese Space Agency (CSA). NASA provides funding for a national research program to exploit the development of these satellites and for the assessment of uses of the data they provide. While other space agencies do not fund hydrological research, they all dialogue with the research community and support research by making data available.

The Committee on Earth Observation Satellites (CEOS) is an international organization charged with coordinating international civil Earth-observing missions and the interaction of these programs with users of satellite data worldwide. CEOS ensures that critical scientific questions relating to Earth observation and global change are covered, and satellite missions do not unnecessarily overlap each other.

Integrated Satellite/In Situ Measurements Activities

The Integrated Global Observing Strategy – Partnership (IGOS-P) is a partnership among international organizations, space agencies, the scientific community, and international research programs. IGOS-P was initiated in 1998 to plan and coordinate observations of the planetary environment, including *in situ* and space-based measurements. The IGOS Partners have adopted a thematic approach with joint planning activities to address particular categories, crosscutting themes, or domains of observations, such as oceans, disaster management, or carbon storage and cycling. In 2003, the IGOS Partners adopted an Integrated Global Water Cycle Observations (IGWCO) theme that provides a framework for water-related observations. Initially, coordination activities are being directed at three priorities: precipitation, surface hydrology, and water resource applications such as irrigation. The theme also provides an umbrella for CEOP and its links with the space agencies. The CEOS Strategic Implementation Team leads the development of the space component of IGOS-P while the GOS programs and their sponsors are leading the development of an *in situ* component.

In 2003, at the first Earth Observing Summit, nations and international environmental programs launched the development of a new observing system paradigm known as the *Global Earth Observing System of Systems* (GEOSS). At the time of this writing, more than 60 nations have joined this effort along with a number of international programs and

the European Union. Participating nations have affirmed the need for timely, high-quality, long-term, global information as a basis for sound decision making, and have committed themselves to develop a comprehensive, coordinated, and sustained Earth observation system. The system builds on the work of IGOS-P and other international observational programs.

Data Products, Distribution, and Storage

An important function of international programs is the production of consistent data sets that can be used with confidence in all parts of the world. For example, GEWEX, through its Global Radiation Panel (GRP), produces a range of global water cycle data sets from satellite observations. One product that is used extensively is the Global Precipitation Climatology Project (GPCP) series of monthly precipitation maps. These data sets are being used to validate general circulation and climate models, to study the global hydrological cycle, and to diagnose the variability of the global climate system. These studies have been aided by extensive efforts to calibrate data sets by eliminating the effects of factors, such as orbital drift, that change the intensity of the signal arriving at the surface.

A number of data and information centers have been established to archive global data products and make them available to all nations. In the past, international programs have encouraged the adoption of international standards for measurement and data processing methodologies, data archival and exchange, and metadata documentation. Consequently, many nations support centers for collecting, standardizing, and distributing global environmental data. While distributed archives and networks accessed through a web-based portal are becoming more common, centralized data centers such as the Global Runoff Data Center (GRDC) continue to play an important role.

Data Centers

The GRDC was formed under the auspices of WCRP and WMO in 1988. GRDC focuses on the acquisition and dissemination of river discharge data on a global scale and the provision of data products and specialized services for the research community, water managers, and water-related programs of the specialized agencies of the UN.

The Global Precipitation Climatology Center (GPCC) is the central *in situ* data component of the GPCP and fulfills other data functions in support of WCRP and WMO. The infrastructure for implementing international data management activities often emerges from activities supported by national governments. The GPCC is an example of this strategy. Specific functions of the GPCC are the collection of rain-gauge-measured precipitation data worldwide, quality control of these data, and calculation of areal mean totals based on the conventionally measured data over land.

For the jointly sponsored GOS programs, a Global Observing Systems Information Center (GOSIC) was established at the College of Marine Studies of the University of Delaware, US, to provide a single entry point for users seeking data and information produced by the global observing systems GCOS, GOOS, and GTOS.

Data Programs

Within the UN system, the HWRP of WMO provides for the collection and analysis of hydrological data as a basis for assessing and managing freshwater resources. The activities under the HWRP concentrate on the measurement of basic hydrological elements from networks of hydrological and meteorological stations; the collection, processing, storage, retrieval, and publication of hydrological data, including data on the quantity and quality of both surface water and groundwater; the provision of such data and related information for use in planning and operating water resources projects; and the installation and operation of hydrological forecasting systems. The program also promotes increased collaboration between national hydrologic services and national meteorological services, particularly in the provision of timely and accurate hydrological forecasts.

The GEMS/Water Programme, initiated by UNEP in 1977, provides authoritative information on the state and trends of inland water quality over the globe. These data are required to support global environmental assessments and decision-making processes. More than 100 countries participate in GEMS/Water. Data records extend from 1977 to the present. Since 1978, GEMS/Water has been hosted at Environment Canada's National Water Research Institute.

Socioeconomic data and data on water use are needed to support water policy decisions. Examples of products that are available include FAO's Cropwat and Climwat programs (described in Section "Water and Food") and WHO/UNICEF Joint Monitoring Programme for Water Supply and Sanitation (JMP), which maintains a database containing water supply and sanitation coverage estimates, along with all the household survey data from which these estimates were derived.

PROGRAMS FOCUSED ON PROCESS AND MODELING STUDIES AND BASIC SCIENCE

The concept of the global water cycle links the physical components of the hydrological cycle, including surface water, groundwater, and atmospheric variables. This concept, which served as the basis of a comprehensive review by Hornberger *et al.* (2001), also has been used as a basis for defining the requirements for water cycle variables (IGOS, 2004). The following section reviews hydrologic research programs that address this cycle as well as the needs of the water management community.

Issues Involved in Hydrological Research

Surface Water

The ICSW of IAHS promotes research in surface water hydrology and its interaction with other aspects of the hydrological cycle. Priority issues include flood and drought prediction, mitigation, and forecasting, but increasing priority is given to interdisciplinary research, including in-stream ecology, wetland ecology, hydrology and health, and knowledge building to reduce international conflict in water.

Initiated in 2003, the Working Group on PUB is a new IAHS program focused on improving the accuracy of predictions in ungauged river basins. PUB is expected to provide an indication of the value of existing and planned measurement networks and new satellite missions, as well as to advance understanding of how river basins function in various parts of the world. PUB functions as a loosely coordinated global network of groups of experts associated with particular regions, sectors, and disciplines.

GAPP supports the Hydrological Ensemble Prediction Experiment (HEPEX) and the Model Parameter Estimation Experiment (MOPEX), which investigates techniques for the *a priori* estimation of the parameters used in hydrologic and coupled models. MOPEX is developing a comprehensive database that contains many years of historical hydrometeorological time series data for select basins and hydrologic parameters for basins worldwide.

Groundwater

The IAHS ICGW focuses on groundwater hydrology, including the scientific basis for groundwater resource assessment and groundwater management, and on new technologies and methodologies that are useful in groundwater quality studies. ICGW working groups deal with groundwater quality, environmental risk assessment, numerical modeling, innovative field and laboratory measurement techniques, advanced field data interpretation methods, characterization of heterogeneous media, and management of the uncertainty of groundwater resources.

Since 1978, the International Ground Water Modeling Center (IGWMC) has advised on groundwater modeling problems and distributed groundwater modeling software, undertaken practical research on applied areas of groundwater hydrology and modeling, and provided technical assistance on problems related to groundwater modeling. It also supports and advances the appropriate use of quality-assured models and groundwater resource protection and management. In addition, the International Groundwater Resource Assessment Center (IGRAC), a UNESCO center of excellence, conducts research and provides expert advice on groundwater issues.

Water Quality

The ICWQ of IAHS deals with issues related to the water quality of hydrological systems, including assessment and management. The commission currently has two working groups: Nutrient Cycling and Management and Urban Water Quality. The commission works with UNESCO IHP on issues of water supply, water quality and human health, integrated assessment of water resources, changes in the water quality of receiving waters as a consequence of land-based activities, scaling issues in water quality, and development and protection of vulnerable environments.

Climate

Because of the continental to global nature of atmospheric processes, hydrology must be able to address the climate-hydrology interface at all scales up to the global level. Conversely, because of the profound implications of climate variability and change for water resources, some water programs have adopted climate issues at the local scale as a priority theme. International research on the climate–hydrology interface generally takes the form of multinational hydrologic research programs that interface with large-scale climate modeling projects.

GEWEX deals specifically with the role of the water cycle in climate. Its main thrust is the production and analysis of global and regional data sets to support climate model development and climate process research, as well as the analysis and modeling of the global water cycle. GEWEX contributes to prediction capabilities on the monthly to interannual time scales. One central research question for GEWEX revolves around the hypothesis that the global water cycle is accelerating and humans play a significant role in that process.

CLIVAR, which was launched in 1995, strives to describe, analyze, model, and predict climate variability at time scales from a season to a century. As part of WCRP, CLIVAR provides insights into the working of the climate system with a primary focus on the atmosphere and the ocean and their interactions. It also focuses on the development of prediction techniques that will allow prediction on seasonal to century time scales. CLIVAR also complements other parts of WCRP such as GEWEX, through its monsoon system studies, and IGBP, through its Earth system modeling.

Past Global Changes (PAGES) provides a unified framework for paleo-environmental research on past climates and extreme events such as floods and droughts by facilitating international cooperation. This coordination embraces paleo aspects of the interactive hydrologic, atmospheric, oceanic, chemical, and biological processes that regulate the Earth system, concentrating on those aspects that relate to potential future changes of importance to humans.

Global Continental PalaeoHydrology (GLOCOPH) is a commission of the International Union for Quaternary Research (INQUA) established to study global paleohydrology during the last 20 000 years. GLOCOPH studies characteristics of past hydrological cycles and their role

in past environmental changes useful for validating the response of global or regional climate models in different environmental settings and prediction of future environmental change.

Land Surface Processes

In 2002, IGBP adopted a new program structure in which terrestrial water issues are addressed by projects in the land, land-atmosphere, and land-ocean themes. Some of this work builds on the success of the Biological Aspects of the Hydrologic Cycle (BAHC) program, a major research element of the IGBP during the period 1988 to 2002. BAHC studies provided a basis for understanding the effects of land use changes on runoff and for assessing the consequences of climate change for water resources. The integrated land-atmosphere project, planned for launch in 2004, supersedes the existing land-based project, Global Change Terrestrial Ecosystems (GCTE). GCTE studied the effects of changes in climate, atmospheric composition, and land use on the structure and functioning of terrestrial ecosystems, and analyzed how these effects lead to feedbacks to the atmosphere and the physical climate system.

Under IGBP's new structure, terrestrial studies will be undertaken in the Integrated Land Ecosystem-Atmosphere Process Study (iLEAPS) as well as in the ongoing Land Use and Land Cover Change (LUCC) and Land Ocean Interactions in the Coastal Zone (LOICZ) projects. iLEAPS will provide an understanding of how interacting physical, chemical, and biological processes transport and transform energy and matter through the land-atmosphere interface. iLEAPS will focus on the processes of land-atmosphere exchange of energy and matter, emphasizing feedbacks and interactions between these two components of the Earth system. LUCC research addresses the problem of land use and land cover dynamics through comparative case study analysis, empirical observations and diagnostic models, and integrated regional and global modeling. Since 1993, LOICZ research has focused on areas where land, ocean, and atmosphere interact. While scientific research remains central to LOICZ, during the next phase there is an increased focus on integrated analysis and synthesis, including the human dimensions.

To obtain a better understanding of the global hydrologic cycle, comprehensive watershed, river basin, and continental-scale process studies are needed. If properly coordinated and planned, process studies can potentially provide observational data in a standardized (i.e. transferable) format and can also improve the understanding of various aspects of the hydrologic cycle. Examples of successful process studies include: the First ISLSCP (International Satellite Land Surface Climatology Project) Field Experiment (FIFE) in the United States and the Hydrology-Atmosphere Pilot Experiment in the Sahel (HAPEX-SAHEL). These projects, carried out as part of the GEWEX ISLSCP experiment have provided a scientific base, professional relationships, and infrastructure for advancing international cooperation in surface hydrology.

ICCLAS (International Commission on Coupled Land-Atmosphere System) promotes the evaluation and usage of outputs generated by global/regional coupled land-atmosphere models for water resources applications, including the management of floods and droughts. Specific topics of study include: the hydrological impacts of future climate, regional hydrology of climate-sensitive regions, especially semiarid and arid areas; historic hydroclimatological variability of relevant regions, catchment and regional scales; hydroclimatically relevant decision-making and risk assessment; and coupled hydrometeorological modeling.

Snow/Ice

The Climate and Cryosphere (CliC) project, initiated by WCRP in March 2000, seeks to assess and quantify the impacts of climatic variability and change on the cryosphere and their feedbacks to the climate system, and to determine the stability of the global cryosphere. Hydrologic expertise is required to address many of its principal scientific questions, such as glacier contributions to global sea level change and the energy and water cycle in regions with land ice, snow cover, and frozen ground. CliC builds on the success of Arctic Climate System Study (ACSYS), which had a focus on the hydrometeorological processes controlling runoff into the Arctic Ocean.

The IAHS ICSI is concerned with the study of snow and ice in all its forms. ICSI has four general priorities: River, Lake and Sea Ice; Seasonal Snow Cover and Avalanches; Glaciers and Ice Sheets; and Ice as a Material (including atmospheric ice, permafrost, and extraterrestrial ice). ICSI working groups also oversee the Snow Models Intercomparison Project (SNOWMIP) that compares the structure and functioning of existing snow models; Snow and Climate Working Group (SCWG) that examines the relationships between snow, ice, atmosphere, and climate on a global scale; River and Lake Ice Working Group (RLIWG) that identifies and quantifies physical and chemical processes in ice-covered freshwater basins, and relates these to the ecology of the systems themselves (e.g. life cycles of fish); and Snow-Vegetation Interactions Working Group (SVIWG) that defines the nature of snow–vegetation interactions and feedback relationships. ICSI also is responsible for UNEP's World Glacier Monitoring Service (WGMS) and has several working groups addressing regional glaciers (Andes and Himalayas) and mass balance techniques for developing new methods for monitoring glaciers.

Extreme Events

The WMO's World Weather Research Programme (WWRP), which seeks to improve weather forecasts on 1- to 14-day time scales, launched The Observing System

Research and Predictability Experiment (THORPEX) to develop a system for the prediction of high impact weather such as hurricanes, severe thunderstorms and associated flash floods, dust storms, and tornados. THORPEX will develop assimilation systems and carry out observing system tests to verify and evaluate the value of experimental and operational remote sensing and *in situ* observing systems in improving forecasts.

Methodologies and Techniques:

IAHS Commissions that focus on methodology cut across the other IAHS Commissions. The ICRS focuses on the use of remote sensing, data transmission, and Geographic Information Systems (GIS) in applications related to hydrological sciences. The Commission currently has two sections, Remote Sensing and GIS. ICT, established in 1991, promotes the development and improvement of artificial and natural tracer methods, and the dissemination of tracer methods to the hydrological community.

Experiments

An important approach to international science involves the launch of focused projects that allow researchers to work together. (Data collection and management aspects of these experiments are described in Section "Experiments and Field Campaigns".) The GEWEX program undertook an internationally coordinated effort to establish a number of focused projects including CSEs. The GEWEX Hydrometeorology Panel (GHP) and its CSEs develop analyses of regional water and energy budgets, and seek to improve the prediction of hydrometeorological phenomena. Over the past decade, scientists involved with the GEWEX program have contributed to intensive studies of specific hydroclimatological regimes (Lawford *et al.*, 2004). These continental-scale river basin studies will provide improved observations and coupled land-atmosphere models. In general, the scientific developments from this research find their way into operational services through the national agencies responsible for flood prediction, weather forecasting, and water resource management.

The ESSP, formed in 2001, facilitates collaboration among the four ICSU global environmental change research programs (DIVERSITAS, IGBP, IHDP, and WCRP) for the integrated study of the Earth system, the changes that are occurring in the system, and the implications of these changes for global sustainability. The programs are planning collaborative activities on Earth system analysis and modeling, water (see Section "Hydrologic Process Studies"), carbon, food security, and health. The water study, known as the Global Water System Project (GWSP), will address how changes in the Global Water System (GWS) (e.g. the system of dams and reservoirs) have influenced patterns of runoff and contributed to possible long-term changes in climate. In addition, they sponsor START (Global Change System for Analysis, Research and Training), a program that carries out capacity building, regional research, and networking activities in Africa, Asia, and the Pacific. START currently is promoting and facilitating the development of a small set of integrated regional studies including LBA, AMMA, and the Monsoon Asia Integrated Regional Study (MAIRS).

Hydrological Contributions to Earth System Modeling

Precipitation and the hydrologic cycle components are major drivers in Earth system modeling. A major international Earth system modeling effort to which hydrologic science makes key contributions is the Global Analysis, Integration and Modelling (GAIM). GAIM's goal is to improve the understanding of how the Earth functions as a system through the use of both data and models. Because of its complexities, Earth system modeling presents a challenge to GAIM and other IGBP and WCRP projects. GAIM has traditionally focused its efforts on global biogeochemical cycles and their links to the hydrologic cycle and to the physical climate system, for natural systems as well as in the context of anthropogenic influences.

WCRP is developing the Coordinated Observing and Prediction of the Earth System (COPES) strategy with the goal of facilitating the prediction of climate and Earth System variability and change for use in an increasing range of practical applications of direct benefit to society. To achieve this goal, COPES will determine what aspects of the climate/Earth system are predictable and those that are not, at weekly, seasonal, interannual, and decadal through to century time scales. In these efforts, COPES will utilize improving observing systems, data assimilation techniques, and models of the climate/Earth system.

Major national efforts to develop Earth system models are under way. For example, in the United States the Earth System Modeling Framework (ESMF) group is developing modeling capabilities to address climate, numerical weather prediction, data assimilation, and other Earth science applications through a multiagency collaboration that includes many of the major national climate, weather, and data assimilation efforts. An ESMF collaborating partner is the Programme for Integrated Earth System Modeling (PRISM), funded by the European Union, which draws together modeling efforts in individual European countries. In Japan, the Frontier Research System for Global Change is carrying out a project with similar aims.

Hydrologic Process Studies

The scope of UNESCO's IHP is broadly defined and covers many categories of water science research and related activities. Its two primary study programs, Flow Regimes from

International Experimental and Network Data (FRIEND) and Hydrology for the Environment, Life and Policy (HELP) rely heavily on hydrological process studies. The purpose of IHP is to improve the scientific and technological basis for the development of methods and expertise for rational management of water resources including environmental protection, and to integrate developing countries into worldwide ventures of research and training. IHP was put in place at the end of the IHD. It has been developed as a series of multiyear programs with IHP-V ending in 2001 and IHP-VI commencing in 2002.

The FRIEND program was initiated in 1985 in Europe. By 2004, FRIEND had grown to involve research institutes, universities, and operational agencies from more than 90 countries. FRIEND is an international research program whose goal is to develop an understanding of the hydrologic variability among regions of the world. Its research program is a collection of international studies in regional hydrology aimed at improving knowledge of hydrological processes and flow regimes through the exchange of data, knowledge, and techniques. This is accomplished in a cooperative manner through mutual exchange of data, techniques, and knowledge among FRIEND scientific partners. FRIEND is active on all continents except North America, where its activities are only now being discussed.

In 2001, ESSP started planning the GWSP, which was formally launched in 2004. GWSP promotes research to improve the knowledge of the interactions of the GWS with the environment over a range of time and space scales. In this context, the GWS is defined as the totality of natural processes, biogeochemical and ecological interactions, human engineering and policy interventions, and domestic and industrial use, and recycling. GWS is seen as both a driver of environmental change and a recipient of the impacts of different external changes.

KNOWLEDGE TRANSFER: APPLICATIONS, ASSESSMENTS, APPLIED RESEARCH, AND OUTREACH

Research is one component of the complex, dynamic environment in which global water-related issues are addressed. International, national, and regional hydrologic research programs are turned to societal benefit through development, education, and institutional change. Effective knowledge transfer underpins these essential activities. Informing policy makers is a critical role for scientific programs. At the policy level, exercises such as the World Water Forum are important to ensure that substantive and reliable hydrological information is brought forward to help in setting the broader sustainable development agenda. Furthermore, getting the best available hydrological information to the right people at all levels of decision-making can have a significant impact on quality of life in the present and water sustainability in the future.

Applications

Scientists are encouraged to develop pathways whereby their research results can be used in more effective decision-making. UNESCO's HELP focuses on in-depth applications in individual basins by characterizing both environmental and anthropogenic/policy concerns and relating current scientific understanding to these needs. HELP, a joint UNESCO/WMO initiative, is led by UNESCO IHP. The HELP network of basins is expanding from a 25-basin pilot phase launched in 2000 to a much larger number of basins in its full implementation in 2004. From the technical perspective, the broad objectives of HELP are to strengthen field-oriented, experimental hydrology using drainage basins (on scales up to 10^4 to 10^6 km^2) in order to address physical (hydrological, climatological, ecological) and nonphysical (technical, sociological, economics, administrative, law) issues.

New techniques developed through research are transferred to service for society through a process referred to as *technology transfer*. The transfer of new technologies to operational services is an essential process, but is one that requires a great deal of planning and nurturing. Case studies that demonstrate the importance of information sharing and transfer are under way through the assessment activities of World Water Assessment Project (WWAP) and collaborative research activities such as GEWEX. Through the efforts of the WMO's HWRP and CHy, national hydrometeorological operational agencies are kept informed about new technologies. WMO programs that facilitate the transfer of models, technologies, and data among nations also make an important contribution to these efforts.

Decision makers frequently may be reluctant to apply the latest research in their decision processes. For example, water resource managers must consider legal, institutional, and cultural factors as well as the timing and form of information, equipment and system constraints, and the risks and liabilities of deviating from an established practice. In order to design useful applications, studies are needed on the use of information in management and policy decisions related to water. IHDP, which was launched in 1990, promotes study of the institutional and human factors that affect society's response to global change. Within the domain of water science, IHDP considers issues such as the role of governance in water management and the implications of private versus public ownership of water. Studies of these issues are important for understanding the context for hydrological research applications.

Frequently, programs that apply the results of water research focus on the needs of specific sectors or address a specific subset of water-related issues. The following

subsections discuss projects that focus on critical information needs across a range of sectors and issues.

Water and Development

National and regional economies often depend on balancing the supply and demand for water. In many regions, the decreasing amounts of uncommitted water constrain economic development. (See e.g. Boehmer *et al.*, 2001). Nations and regions constrained in this way represent challenges to global development, stability, and sustainability; therefore, issues of water for development are global concerns that require support from science.

UNDP operates in 166 countries, where it helps to strengthen national capacities to alleviate poverty. Resolving water issues is central to poverty alleviation and human and ecosystem health. Key concerns include combating desertification and helping vulnerable populations adapt to climate change. UNDP advances its programmatic goals in these areas by applying hydrologic science in collaboration with other international bodies.

Water and Health

Clean water is critical for life and health, and the supply of safe water for human consumption is a primary social concern. By the current estimate, water-related illness accounts for more than 2.2 million deaths per year worldwide (UNESCO-WWAP, 2003). The provision of clean water for drinking and sanitation services is a central theme in the MDGs.

The Water, Sanitation and Health Program (WSHP) of WHO addresses aspects of water, sanitation, and hygiene where the health burden is high, knowledge levels are low, and where interventions could make a major difference. Applied research in hydrologic sciences addresses issues related to drinking water quality, bathing water, water supply and sanitation monitoring, sanitation and hygiene development, water-associated pathogens, wastewater use, health in water resources development, and emerging issues in water and infectious diseases.

Water and Food

Water management is a critical element of food production, especially when agricultural irrigation is used to supplement inadequate rainfall. The Water Resources, Development and Management Service (AGLW) of the FAO addresses the sustainable use and conservation of water in agriculture. It assesses water resources, monitors agricultural use, assists in water policy formation, and promotes irrigated agriculture and efficient water use through management innovations, modernization, and institutional reforms. The FAO relies on research products and observations for its advisory services. It maintains a global information system to support irrigation management through Cropwat, a decision-support system that estimates water balance components such as evapotranspiration, crop water requirements, and crop irrigation requirements. Cropwat is used in combination with FAO's global climatic database to optimize irrigation scheduling and water allocation for various crops worldwide.

The Consultative Group on International Agricultural Research (CGIAR), created in 1971, supports a system of 16 Future Harvest Centers that work in more than 100 countries to use hydrologic and other sciences to help reduce hunger and poverty, improve human nutrition and health, and protect the environment. Through its Challenge Program on Water and Food, CGIAR sponsors research on knowledge and methods for growing more food with less water. This research has a geographical focus provided by Benchmark Basins.

The International Water Management Institute (IWMI), a Future Harvest Center, focuses on the sustainable use of water and land resources in agriculture and on the water needs of developing countries. IWMI also identifies priority water management and food security issues and develops, tests, and promotes management practices and tools that can be used to more effectively manage water and land resources and address water scarcity issues.

ESSP is addressing the link between water and food through the Global Environmental Change and Food Systems (GECAFS) project launched in 2004. Research results and databases resulting from this project will contribute to improving food provision and minimizing environmental impacts of food production, distribution, and waste.

Water, Weather, and Climate

For over 65 years, the WMO and its predecessor, the International Meteorological Organization, have supported national hydrological services, river basin authorities, and institutions responsible for water management in a wide range of activities through HWRP. HWRP promotes activities in operational hydrology and furthers close cooperation between meteorological and hydrological services. HWRP also promotes improvements in the capabilities of developing countries to independently assess their water resources on a continuous basis, to respond to threats of floods and droughts, and to meet the requirements for water for various uses. In addition, HWRP facilitates the sharing of new models, technologies, and data among national operational hydrometeorological agencies and services.

The WCP (described in Section "Joint and Multisponsor Programs") has undertaken a project that applies advances in data, climate knowledge, and prediction capabilities to limit the negative impacts of climate variability and improve planning. This project, the Climate Information and Prediction Services (CLIPS), includes an expert team on climate and hydrology that monitors scientific developments and provides guidance on the use of climate predictions in water resources and flood management systems. Its main activities are training, demonstration/pilot

projects, liaison with research programs, and networking. WCP-Water also undertakes projects that utilize results from hydrological research.

Water and Environment

Water is a central determinant of ecosystem health and a major medium of transport for pollution. International programs in the hydrologic sciences that address environmental issues have multiplied in the past two decades. Since its inception in ICSU in approximately 1994, the SCOWAR (Scientific Committee on Water Resources) provided a scientific focus for addressing water issues. In 1996–1997, the committee narrowed its focus to the environmental aspects of water management. SCOWAR identified knowledge gaps and used existing databases to make ecological predictions possible. GWSP (described in Section "Hydrologic Process Studies") replaced SCOWAR in 2003.

DIVERSITAS, an international global environmental change research program under ICSU, promotes integrative biodiversity science by linking biological, hydrological, ecological, and social disciplines in order to produce an understanding of biodiversity loss, and to draw out the implications for conservation and sustainable biodiversity policies.

The UNEP Freshwater Unit supports the goals of environmentally sustainable development and enhanced environmental quality by promoting the integrated management and use of freshwater resources. Its activities include the development of curriculum and training material and the organization of international and regionally focused workshops. It uses hydrologic information and science in its environmental inventory, analysis, diagnosis, and action planning activities, and as a basis for promoting appropriate technologies.

Since its inception in 1991, the Global Environment Facility (GEF), administered by the World Bank in partnership with UNDP and UNEP, has provided grants to developing countries for water projects and activities, including transboundary water projects (e.g. groundwater, land degradation, and persistent organic pollutants) that protect the global environment and promote sustainable livelihoods. Many of these projects have had a substantial hydrological research component.

Assessments

Assessments provide a baseline understanding of the current status of a resource from which the future is projected. They can be used to provide insight on the nature and role of change. Water research is needed to provide accurate, comprehensive, and reliable assessments. The World Water Assessment Project (WWAP) undertakes assessments of the state of the world's freshwater resources and ecosystems; identifies critical issues and problems; develops indicators and measures progress towards achieving sustainable use of water resources; helps countries develop their own assessment capacity; documents lessons learned; and publishes a World Water Development Report (WWDR) at regular intervals. In support of these activities, the WWAP develops data sets and supporting information technologies for data interpretation, comparative trend analyses, and modeling. Although the program primarily focuses on terrestrial freshwater, it also addresses problems in marine near-shore environments and coastal zone regions where waters receive pollution and sediments from land-based sources or are under threat from the flooding of rivers and potential sea level rise. WWAP is the flagship program of UN Water, which coordinates UN initiatives involving freshwater.

IPCC carries out comprehensive climate assessments that cover the water-climate links. Established by WMO and the UNEP in 1988, the IPCC assesses the scientific understanding of human-induced climate change, its potential impacts, and options for adaptation and mitigation. IPCC assessments are based mainly on published scientific/technical literature. Many of the studies of the effects of climate on water resources, such as the US National Assessment of the potential consequences of climate variability and change on water (Gleick and Adams, 2000) have drawn heavily from the IPCC assessments.

Other UNEP-sponsored assessment programs include the Global Resource Information Database (GRID) and GIWA. GRID was established in 1985 as part of GEMS (described in Section "Data Programs"). It is a network of centers that collect and disseminate information on the state of natural resources worldwide through the open exchange of global and regional environmental geo-referenced data sets. Twelve cooperating GRID centers contribute data to this database system. GIWA was initiated in 1999 as a four-year project to produce a comprehensive and integrated global assessment of international waters. It has focused on the ecological status of 66 water areas in the world and the causes of their environmental problems.

IGRAC is part of a family of global information centers and GOSs for improving the understanding and management of freshwater resources. IGRAC, which was launched in 1999 by UNESCO, WMO, and the Netherlands, is also one of the UNESCO global centers of excellence. It is developing an interactive Global Groundwater Information System and groundwater assessment guidelines and protocols.

Nongovernmental institutes also undertake assessment activities with global scope that rely on water research. The World Resources Report (WRR), a biennial report series started in 1986, produced by the World Resource Institute and its partners, UNDP, UNEP, and the World Bank, assesses global environmental trends including, agriculture and food, coastal, marine and inland waters, freshwater, and biodiversity. Other reviews of the state of global and

regional water resources include: the biennial series, *The World's Water,* produced by the Pacific Institute (Gleick *et al.*, 2002), and the Worldwatch Institute's "Pilot Analysis of Global Freshwater Ecosystems" (Revenga *et al.*, 2000).

Applied Research: Regional and National Research Institutes and Centers

Applied research makes the critical link between science and benefits to society, but the application process is not always straightforward. The distinction between basic and applied research frequently allows for large areas of overlap. The results of basic research can find immediate operational uses and the application of studies carried out at centers for applied research sometimes does not occur. This overlap is evident in the missions of many national and regional research centers and programs.

UNESCO has established regional centers for research and training that provide facilities for capacity building, training, and research focused on regional needs. The following is a list of existing centers that focus on the area of water science:

- International Research and Training Center on Erosion and Sedimentation (IRTCES), Beijing, China;
- Regional Humid Tropics Hydrology and Water Resources Center for South-East Asia and the Pacific (WRCSEAP), Kuala Lumpur, Malaysia;
- Regional Water Centre for the Humid Tropics of Latin America and the Caribbean (CATHALAC), Panama City, Panama;
- Regional Center on Urban Water Management (RCUWM), Teheran, Islamic Republic of Iran; and
- Regional Center for Training and Water Studies of Arid and Semi-arid Zones (RCTWS), Egypt.

Several new centers have been proposed and are in various stages of development. These include a Regional Center for the Management of Shared Groundwater Resources, Utrecht, The Netherlands (under the auspices of UNESCO and WMO); a Regional Center on Urban Water Management, Santafé de Bogotá; a Regional enter for Ecohydrology, Warsaw, Poland; and a Regional Center on Drought in Africa, South Africa.

Many of the research and information programs that address the problems and opportunities outlined in the sections above on "Water and Development", "Water and Health", "Water and Food", "Water, Weather, and Climate", and "Water and Environment" are carried out by agencies through centers supported by national governments. The following partial list identifies some of these principal centers.

Hydrologic research at the Centre for Ecology and Hydrology (CEH) builds on the former Institute of Hydrology (IH), which led hydrologic research in the United Kingdom since its inception in 1968. Research undertaken at CEH extends from water and energy fluxes to processes such as evaporation, interception, and infiltration, to mathematical modeling of the hydrological cycle and chemical processes above and below ground.

Established in 1974, the National Institute for Environmental Studies (NIES) in Japan conducts basic research on environmental sciences, including water sciences, from the perspective of various disciplines, such as physics, chemistry, biology, health sciences, engineering, and economics. It supports the Center for Global Environmental Research (GER), which provides research support facilities and monitoring data for integrated environmental research.

The Stockholm Environment Institute (SEI) has conducted water research since 1989. It developed the Water Evaluation and Assessment Planning Tool (WEAP) and has used it to develop scenarios that have advanced sustainable water development.

Commonwealth Scientific and Industrial Research Organization (Land and Water) (CSIRO) in Australia works with its partners to find scientific solutions to water problems through multidisciplinary research, applying knowledge and research results from hydrology, hydrogeology, soil science, ecology, atmospheric science, remote sensing, and the social sciences.

The Global Hydrology and Climate Center (GHCC) brings together the NASA Marshall Space Flight Center (MSFC), the State of Alabama's Space Science and Technology Alliance (SSTA), and the Universities Space Research Association (USRA) to undertake hydrologic research that contributes to understanding and predicting the Earth's global water cycle, its connections to climate variability and weather, and its interactions with society. The National Oceanic and Atmospheric Administration (NOAA) and NASA also sponsor individual university centers for studies of the application of satellite and climate data to water resources management.

The German Federal Ministry of Education and Research (BMBF) sponsors the Global Change in the Hydrologic Cycle (GLOWA) Program to develop simulation-tools and instruments as a basis for sustainable water management at the regional level (river basins of approx. 100 000 km^2). Science themes include natural variability of precipitation, variations caused by human activities, and their effect on the hydrological cycle; interactions between the hydrological cycle, the biosphere, and land use; and water availability and conflicting water uses. In addition to research, GLOWA projects train scientists in developing countries and develop mechanisms for knowledge transfer.

The National Water Research Institute of Environment Canada, which has branches in Burlington, Ontario, and Saskatoon, Saskatchewan, undertakes a wide range of water research including hydrology, hydrogeology, aquatic

ecology, and limnology. It specializes in hydrologic processes in the Great Lakes and the Arctic.

Outreach

As used here, the term outreach encompasses a range of activities from the conferences and newsletters of professional societies to fostering technical competence in developing countries by international organizations. It includes efforts to raise awareness in the general public and provide access to repositories of information, specialized training workshops, grassroots institution building, ministerial briefings, forums for discussion of controversial issues, and similar activities. Critical elements in outreach include information exchange, education/training, and capacity building.

Public outreach regarding the value of hydrologic research and the uses of water science is important for international water programs because they increase awareness of the benefits and results and promote use of tools developed or improved as a result of water research and build a constituency for research. Outreach activities in education prepare the human resources needed to support continued progress in water science. Along with technical training and institutional capacity building, they also increase the abilities of nations to take advantage of the benefits of research and provide more equal access to those benefits. Outreach within and among water scientists and other water professionals facilitates the exchange of information vital to scientific and technical progress.

Outreach is a component of many organizations and programs, but often it is most effective when carried out by groups that give priority to this activity. The following sections provide a sample of the range of programs, organizations, and networks committed to outreach activities.

Education, Training, and Capacity Building

Two academic institutions within the UN system specifically address education, training, and capacity building in the hydrologic sciences. UNESCO and the Institute for Infrastructural, Hydraulic and Environmental Engineering (IHE) Delft have recently established an Institute for Water Education (IWE) in the Netherlands to make the knowledge of water management more accessible worldwide. IHE has offered training to water professionals from developing countries since 1957 and has expanded its curriculum to encompass the multidisciplinary needs of integrated water resources management. The United Nations University-International Network on Water, Environment and Health (UNU-INWEH) was formed in 1996 to strengthen water management capacity through training, particularly of experts from developing countries, and to provide on-the-ground support for projects.

START (see also Section "Experiments") contributes to international hydrologic sciences by building regional research capacity and providing training for regional scientists. It promotes research in the regional origins and impacts of global environmental changes including changes in the water cycle. START is a system of interconnected regional research networks (RRNs), regional research centers (RRCs), and regional research sites (RRSs) being developed by the ESSP. Each of the RRCs serves as the information center for the RRN and provides for the synthesis of results from various disciplines concerned with global change phenomena. The RRSs are institutes in the region with specialized expertise that allows them to carry out research on core projects.

There are numerous international education, training, and capacity building activities associated with universities. For example, the Water, Engineering and Development Centre (WEDC), founded in 1971 at Loughborough University in the United Kingdom, offers education, training, research, and consultancy related to the planning, provision, and management of infrastructure for development in low- and middle-income countries. Some university-sponsored outreach programs focus on young students, such as the Global Rivers Environmental Education Network (GREEN), initiated in 1984 at the University of Michigan, which provides opportunities for youth to learn more about water quality at the local watershed scale and to contribute to local water management. Other activities have broader aims; the Universities Council on Water Resources (UCOWR) involves universities in the United States and throughout the world in education, research, and public service activities relating to water resources, including information support for policy development.

Information Exchange

Scientific and professional organizations, through regular meetings, newsletters, journals, and other communication mechanisms, traditionally have served as conduits for information exchange. At the same time, symposia, policy briefings, newsletters, and brochures, produced by organizations that operate at the science-policy interface, have provided the public with scientific information. With the spread of the Internet throughout the world, electronic networks are emerging as the major mechanism for information sharing. Web pages, electronic clearinghouses, and "bulletin boards" have joined traditional professional associations, advisory committees, workshops, and conferences in the information toolbox. In addition, programs aimed specifically at developing dialogues among scientists, policy makers, and stakeholders, such as the DWC have emerged, which take advantage of all these tools. The following list, while incomplete, does provide an overview of many organizations that facilitate the exchange of hydrologic and related information, often within an applications context.

Professional Associations

The IAHS is a professional association of scientists from the broad range of hydrologic sciences (see Section "International scientific associations" for details).

The International Water Association (IWA) is a global network of water professionals, spanning the continuum between research and practice, and covering all facets of the water cycle. Formerly the International Water Quality Association, the IWA focuses on the science and management of drinking water, wastewater, stormwater, and the conservation of water resources.

Since its formation in 1972, the International Water Resources Association (IWRA) has worked to improve water management worldwide through dialogue, education, and research. It actively promotes the sustainable management of water resources by improving the understanding of the physical, biological, chemical, institutional, and socioeconomic aspects of water.

The International Association for Environmental Hydrology (IAEH) is a worldwide association of environmental hydrologists that enables environmental hydrologists and engineers, especially in developing countries, to share technical information and exchange ideas related to hydrology and the environment.

IAH is a scientific and educational organization, founded in 1956, whose aims are to promote research on the understanding and management of groundwater.

Regional and Subspecialty Organizations and Associations

The International Network of Basin Organizations (INBO) facilitates exchanges of experiences and expertise among organizations interested in river basin management. It promotes sound water management, facilitates the implementation of basin management tools, and promotes information and training programs for people involved in water management.

The International Association of Hydraulic Engineering and Research (IAHR) promotes, advances and exchanges of knowledge of engineering techniques for water resources, river and coastal hydraulics, risk analysis, energy, environment, disaster prevention, and industrial processes. IAHR also operates the European Engineering Graduate School in Stuttgart, Germany.

The International Association for Sediment Water Science (IASWS) promotes, encourages, and recognizes excellence in scientific research related to sediments and their interactions with water and biota in fluvial, lacustrine, and marine systems. It also fosters collaborative research and dialogue among Earth scientists, biologists, chemists, and environmental engineers with an interest in sediment–water interactions.

The International Coordinating Committee on Reservoir Sedimentation (ICCORES), founded in 1992, brings together experts from water-related international associations to promote the combined action of various disciplines and experiences gained in different countries for addressing the problems of reservoir sedimentation.

The International Commission on Large Dams (ICOLD) provides a forum for the exchange of knowledge and experience in dam engineering. Founded in 1928, it supports the safe, efficient, economic, and environmentally friendly construction of dams.

The International Commission on Irrigation and Drainage (ICID), established in 1950, is dedicated to enhancing the worldwide supply of food and fiber by improving water and land management, especially irrigation, drainage, and flood management techniques.

The International Association of Theoretical and Applied Limnology (Societas Internationalis Limnologiae, SIL), which was founded in 1922, promotes and communicates new and emerging knowledge among limnologists to advance the understanding of inland aquatic ecosystems and their management.

Since its founding in 1999, the International Water History Association (IWHA) has established a network of experts to explore the complex processes shaping water resource use.

The Small Island Developing States (SIDS) Network (SIDSnet) connects 43 states in the Pacific, Caribbean, Atlantic, Indian Ocean, Mediterranean, and African island nations. It encourages the use of information and communication technologies to enable SIDS to attain sustainable development objectives. The project was launched in 1998 through UNDP's Sustainable Development Networking Programme (SDNP) and the Alliance of Small Island States (AOSIS).

The Inter-Islamic Network on Water Resources Development and Management (INWRDAM) is an intergovernmental, autonomous organization operating under the umbrella of the Standing Committee on Scientific and Technological Cooperation (COMSTECH) of the Organization of the Islamic Conference (OIC). Established in 1987, INWRDAM is hosted in Amman by the government of Jordan.

MEWIN (Middle East Water Information Network), founded in 1994, improves access to information and data on Middle East water resources and issues, and encourages cooperative planning, use, and management of the resource.

Public Information and Advocacy

The Pacific Institute for Studies in Development, Environment and Security has a Water and Sustainability Program that integrates several major projects to address freshwater problems across applications from agricultural production to ecosystem health. It publishes *The World's Water* (see Section "Assessments") and maintains an open-access database on which this biannual assessment is based.

Since its inception in 1974, the Worldwatch Institute has undertaken interdisciplinary research with a global focus on water and interactions among key environmental, social, and economic trends.

The World Wildlife Fund (WWR) – Living Waters Program provides background information on freshwater and WWF's objectives to safeguard freshwater systems.

The International Rivers Network (IRN) was initiated in 1985 by environmental activists to halt and reverse the degradation of river systems, promote sustainable alternatives to damming and channeling rivers, and increase awareness of the value of rivers and their importance for society.

LakeNet is a global network of individuals and organizations in more than 90 countries working for the conservation and sustainable management of lakes. The LakeNet Secretariat is a US-based nonprofit organization.

Electronic Networks and Web Portals

The WaterWeb Consortium is dedicated to improving communications and information access to help address the world's water problems. It maintains a listing of web links containing web-based data inventories and local network portals.

The UNESCO Water Portal provides links to the current UNESCO and UNESCO-led programs on freshwater and serves as an interactive entry point for websites of water-related organizations, including water links, water events, learning modules, and other on-line resources.

The Global Applied Research Network (GARNET) facilitates the sharing of applied research information between researchers working in the water and sanitation sector.

The International Waters Learning Exchange and Resource Network (IW: LEARN) mission is to build an Internet-based "global knowledge community" to protect, restore, and sustain the world's aquifers, great lakes and river basins, coastal zones, seas, and oceans, and emphasizes building capacity among transboundary water resource projects.

SUMMARY

As outlined in the preceding pages, international hydrological sciences have followed a unique development path. Opportunities for international coordination have expanded greatly in the past two decades as world attention has focused on issues of environment, climate, and freshwater sustainability. New capabilities of satellite systems and the gains that can be realized from better integration of observation systems are driving the development of coordination mechanisms and integrating structures. This section considers some factors that will continue to affect the development of international hydrological sciences in the coming decades and considers emerging structures that may strengthen the coordination needed to realize its promise.

Challenges in the Coordination of International Science

There is a clear requirement for continued growth of international hydrologic sciences. Currently, several stable and highly respected organizations, such as the IAHS, bring together hydrologists from many different specialties and provide a forum for them to discuss the advances in their science. In addition, there are a number of organizations that focus on water policy and the use of hydrologic science to better understand specific issues. The emphasis of the UN on issues related to climate change and sustainable development has provided new opportunities for hydrology that supports large-scale understanding of the climate and the Earth system, or that supports the assessment, monitoring, and forecasting of water availability. In addition, the interest of the space sector in increasing the use of satellite data for water management is leading to new opportunities for hydrologic research. The broad interest of international programs in some branches of hydrologic science has supported growth in those sectors. However, as the competition for funds increases, it is unclear whether the past rate of growth can continue.

Hydrologic sciences have always been highly multidisciplinary. Some efforts have been made to define the boundaries of hydrologic science (e.g. NAS, 1991), but these efforts have been only partially successful. The range of disciplines required to work in an integrated way on water issues is growing, and the hydrologic sciences are drawing on a wider range of scientific groups to address complex problems. In addition, the hydrological sciences are commonly applied to decision-making in nonscientific arenas, where understanding of the decision context can be as influential as scientific understanding.

In addition, the hydrologic sciences must deal with scale issues associated with linking phenomena from the watershed (catchment) to global scales and from seconds to centuries. Global-scale hydrology and local hydrology require different approaches; for example, at the watershed scale, heterogeneities persist in ways not seen in oceanography or meteorology. When dealing with large-scale problems, it is necessary to summarize these heterogeneities by relatively simple parameterizations. Beyond the scientific challenge this implies, it introduces tensions within the hydrologic sciences because some hydrologists can feel uncomfortable that the parameterizations are not faithful to the underlying physics. On the other hand, parameterizations that can be used in coupled land-atmosphere models are necessary to ensure that hydrological processes are properly accounted for in climate models.

Other challenges that are pronounced in the hydrologic sciences include the essential reliance on *in situ* data collection and the issues of network maintenance, data standards, and access of such reliance entails, including the exchange of sensitive water-related data across national

borders. All these difficulties are at the root of many of the challenges faced by the international hydrological science community. Among the most pressing challenges are:

1. *Funding and prioritization:* There is a pressing need to convert competition to synergy and efficiency. Since World War II, the United States and other developed countries have tended to be strong players in international programs in which there is a major atmospheric component. However, the lack of US involvement in some mainstream programs for several decades, such as UNESCO, has led to a reduction of US international contributions in these program areas. In spite of this reduction, the United States has some excellent applications programs at the regional and national levels (e.g. NOAA's Regional Integrated Science and Assessment projects). The satellite agencies of the world, especially NASA, have been in the forefront of encouraging a continental and global-scale perspective of surface water distribution. The challenge is to forge a unified scientific basis for the study of global hydrological systems.
2. *Networks and access to data:* The need for a framework for water cycle science and observations is becoming urgent because of the erosion of national hydrometric observational networks and gaps in the data sets held by global data centers (e.g. GRDC). In many countries, routine hydrological observations are made that could be used for freshwater assessments, monitoring, and climate research. However, an international hydrological network that operates on a standardized set of agreed-upon procedures for data collection, dissemination, analysis, and use does not exist. Many countries have very sparse hydrometeorological measurements. Furthermore, some countries will not release their data, because of national data policy restrictions. The United States has been a leader and role model in making its hydrologic information available to all users (see e.g. **`http://www.water.usgs`**) at a time when even some developed countries (e.g. Canada and Belgium) have removed their hydrologic information from public domain. An overall observational strategy for hydrometric measurements over land must be developed and nations should be encouraged to make commitments to support it. The free and open access to hydrometric data should be adopted as a basic principle for this network, as required by most interpretations of WMO resolution (CgXIII Resolution #25 adopted in 1999). The lack of free and open data exchange is a significant barrier to the international science community in many areas, including climate modeling (see, for example, the discussion by the Ad Hoc Group on Global Water Data Sets of the International Association of Hydrological Sciences, 2001). Remote sensing methods, primarily employing satellites, are increasing the instantaneous availability of information globally. Remote sensing is sometimes viewed as the solution to these problems; however, *in situ* measurements also are critical for the development and validation of estimates derived from remote sensing data and the interpretation of their implications.
3. *Developing a hydrologic perspective:* The growth of a recognized voice for international hydrology has not been as rapid as it has been in the fields of meteorology and ocean science. While the UN has one agency for meteorology, at least 13 agencies have some responsibility for water. On the services side, the national hydrologic services have not had the same requirement for data sharing and joint approaches to research as the meteorological services have because predictions depended only on information from local and upstream watersheds rather than the entire globe. When basins extend across national boundaries, the sharing of data between the upstream and the downstream countries is limited in some cases. New prediction capabilities, advances in transferability of models, and new integrated approaches to water management are slowly changing this attitude.
4. *Strategies for integration:* Recently, Europe and other countries have adopted policies that will lead to a stronger emphasis on integrated river basin management and a need to bring together all aspects of water issues with land management and socioeconomic considerations. For example, water use is highly dependent on water quality, which in turn is closely tied to land use and land use changes. To be effective, future water policy will need to be integrated with land use policies. Integration will require surface water quantity, quality, and groundwater issues to be considered and resolved in a more comprehensive knowledge framework. Research and data collection activities will need to become more multidisciplinary and to expand their perspectives to provide an adequate base for this integrated approach, which in turn will lead to further demands for integration.
5. *Efficient support for water managers:* Increases in the application of automation, satellite data, assimilation and prediction techniques, and the Internet are leading to higher expectations for efficiency in managing water systems. Better integration of scientific understanding into decision processes is needed. Choices will be influenced by the values held by the national and regional governments overseeing the decision process. The assessment of the options requires inputs from the water science community and guidance on criteria for determining the advantage of one strategy over another.
6. *Bridging language gaps:* Hydrology is essentially an interdisciplinary science. It is becoming even more

complex as it is pressed to address high priority science questions in a global context. The languages of the individual disciplines concerned with the water cycle can facilitate communication among its specialists, but impede communication with others. As the needs force cooperation among an expanding range of disciplines, the broad, social challenge of communicating across disciplines grows. Some programs, such as the GWSP, are addressing this challenge explicitly through the development of a lexicon. Other strategies involve projects that demand direct interactions and the development of long-term relationships among scientists of different disciplines.

Long-term relationships also appear to be essential for science to have an impact on decision-making. If non-scientists and scientists speak different languages, as C.P. Snow suggested, the hydrologic sciences must develop more effective mechanisms for communicating with research users from other backgrounds and for applying scientific results to the solution of practical problems.

7. *Emerging structures:* In the area of environmental sciences, the need for greater integration has been realized and led to the formation of the ESSP in 2001. This partnership brings together expertise from climate, hydrology, biology, aquatics, and human dimensions (DIVERSITAS, IGBP, IHDP, and WCRP) to address priorities for humanity. While ESSP studies will involve macroscale hydrology, there are some aspects of hydrology and water science at the watershed scale that may find only limited involvement in such efforts. ESSP studies also will increase the demand for socioeconomic data in support of hydrological research. This raises the question, "Is there a need to develop a new interdisciplinary framework that will allow hydrologists who work at the conventional watershed scales to become more integrated into the global perspective on water problems, or does the current suite of associations, committees, organizations, and programs outlined in this article provide adequate coordination?" If a new framework is needed, what form should it take?

To deal with the growing realization that water will be one of the critical environmental issues of the twenty-first century, many programs have emerged that require hydrological expertise. Many of these programs are outside the traditional governmental framework for water organizations and involve partnerships with the private sector. It is not clear whether these partnerships will lead to different perspectives on water (e.g. changes in the view that water is a public good and each human should have access to a certain quantity of safe water as a basic human right). However, it is likely that these partnerships will also extend into the research area and influence future research priorities. The hydrologic research community is not entirely prepared for this possibility.

ACSYS – Arctic Climate System Study

AGLW – Water Resources, Development and Management Service (FAO)
(**http://www.fao.org/ag/agl/aglw/**)

AMMA – African Monsoon Multidisciplinary Analysis
(**http://www.ofps.ucar.edu/amma/amma_summary.htm**)

AOSIS – Alliance of Small Island States
(**http://www.sidsnet.org/aosis/**)

APN – Asian Pacific Network for Global Change Research
(**http://www.apn.gr.jp/indexe.html**)

BAHC – Biological Aspects of the Hydrological Cycle
(**http://www.pik-potsdam.de/~bahc/**)

BALTEX – Baltic Sea Experiment
(**http://w3.gkss.de/baltex/**)

BMBF – German Federal Ministry of Education and Research

CATHALAC – Water Center for the Humid Tropics of Latin America and the Caribbean
(**http://www.cathalac.org/**)

CBD – Convention on Biological Diversity

CEH – Center for Ecology and Hydrology
(**http://www.nwl.ac.uk/ih/**)

CEOP – Coordinated Enhanced Observing Period
(**http://www.ceop.net** and **http://www.usask.ca/geography/MAGS/GHP/ceop_issues.html**)

CEOS – Committee for Earth Observation Satellites
(**http://www.ceos.org/**)

CGIAR – Consultative Group on International Agricultural Research
(**http://www.cgiar.org/** and **http://www.waterforfood.org/**).

CHy – Commission on Hydrology

CLIVAR – Climate Variability and Predictability
(**http://www.clivar.org/**)

CliC – Climate and Cryosphere Project
(**http://clic.npolar.no/**)

CLIPS – Climate Information and Predictions Services
(**http://www.wmo.ch/web/wcp/clips2001/html/**)

COMSTECH – Standing Committee on Scientific and Technological Cooperation
(**http://www.comstech.org.pk/**)

COPES – Climate Observing and Prediction in the Earth System

CPWC – Cooperative Programme on Water and Climate
(**http://www.waterandclimate.org/home.asp**)

CSA – Chinese Space Agency

CSD – Commission on Sustainable Development
CSE – Continental Scale Experiment (**http://www.gewex.com/cseslocation.html**).
CSIRO – Commonwealth Scientific and Industrial Research Organization (Land and Water: **http://www.clw.csiro.au/index_alt.html**)
DIVERSITAS (See: **http://www.diversitas-international.org/**)
DWC – Dialogue on Water and Climate (**http://www.waterandclimate.org/home.asp**)
ECA – Economic Commission for Africa
ECE – Economic Commission for Europe
ECLAC – Economic Commission for Latin America
ESA – European Space Agency
ESCAP – Economic Commission for Asia and the Pacific
ESCWA – Economic and Social Commission for West Asia
ESMF – Earth System Modeling Framework
ESSP – Earth System Sciences Partnership (**http://www.ess-p.org/**)
FAO – Food and Agriculture Organization (**http://www.fao.org/**)
FIFE – First ISLSCP Field Experiment (**http://www.esm.versar.com/fife/fifehome.htm**)
FRIEND – Flow Regimes from International Experimental and Network Design (**http://www.nwl.ac.uk/ih/www/research/bfriend.html**)
GAIM – Global Analysis, Integration and Modelling (**http://gaim.unh.edu/**)
GAME – GEWEX Asian Monsoon Experiment (**http://www.hyarc.nagoya-u.ac.jp/game/**)
GAPP – GEWEX Americas Prediction Project (**http://www.ogp.noaa.gov/mpe/gapp/**)
GARNET – Global Applied Research Network (**http://www.lboro.ac.uk/departments/cv/wedc/garnet/grntover.html**)
GCOS – Global Climate Observing System (**http:xs//www.wmo.ch/web/gcos/gcoshome.html**)
GCTE – Global Change Terrestrial Ecosystems (**http://www.gcte.org/**)
GECAFS – Global Environmental Change and Food Systems (**http://www.gecafs.org/**)
GEF – Global Environmental Facility (**http://www.gefweb.org/**)
